Abstract—Computer network attacks are among the most significant and common threats against computer-wired and wireless communications. Intrusion detection technology is used to secure computer networks by monitoring network traffic and identifying attacks. In this paper, we investigate and evaluate the application of four machine learning classification algorithms for identifying attacks that target computer networks: DDoS, Brute Force Web, and SQL Injection attacks, in addition to Benign Traffic. A public dataset of 80 features was used to build four machine learning models using Random Forest, Logistic Regression, CN2, and Neural Networks. The constructed models were evaluated based on 10-fold cross-validation using Classification Accuracy (CA), Area under the Curve (AUC), F1, Recall, Specificity, and Sensitivity metrics in addition to Confusion Matrix, Calibration, Lift, and ROC plots. The Random Forest model achieved 98% in the CA score and 99% in the AUC score, while the Logistic regression achieved 90% in the CA score and 98% in the AUC score.

Keywords—Machine learning; data mining, cyber security; computer networks; intrusion detection

I. INTRODUCTION

Computer networks are pivotal in today's world. They connect people, machines, and systems on various scales. Cisco has estimated that 29 billion devices will be connected through computer networks by 2023 [1].

However, network communication security is subject to being hampered by several novel attacks, which necessitate more effective monitoring, detection, identification, and prevention of network attacks which remains an unsolved challenge in the cyber world. This is due to the variety, complexity, and ever-growing sophistication of the technology utilized in these attacks.

Machine learning has successfully solved similar problems in various domains and applications [2, 3] using several supervised and unsupervised learning algorithms [4-6]. This success can be inspired to solve problems in network security by detecting and identifying various types of intrusion attacks that enable monitoring and prevention of such attacks.

This work investigates and evaluates the use of machine learning technology for detecting and identifying four types of network traffic: DDoS attacks, SQL Injection, Brute Force Web attacks, and Benign Traffic. Four machine learning techniques were applied in this study. These include Random Forest (RF), Logistic Regression (LR), CN2 Rules Inducer, and

Neural Networks (NN). The constructed models were then evaluated based on Classification Accuracy (CA), Area Under the Curve (AUC) [7], Precision, Recall, and F1 metrics [8]. A confusion matrix was also created for each constructed model [9]. The Calibration, Lift, and Receiver Operating Characteristic (ROC) curves were used to compare and confirm the validity and robustness of the created models [10].

The dataset in this work was sampled from a publicly simulated big dataset which was created by the Communications Security Establishment (CSE) and the Canadian Institute of Cybersecurity (CIC) for Intrusion Detection Systems (IDS). The dataset was published under the name CSE-CIC-IDS2018 [11, 12]. The original dataset comprises 16 million samples described using 80 features related to the traffic flow on the network [13, 14]. The dataset was acquired using the Amazon Amazon Web Services (AWS) Command Line Tool (CLI) [12] and underwent intensive processing involving intensive filtering, sampling, integration, and randomization procedures. It was then explored to examine its quality, distribution, and potential. The sampled data covers three types of attacks: (1) Distributed Denial of Service (DDoS) Low Orbit Ion Cannon (LOIC) Datagram Protocol (UDP), which is referred to as DDOS LOIC-UDP attacks; (2) Structured Query Language (SQL) Injection attacks; (3) Brute-Force Web attacks in addition to Benign Traffic.

Research Problem: Network attacks are difficult to detect and identify using normal network hardware and software tools. Differentiating normal Traffic from network attacks is a complex task that might create threats to network security and interrupt services.

Research Question: Can machine learning classification algorithms detect and identify network attacks based on the numerous characteristics of network traffic flow?

Research Objectives: Investigate and evaluate the use of four machine learning algorithms for detecting and identifying common types of network attacks. The resulting models can be embedded in the network firewall, proxies, routers, and other security tools, suites, and solutions.

Research Contribution:

- 1) Creating successful machine learning models that can be used for detecting and identifying types of network attacks.
- 2) Identifying significant traffic features can be used as predictors for identifying and detecting network attacks.

Section II provides a theoretical framework for the conducted research, while Section III reviews the related work. Section IV describes the dataset, while Section V describes the research methodology applied in the study. Section VI describes the research results, Section VII discusses the obtained results, and Section VIII draws a conclusion and comments on the limitation and the future work which can extend this study.

II. RELATED WORK

This section reviews five of the most relevant works on intrusion detection using machine learning.

A study was reported in [15] which aimed at investigating the use of A Convolutional Neural Network (CNN) and Recurrent Neural Networks for detecting denial service (DoS) attacks using the CSE-CIC-IDS2018 and Knowledge Discovery in Databases (KDD) Cup 1999 data. The Convolutional Neural Network (CNN) model detected the Denial of Service (DoS) attacks using the CSE-CIC-IDS2018 dataset with a CA score of 91.5% and 99% using the KDD Cup 99 dataset. On the other hand, the Recurrent Neural Network (RNN) model could classify the CSE-CIC-IDS2018 with a CA score of 65% and a CA score of 93% based on the KDD Cup 99 dataset.

In [16], Andercut reported applying the K-Nearest Neighbor (KNN) algorithm in identifying attacks from benign Traffic with a CA score of 99% using 9/10 of the files in the CSE-CIC-IDS2018 dataset. However, the model scored a CA score of 72% using one of the files in the dataset.

The Iterative Dichotomiser 3 (ID3) and Naïve Bayes algorithms were used in [17] to detect four attack classes and a normal traffic class using the KDD Cup 99 dataset. The study reported a CA score between 97% and 99% in classifying Probe, DoSm R2L, and Normal classes and 94% in predicting attacks that belong to the U2R class.

A study reported using K-Nearest Neighbor Classifier (KNN), Naïve Bayes, Adaboost with Decision Tree, Support Vector Machine, and Random Forest using CSE-CIC-IDS2018 in identifying portrayal botnet attacks with a reported accuracy of 99% [18].

A study in [30] reported using KNN, Random Forest, and Logistic Regression to identify botnet and infiltration attacks using the CSE-CIC-IDS2018 dataset. The applied algorithms identified the attacks with a CA score of 90%.

The related work analysis shows that most of the surveyed studies were conducted to identify a subset of the attacks in the CSE-CIC-IDS2018 and KDD Cup 99 datasets with a CA score ranging from 65% to 99%. However, most studies that reported high CA scores aimed at identifying only one or two types of attacks.

Furthermore, the performance of the applied machine learning techniques scored better when they were applied to the KDD Cup 99 dataset, which contains much fewer samples and much fewer features than the CSE-CIC-IDS2018 dataset. On the other hand, most of the reported studies used the CA metric

to evaluate the performance of their reported models, while some used other metrics only to confirm the CA score.

III. THEORETICAL FRAMEWORK

Here we provide a brief overview of the concepts related to network intrusion attacks and the machine learning techniques applied in this study.

A. Network Attacks

Network attacks are "a set of malicious activities that disrupt, deny, degrade, or destroy information and services in a computer network." The attacks are usually carried out by sending streams of data that intrudes to affect the availability, integrity, privacy, and secrecy of the services and data communicated through the targeted network [19]. Four types of computer network traffic are investigated in this work: Benign, DDos-LOIC-UDP, Brute-Force-Web, and SQL Injection attacks.

- Brute-Force Web: attacks that aim at cracking vulnerable computer networks that depend on weak user credentials, which consist of weak usernames and passwords [11, 20, 21].
- Distributed Denial of Service (DDoS): attacks designed to target network or web servers with limited bandwidth by overwhelming them with requests from tens or hundreds of distributed URL addresses [11, 22, 23]. DDOS LOIC-UDP stands for Distributed Denial of Service (DDoS) Low Orbit Ion Cannon (LOIC) Datagram Protocol (UDP).
- SQL Injection: stands for Structured Query Language (SQL) attacks. It works by injecting code into databases to gain unauthorized access to data by executing unsolicited queries or damaging the integrity of your database [11, 24-27].
- Benign Traffic: generated to realistically simulate the normal and usual behavior of human users in a typical and normal computer network [11, 16, 19].

B. Machine Learning

- Machine learning is an artificial intelligence field that aims to mimic the human learning process by creating algorithms fed with data [28]. Machine learning techniques are divided into two categories: supervised and unsupervised. While supervised learning aims to find patterns in pre-labeled data, unsupervised learning depends on finding patterns based on data self-labeling [2, 3, 5].
- Random Forest: An ensembled supervised learning technique for regression, classification, and feature ranking. The Random Forest algorithm builds multiple trees created based on a recursive partitioning approach that divides the feature space into several regions that encapsulate a set observation with relative values of responses. The random-forest algorithm is applied to many variables with hard-to-analyze relationships

[29-31]. Random Forest were applied by recent studies in detecting intrusion attacks [32-35].

- Logistic Regression: A supervised learning algorithm that works by assuming a non-linear relationship between features using a logit function that is used to predict the probability of data belonging to a predefined class which is assigned a value between 0 and 1 and then labeled with the closest value (0 or 1). Unlike linear regression, Logistic Regression can be applied to numerical and nominal data [36]. Examples of recent studies that reported the successful use of Logistic Regression in intrusion detection are available in [6, 34, 37].
- CN2: A rules induction algorithm that aims at inducing simple and understandable rules in the form of (if-then-statements). The CN2 algorithm is used for solving classification problems and is known for its ability to handle noise in data [38]. A recent comparative study reported using CN2 in network security [39].
- Neural Networks: A supervised machine learning technique that simulates thinking in the brain. It consists of interconnected neurons organized into a set of layers that input, output, and one or more hidden layers. The algorithm can achieve learning by example by adjusting the triggering weights assigned to the neurons using a sigmoid function and then adjusting through backpropagation. Neural Networks can solve regression and classification problems [40, 41]. Several example studies reported that the neural networks technique was successful in detecting network intrusion attacks [18, 42, 43].

IV. DATASET

The original dataset in this research is a simulated public dataset published by the Communications Security Establishment (CSE) and the Canadian Institute of Cybersecurity (CIC) for Intrusion Detection Systems (IDS) under the name CSE-CIC-IDS2018 dataset. The dataset was collected over a sixteen-day period which extends between 14/02/2018 and 20/03/2018.

The data was labeled with the date of its recording and then stored in a Comma Separated Values (CSV) file corresponding to that date. The dataset can be described as big data as it consists of 16 million records distributed over 80 features which cover: attack type, time stamp, protocols, and number, in addition to 76 other features which are related to the typical flow and Traffic of data in a computer communication network such as flow duration, packet number, bytes number, size of the packet, etc. More details about the original dataset can be found in [13, 14].

The dataset was sampled as a representative sample of the original data. The sampled dataset consists of 1,359 records. It covers three types of network attacks: (1) DDOS LOIC-UDP attacks; (2) SQL Injection attacks; (3) Brute-Force Web attacks in addition to Benign Traffic.

V. METHODOLOGY

The method applied in this study consists of five stages that correspond to the typical phases of popular data mining process models [2, 44], which cover: (1) Data acquisition, (2) Data preprocessing, (3) Data exploration, (4) Model construction; and (5) Model evaluation. Fig. 1 illustrates the applied research method and its involved five stages.

A. Data Acquisition

The data acquisition procedures involve obtaining the dataset by accessing, downloading, and storing it in the proper file format. The dataset is stored on Amazon AWS and was obtained using the AWS CLI tool [12].

B. Data Preprocessing

Due to the vast number of records in the dataset, which consists of 16 million records, the dataset must be treated as big data. The data needs intensive preprocessing procedures, which involve data filtering, randomization, sampling, and combining to construct a representative and informative dataset which can be used to construct useful models that can achieve excellent performance while avoiding both under-fitting and over-fitting through achieving balance in class distribution [5].

C. Data Exploration

Data exploration aims at prospecting the dataset and examining its quality, distribution, and potential toward achieving the desired machine learning objectives.

The data exploration procedures involve investigating and visualizing the dataset distribution to confirm the sufficiency of the dataset in each predicted class and to ensure the balance of samples in each class.

The relationship between variables is also visualized and examined using projection plots to uncover relationships between the data set features. The data exploration also involves assessing the importance of dataset features and their contribution toward enhancing the power of the classifier's prediction. Applied variable importance algorithms include the popular information gain (IG) and Gini algorithms.

Fig. 1. The five stages of the applied research method.

D. Model Construction

The model construction phase will involve building four prediction models using four classification algorithms which include (1) Random Forest; (2) Logistic Regression; (3) CN2; and (4) Neural Networks.

E. Model Evaluation

The model evaluation phase involves scoring the performance of all the constructed classification models using Classification Accuracy (CA), Area Under the Curve (AUC), and F1 metrics [7, 45]. The equation for calculating the classification accuracy (CA), Precision, Recall, and F1 are described by Equations 1, 2, 3, and 4.

$$\text{Classification Accuracy (CA)} = \frac{TP+TN}{N} \quad (1)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (2)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (3)$$

$$F1 = \frac{2TP}{2TP+FP+FN} \quad (4)$$

Where TP represents the number of samples classified as belonging to the assigned class, TN represents the number of samples classified as not belonging to the assigned class. N is the total number of samples.

In addition to constructing a confusion matrix [9] for each successful model, the performance of all models is visualized and confirmed using the Lift, Calibration, and ROC curves [10].

VI. RESULTS

A. Data Acquisition Results

The CSE-CIC-IDS2018 dataset [13] was downloaded using the AWS CLI tool from the Amazon AWS website [12]. The dataset is managed by the Canadian Institute of Cybersecurity (CIC) [14]. The data was exported and stored in 10 CSV files. Each file was labeled with a name that represents the data acquisition date.

B. Data Preprocessing Results

The data processing procedures involved combining the dataset into one file and then filtering the dataset to contain the dataset records that correspond only to the three classes of attacks considered in this study in addition to a benign class: and excluding all other records.

The resulting dataset was filtered once again and then spitted into four datasets, each representing only one attack classification to the benign class. Each of the four datasets was stored in a separate CSV file which was then loaded and sampled using a stratified random method that involved dividing the dataset into several homogeneous groups. The size of each sample size is a maximum number of 400 records. This number was set to tackle the dataset's size complexity due to the Computer's limited power in this experiment.

The four resulting datasets were then randomized and then combined in a single dataset that was stored again in another CSV file which contains a total of 1359 records, where 400 records represent each of the DDOS LOIC-UDP, Brute Force Web, and Benign classes, and 159 records represent the entire dataset recorded for the SQL Injection attack class.

C. Data Exploration Results

The data exploration involved examining the dataset quality, its trends and distribution, and finding the correlation and association between the dataset features.

The sampled dataset consists of 1,359 samples distributed over four classes. Each class contains 400 samples, except the SQL Injection, which contains only 159 classes, representing 100% of the samples recorded in the original dataset. The sampled dataset has n and use and no significant outliers. Fig. 2 illustrates the distribution of the dataset over the four assigned classes.

The dataset trends were analyzed using the data projection method, which involves projecting the data samples over four selected dimensions. The projection results show a considerable influence on the time feature and the packet lengths, as shown in Fig. 3. This result was consistent with the variable importance calculated based on the Information Gain and Gini.

The variables were also ranked using Gini and Information Gain (IG) algorithms. Both algorithms agreed on ranking the top four important features, including Fwd Pkt Len Max, Tot Len Fwd Pkts, Subflow Fwd Byts, and Fwd Header Len.

The Gini algorithm ranked the Timestamp feature as number nine, while information ranked it as a number. On the other hand, while Gini ranked the number of the forwarded bytes sent in the initial window as number seven, the Information Gain algorithm ranked it as number nine. Analyzing the variable's importance ranking results was useful in prospecting the dataset's potential in predicting the attack classes. Table I ranks the top-ten features based on Gini and Information Gain variable importance ranking algorithms.

TABLE I. TOP-TEN VARIABLE IMPORTANCE RANKING

#	GINI Ranked Feature	Score	Information Gain Ranked Feature	Score
1	Fwd Pkt Len Max	0.796	Fwd Pkt Len Max	1.56
2	TotLen Fwd Pkts	0.72	TotLen Fwd Pkts	1.43
3	Subflow Fwd Byts	0.72	Subflow Fwd Byts	1.43
4	Fwd Header Len	0.72	Fwd Header Len	1.36
5	Fwd Pkt Len Mean	0.70	<i>Timestamp</i>	1.33
6	<i>Fwd Seg Size Avg</i>	0.70	Fwd Pkt Len Mean	1.30
7	<i>Fwd Win Byts</i>	0.68	<i>Fwd Seg Size Avg</i>	1.30
8	Pkt Len Max	0.68	Pkt Len Max	1.29
9	<i>Timestamp</i>	0.66	Fwd Win Byts	1.26
10	Tot Fwd Pkts	0.62	Tot Fwd Pkts	1.22

Fig. 2. Distribution of dataset records over the selected four classes.

Fig. 3. An example of samples projection over an asset of four features.

D. Model Construction Results

Four models have been constructed in this study using four classification algorithms which include: Neural Networks, CN2, Logistic Regression, and Random Forest. The constructions of the Logistic Regression and Random Forest were the fastest, while the construction of the neural networks was the slowest, and the CN2 model was the second slowest.

E. Model Evaluation Results

The four created models were evaluated using three performance metrics: Classification Accuracy (CA), Area under the Curve (AUC), and F1.

The Random Forest model performed best with a CA score of 98%, an AUC score of 99%, and an F1 score of 98%. The Logistic Regression model scored the second-best performance, scoring 90% in the CA metrics, 98% in the AUC metrics, and 91% in the F1 metrics.

The CN2 achieved satisfactory results with a CA performance of 70%, an AUC performance of 94%, and an F1

performance of 63%, while the neural network model failed to achieve satisfactory results. Table II shows a comparison between the performances of the four constructed models.

The confusion matrices of the three successful models confirm the validity of the models for predicting the classification of all classes except the CN2 model, which failed to predict the Benign class. At the same time, it performed excellently in predicting the three other classes.

The confusion matrix of the CN2 model is illustrated in Table III. It shows that it performed well in predicting all attacks but poorly in predicting benign Traffic. On the other hand, its confusion matrix is illustrated in Table IV; despite the excellent performance of the Logistic Regression model in predicting Benign Traffic, Brute-Force Web, SQL Injection, and DDOS attacks. Shows its inferior performance in predicting Brute-Force Web attacks. The confusion matrix of the Random Forest model shown in Table V was the best, as the model performed excellently in predicting all classes.

TABLE II. CLASSIFICATION MODELS PERFORMANCE

Model	AUC	CA	Precision	Recall	F1
Random Forest	0.99	0.98	0.98	0.98	0.98
Logistic Regression	0.98	0.90	0.94	0.90	0.91
CN2 Rule Inducer	0.94	0.70	0.82	0.71	0.63
Neural Network	0.50	0.27	0.27	0.28	0.27

TABLE III. CN2 MODEL CONFUSION MATRIX

		Predicted				Sum
		Benign	DDOS attack-LOIC-UDP	Brute Force -Web	SQL Injection	
Actual	Benign	4	1	49	346	400
	DDOS attack-LOIC-UDP	1	399	0	0	400
	Brute Force -Web	0	0	298	2	400
	SQL Injection	0	0	4	159	159
	Sum	5	400	447	507	1359

TABLE IV. LOGISTIC REGRESSION CONFUSION MATRIX

		Predicted				Sum
		Benign	DDOS attack-LOIC-UDP	Brute Force -Web	SQL Injection	
Actual	Benign	399	0	1	0	400
	DDOS attack-LOIC-UDP	0	399	0	0	400
	Brute Force -Web	0	0	275	125	400
	SQL Injection	0	0	4	155	159
	Sum	399	399	281	280	1359

TABLE V. RANDOM FOREST CONFUSION MATRIX

		Predicted				Sum
		Benign	DDOS attack-LOIC-UDP	Brute Force -Web	SQL Injection	
Actual	Benign	398	0	1	0	400
	DDOS attack-LOIC-UDP	0	400	1	0	400
	Brute Force -Web	0	0	385	15	400
	SQL Injection	0	0	3	156	159
	Sum	399	399	281	280	1359

Fig. 4. An example sieve plot that shows the performance of the random.

A sieve plot was constructed for the Random Forest model to visualize the model performance, shown in Fig. 4. The correctly classified samples are represented by blue rectangles. In contrast, the wrongly classified samples are shown in red colors. The size of the rectangles corresponds to the size of the classified samples.

The Calibration curve, shown in Fig. 5 also confirms the validity and robustness of the constructed models. The closest the curve to the logistic function curve is, the better. While the

Fig. 5. Calibration curve shows the performance of the four constructed classification models.

Random Forest and Logistic Regression both show excellent performance, the performance of the CN2 model is relatively modest. In contrast, the performance of the Neural Network model was inferior as it appears as a straight flat line in the plot.

The Lift curve shows the relation between the predicted positive samples and those positive. The Lift curve in Fig. 6 confirms the validity of the Random Forest and Logistic Regression models. They both have excellent curves, and while the CN2 model shows a fluctuating curve, the neural network model performance was poor. This is demonstrated by their excellent lift curves showing the relationship between the predicted positive samples and those that are positive. While the CN2 model shows a fluctuating curve, the neural network model performance was inferior.

The ROC curve in Fig. 7 confirms the robustness and consistency of the performance of the constructed models, where the Random Forest model achieves the best performance. The region under its curve covers a large portion of the chart, followed by the Logistic Regression and CN2 model. However, the performance of the neural networks model was poor as its ROC curves pass through the baseline of the middle region, which indicates that its performance matches the performance achieved by a random model.

The region under the curve of the Random Forest model is the largest in the ROC chart, followed by the Logistic Regression and the CN2 models, respectively. The curve of the neural networks model was found to be poor as its performance curve passes through the baseline of the ROC, which matches the performance of a random stochastic model.

Fig. 6. A lift curve that shows the performance of the four constructed classification models.

Fig. 7. The ROC curve of the constructed models.

VII. DISCUSSION

The results of this study confirmed the validity of the applied machine learning algorithms for detecting and identifying three classes of network attacks and a benign class depending on several features related to computer traffic.

Furthermore, the variable importance ranking results conducted using GINI and Information Gain successfully identified Fwd Pkt Len Max, Tot Len Fwd Pkts, Subflow Fwd Byts, and Fwd Header Len. As the most prominent features for identifying network attacks. This result is consistent with the data exploration stage findings and the network security domain knowledge discussed in the literature [18, 46].

The Random Forest classifiers scored a CA score of 98%, while the Logistic Regression model scored a CA score of 90%. The Random Forest model achieved an AUC of 99%, while the Logistic Regression model achieved 98%. On the other hand, the CN2 model scored a modest CA performance of 70%, while the Neural Network model failed with a CA score of only 27%. The robustness of the Random Forest and Logistic Regression algorithms in creating the two most successful models was confirmed by the excellent performance shown in the confusion matrix for the two models and the results of the Lift and Calibration curves.

When comparing the results of this study with the results of other studies reported in the literature, in this respect, the results reported in this study outperformed all the excellent results reported in the surveyed literature. While most of the surveyed studies which achieved high CA Scores focused on identifying one or two types of network attacks. For example, the surveyed study reported in [15] aimed at detecting denial of service (DoS) attacks, while the study reported in [16] aimed at distinguishing benign Traffic from network attacks. The study reported in [30] aimed to distinguish botnets from infiltration attacks, while the study reported in [18] aimed to identify portrayal from botnet attacks. In comparison, the Random Forest model that was created in this work was successful in identifying four classes of network traffic: (1) Brute-Force Attacks; (2) Distributed Denial of Service Attacks (DDoS); (3) SQL Injection Attacks; and (4) Benign Traffic with an excellent 99% CA accuracy and 98 AUC.

In addition, the result of this study is quite significant when considering the type of dataset used in this study. This study was applied using a sample of the CSE-CIC-IDS2018 dataset, which is more challenging than the KDD Cup 99 that was used in some of the studies as reported in [15, 17] since CSE-CIC-IDS2018 is larger and it also has more features when compared to the KDD Cup 99 dataset.

However, the limitations of this study come from its dependence on using simulated data rather than real-world ones. In addition, the other important constraint in this study was the limited computational power of the standard PCs, which caused some issues related to the long execution time while experimenting.

VIII. CONCLUSION

This work has successfully investigated and evaluated the use of four machine learning algorithms: Random Forest, Logistic Regression, CN2, and Neural Networks for detecting and identifying three types of network traffic attacks: DDoS, Brute-Force Web, and SQL Injection, in addition to Benign Traffic.

The study provided a positive answer to the research question and successfully achieved the research objectives. Four machine learning algorithms were applied to a randomized sample of the CSE-CIC-IDS2018 dataset: Random Forest, Logistic Regression, CN2, and Neural Networks. Random Forest scored a CA score of 98%, while Logistic Regression scored 90%. Random Forest scored 99% in the AUC metric, while Logistic Regression scored 98%.

The results obtained in this study contribute towards solving some of the most important problems in computer network traffic and cyber security. These contributions can be summarized as (1) Creating successful machine learning models that can be deployed to detect and identify three types of network attacks based on network traffic data; (2) Identifying significant network traffic features that can be used as predictors for providing fast, accurate and reliable detection and identification of network attacks. These contributions can contribute towards developing solutions that help for preventing, monitor, and mitigate harmful computer network attacks, which affect the reliability, efficiency, and availability of the services provided by computer networks.

The practical use of the successful results that are reported in this study implies deploying the two most successful models reported in this study: Random and Logistic Regression, by embedding them in a network router, security suit, proxy, or firewall system in order to detect, identify or filter network traffic that creates a potential threat to the network.

Future work could be conducted to cover more machine learning techniques and more types of network attacks. In addition, a more real-world dataset can also be used rather than depending only on a simulated one. In addition, more powerful computers can also be used to conduct the same or a comprehensive study on the entire dataset rather than on a sample of it.

Abstract—Seagrass ecosystems are coastal ecosystems with high species diversity, especially fish. Fish diversity determines the abundance of communities based on the number of species. Detection of fish directly (in-situ) and conventionally by catching them requires more energy, costs, and relatively needs time. Therefore a computer vision method is needed that can detect fish well using underwater images. The fish detection model used Masked-Otsu Thresholding, HSV color space with closing techniques in morphological operations. The dataset is in the form of 130 underwater images, divided into 80% training data and 20% testing data. The test results showed a model accuracy value of 0.92, Precision value of 0.84, Sensitivity value of 0.93, and F1 Score of 0.88. With these results, the model could detect fish in the seagrass ecosystem.

Keywords—Fish Detection; HSV color space; masked-otsu thresholding; morphological operation; seagrass ecosystem

I. INTRODUCTION

Seagrass ecosystems are ecosystems in coastal areas with a high diversity of species, especially fish. These varieties are variations in how species interact with each other in their environment. Diversity indices are useful for determining abundance in a community based on the number of species in a location, such as the research of R. Machrizal et al. on the diversity of macrozoobenthos species[1], fish assemblages[2], seahorses species[3], sea cucumber[4]. Detection and classification of fish in seagrass ecosystems are done manually by fishing, photographing, recognizing, and recording in the ledger. This technique is quite good but takes a long time and costs a relatively high amount. Therefore, computer vision techniques and digital image processing will be very helpful.

The underwater environment is more complex than the above-water surface. Sunlight entering the water will undergo absorption and dispersal of light by water media and floating particles in water. The light absorption and dispersal effect results in color distortion, low contrast, and blur in the resulting underwater image[5]. In addition, the difference in attenuation causes the underwater image to be bluish, greenish, or other colors. In addition, the image contains foreground and background caused by the placement of the camera, which is difficult to get close to the observation object. That observation object will be smaller than the background image. Caused bias in the object detection process. It is challenging to make underwater observations using both underwater images and videos.

One solution to separate the background to get the desired object is to use an image segmentation technique based on RoI (Region of Interest). One of the RoI segmentation techniques is the Otsu Thresholding method. The otsu method[6] aims to automatically segment the histogram value of the grayish image in two different regions by entering a threshold value. After the background has been successfully separated, this value is used to detect objects.

Fish detection has been carried out [5][7][8][9] using fish data taken on land, namely by taking photos of fish manually or taking data in an aquarium that has good lighting. In addition, research on fish detection using underwater video was carried out by [10][11]. Retrieving datasets in a limited environment (aquarium) results in a simpler background and foreground. Data collection in the original environment, such as in the seagrass ecosystem, has a more complex background, such as the color of fish objects similar to seagrass leaves or water.

This study used primary data from UTS (Underwater Televisual System) equipment on Beralas Pasir Island, Bintan Regency, Riau Islands, Indonesia. In this study, underwater image data is used, with the area of fish observation objects, seagrass leaves, and transects. Analysis of the underwater image dataset used in this study, it can see that fish objects swimming between seagrass leaves have a color that is almost similar to the color of water or seagrass leaves, that the shape of the fish tends to be smaller (narrow object area) compared to the image background, this makes it difficult to detect it, therefore to remove the background of the underwater image and obtain the detection object, then otsu thresholding is used. The use of HSV color space and morphological operation to obtain a range of HSV values used for area detection of fish objects. This study aims to create a fish detection model associated with seagrass beds on Beralas Pasir Island, Bintan Regency, Riau Islands, Indonesia, using Masked-Otsu in HSV color space. By determining research questions as follows:

R1: How to segmentation of fish objects with an underwater image background using the masked-otsu algorithm.

R2: How to detect fish by applying a range of HSV values and object contours through morphology operation.

II. RELATED WORKS

Research on fish detection in seagrass ecosystems has been widely practiced. Most of this research is still done manually, namely by catching fish, being photographed, recognized, and recorded in books. The results have been good, but it requires a lot of time and cost [12][13][14][15][16].

Recently, the use of machine learning and deep learning for fish detection has been widely carried out, and extensive resources and longer time consumption have become considerations in this technique. Meanwhile, digital image processing techniques such as segmentation that can separate the background and foreground with less time consumption can be further developed.

Petrelis Nikos [17] in 2021, utilizing image processing and deep learning techniques to estimate the length, height, and area of fish through fish morphological features and CNN methods, fish objects are visible in shape, and the system built has estimation errors of 1.9% and 13.2%. In 2021, Shoffan Saifullah et al. [7] detected fish through morphological operation and K-Mean segmentation, using photos of fish taken on land so that fish objects were visible, obtaining an SSMI distribution value of 0.9994. Heningtyas research et al. in 2020 [8], using the Expectation Maximization (EM) segmentation algorithm, photos of fish objects taken from an aquarium with good lighting obtained an accuracy of 89.14. Kartika et al. in 2016 [9] classified Koi fish using Naïve Bayes and SVM using K-Fold Cross Validation in HSV space; The Koi Fish image was taken on land, and the study results had a success rate of 0.968. Anggraeny research et al. in 2020 [18] detected fish with the Histogram of Oriented Gradients (HOG) algorithm and AdaBoost-SVM, the accuracy of which was achieved at 0.848. In this Studi, we propose a masked-otsu thresholding segmentation technique to separate objects from the background. The object area is divided into 3, namely the fish, seagrass leaf, and transect areas. After the object is separated from the background, fish detection uses upper and lower HSV color space values and morphological operations with the closing technique. The contribution of this study is to detect fish in complex dynamic environments, namely in seagrass ecosystems, by separating the background of underwater imagery to obtain fish objects.

III. RESEARCH METHODOLOGY

Broadly speaking, this research consists of several stages, namely: Starting from collecting datasets in the form of underwater images with a size of 620x480 pixels as many as 130 RGB image data, Fig. 1 shows the system flowchart, and Fig. 2 shows the original underwater image.

The original underwater image is cropped at the top to remove the color of the water so that the cropping image is 620x330 pixels. This image is later used to detect fish in a seagrass frame. Furthermore, this dataset will be divided into 2, namely Data Training as much as 80% and Data Testing as much as 20%.

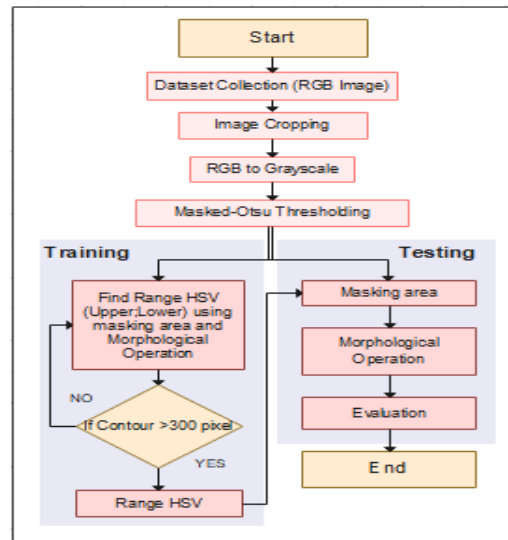

Fig. 1. Research phases.

Fig. 2. Original underwater image.

The third step converted the RGB image to Grayscale. Then, the grayscale image was converted again into a binary image using the Otsu Threshold Method to separate objects (fish) from the background; a threshold value of 120/255 or 0.47 was used.

In the training stage, a search for HSV value range values is performed to detect fish areas, using masking areas and morphological operations. The morphological operation used is a closing operation to close gaps or remove small holes between contours so that it can soften a large object without changing the object significantly.

The equation of the closing operation with the notation A (original image) and B (structuring element) is as follows:

$$A \bullet B = (A \oplus B) \ominus B \quad (1)$$

Dimension search for detecting objects using the HSV value range is by setting the Upper and Lower values based on the reference object (fish) specified in the thresholding process. The testing stage will be implemented value at range determination is done by paying attention to the area of the object to be detected; if the range is too wide, then unwanted objects will appear; on the other hand, if the range is too narrow, cannot detect the object.

In the testing phase, the masked-otsu threshold result image, given masking, namely the area that is included in the HSV value range that has been obtained previously set as the object dimension. Then the morphological process of closing the area object is carried out; if the contour value is > 300 pixels, it will be marked as fish. The last step is to evaluate by looking for Accuracy, Precision, and Recall values from fish detection models in the seagrass ecosystem. Accuracy, Precision, and Recall using the confusion matrix are as follows:

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (2)$$

$$Precision = \frac{TP}{TP + FP} \quad (3)$$

$$Sensitivity = \frac{TP}{TP + FN} \quad (4)$$

$$F1\ Score = 2x \frac{Precision \times Sensitivity}{Precision + Sensitivity} \quad (5)$$

Where TP (True Positive) is the number of fish objects successfully detected, TN (True Negative) is the number of non-fish objects (seagrass and transects) detected as non-fish objects, FN (False Negative) if the fish object is not successfully detected as fish. Finally, FP (False Positive) refers to the object that is not fish (seagrass or transect) and is recognized as fish.

IV. RESULT AND DISCUSSION

The data set used in this study is in the form of an underwater image with a size of 640x480 pixels, as many as 130 RGB image data, after cropping the original image's dimensions to 640x330 pixels. Each image is divided into three sample areas: fish, seagrass, and transect. After the dataset is formed, the next step is to cut the top of the image to remove the color of the water so that later this image is used to detect fish in the seagrass frame. Fig. 3 shows the change of the original image to a threshold image with masked-otsu in RGB space.

The dataset is divided into 80% for the training stage, 104 underwater images, 20% for the testing stage, or 26 images. All of these images will be thresholds, then at the image training stage, as many as 104 are used to train the model so that it can detect fish objects; the HSV value range is obtained as follows:

$$\text{Lower} = [74,83,190]$$

$$\text{Upper} = [88,99,230]$$

This value is implemented in the data test, after which masking the area for the object's dimensions is included in the HSV value range. Then a closing operation is carried out to close the gap between the contours so that the corresponding object contour is obtained, namely the contour value > 300 pixels marked as fish. While if the contour value ≤ 300 will be discarded. Fig. 4 shows the fish detection process starts by changing the RGB image from implementing Otsu thresholding to HSV color space, masking area, and operation morphology until the fish object is successfully detected.

At the training stage, the accuracy level is calculated using Equation (2) with 104 underwater image data covering three

area objects: Fish, Seagrass, and Transect. The total area used is 314 areas. Based on the experiments, an accuracy of 0.91 or 91% was obtained, which means that the model can correctly predict the area of objects (fish, seagrass, and transects) (Positive).

Meanwhile, at the testing stage, a dataset of 26 underwater images was used. Fig. 5. Show a confusion matrix for testing data.

Fig. 3. Change of original Image to threshold image in RGB space.

Fig. 4. Fish detection process.

		Actual	
		TP	FP
Predicted	TP	26	5
	FN	2	52

Fig. 5. Confusion Matrix on testing data.

Fig. 6. False Negative (FN) on testing data.

Fig. 7. False Positive (FP) on testing data.

The FN error appears when the model cannot detect the fish object as a fish, as in Fig. 6. Meanwhile, FP occurs because the model states a non-fish object as a fish, where the non-fish object can be seagrass or transect. Fig. 7 shows False Positive.

Based on Table I of the data testing results, there is an increase in the percentage of data testing accuracy values compared to the results of training data experiments by 1%. This increase in accuracy percentage is not significant, so the model created is already optimal. The detection error rate is 0.08 or 8%. This detection error is caused by the presence of FN and FP on the model. The error arises because the area of the fish to be detected is narrow, blurry, and unclear; besides that, the shape and color of the fish are almost the same as the seagrass leaf. Even with ordinary eyes, this fish is difficult to detect.

In addition to the Accuracy value, Table I also shows a Precision value of 0.84 or 84%. This Precision value signifies the reliability of a reliable model for repeated data testing. The sensitivity value is obtained at 0.93 or 93%, which means that the model can detect or give a True value to positive data. Then last is the F1 Score. The F1 Score is 0.88 or 88%, meaning that the model is capable and reliable in detecting fish well.

TABLE I. DETAIL RESULTS OF TESTING DATA

Accuracy	Precision	Sensitivity	F1 Score
0.92	0.84	0.93	0.88

Fig. 8. Fish Detection Model Without HSV.

This study also tried to test fish detection directly, namely from masked Otsu Thresholding directly carried out the morphological process of the operation without using the HSV color space range value. The results are shown in Fig. 8. The picture shows that the detection results could not be better because the error rate that occurs is high, and the detection results are widened.

V. CONCLUSION

Based on the test results on the testing data, an accuracy value of 0.92 was better than the accuracy of the training data of 0.91. It is not significant, meaning that the model built is optimal for detecting fish. In addition to accuracy, the model gets a Precision value of 0.84 which means it can be relied upon for repeated data testing. The Sensitivity value is 0.93, which means that the model can detect or give a correct value to positive data. Then last is the F1 Score. The F1 Score is worth 0.88, meaning that the model is capable and reliable in detecting fish well.

The test results also showed a misdetection of 8%. The error arises because the area of the fish to be detected needs to be narrower, opaque, and unclear. Besides that, the shape and color of the fish are almost the same as the seagrass leaf. Even with ordinary eyes, this fish is difficult to detect. This cause the resulting underwater image to have low contrast and blur. The next study is to create a fish detection model that can capture small fish dimensions with a fish shape or color almost the same as the color of water and seagrass leaf based on video using the GMM (Gaussian Mixture Model) algorithm and morphological Operation. Using datasets in the form of underwater videos considering fish objects will look moving and can be distinguished from the image background. GMM was chosen because this algorithm effectively separates the background and foreground on the input frame sequence compared to Otsu Thresholding.

ACKNOWLEDGMENT

This research was supported by Penelitian Disertasi Doktor (PDD), Contract No. 3792 /IT3. L1/PT.01.03/P/B/2022. Seagrass ecosystem data set used in this paper is obtained from DDRG-LIPI research grant, Contract Number: B-1201/IPK.02/KS/III2018 and Number: 238/KS/00/00/2018 to Prof. Dr. Indra Jaya/FPIK-IPB. The authors also would like to thank Muhammad Iqbal for preparing the data set.

Abstract—The fourth industrial revolution is a technological advancement that is posing new challenges in manufacturing and services. Industries must adopt innovations to create value-added for their products and services to gain a competitive advantage and increase production efficiency. Therefore, this research aims to study the factors that influence the application of Industry 4.0 technology for managing electrical appliance production by focusing on five major factors: the internet of things, cloud manufacturing, big data analytics, additive manufacturing, and cyber-physical systems, which can be further subdivided into 23 sub-factors. The fuzzy analytic network process (FANP) technique is used to prioritize the factors to develop criteria for selecting appropriate applications of Industry 4.0 technology in manufacturing. Besides, a questionnaire based on the FANP approach is used to collect data from 82 electrical appliance manufacturers to calculate the weight of each factor. Consequently, the Internet of Things is ranked first, followed by big data analytics and additive manufacturing. While the results have indicated the importance of sub-factors as data-driven, data collection, tracking, monitoring, and automation, respectively. The benefit of this research is that manufacturers of electrical appliances can use this research as a criterion for implementing Industry 4.0 technology for long-term effectiveness.

Keywords—Industry 4.0; big data analytics; internet of things; cloud manufacturing; additive manufacturing; cyber-physical systems; fuzzy analytic network process

I. INTRODUCTION

The manufacturing industry is currently undergoing a transformation in innovation and technology, which is pushing successful output. Connectivity and data analytics advancements are a part that can help the manufacturing industry create value-added and competitive advantages for its products and services. Therefore, integrated production processes are critical in the industrial revolution to enhance production levels and make them more efficient by incorporating Industry 4.0 concepts such as Internet technology, communication technology, and automated production. Besides, the manufacturing system is combined with precision machine tools and devices that may be connected to the internet for efficient production control and data analysis. Various industries have adapted to the Industry 4.0 transformation using new technologies, which will create

new business needs and opportunities [1, 2], including machine-to-machine communication for automated control [3, 4]. Therefore, smart factories must have sensors connected to devices or machines to control their operations effectively, resulting in real-time data management and exchange [5, 6]. Additionally, these devices or machines in the manufacturing process can help to create effective preventive maintenance plans for machines and equipment in production [7, 8]. Technological advances enable the detection and processing of communication capabilities with devices and services, resulting in higher standards and a more efficient manufacturing operating environment [1, 7, 9]. Consequently, Industry 4.0 technology is a necessary technology for increasing production efficiency and creating sustainability.

This study presents the challenges of sustainable manufacturing in Industry 4.0, intending to study the impact of various factors in the application of Industry 4.0 in the manufacturing of electrical appliances, as well as the significance of these factors in forecasting decision-making's tendency in the future application of Industry 4.0 technology. The fuzzy analytical network process (FANP) approach in the multiple criteria decision-making principle (MCDM) is used in this research because FANP can simplify complex problems and allow dependence and feedback in the hierarchy. Thus, the FANP approach is applied for prioritizing factors to analyze and compare their relative importance, which impacts the decision-making for applying Industry 4.0 technology in the electrical appliance industry. Finally, the study's findings will assist stakeholders in making informed decisions in terms of the implementation of Industry 4.0 technology in their manufacturing processes to increase their businesses' competitiveness and performance in the long run.

In the first section, we review Industry 4.0 technology and its applications to determine the factors that affect the application of Industry 4.0 technology in manufacturing. In the following section, we describe the research methodology used in this study, as well as related theories such as the fuzzy set and fuzzy analytical network process, which are used for prioritizing factors influencing decision makers in electrical appliance manufacturers in terms of Industry 4.0 technology application. The study's results have shown the importance of factors and sub-factors including their ranking by FANP in

Section IV. Section V discusses the findings and management implications. Finally, Section VI concludes with a summary of the study's findings, limitations, and future research.

II. LITERATURE REVIEW

Building a competitive advantage requires the development of systems [10], whereas the evolution of Industry 4.0 enables more transparent resource utilization through efficient practices in both production and innovation [11, 12]. Furthermore, the government has recognized the critical importance of Industry 4.0, information technology, and the environment in driving the economy, issuing a slew of regulations to support and safeguard them [13]. By incorporating intelligent mechanisms and automation in the industrial environment, Industry 4.0 enables businesses to improve production processes [5]. The challenges of Industry 4.0 encompass not only the technological dimension, but also the organizational, social, and national economic dimensions. Thus, organizations and governments must adapt to Industry 4.0 to achieve operational success [14]. The fourth industrial revolution is the result of rapid technological advancement [15], as evidenced by the interconnection of intelligent manufacturing systems used in Industry 4.0. The goal is to create human-machine interaction by automating and resilient production, parts and product tracking, and machine-to-machine communication. This will result in increased

productivity and lower costs. To enable on-demand production and more efficient supply and demand, the intelligent manufacturing system will connect product design, analytics, manufacturing processes, stock and supply chain systems, product customization, delivery systems, and customers [16]. While, the Internet and technology are future-oriented, and they improve the human-machine interaction paradigm to provide added value to processes [14, 17, 18]. Information technology is a critical component of the economy's driving force [19], enabling the digitization of production processes, the relationships between physical and controllable objects, and the improvement of integration between the physical and digital worlds [20]. Manufacturing technologies are being developed to communicate and deliver big data, allowing businesses to improve forecasting and productivity [21, 22]. Additionally, the technology incorporates processing capabilities to improve manufacturing processes, organizational interactions, human resource utilization, waste reduction, environmental impact reduction, energy savings, as well as the industrial value chain, all of which contribute to sustainability [5]. From the literature review of Industry 4.0, this study has identified five major factors affecting the application of Industry 4.0 technology as follows: Internet of Things (IoT), Cloud Manufacturing (CMg), Big Data Analytics (BDA), Additive Manufacturing (AM), and Cyber-Physical Systems (CPS), as shown in Table I.

TABLE I. PREVIOUS RESEARCH ON THE APPLICATION OF INDUSTRY 4.0 TECHNOLOGY

A. Internet of Things

The Internet of Things (IoT) is a collection of intelligent devices and sensors that can communicate with one another via the Internet [7, 23]. It can identify specific physical and virtual connections for communication, configuration, management, and data collection [14, 17, 18]. Besides, IoT can accurately monitor and measure a wide range of processes, such as real-time tracking, predictive maintenance, production volume management, and sales data [21]. Consequently, the collected data is routed to a central processing system for analysis and decision-making, resulting in solutions in automated manufacturing processes, lower production costs, and higher technological standards [20, 22]. IoT also has access to product lifecycle data, allowing products to be traced from the factory to the customer [23]. Furthermore, it can improve product cycle visibility, reduce resource consumption, increase productivity [24, 25, 26] provide maintenance traceability, monitor labor activities, and improve work safety [27, 28], as well as manage resources for increasing competitiveness and long-term success.

1) *Monitoring*: The process of visualizing the recording data from real-time monitoring of the status change of production parameters to a specified standard was known as monitoring [29]. It was possible to continuously monitor or audit production data by recording, analyzing, or evaluating traceability data in real-time [30]. When non-standard problems such as critical overloads or insecurity were detected, the collected data could be assessed, and timely corrective action could be ordered [31]. Thus, organizations must regularly monitor and control operations under countermeasures to ensure process reliability, flexibility, and long-term productivity.

2) *Tracking*: A system that enabled the periodic monitoring of operational procedures and displays the data could be useful for analyzing current and future situations. Controlling and processing operations could also check the status of each step of the process, allowing for real-time tracking of goods flow [20]. Thus, Internet of Things applications that connect all relevant departments to collaborate via the Internet could improve efficiency in operational control decentralization [32, 33]. It provided a real-time tracking system for the manufacturing process, making the operation more convenient and increasing customer confidence.

3) *Information*: Information was created by processing and analyzing data from the Internet and presenting it in the form of knowledge that was applied to the workplace. Quality information must be accurate and up to date, as well as consistently stored. It is also supported by paperwork reduction, production management access, and inventory management [30]. Complex work systems and real-time decision-making necessitated the use of information as well. Thus, managing the flow of goods in processes enabled supply chain participants to track the flow of goods in real time and make precise decisions based on the information obtained

[29]. Consequently, precise data acquisition and management were accomplished, allowing for more efficient operations.

4) *Automation*: IoT automation connected the entire network and shared data with linked systems based on requirements [31, 34], allowing for cost-effective, convenient, and safe operations. Using automated systems, humans can perform high-accuracy and risky tasks. Furthermore, controlling or receiving commands in real-time [35], between devices or machines based on connectivity requirements resulted in increased production and management capabilities.

B. Cloud Manufacturing

Cloud manufacturing is a data collection and processing system that collects and processes data with servers on computer networks. It also included services and applications that could use a network connection to access and process data or resources on the Internet [7, 25]. In addition, cloud manufacturing was a technology that involved the delivery of computing resources via the Internet, resulting in lower operating costs and increased response time efficiency. It also enabled data access from any location at any time, responsive data sharing, and supply chain support continuity [36, 37]. Therefore, cloud computing technology could make storing and processing large amounts of data more efficient. It could also develop new services, such as quality monitoring and control functions that improve operations and production efficiency [23].

1) *Security*: Database management security was a critical aspect of security. Particularly concerning was the provision of information to third-party cloud systems [38] because corporate data includes customer data, business data, employee data, intellectual property, and so on [39]. As a result of the various levels of information security requirements that underpin cloud services as well as search and access capabilities, the issue of information security was a huge challenge in services. Data security risks might negatively impact the organization; therefore, trust in cloud service recipients is required [31].

2) *Resources as service*: The service-oriented manufacturing model was designed to manage resources by providing cloud-based manufacturing solutions, on-demand network technology services, cloud service capabilities, and service platforms [34, 40]. It was a model that combines various technologies to facilitate collaboration, including sharing and managing production resources [41], where cloud manufacturing entailed the transformation of production resources (hardware and software), cloud service capabilities, and the ability to control services, as well as the management of production resources, processes, operations, and Internet transactions [40].

3) *Orchestration*: Capabilities for customer-focused collaboration and the creation of a new production line from a dedicated manufacturing service [40], were additional cloud manufacturing services for creating capabilities such as intelligent routing, preparation, data integrity checking, and security [41, 42], as well as business process service

management that could be modeled and structured to support a smooth business.

4) *Resource management*: Cloud productivity capabilities enabled organizational planning and resource allocation to achieve goals. In resource management, resource simulation must consider the importance of resource diversity, user demand requirements, and performance requirements [31, 38] by connecting objects and production resource management for supporting manufacturing [43, 44]. Besides, it was a tool for organizing and managing information about production resources, including physical and virtual resources to maximize resource management capabilities [42].

5) *Utilization*: Using cloud computing technology facilitates and shares data to maximize productivity utilization [45], and the availability of dynamic cloud management would meet real-time needs [34]. By allocating production resources appropriately, cloud manufacturing could reduce costs and increase resource utilization. This allows for a smooth transition from service-oriented manufacturing to remediation [46], resulting in improved utilization or capacity of production resources.

C. Big Data Analytic

Big data analytics is a challenge for corporate performance in driving manufacturing because it can be used for real-time communication, monitoring, and transactions via multi-directional data networks and supported digital supply chain strategies [16]. On the other hand, data collection, analysis, and dissemination from machines and equipment enable efficient data storage, monitoring, and decision-making evaluation. [20, 47]. Meanwhile, predictive analytics, agility, and business insights [21], enable machines and devices to analyze data trends with artificial intelligence, including rapid communication of customer data, which can improve product quality and the business's supply chain [23]. Consequently, big data analytics improves the ability to collect data in real-time to meet objectives on time [48, 49, 50]. Furthermore, it can also learn from data for more accurate predictive production.

1) *Predictive*: Predictive analytics provided insights into potential trends [51] by utilizing mathematical techniques, simulations, multi-criteria decision-making, planning automation, risk management, and demand forecasting, among other things [52]. Predictive analytics also employed planning and control to accurately forecast production to meet demand and make real-time decisions.

2) *Data collection*: Data collection enabled real-time decision-making by analyzing data from various sources such as production data, customer feedback, or product ordering systems [33]. The data would be saved and collected in the storage system for further analysis [31]. To derive value from various types of data stored on demand, organizations must collect a large amount of data and require adequate data storage to support big data from resources.

3) *Data-driven*: Data-driven played an important role in supporting organizations' management, strategic planning, and

goal setting, which necessitated large data storages to support big data in multiple formats while maintaining data quality and accuracy. Thus, the ability to process and control operations with big data has been applied to learning, analysis, and event-based decision-making. Consequently, data-driven systems capable of optimizing both production and predictive production are created [33, 52]. Besides, the visual ability of data flow throughout the supply chain, such as service quality, forecast accuracy, production efficiency, and inventory planning, would result in improved supply chain collaboration and effective network response [53].

4) *Accuracy*: Big data analytics could deliver real-time data quickly and accurately, as well as exchange data in planning, controlling, and forecasting for accurate decision-making [52]. In addition, big data analytics was critical in enabling multidimensional data to be considered and presented with accuracy, resulting in resource utilization that was consistent with demand, reducing losses and costs, controlling quality, and increasing productivity [21, 33]. Moreover, big data analytics enabled real-time decision-making based on accurate data analysis results. It could be analyzed using big data platforms, which could generate sophisticated analytical models tailored to the situation and ensure more accurate production.

D. Additive Manufacturing

Additive manufacturing, also known as 3D printing, is a technique for creating parts from computer-aided designs, and it is most used to create prototypes [51, 33]. It is a manufacturing challenge that could replace traditional production, making it more convenient and supporting low-volume production [54, 35, 55]. Additive manufacturing aids product design in meeting needs and complexity, bringing products to market faster, and lowering transportation and storage costs. It also reduces material waste, improves, and develops products, and facilitates prototyping [23, 21, 22]. Thus, additive manufacturing technology has the potential to reduce production time and machine and raw material modification costs, improve reverse engineering ease, rapidly create new products and reproducibility, conduct testing and validation, increase customer satisfaction, and boost competitive advantage.

1) *Prototype*: Rapid prototyping played an important role in enabling diversified and enhanced production through technology for part design and creation, on-demand prototyping, minimizing design errors, prototyping testing and validation, pre-production customization, and product life cycle in new product development, which could be quickly adapted to change and meet market demands [21]. Furthermore, rapid prototyping increased the versatility of the fabrication process by enabling customization, ease of on-site production, and cost savings in production time and machine tool replacement, including raw materials [33]. Besides, prototyping was cost-effective and could lead to customer satisfaction.

2) *Flexibility*: The flexibility of additive manufacturing had accelerated the development and production of new products while also enabling convenient improvements or modifications to existing products [33]. Moreover, sophisticated and iterative products could be designed more quickly, saving money and time compared to traditional manufacturing methods while maintaining quality, durability, and functionality. In smart manufacturing, testing and validation were essential components of additive manufacturing [20], allowing manufacturing processes to be managed more efficiently.

3) *Optimization*: Additive manufacturing was a crucial method for structural design and manufacturing, as well as scalability, product design, and production integration. Furthermore, additive manufacturing could be used to create homogeneous structures with multiple sizes or layers [56]. This was an evolutionary structure optimization in which the optimal structure was determined by appropriate material distribution, resulting in the automatic optimization of specific input data.

4) *Reduction*: Because of the low scrap rate and easy disassembly of the structure for design and production, using additive manufacturing techniques could help manufacturers save money and support costs while also reducing waste [33]. Additive manufacturing techniques might also reduce the amount of labor, machinery, and equipment used in the manufacturing and prototyping of parts, which is especially labor-intensive and expensive in metal prototyping. Additionally, using additive manufacturing techniques could reduce costs associated with manufacturing, assembly, and inventory, resulting in more efficient prototype production.

E. Cyber-Physical System

A cyber-physical system (CPS) is an integrated engineering system that connects the physical and cyber worlds [42, 44, [57]. The physical world consists of devices, machines, humans, systems, etc. Whereas, the cyber world, also known as the digital world, processes and controls the physical world by connecting it with the Internet of Things (IoT), which oversees the physical world's connectivity, communication, and data transfer to the cyber world. While the cyber world computes, analyzes, or decides to send feedback control data to the physical world automatically. It also encourages the monitoring and control of environmental changes to facilitate manufacturing operations [20, 22] as a technology for management systems that wisely connect physical resources [38, 31, 43] As a result of this, machine performance, quality inspection, and control functions, as well as operation and production, have all improved [56, 40].

1) *Collaboration*: By directly processing data on the Internet, cyber-physical systems could collaborate indefinitely [33]. Computer collaboration in physical process operations such as machine and equipment control, warehouse management, and production process management could be planned and controlled by analyzing and processing data contained in the system [20, 58] to support collaboration,

collaboration and resources, data sharing between service providers, and these capabilities were complementary to integration and collaboration [52].

2) *Detects production system*: Sensing production systems connected with computers to exchange data (interface), such as the interaction between computer users, machines, and equipment [33]. Whereas cyber-physical systems could monitor, measure, perceive, and control system conditions to meet goals or prevent errors in the manufacturing process, including fault detection (Downtime due to faults, workflow restrictions, and error notification). Besides, identifying the source of the defective process improved systems to prevent faults from recurring.

3) *Decision-making*: Data obtained from the manufacturing process was used to drive decision-making processes, allowing cyber-physical systems to perform better [59]. Numerous real-time data exchanges occurred between systems to ensure the continuity of decision-making and situation management, resulting in a reduction in data planning errors and complex decision-making processes [20]. Additionally, this enabled analysis and decision-making to control systems and achieve goals. Furthermore, Intelligent decision-making and control, machine control, and troubleshooting all contributed to faster and more accurate decision-making, which increased productivity.

4) *Visibility and traceability*: Visibility and traceability were components of the cyber-physical system that assisted employees in making simple proactive decisions, inspecting parts, controlling quality, and planning and controlling production. Manufacturing traceability and intelligent forecasting in supply chains are supported to eliminate employee concerns [52] by automatically computing, analyzing data, and transmitting feedback control.

5) *Synchronization*: the cyber-physical system would be able to synchronize various production activities such as planning and controlling in real-time [52] based on orders, production processes, and responses. By synchronizing the production process with other related processes, it created production process continuity [45].

6) *Intelligent*: Cyber-physical systems, powered by intelligent data, digitized data that could be used for automated audits, data processing, and monitoring. as well as modeling. Automated learning relied on constantly changing data to make accurate predictions and intelligent decisions. Sensor systems were used in the production and maintenance of machines and equipment [20], to make them more reliable and efficient, and they were a smart manufacturing innovation.

III. MATERIALS AND METHODS

In this study, the survey method was used for data collection, which was followed by quantitative research. The research tool was a questionnaire based on five main factors and a fuzzy analytical network process approach: Internet of Things, cloud manufacturing, big data analytics, additive manufacturing, and cyber-physical system, as shown in Fig. 1.

Fig. 1. Conceptual framework of the application of Industry 4.0 technologies in manufacturing.

Fig. 2. The research framework of the application of Industry 4.0 technology.

According to the Institute of Electrical and Electronics, the population in this study consisted of 440 electrical appliance manufacturers in Thailand, with the Yamane’s formula [68] indicating that the sample size for the study was 82 samples. Following the completion of the questionnaire, the researcher distributed it to 82 respondents sampled using the snowball method who were decision-makers in the implementation of industry 4.0 in electrical appliance manufacturers. At the start of this survey, experts from electrical appliance manufacturers were identified and called in to ask their permission to answer the questionnaire about the factors affecting the application of industry 4.0 technology in electrical appliance manufacturing. Following that, the data from the questionnaire were analyzed and carried out following the steps in the research framework depicted in Fig. 2.

A. Fuzzy Set

Zadeh (1965) developed a fuzzy set theory to deal with situations involving uncertainty, imprecision, and vagueness. Currently, fuzzy set theory is frequently used in multiple criteria decision-making techniques for practical applications in uncertain settings, and it is also effectively applied for modeling human decisions and judgments. [69, 70, 71]. The theory also allows for the application of mathematical operations and programming to the fuzzy domain. In general, a membership function defines the fuzzy set, which represents the grade of any element x of X that has partial membership to

M . The degree to which an element belongs to a set is determined by a value between zero and one. Thus, the element x belongs to M , $\mu_M(x) = 1$ and $\mu_M(x) = 0$ [69, 72].

The triangular fuzzy number is made up of three parameters: (l, m, u) where $l \leq m \leq u$. The membership function $\mu_M(x)$ of TFN is derived by Eq. (1).

$$\mu_M(x) = \begin{cases} (x - l)/(m - l) & l \leq x \leq m \\ (u - x)/(u - m) & m \leq x \leq u \\ 0 & \text{otherwise} \end{cases} \quad (1)$$

Let $X = \{x_1, x_2, \dots, x_n\}$ represent an object set and $U = \{u_1, u_2, \dots, u_n\}$ represent a goal set. Chang (1992) extent analysis method takes each object and performs extent analysis for each goal g_i . For each object, m extent analysis values with the following signs can be obtained:

$$M_{g_i}^1, M_{g_i}^2, \dots, M_{g_i}^m, \quad i=1,2,\dots,n \quad (2)$$

Where $M_{g_i}^j$, ($j = 1, 2, \dots, m$) represents in triangular fuzzy numbers.

B. The Fuzzy Analytical Network Process

The fuzzy analytic network process (Fuzzy ANP) is a multiple criteria decision-making (MCDM) technique that employs both criterion interdependence and criterion inner dependence with the pairwise comparison matrix. In this

study, we present Chang's (1992, 1996) extent analysis method because the steps are simpler than those of the other fuzzy ANP techniques. The following are the steps of Chang's (1992, 1996) extent analysis approach:

$$S_i = \sum_{j=1}^m M_{gi}^j \otimes [\sum_{i=1}^n \sum_{j=1}^m M_{gi}^j]^{-1} \quad (3)$$

To obtain $\sum_{j=1}^m M_{gi}^j$, perform the fuzzy addition operation on m extent analysis values for a specific matrix so that:

$$\sum_{j=1}^m M_{gi}^j = (\sum_{j=1}^m l_j, \sum_{j=1}^m m_j, \sum_{j=1}^m u_j) \quad (4)$$

And to obtain $[\sum_{i=1}^n \sum_{j=1}^m M_{gi}^j]^{-1}$, perform the fuzzy addition operation of extent analysis values for a specific matrix so that:

$$\sum_{i=1}^n \sum_{j=1}^m M_{gi}^j = (\sum_{j=1}^m l_j, \sum_{j=1}^m m_j, \sum_{j=1}^m u_j) \quad (5)$$

Then compute the inverse of the vector in the preceding equation so that

$$[\sum_{i=1}^n \sum_{j=1}^m M_{gi}^j]^{-1} = \left(\frac{1}{\sum_{i=1}^n u_i}, \frac{1}{\sum_{i=1}^n m_i}, \frac{1}{\sum_{i=1}^n l_i} \right) \quad (6)$$

The degree of possibility of $M_2 = (l_2, m_2, u_2) \geq M_1 = (l_1, m_1, u_1)$ is defined as:

$$V(M_2 \geq M_1) = \sup[\min(\mu_{M_1}(x), \mu_{M_2}(y))] \quad (7)$$

and can be equivalently expressed as follows:

$$V(M_2 \geq M_1) = \begin{cases} 1 & \text{if } m_2 \geq m_1, \\ 0 & \text{if } l_1 \geq u_2, \\ \frac{l_1 - u_2}{(m_2 - u_2) - (m_1 - l_1)} & \text{otherwise} \end{cases} \quad (8)$$

$$V(M \geq M_1, M_2, \dots, M_k) = \min V(M \geq M_i), \quad i = 1, 2, \dots, k \quad (9)$$

Assume that:

$$d(S_i) = \min V(S_i \geq S_k), \quad k = 1, 2, \dots, n; k \neq i \quad (10)$$

Then the weights vector is computed by:

$$W' = (d(S_1), d(S_2), \dots, d(S_n))^T \quad (11)$$

And then, weight vectors are normalized as follows:

$$W = (d(A_1), d(A_2), \dots, d(A_n))^T \quad (12)$$

IV. RESULTS

For this study, the application of Industry 4.0 technology can be divided into five groups: Internet of Things (IoT), Cloud Manufacturing (CMg), Big Data Analytics (BDA), Additive Manufacturing (AM), and Cyber-Physical System (CPS). As illustrated in Fig. 2, each group includes several applications of Industry 4.0 technologies in manufacturing. Consequently, the goal of this research is to propose an industry 4.0 application for electrical appliance manufacturers' management to select appropriate technologies to integrate into their manufacturing processes to increase productivity and gain a competitive advantage. In this section, the research

process can be divided into six steps to evaluate the factors affecting the application of 4.0 technology and prioritize those factors for appropriate decision-making by electrical appliance manufacturers in the application of industrial 4.0 technology. The first stage identifies the application of industry 4.0 technology for the framework of factors and sub-factors, as determined by a questionnaire survey using the fuzzy A technique to compute the weights of the factors and sub-factors. The application is built on the steps from the previous section and is explained step by step along with the results.

Step 1: The fuzzy scale is used to determine the important weighting of main factors and sub-factors from a decision-maker in charge of an organization's Industry 4.0 application management. Select appropriate linguistic variables to represent the relative weight of the factors. Using the linguistic scale in Table II, a pair-wise comparison is prepared for each factor based on expert opinion.

Step 2: A questionnaire survey is used to collect data from 82 electrical appliance manufacturers to investigate the application of Industry 4.0 technology for management in practices.

Step 3: Compute the consistency ratio (CR) by Eq. (13).

$$CR = \frac{CI}{RI} \quad (13)$$

$$\text{When } CI = \frac{(\lambda_{max} - n)}{(n-1)} \text{ and } \lambda_{max} = \sum_{i=1}^n [\sum_{j=1}^n a_{ij} W_j]$$

The CR value should be less than 0.1, indicating that the weights determined by decision-makers are consistent. If the CR value is greater than 0.1, it indicates that the determined weights are inconsistent. Thus, the research should begin with a review of the main factors and sub-factors.

Step 4: Compute the average fuzzy evaluation matrix based on the questionnaire survey, as well as the local weights of the main factors and sub-factors, as shown in Table II-VII.

Step 5: As illustrated in Table IX, compute the inner dependence weights and dependencies among the factors considered to be the main factors.

Step 6: To compute the global weights of sub-factors, multiply the local weights of the sub-factors by the interdependent weights of the main factors, as shown in Table X.

When weights of main factors were calculated, it was discovered that the Internet of Things was the most important, accounting for 34.3 percent of the total, the Big Data Analytics accounted for 31.0 percent, Cloud Manufacturing factor 12.5 percent, and Cyber-Physical System 9.4 percent respectively, as shown in Table III.

In terms of Internal of Things, tracking was identified as the most significant sub-factor in this area, accounting for 30.7 percent. Monitoring is the second most significant sub-factor, accounting for 27.2 percent, while Automation and Information had declined in importance, accounting for 25.7 percent and 16.5 percent, respectively, as shown in Table IV.

TABLE II. LINGUISTIC SCALE FOR RELATIVE WEIGHTS OF FACTORS

Risk Level	Triangular Fuzzy Scale	Triangular Fuzzy Reciprocal Scale
Just equal	(1, 1, 1)	(1, 1, 1)
Equally important	(1/2, 1, 3/2)	(2/3, 1, 2)
Weakly more important	(1, 3/2, 2)	(1/2, 2/3, 1)
Strongly more important	(3/2, 2, 5/2)	(2/5, 1/2, 2/3)
Very strongly more important	(2, 5/2, 3)	(1/3, 2/5, 1/2)
More important	(5/2, 3, 7/2)	(2/7, 1/3, 2/5)

TABLE III. LOCAL WEIGHT AND PAIR-WISE COMPARISON MATRIX OF “MAIN FACTORS”

Main Factors	Internet of Things	Cloud Manufacturing	Big Data Analytics	Additive Manufacturing	Cyber-Physical System	Weights
Internet of Things	1.000, 1.000, 1.000	1.282, 1.738, 2.201	1.088, 1.516, 1.967	1.451, 1.951, 2.451	1.555, 2.055, 2.555	0.343

Automation	0.929, 1.252, 1.650	0.704, 0.974, 1.305	0.983, 1.407, 1.854	1.000, 1.000, 1.000	0.257

The weight of cloud manufacturing, Resource Management was the most important in this category, accounting for 27.4 percent, The second most important sub-factor was Resource as Service for 22.6 percent, followed by Orchestration for 21.4 percent, Utilization 18.8 percent, and Security 9.7 percent, respectively, as shown in Table V.

The weight of sub-factors in Big Data Analytics revealed that Data-Driven for 36 percent was the most significant sub-factor in this domain. Meanwhile, the second most important sub-factor was Data Collection for 33.4 percent, followed by Accuracy for 18.2 percent, and Predictive for 12.4 percent, respectively, as shown in Table VI.

The weight of Additive Manufacturing was considered, the findings indicated that the Flexibility was the most important in this area for 26.3 percent, Prototype accounting for 26.0 percent, Optimization for 25.3 percent, and Reduction for 22.4 percent, respectively, as shown in Table VII.

When considering the weight of sub-factors in the Cyber-Physical Production Systems domain, Decision-Making Processes was the most important at 21.4 percent, followed by Visibility and Traceability, which accounted for 20.9 percent. The Detects Production System was the second important sub-factor that accounted for 17.4 percent, followed by Collaboration for 14.7 percent, Synchronization for 14.2 percent, and Intelligent for 11.5 percent, respectively, as shown in Table VIII.

The decision-makers performed pairwise comparisons for main factors and sub-factors, which were then analyzed using fuzzy ANP. According to the findings, the "Internet of Things" was the most important factor, with an interdependent weight of 31.98 percent. The second most important factor, with a weight of 29.63 percent, was "Big Data Analytics", while "Additive Manufacturing," "Cloud Manufacturing," and "Cyber-Physical Systems" had interdependent weights of 14.17, 13.82, and 10.41 percent, respectively. In terms of important sub-factors, the results showed that "Data-Driven" was the most important sub-factor that influenced decision-makers, with a global weight of 10.67 percent. Next, "Data Collection" was ranked second with a global weight of 9.90 percent, followed by "Tracking," "Monitoring," and "Automation," with global weights of 9.81, 8.69, and 8.22 percent, respectively. The bottom five sub-factors in terms of

importance were "Detects Production," "Collaboration," "Synchronization," "Security," and "Intelligent," with global weights of 1.81, 1.53, 1.48, 1.34, and 1.20 percent, respectively. Therefore, these sub-factors had less influence on the decision-maker when selecting industry 4.0 technologies for their production management.

V. DISCUSSION

According to the findings of this study, the Internet of Things (IoT) is the most important because it can be linked to machines or equipment in the automated manufacturing process, such as the Automated Guided Vehicle (AGV) for loading raw materials into the production line. Robots and packaging equipment must operate in line with production flow to improve work efficiency, productivity, cost reduction, and human error. Furthermore, IoT may also be used to build interactions or data transmission amongst equipment to

maintain production running smoothly and in line with standards. Meanwhile, traceability and real-time data exchange can help manufacturing be more efficiently monitored and planned. Because the electronics industry typically uses just-in-time manufacturing methods, raw materials or parts must be arrived on time to meet production plans in both quantity and quality. For this reason, the IoT is used to connect production data with suppliers to control and track the flow of production parts to ensure continuity by predefined production plans against real-time targets. This enables the manufacturer and its suppliers to have access to the same data sources and use data to boost productivity while also storing big data for analysis and intelligent decisions. In terms of inventory management, the IoT can perform quick counts and control the right amount of inventory levels to ensure reliable raw material delivery.

Big data analytics is an important secondary factor in managing big data both inside and outside the organization for analytics to enhance decision-making, machine maintenance predictions, data modeling for summary reporting, data connecting across the manufacturing process, predictive analytics, and data linking between suppliers and customers. Overall, big data analytics can use the information gleaned from data analysis to assist all relevant departments in standardizing and systematically receiving the same information, resulting in more efficient work. By creating prototypes, additive manufacturing is now beginning to play an important role in both product development and manufacturing processes. New product prototypes are created during the stages of concept, prototype development, testing, and production for presenting customers with the product appearance, making decisions, and understanding the product details more easily. Furthermore, additive manufacturing enables manufacturers to more easily and quickly adjust parts to meet customer needs, reducing the time and cost spent on modifying prototype parts and allowing for greater flexibility in product development.

Cloud manufacturing is crucial for connecting accurate and up-to-date data with suppliers and customers. Additionally, cloud computing manages data collection and services both inside and outside the organization by carrying out manufacturing operations over the Internet that responsible is for the supervision of the organization's IT department. Moreover, Electronic Data Interchange (EDI) is used for data exchange between suppliers and customers to reduce errors and duplication of documents. Meanwhile, EDI enables faster and more accurate data transfer, as well as making papers easier to search and available only to authorized users. It also makes use of real-time correlation and efficient data exchange. The cyber-physical system is the least important of the main factors in this study. Robots or automated machines, for example, are pre-programmed for control in a manufacturing process. Subsequently, data obtained from machine or robot operations are not sent back and forth between the physical and cyber worlds for automatic control of machines or robots in the physical world. The design and development of cyber-physical systems in the electrical appliance business demands numerous aspects, as well as the challenges of designing software that analyzes and

operates entire systems. Therefore, organizations must invest more effort and finances in developing the software.

In terms of sub-factors, the findings of this study have indicated that data-driven is the most important sub-factor because the electrical appliance industry has a diverse range of models and clearly defined production lines. It is also a type of just-in-time production (JIT) in which raw materials and spare parts from various suppliers are processed into a large number of production lines in a specific time frame. To ensure continuity and accuracy, it is critical to be data-driven, which means that production planning data must be aligned with market demand. While production model sequencing must be consistent with the availability of quality data, raw materials, and spare parts. Moreover, data on the availability of machines and equipment on the production line require predictive maintenance to avoid malfunctions during production. As stated above, data-driven can significantly improve the manufacturer's production efficiency. Another important sub-factor in collecting data from various production activities is data collection. Large amounts of accurate data must be collected throughout the manufacturing process to analyze it and make decisions quickly and precisely on time. In terms of the significance of data collecting, if a decision is delayed or made incorrectly, the production will not be able to operate as planned. Meanwhile, production costs will rise when manufacturing time is extended. Furthermore, the following manufacturing plan will be interrupted and delayed, resulting in the corporation failing to deliver products on time to customers. Therefore, data collection must be accurate and real-time to meet as several customer requirements as possible.

Traceability is an important sub-factor for tracking the flow of parts and raw materials from suppliers to the production line. Traceability also allows the inspection of parts with serial numbers, lot numbers, and manufacture dates to be rapidly tracked back and standardized, which is very useful in the case of a problem. To keep planning on track and build trust with customers, it is necessary to track and monitor each manufacturing process to assess the availability of all spare parts and raw materials before production begins. Monitoring requires reporting the production situation in real time and comparing it to the target by connecting the data via the internet network. Meanwhile, it displays the operational status of machines and equipment in the production line, as well as performance reports in the manufacturing process as compared to the plan. Consequently, monitoring is an essential component for having a real-time overview of the production situation and managing production efficiently. Automation is crucial for driving the production of electrical appliances to reduce costs and increase manufacturing efficiency. Besides, it can also help to automate the primary and secondary production lines as well. However, the manufacturer must first determine which production processes, such as production line systems or packaging systems, require automation. Finally, automation will aid in the faster and more consistent improvement of production processes, providing customers with confidence.

For less important sub-factors, this study has discovered that the detects production system monitors a variety of

parameters due to its connection with machines or equipment and manufacturing processes. Fully automated systems necessitate significant capital investments for ongoing improvement, which compels careful consideration of improvement priorities. For collaboration and synchronization, they collaborate with the physical and cyber worlds to integrate systems in production processes that are time-consuming to improve. By synchronizing communication with machines and equipment, it is necessary to prepare various equipment to support the connection between the cyber-physical system and the production process, making it more convenient and efficient in monitoring and controlling the production process. Furthermore, electrical appliance production activities involve complex multiple steps in production processes that require employee and machine integration. The security of the operating system during the manufacturing process must be stable and free of cyber threats. Only on-premise operating systems or private clouds will be used by electrical appliance manufacturers and business partners for internal storage and services. Therefore, operating system risks require data security countermeasures against accidental data leakage and data theft. For another sub-factor, intelligence is the least important as manufacturers prioritize process automation and robotics to improve manufacturing processes to be fast, low-cost, and data-driven for precision and effective decision-making. As a result, intelligent technology is a self-determining intelligent technology that requires the preparation of a large data structure to drive intelligent manufacturing, which requires the implementation of a continuous development plan.

VI. CONCLUSION

The fourth industrial revolution is currently posing challenges for many industries, particularly the consumer electronics industry, and IoT is one of the key tools for this change because it can improve and connect machines and equipment on the production line to automate and optimize production efficiency while lowering costs. On the other hand, companies that want to use Industry 4.0 technology, must think carefully due to the high capital investment required. As a result, this research investigates the factors influencing the application of Industry 4.0 technology for electrical appliance manufacturers so they can reap the full benefits of this Industry 4.0 technology, such as increased revenue, profit, productivity, and efficiency. as well as cost savings.

The internet of things, cloud manufacturing, big data analytics, additive manufacturing, and cyber-physical systems were identified as five factors influencing the appliance industry's efforts to adopt Industry 4.0 technologies in this study. The Internet of Things is the most important factor in the application of Industry 4.0 technologies, followed by big data analytics, additive manufacturing, cloud computing, and cyber-physical systems in descending order of importance. Data-driven, data collection, tracking, monitoring, and automation are the top five sub-factors influencing appliance manufacturers in implementing Industry 4.0 technologies, while detecting production systems, collaboration, synchronization, security, and intelligence have less influence on decision-makers in applying Industry 4.0 technologies to their appliance manufacturing. Based on the study's findings,

electrical appliance manufacturers can use factors and sub-factors to select the best industrial technology for improving production management and company performance both financially and profitably.

According to the study's findings, they have identified the factor of the Internet of Things (IoT) as the most important because the IoT can be connected to machines and equipment for production continuity. Furthermore, IoT can track and present real-time data to improve the speed and efficiency of manufacturing. Therefore, IoT capabilities can connect existing machines and devices to new equipment outfitted with IoT systems to improve production and warehouse management performance. It is also critical for big data analytics to manage production resources using data from operating systems. Furthermore, data from sensors, devices, and machines is continuously collected and stored as big data for analysis and process planning, as well as manufacturing to achieve operational precision throughout the procurement of production equipment. It is crucial for just-in-time production planning, which demands high precision in terms of production time and raw material supply cycle in order to deliver products to consumers on time. Additive manufacturing is an important part of new product development because it can reduce the steps and costs associated with prototyping for customers. This makes it easier for customers to understand the product and allows them to quickly modify the prototype to meet their needs, providing flexibility in developing new products. Therefore, it can minimize the cost of new product development and launch products to market faster. Cloud computing is considered as the operating systems used within the enterprise, supplier, and customer networks to ensure the stability and security of real-time connections and data relationships in cloud computing. While cyber-physical systems connect the physical and cyber worlds. Thus, manufacturers must consider numerous dimensions when integrating the entire system, which necessitates adequate personnel and budget planning for continuous development.

In terms of the significance of sub-factors, data-driven is a sub-factor that requires a lot of attention. Because the electrical appliance industry produces a wide range of products and employs just-in-time production systems, manufacturers must manage a large amount of data related to suppliers and customers continuously and in real-time. By connecting to the Internet of Things system, machines and devices will send important data for processing and analyzing big data to monitor the availability of raw materials and spare parts to ensure that manufacturers can produce as planned. Data collection is considered for accurate analysis and decision-making. Because the supply chain in the electronics manufacturing industry is complex, each process generates unique data that is linked both inside and outside the organization, necessitating careful consideration of data importance. Traceability requires tracking the flow of parts, raw materials, and goods to build customer trust and provide real-time production data linked to production processes, resulting in more efficient production management. However, automation is now very important in the production of electrical appliance manufacturers to meet the needs of

Industry 4.0, which requires developing automated machines to work instead of more humans. Improved production lines were required to automatically assemble parts for faster, more accurate, and standardized operations.

In implications for management, this research benefits electrical appliance manufacturers in terms of utilizing the factors in this study to appropriately determine the application of Industry 4.0 technology in their production. Because manufacturers have limited budgets, it is necessary to prioritize and select cost-effective and appropriate Industry 4.0 technologies used in production to increase the enterprise's productivity and competitiveness. In terms of research limitations, the sample size of this study is mostly medium to large-sized companies, tier 1st parts manufacturers, and electrical appliance manufacturers that have the potential to apply Industry 4.0 technology at the moment, whereas the sample size of SMEs is small, and they face obstacles in applying Industry 4.0 technology due to limited funding. However, small, and medium-sized enterprises (SMEs) are numerous and play an important role in driving the country's economy, both in terms of income generation and job creation. Consequently, future research will concentrate on studying problems and obstacles in the application of Industry 4.0 technology by SME businesses for the benefit of SME production development, as well as improving SMEs' competitiveness to compete with other large companies in the market.

Abstract—Patient no-show for a booked medical appointment is a significant problem that negatively impacts healthcare resource utilization, cost, efficiency, quality, and patient outcomes. This paper developed a machine learning framework to predict pediatric patients' no-shows to medical appointments accurately. Thirty months of outpatient visits data were extracted from data warehouse from January 2017 to July 2019 of the Ministry of National Guard Health Affairs (MNGHA), Saudi Arabia. The researchers retrieved the data from all healthcare facilities in the central region, and more than 100 attributes were generated. The data includes over 100,000 pediatric patients and more than 3.7 million visits. Five machine learning algorithms were deployed, where Gradient Boosting (GB) algorithm outperformed the other four machine learning algorithms: decision tree, random forest, logistic regression, and neural network. The study evaluated and compared the performance of the five models based on five evaluations criteria. GB achieved a Receiver Operating Characteristic (ROC) score of 97.1%. Furthermore, this research paper identified the factors that have massive potential for effecting patients' adherence to scheduled appointments.

Keywords—No-show; machine learning; healthcare medical appointments; predictive analytics

I. INTRODUCTION

Outpatient no-show in a healthcare setting is the non-attendance of confirmed medical appointment by the patient [1-2]. The outpatient medical appointment no-show is a significant issue for healthcare facilities since utilizing resources is ineffective and widens the appointment waiting time. Thus, accurately predicting the patient no-show will reduce the financial cost, increase productivity, enhance the quality of care noticeably, and increase the patient's satisfaction [2-8] considerably.

The demand for outpatient medical services in the Kingdom of Saudi Arabia (KSA) is increasing substantially [5]. There is an average of 70K medical appointments at the Ministry of National Guard Health Affairs (MNGHA) central region medical, of which around 10% are related to pediatric cases. Presently, there is no effectible deployed digital tool in the Electronic Health Records (EHR) that can accurately predict the patient of high risk of no-show [5-6, 9]. As a result,

the healthcare in KSA could utilize the advancements in machine learning techniques to construct a digital solution that can identify outpatients with a high possibility of not attending their medical reservation.

Machine learning can be used to build an intelligent digital solution that can provide healthcare with a data-driven system to enhance the patient's adherence to the medical appointment and predict patient behavior toward non-attendance of a scheduled medical appointment. Historical collected data in the EHR system can be utilized to forecast future patient visits. Therefore, an intelligent digital health solution can allow healthcare facilities to strategically create and manage a long-term projection plan for their medical resources [10-16].

This research study aims to develop an intelligent data-driven approach based on a machine learning technique to learn from more than three million extracted pediatric medical records from MNGH database systems to predict outpatient no-show medical appointments smartly. Other objectives are to predict patient behavior and identify the aspects that can be useful to forecast no-shows.

The remaining research paper is organized as follows. Section II covers the related work, while Section III details the methods. The results and discussion are presented in Section IV. Finally, Section V gives the conclusions and future work.

II. RELATED WORK

This section summarized machine learning solutions to predict no-shows in healthcare facilities. Most of the articles in the literature focused on adult cases. Harvey et al. [17] used a logistic regression algorithm to predict the non-appearance of patients from booked radiology examinations. They achieved 75.3% for the Area Under the Receiver (AUC) operator. Chua and Chow [18] extracted a no-show administrative dataset and employed Multiple Logistic Regression (MLR). They scored 72% for AUC. Dantas et al. [19] collected more than 13K records related to bariatric surgery no-show appointments. They achieved an accuracy of 71% using the Logistic Regression algorithm. Likewise, Kurasawa et al. [20] used a Logistic Regression algorithm to forecast the no-show of diabetic patients. Their best model scored 75.7% and 65.9% for precision and recall, respectively.

Furthermore, Mohammadi et al. [21] achieved the best result of 86% of AUC using Naive Bayes on a dataset of 73,811 records, while AlMuhaideb et al. [22] achieved 86.1% of AUC using Hoeffding algorithms on outpatient no-show appointments. Goffman et al. [23] used Logistic Regression on a dataset based on demographic and appointment descriptions and the past patient's activities. They achieved an AUC of 71%. Moreover, Nelson et al. [24] created a predictive model for imaging no-show appointments. They got the best result with the Gradient Boosting algorithm, with 85% and 51.1% for AUC and precision, respectively. Lee *et al.* [25] collected two years of data on no-shows, where they applied three machine learning algorithms: Logistic Regression, Decision Tree, and Random Forest. Random Forest achieved the best results (accuracy of 72.9%).

III. METHODOLOGY

A. Dataset and Attributes

Thirty months of outpatient visits were extracted from the Ministry of National Guard Health Affairs (MNGHA) data warehouse from January 2017 to July 2019. The data were retrieved from all the medical facilities in the central region. The central region has the largest medical facilities of the MNGHA, where more than 70K appointments are booked monthly. The retrieved dataset consists of more than 3,733,580 million pediatric patient visits related to 104,640 pediatric patients. The patient's arrival time at the clinic is used to label the record as show (timestamp) or no-show (no timestamp).

The distribution of genders is almost equal, with 49.3% as female patients and 50.7% as male. In comparison, most patients were Saudi nationals (90%) since the hospital mainly serves employees of national guards and their families, Table I. However, the Saudis have the highest no-show rate of 99% (miss at least one medical appointment), Table I.

TABLE I. STATISTICAL DESCRIPTION OF PATIENTS (N= 104640)

Attributes	No-Show N%	Show N%	Total %
Age:	6651 (90.5%)	701 (9.5)	7352 (7%)
Infant (0-12 Months)	19187	10729	29916
Toddler (1-3 Years)	(64.1%)	(35.9%)	(28.6%)
Preschool (3-6 Years)	7986 (63.9%)	4503 (36.1%)	12489 (12%)
School-age (6-12 Years)	16733	12719	29452
Adolescent (12-14 Years)	(56.8%)	(43.2%)	(28.1%)
	12422	13009	25431 (24.3)
	(48.8%)	(51.2%)	
Gender:	22202	29373	51575
Female	(47.5%)	(50.6%)	(49.3%)
Male	24427	28638	53065 (50.7)
	(52.5%)	(49.4%)	
Nationality:	362 (0.7%)	696 (1.1%)	1058 (1%)
Non-Saudi	46267	57315	103582 (99%)
Saudi	(99.3%)	(98.9%)	

The data warehouse team filtered out unnecessary records to reduce the noise in the extracted data. Categorical attributes such as gender and age were converted into an integer. The age attribute was calculated based on the difference between the birthday and appointment dates. The age attribute was grouped into five categories: i) infant (0-12 months), ii) Toddler (1-3 years), iii) Preschool (3-6 years), iv) School-age

(6-12 years), and v) Adolescent (12-14 years). A new attribute, lead days, was derived from the dataset. The lead days attribute is a derived attribute calculated as the number of days between the booking of the appointment and the scheduling day. The historical behavior of the patients was included since it could contain helpful information to predict future outcomes. Therefore, the number of walk-ins, scheduled appointments, emergency visits, and canceled medical appointments were included for all patients.

TABLE II. DESCRIPTION OF THE ATTRIBUTES

Attribute	Description
1) Gender	Male, Female
2) Age Category	Five age categories
3) Nationality	The nationality of the patient
4) Medical Department code	The code of medical/clinic
5) Hospital code	The code of referral hospital /clinic
6) Patient Services Department Type: a) Patient service b) Business center	Type of patient insurance
7) Address code	The primary health care clinic location (used for the patient's address)
8) Appointment type code: New Patient (NP) First visit (FV) Follow-up (FU)	Type of Appointment New Patient First Visit Follow-up Visit
9) Patient Services Department Type Cod: First visit (FV) Follow up (FU)	Type of patient insurance First Visit Follow-up Visit
10) Lead Days	Derived: the time difference in days between the booking of the appointments and the day of the appointments
11) Cancellation Flag: a) Yes= appointment cancelled b) No = not cancelled	Derived: count how many Check-ins Cancellation was Yes as total Derived: count how many Check-ins Cancellation was No as total
12) Medical Treatment Reservation Type Code: a) 1= Schedule b) 2= Walk-in	Derived: count how many Scheduled reservations as the total Derived: count how many Walk-in reservations as total
13) Medical Treatment a) Yes= patient treated b) N= not treated	Derived: count how many patients treated as total Derived: count how many patients not treated as total
14) On Foot visit a) 1= Yes b) 0 = No	Derived: count how many On Foot visit was Yes as total Derived: count how many On Foot visit was No as total
15) Emergency visit a) 1= Yes b) 0 = No	Derived: count how many Emergency visits were Yes as total Derived: count how many Emergency visits were No as total
16) Flu Season	Flu season from Oct-Nov and March-April
17) Distance (km)	The distance between the referring clinic and the Central Medical center of MNGHA at Riyadh City
18) Class No-Show	class show=0 or No-show=1

The historical visits of the patients are grouped together, and nine statistical values were calculated for 11 attributes (attributes 7 to 17 from Table II) which were minimum, maximum, standard deviation, variance, mean, median,

skewness, and kurtosis. After the preprocessing phase, the dataset consists of 558,721 records with 106 attributes, including the class; Table II shows the description of the attributes.

B. Machine Learning Algorithms and Evaluation Criteria

This study involves five machine learning algorithms for classification data tasks. That includes Random Forest (RF), Gradient Boosting (GB), Logistic Regression (LR), Neural Network (NN), and Decision Tree (C4.5). RF and C5.4 are machine-learning algorithms from the family of decision-tree class algorithms. Gini impurity, information gain, and other techniques are used to build the tree structure; further algorithms description can be found in [26-29].

On the other hand, the Gradient Boosting algorithm is a boosting algorithm. It utilizes a number of weak classifiers through the ensemble method to build strong learners. The algorithm used gradient descent with other techniques to complete building the model; further algorithm descriptions can be found in [26,30]. Logistic Regression (LR) can be described as a simple Neural Network (NN). LR can be viewed as a one-layer NN. LR and NN utilized many techniques to build the classification model of a binary class; further algorithm descriptions can be found in [26].

We evaluated and compared the five model's performance based on four evolution criteria: sensitivity (recall), precision, F-score, and accuracy. We considered True Positive (TP) Rate, False Positive (FP) Rate, True Negative (TN), False Negative (FN) Rate, and Receiver Operating Characteristic (ROC). These are defined as:

- True Positive (TP) Rate represents the number of no-show patient events classified as No-show, calculated based on equation 1:

$$TPR=TP / (TP + FN) \quad (1)$$

- False Positive (FP) Rate represents the number of show patient events classified as a no-show, calculated based on equation 2:

$$FPR=FP / (FP + TN) \quad (2)$$

- True Negative (TN) Rate represents the number of show patient events classified as a show, calculated based on equation 3:

$$TPR=TN / (TN + FP) \quad (3)$$

- False Negative (FN) Rate represents the number of no-show patient events classified as a show, calculated based On equation 4:

$$FPR=FN / (FN + TP) \quad (4)$$

- Receiver Operating Characteristic (ROC) score is a classification performance to show a false positive rate versus a true positive rate across a series of cut-off points and selecting the optimal cut-off point.

IV. RESULTS AND DISCUSSION

The dataset was divided into 80% training and 20% testing. Table III shows the performance of the machine

learning algorithms on an unseen testing dataset. Random Forest (RF) and Gradient Boosting (GB) outperformed the other classifiers on all five evaluation criteria. GB achieved 97.1% for ROC, which was 0.5% higher than RF. On the other hand, the score is higher than GB in terms of false positive rate (5.8% for RF and 5.9% for GB). In general, GB can be considered the champion model with an AUC of 97.1%.

Accurately predicting the intention of patients showing or no-showing to their medical appointment is considered an interesting and challenging goal for healthcare providers. Machine learning has become popular in healthcare research because of machine learning algorithms' ability to discover hidden patterns in the datasets, predict future outcomes and recognize the most relative attributes.

The machine learning algorithms were applied to more than half a million aggregated records with complex relations between attributes (predictors) and class labels with more than 100 attributes. The results of Gradient Boosting in predicting outpatient no-show outperforms traditional algorithms applied by previous research studies in Section II.

Analysis of the most used relevant attributes by machine learning shows that specific attributes significantly impact patient appointment adherence. The attributes are the traveling distance between the patient's residence and the medical center, the increased number of days between booking an appointment and the scheduled day (lead days), clinical medical services, and appointment time and day.

The rate of patient adherence to scheduled appointments can be increased by utilizing other resources. The medical facilities can use Short Message Service (SMS), an automated phone calls reminders 2-3 days before the medical appointment, mainly if the lead time is so long (more than four months). Furthermore, changing the lead days to be no more than 2-3 months [31-32].

Regarding model deployment, the machine learning framework used to build the model is a standard approach that can be integrated effortlessly within the digital healthcare system [33-34]. The research study has two limitations. Firstly, the dataset was retrieved from one region in KSA; therefore, more data from other regions can improve the robustness of the model if the model is deployed on different regions' digital systems. Secondly, the attributes are mainly extracted from an EHR in which other factors that influence the no-show rate are not included. These factors, such as personal reasons, availability of transportation, cultural background, educational level of the parents, and environmental conditions (e.g., weather circumstances), are not available in the digital healthcare system.

TABLE III. THE PERFORMANCE OF CLASSIFIERS ON TEST DATA

Evaluation Criteria	DT	RF	LR	NN	GB
ROC	94.8%	96.4%	95.0%	95.2%	97.1%
TPR	89.7%	90.0%	89.5%	89.7%	90.0%
FNR	10.3%	10.0%	10.5%	10.3%	10.0%
TNR	93.1%	94.2%	92.1%	91.9%	94.1
FPR	6.9%	5.8%	7.9%	8.1%	5.9%

V. CONCLUSION

In summary, machine learning's ability to acceptably predict no-shows provides a new potential digital solution for healthcare facilities to take advantage of intelligent solutions. This paper used five machine learning algorithms, namely, Decision Tree, Random Forest, Gradient Boosting, Logistic Regression, and Neural Network, applied to MNGH's extracted dataset from the data warehouse system.

The model was trained and tested using a dataset with different metrics to compare the results. Results show that Gradient Boosting achieves high performance for decision-making by the healthcare appointment management team. Furthermore, the study identified factors that increase the no-show rate, such as location, lead days between the reservation day and appointment day, appointment time of the day, and the type of medical services. Recommendations to increase the adherence of the no-show by patients have also been provided in Section IV.

Future work is to obtain more datasets from healthcare systems (for example, laboratory and medication data) and integrate weather data and patient background data such as educational level, transportation availability, and cultural background.

Abstract—Ultrasound imaging is the safest and most widely used medical imaging technique available today. The main disadvantage of ultrasound imaging is the presence of speckle noise in its images that may obscure pathological changes in the body and makes diagnosis more challenging. Therefore, many techniques were proposed to reduce speckle and improve image quality. Unfortunately, variations of their performance with different scan parameters and due to their methodologies make it hard to choose which one to adopt in clinical practice. In this work, we consider the problem of combining the information from multiple speckle filters and propose the use of principal component analysis to find the optimal set of weights that would retain the most information and hence would better represent the data in the final image. The new technique is implemented to process ultrasound images collected from a research system and the outcomes are compared to the individual techniques and their average using quantitative image quality metrics. The proposed technique has potential for utilization in clinical settings to provide consistently better-quality combined images that may help improve diagnostic accuracy.

Keywords—Image quality metrics; principal component analysis; speckle reduction; ultrasound imaging

I. INTRODUCTION

Ultrasound imaging is one of the most widely used medical imaging techniques available today. It offers a versatile tool for scanning soft tissues and blood flow in the body with applications in abdominal, cardiac, vascular, musculoskeletal, obstetrical and gynecological imaging. Since pulse-echo ultrasound imaging uses weak ultrasonic pulses in human tissues, it is presently considered among the safest medical imaging modalities. It is even allowed to be used for obstetrical applications to assess the health of the fetus. Furthermore, ultrasound imaging systems are available in different forms that include smartphone-based systems or portable scanners that target basic applications such as abdominal imaging and are available at very low cost. They also extend to high-end systems that target specialized applications such as surgical or echocardiographic systems at much higher cost. Therefore, the utility of ultrasound imaging technology extends across the different layers of healthcare delivery to include populations in low-income areas all the way to those receiving care at specialized hospitals. The versatility of ultrasound imaging is

expected to lead the technology to become a necessary tool for general practitioners just like the stethoscope.

The main barrier to wider adoption of ultrasound imaging in medicine is the noisy appearance of its output images, which makes the task of reading images more challenging compared to several other modalities [1]. This presence of noise causes problems in the interpretation of ultrasound images particularly when slight pathological variations are present within. Consequently, the problem of image denoising in ultrasound images has been addressed by research from academic and industrial researchers. Improving the quality of ultrasound images by reducing noise is likely to expand its utility and introduction into new applications [2].

In addition to the random noise expected from the electronics used in collecting ultrasound imaging echoes, a deterministic yet unknown type of noise-like texture called speckle noise appears as a direct result of the way ultrasound imaging is performed [3]. Ultrasound imaging works by transmitting an ultrasonic wave burst through the tissues from a probe. This wave travels through the different layers of tissues producing reflected and scattered echoes [4]. The reflection of waves happens when the size of interfaces is larger than the wavelength of ultrasound waves, while scattering happens when the interfaces are significantly smaller than this wavelength [1]. The ultrasound wavelength is less than a millimeter in the frequency range of ultrasound imaging and hence, organ boundaries and walls of large blood vessels produce reflected waves, while small vessels and the cellular matrix within organs produce scattered waves [3][4]. Since such interaction modes depend on the ultrasound transducer shape, frequency and orientation as well as the complex three-dimensional shapes, sizes and organizations of the interfaces within the tissues, the interference pattern of echoes from many interactions results in a pattern of constructive and destructive interferences that appears as a pseudo-random noise in the final image called speckle noise [5]. The speckle noise is different from the random noise encountered from thermal noise in the analog front-end electronics for example in that the speckle pattern remains stationary as long as the imaging conditions are maintained. On the other hand, random noise pattern changes with time and therefore temporal averaging is usually done to reduce its effect on the image [6]. Therefore, speckle reduction cannot be done with temporal averaging and requires fundamentally different approaches to perform [7][24].

In this work, we consider the problem of combining the information from multiple speckle filters and propose the use of principal component analysis to find the optimal set of weights that would retain the most information and hence would better represent the data in the final image. The new technique is implemented to process ultrasound images acquired from an ultrasound imaging research system and the outcomes are compared to the individual techniques and their average using quantitative image quality metrics. The proposed technique has potential for utilization in clinical settings to provide consistently better-quality combined images that may help improve diagnostic accuracy.

II. LITERATURE REVIEW

Many research studies were performed to address the problem of speckle reduction. Based on their fundamental approach, the research in this area can be generally categorized as being either acquisition-based or postprocessing-based. The acquisition-based approach works by collecting and averaging several images with slightly different imaging parameters such that their speckle patterns are different [1][5][6]. Even though this approach offers an apparently simple solution that takes advantage of the speckle formation physics, it is practically difficult to implement and costly on ultrasound imaging systems and adds constraints on the maximum frame rate that may limit some clinical applications.

On the other hand, the postprocessing-based approach has received more attention from most research groups given that it uses the acquired image without any modifications to the data acquisition method on the ultrasound imaging system. The techniques in this category apply image filtration to suppress speckle noise while trying to maintain the other image features such as the edges. Therefore, a general-purpose digital image processing system with access to the image storage of the ultrasound imaging system can be used to perform its job. As such, it can work on an external computer with a frame grabber or other means to collect ultrasound images from an existing ultrasound imaging system without making any changes to it. With the advances made in computing hardware and software including parallel processing and graphics processing units (GPUs), this approach offers versatile solution that meets practical need to work with existing ultrasound imaging systems.

The existing postprocessing methods can be broadly classified based on their filtration strategy into four distinct classes, with many hybrids across them. Based on how the filtration is done, such methods use linear, nonlinear, physics-based methods like anisotropic diffusion, or wavelet shrinkage filtration [6]. The linear filtration works in the image domain using spatial domain filters and includes such techniques as first-order statistics filtering, local statistics filtering with higher moments, and homogeneous mask area filtering [8][9][10]. The nonlinear filtration is similar to linear filters in being image-based method but the spatial domain filters in this class relies on nonlinear functions such as median filtering, linear scaling filter, geometric filtering, and homomorphic filtering [11][12][13][14]. The physics-based class attempts to utilize simulations of physical phenomena such as diffusion to

reach a more homogeneous texture and reduce speckle noise. Examples of this class include anisotropic diffusion filtration and its variants [7][15][16][17][18]. The wavelet shrinkage methods decompose the texture in the wavelet domain and truncation of small coefficients related to speckle noise [19][20][21][22]. Several hybrid methods that combine techniques from two or more of these classes between the above methods were also studied in the literature [23][24].

In spite of the good performance reported by the above speckle reduction methods to improve ultrasound images, there remain major issues that hinder their clinical utility in routine practice. The most important of these is that their performance has wide variability across different techniques and even within the same technique for different ultrasound image characteristics. This makes it difficult to choose one technique to adopt in a particular clinical setting given the wide variability of image characteristics with different selected imaging parameters such as ultrasound frequency, depth, and ultrasound probe geometry. Furthermore, the limited success in combining advantages from different categories of speckle reduction techniques with the present hybrid methods indicates a gap in the research within this area. Therefore, the development of a hybrid technique that would allow for a consistent performance while offering a way of combining image quality advantages from different categories would be highly desired to boost performance in clinical use.

Principal component analysis (PCA) was utilized in ultrasound imaging applications using different approaches. In [25], the authors proposed a speckle reduction method based on the segmentation of the ultrasound image into overlapping regions followed by the application of PCA to the set of segmented regions after reshaping each into a vector. This is similar in principle to the approach in [26] in other image denoising applications where local pixel grouping was used before PCA, and a multistage process is applied iteratively to improve denoising performance. Also, a similar approach was used in [27], where the authors also proposed the use of PCA to denoise multi-frame optical coherence tomography data after dividing them into 3D blocks. In [28], the authors presented a survey of blind source separation applications such as PCA in ultrasound imaging and suggested that it can be used to filter out clutter and noise using spectral thresholding. They pointed out the difficulty to make such techniques work adaptively because of the variations in clutter and noise subspaces across different applications. In [29], the authors proposed an approach for speckle noise suppression in medical ultrasound Images by combining PCA and nonlinear diffusion. In this technique, the PCA is used as an orthogonal transformation to a domain where the nonlinear diffusion is applied after bit plane slicing then the results is transformed back using inverse PCA to form the denoised image. In [30], the authors suggested the use of PCA to reduce the speckle noise in echocardiography frame sequences Using PCA. They reshaped each frame into a vector and performed PCA on the set of vectors obtained from the frame sequence. The resultant PCA underwent a process similar to wavelet shrinkage whereby the subspace components corresponding to small eigenvalues below a certain threshold were omitted and the remaining components were used to reconstruct the denoised image. In

[31], the authors proposed a hybrid of several denoising approaches where PCA is used to combine the outputs of those approaches to obtain the denoised image.

Even though the previous studies included interesting applications of PCA in different aspects of ultrasound imaging, their techniques did not address the problem of optimal combination of information from multiple speckle reduction categories. This problem will be addressed in this work.

III. METHODOLOGY

The received signal in ultrasound imaging can be modeled as the sum of a true signal coming from reflections and scattering from underlying tissue interfaces and a superimposed random noise mainly from the electronics used in the analog front-end of the system. The true signal component can be further subdivided into signal from specular reflectors that delineate the major interfaces within the field of view, and another component coming from the summation of many wavelets coming from scatterers resulting in pseudo-random pattern of signal intensities called speckle. Unlike random noise, the speckle pattern depends on the underlying tissue characteristics such as cell sizes and distributions. Therefore, while the random noise changes with every acquisition, the speckle pattern remains the same provided that the same imaging conditions such as location of probe and imaging frequency and transmission focal points remain unchanged.

This study starts by recognizing the fact that there are many present techniques for speckle reductions that perform very well in some applications while others perform better in other applications. Rather than attempting to propose yet another technique, this study searches for a way to develop a hybrid method that combines several techniques in such a way to perform consistently at the peak performance. The research hypothesis is that using techniques from different speckle reduction categories combined using a technique that minimizes information loss such as principal component analysis would achieve that goal.

From the theory of principal component analysis technique, the first principal component is a smart way of representing the information present in a set of data vectors (or observations) whereby a set of weights are calculated such that it adaptively and optimally retains more information from the original data vectors than any other combination [36]. For example, in theory, the first principal component allows better representation of the original data than simple combination with equal weights as in averaging. This is the basis for our new method to combine data from different speckle reduction filters. In particular, four popular speckle reduction filtering techniques as examples from the four main postprocessing categories (without loss of generality) are used along with the original image as the input to the principal component analysis to find the optimal way of combining their information. These techniques are wavelet shrinkage [19][21], relaxed median

(RMedian) filtering [13][14], speckle reducing anisotropic diffusion (SRAD) [15][16][17], and local statistics based filtering (Lee) [8][9]. The implementation parameters were used as in the most recent variant in each technique.

The details of the new methodology are as follows. Ultrasound images are collected as a set of lines (or sticks) that span the scanned region in a linear or a sector manner depending on the imaging probe used. The resulting data are called the stick data and are used to form the properly formatted output image by the image reconstruction technique given the scanning parameters and geometry information. The use of stick data rather than image lines maintains all data points independent by avoiding point correlations from interpolation operations. They also help reduce the computational cost of applying different processing methods on the data. The new technique is implemented by forming a matrix containing the set of vectors with the original data and four filtered versions and use PCA to find the optimal weights to combine them.

Let the original stick data image be $f(m, n)$ of size $M \times N$. The original stick data image is processed using four speckle filtering techniques, namely, wavelet, relaxed median, SRAD and Lee filters. The outcomes from these four filters will be $f_W(m, n)$, $f_R(m, n)$, $f_S(m, n)$ and $f_L(m, n)$ respectively. The observations data matrix D is composed by reformatting the original and four processed stick data images of size $M \times N$ into $MN \times 1$ column vectors, F, F_W, F_R, F_S , and F_L , where each is placed as a column in the D matrix of size $MN \times 5$.

$$D = [F \mid F_W \mid F_R \mid F_S \mid F_L]. \quad (1)$$

The covariance matrix COV_D of size 5×5 is estimated as,

$$COV_D = [\hat{F} \mid \hat{F}_W \mid \hat{F}_R \mid \hat{F}_S \mid \hat{F}_L]^T \cdot [\hat{F} \mid \hat{F}_W \mid \hat{F}_R \mid \hat{F}_S \mid \hat{F}_L], \quad (2)$$

where $\hat{F}, \hat{F}_W, \hat{F}_R, \hat{F}_S$ and \hat{F}_L are the centered versions of their original vectors after subtracting their mean values. Then, the principal component analysis is performed on COV_D to obtain the vector of coefficients W_{PC} of the principal component (that is, the eigenvector for the largest eigenvalue of the covariance matrix). The reformatted column vector G of size $MN \times 1$ representing the final processed stick data image $g(m, n)$ of size $M \times N$ is then computed as the weighted average of all images as,

$$G = \frac{D \cdot W_{PC}}{\text{sum}(W_{PC})}. \quad (3)$$

Here, $\text{sum}(W_{PC})$ is the summation of W_{PC} vector components to ensure that the weighted average weights add to unity. The final processed stick data image $g(m, n)$ of size $M \times N$ is obtained by reformatting G and is sent to image reconstruction to generate the final display image. A block diagram of the new method is presented in Fig. 1.

Fig. 1. Diagram showing the steps of the new technique whereby original stick data and its filtered versions multiple speckle reduction techniques undergo PCA to estimate the best weights to combine them for best information retention.

To compare the results between the new technique and averaging in a quantitative manner, several image quality metrics are used to assess the outputs from both techniques as they were applied to several data sets acquired using different imaging conditions (for example, different probes and different applications). The image quality metrics used are root mean squared error [6], Laplacian mean squared error [32], Minkowski error metric [33], structural similarity index (SSIN) [33], , universal quality index (Q) [33][34], signal-to-noise ratio (SNR) and peak signal-to-noise ratio (PSNR) [35]. This allows for objective assessment of the results. The detailed mathematical definitions of such metrics are as follows.

The root mean squared error (RMSE) is the square root of the average of the squared error over the whole image. It is generally considered as an approximation of the standard error.

$$RMSE = \sqrt{\frac{1}{MN} \sum_{m=1}^M \sum_{n=1}^N (g(m, n) - f(m, n))^2}. \quad (4)$$

The Laplacian mean squared error (LMSE) is the squared error between the Laplacian of the original and processed images averaged over the entire image. It generally assesses the edge preservation in the processing algorithm. A better-quality processed image will have a lower RMSE value.

$$LMSE = \frac{1}{MN} \sum_{m=1}^M \sum_{n=1}^N (g_L(m, n) - f_L(m, n))^2, \quad (5)$$

where $g_L(m, n)$ and $f_L(m, n)$ are the Laplacians of the processed and original images respectively. A better-quality processed image will have a lower LMSE value.

The Minkowski error metric computes the norm of the difference between the original and processed images using different vector norms. The equation for β -norm Minkowski error metric is given as,

$$ErrorM(\beta) = \sqrt[\beta]{\frac{1}{MN} \sum_{m=1}^M \sum_{n=1}^N |g(m, n) - f(m, n)|^\beta}. \quad (6)$$

Here, we compute the Minkowski error metrics for β values of 3 (ErrorM3) and 4 (ErrorM4). A better-quality processed image will have lower ErrorM3 and ErrorM4 values.

The signal-to-noise ratio (SNR) is an important measure of how the processed signal improved in suppressing noise. A better-quality processed image will have a higher SNR value.

$$SNR = 10 \log_{10} \left(\frac{\sum_{m=1}^M \sum_{n=1}^N (g^2(m, n) - f^2(m, n))}{\sum_{m=1}^M \sum_{n=1}^N (g(m, n) - f(m, n))^2} \right). \quad (7)$$

The peak signal-to-noise ratio (PSNR) measures the resemblance of the processed image and the original image. A better-quality processed image will have a higher PSNR value.

$$PSNR = -10 \log_{10} \left(\frac{RMSE^2}{\max\{f(m, n)\}} \right), \quad (8)$$

where $\max\{f(m, n)\}$ is the maximum intensity value in the original image.

The universal quality index (Q) models any distortion as a combination of three different factors, which are loss of correlation, luminance distortion, and contrast distortion.

$$Q = \frac{\sigma_{gf}}{\sigma_g \sigma_f} \cdot \frac{2\bar{f}\bar{g}}{\bar{f}^2 + \bar{g}^2} \cdot \frac{2\sigma_g \sigma_f}{\sigma_g^2 + \sigma_f^2}, \quad (9)$$

where \bar{f} and \bar{g} are mean values of the original and processed images respectively with their standard deviations σ_f and σ_g . Also, σ_{gf} represents the covariance between the original and processed images. A better-quality processed image will have a higher Q value.

The structural similarity index (SSIN) between the original and processed images is a more general form of Q developed by the same research group. A higher value of SSIN indicates a higher quality processed image.

$$SSIN = \frac{(2\bar{f}\bar{g} + c_1)}{(\bar{f}^2 + \bar{g}^2 + c_1)} \cdot \frac{(2\sigma_{gf} + c_2)}{(\sigma_g^2 + \sigma_f^2 + c_2)}, \quad (10)$$

where c_1 and c_2 are constants computed as 0.01 and 0.03 of maximum value in image dynamic range respectively (255 in the case of ultrasound images).

IV. EXPERIMENTAL SETUP AND DATA COLLECTION

The experimental ultrasound imaging data were acquired using an ultrasound imaging research system (Digison Digital Ultrasound Research system, Mashreq., Egypt) [38]. A customized research interface was used to set all imaging parameters and allowed the acquisition and storage of raw data samples at high sampling rates of 50 M Samples/s at a

quantization of 16 bits. To ensure that the collected data set includes diverse image characteristics, imaging experiments were performed using several multifrequency ultrasound transducers including different linear and convex array probes including an endo-cavity probe. Furthermore, the experiments included different clinical applications on human volunteers and scanning of a tissue-mimicking quality assurance phantom (CIRS Inc., U.S.A.). A total of 10 images were collected for each experiment to do temporal averaging to remove present random noise. The complete data set included the results from 26 different imaging experiments with a total of 260 images. Fig. 2 demonstrates a sample image from each of the 26 imaging experiments to show the wide variation in their nature and characteristics. The conventional ultrasound signal processing stack was used to perform peak detection using Hilbert transformation then resampling to reduce the number of samples in each line to 512. The number of acquired lines for each imaging experiment was 128 and this 128×512 data array of resampled line data was called the stick data. The new technique was applied on the stick data to obtain the final processed image. The final image reconstruction from the processed stick data was subsequently performed to obtain the final processed images. The new methodology was implemented using Matlab 2022b (Mathworks Inc., U.S.A.). The data processing system was a desktop computer with 11th generation Intel® Core™ i7 processor and 32 GB of RAM running a 64-bit Windows 11 Home Edition operating system.

Fig. 2. Illustration of the different imaging experiments performed in this study.

V. RESULTS AND DISCUSSION

Example qualitative results of applying the new methodology compared to the original images and the results from individual speckle reduction filters as well as their average are shown in Fig. 3. To better demonstrate the performance, the results from imaging experiments using three different probe geometries were included for both the tissue-mimicking phantom and real human scans. The qualitative evaluation can be done by observing the smoothness of speckle texture as well as the sharpness or definition of edges in each image as compared to the original. As can be observed,

variations in both are found across the results from the individual speckle reduction filters where better smoothness comes at the cost of blurry edges such as with the Lee filter results. This can be seen more clearly in the results from phantom experiments given the structure of the phantom. In the results from all image experiments, the proposed PCA-based hybrid technique offers smoothness and edge definition that is comparable to the best of all individual techniques. Furthermore, the results from the simple average of individual techniques appear to partially inherit the quality issue such as blurring more prominently than the new technique.

Fig. 3. Experimental results from the new technique are compared to those from the individual techniques used in addition to their average. the results are provided for different probe geometries and scan parameters from both a tissue-mimicking phantom and human volunteers.

The quantitative evaluations of the results are provided in Table I, which presents the percentage mean change in image quality metrics compared to the new PCA-based hybrid technique along with its standard deviation and p-value of statistical significance over the set of 26 experiments. For each metric, the percentage mean change of a particular technique is calculated as the average of the difference between the metric values of that particular technique and the new PCA-based hybrid technique, divided by the average of that metric for the new PCA-based hybrid technique. This formula was chosen to make the percentage change always relative to the same quantity across different techniques to make consistent comparisons. For better inspection of the results, the image quality metrics were grouped into either error or quality metrics as shown in the first column. When a technique has a positive percentage mean change in the error metrics, this means that its error metric is higher than that of the new technique, which would indicate lower performance. ON the other hand, a lower performance in the quality metrics is when a technique has a negative percentage mean change in the error metrics, which means that its quality metric is lower than that of the new technique. As can be observed, the results indicate that the new PCA-based hybrid technique offers better performance across all metrics with varying degrees. For example, in the universal quality index that deterioration varies

from -2.77% for relaxed median filter to -30.55% for wavelet filter. It should be noted that the other metrics for these same techniques were very different where for example they were higher by 107.84% and 97.9% respectively for Laplacian mean squared error. This generally demonstrates the issue of variable performance of individual techniques across metrics where some perform better on quality and others on error metrics. One final observation is that the performance of the new PCA-based hybrid technique was consistently superior to that of the average of individual techniques, with significantly higher improvements in error metrics than quality metrics.

In order to ensure that the detected mean changes are statistically significant, a two-sample student t-test was applied and the p-values are listed in the same bin as the percentage mean change in Table I. A significance level of 0.05 was used and higher p-values where statistical significance cannot be confirmed at that level were denoted with “*” in the table. As can be observed, only three results were not statistically significant and they were all for the relaxed median filter. All results for the average of individual techniques were statistically significant indicating that there is a real performance boost. The overall results generally support the research hypothesis that the performance of the new PCA-based hybrid technique is better than or not different from the best individual technique.

Fig. 4. Experimental results showing example quality metrics Laplacian Mean Squared Error (LMSE), structural similarity index (ssin), and universal quality index (Q) for 26 imaging experiments.

In order to illustrate the variability of metric values across different imaging experiments, Fig. 4 presents the values of Laplacian mean squared error, structural similarity index and universal quality metrics for each of the 26 imaging experiments. It can be observed that the different techniques have significant variability when applied to different experiments with different probe geometry and scan parameters. Furthermore, it is evident that the performance of the new PCA-based hybrid technique is better than or equal to the best individual technique in the majority of experiments, which again confirms the validity of the research hypothesis of developing this method. It can be also observed that the results from the average of individual techniques always lie in the middle of all individual techniques. This means that it may be considered as a way of obtaining consistent results from all techniques, but its performance will not be the best.

In order to verify the importance of including the original image in the observations matrix along with those from the speckle filters, the new technique was implemented with only 4 columns in the observations matrix D by excluding the original image. The quantitative evaluations of the results are presented in Table II. As can be observed, the obtained outcome has mixed performance across each metric as evident by the mixed negative and positive values in each. This indicates the results of excluding the original image are significantly worse than with the original image included. Furthermore, the results of excluding the original image appear to be very close to those of the average of individual techniques. This is evident from the small percentage mean differences and from the fact that there is no statistically significant difference between applying the new method with excluding the original image and that of the average of individual techniques. This indicates the important role of the information in the original image in guiding the estimation of weights used to combine it with the different individual techniques. To demonstrate this further, the computed weights for all experiments are shown in Fig. 5. As can be seen, the weights vary significantly across imaging experiments, which outlines the importance of their adaptive estimation. The weights for the original image were second highest in the majority of experiments indicating its importance in the outcome.

With the performance advantage of the PCA-based hybrid technique established by the results, the main challenge for its widespread application appears to be mainly computational. Rather than using an individual speckle filter, four filters need to be applied in the new method. The computations needed to perform the new technique can be divided into the computations needed for the speckle filters (which may vary with implementation), covariance matrix estimation, principal component analysis of a 5×5 matrix, the weighted average of 5 stick data images. Nevertheless, this computational cost can be considered reasonable for real-time performance especially with current high processing power available in modern digital ultrasound imaging systems. Furthermore, since we require only the first eigenvector corresponding to the maximum eigenvalue, significantly faster solvers can be utilized [37].

TABLE II. PERCENTAGE MEAN CHANGE IN IMAGE QUALITY METRICS COMPARED TO THE NEW PCA-BASED HYBRID TECHNIQUE WITHOUT INCLUDING ORIGINAL IMAGE IN OBSERVATIONS MATRIX ALONG WITH ITS STANDARD DEVIATION AND P-VALUE OF STATISTICAL SIGNIFICANCE OVER THE SET OF 26 EXPERIMENTS

Assessment Metrics		Wavelet	RMedian	SRAD	Lee	Average

VI. CONCLUSIONS

In this study, the combination of information from multiple speckle filters is considered and the use of principal component analysis is proposed to find the optimal set of weights that would retain the most information and hence would better represent the data in the final image. The new technique is implemented to process ultrasound images acquired from a research system and the outcomes are compared to the individual techniques and their average using quantitative image quality metrics. The results confirm that the new PCA-based hybrid technique offers consistent high performance across different experiments. The proposed technique has potential for utilization in clinical settings to provide

consistently better-quality combined images that may help improve diagnostic accuracy.

ACKNOWLEDGMENT

This project was funded by the Center of Excellence in Intelligent Engineering Systems (CEIES), King Abdulaziz University, Jeddah, under Grant No. (CEIES-16-07-01). The authors, therefore, acknowledge the technical and financial support of King Abdulaziz University.

Application of Artificial Intelligence-Genetic Algorithms to Select Stock Portfolios in the Asian Markets

Luu Thu Quang

Ho Chi Minh University of Banking, Vietnam

Abstract—The paper's main goal is to use a genetic algorithm to find the best stock portfolio that meets the criteria of high return and low risk, allowing investors to adjust the appropriate proportion for each share. Using the Python programming language based on the Jupyter Notebook engine, this paper introduces a model of six stock portfolios, each of 30 stocks selected with market capitalization and high liquidity criteria of six markets in the Asian region. The results show that the four portfolios created from the markets of Vietnam, Thailand, Philippines, and Singapore meet both the return and risk objectives. The Malaysian market only meets the risk target, but the portfolio's return is not close to the expected ratio. Meanwhile, the Indonesian market outperformed expectations in terms of profits, but high profits come with high risks, so this market carries a concerning level of risk when compared to the profit and loss of other markets. The suggested stock allocation levels for each portfolio are based on the above results. Finally, the author proposes several policy implications related to the management and operation of the market to limit unnecessary price fluctuations of the stock and affect the business model of companies.

Keywords—Artificial intelligence; genetic algorithms; optimal portfolio; Sharpe ratio; Asian stock market

I. INTRODUCTION

When learning about investment, optimizing the return on a portfolio is one of the most challenging issues in the financial sector. Since it is a process that is not simply a combination of individual stock codes with unexamined investment ratios, investors need to find ways to maximize the profitable investment and limit risk by understanding the market and setting themselves a desired level of return with an acceptable risk level. Dealing with this problem, recently, several artificial intelligence-based methods such as genetic algorithms have been applied to overcome this problem. Genetic algorithms (GAs) are optimal methods. They are widely used in many different fields such as medicine, engineering, electronics, not only the field of financial investment analysis to optimize value and solve problems through the fundamental processes of selection, breeding, and mutation between individuals in the population to create better latter-generation individuals, improving the adaptability of that individual in a more natural environment.

There have been many studies applying genetic algorithms to investments. However, the scope of the above studies is in the overseas market, where the market characteristics are quite

different from the market in Southeast Asia. In Southeast Asia, studies of this method of migration algorithms have been applied and studied in many other fields such as health, biology, engineering, construction, information technology to solve different problems. The application of this method to the financial sector is still relatively small. Therefore, implementing this research in the Asian market is necessary and feasible, especially in the growing and constantly changing stock market.

An optimal portfolio is an asset allocation, or in other words, a group of different stock choices that provide the highest rate of return per unit of risk an investor is willing to accept. In addition, the optimal portfolio is considered to be the one with the maximum Sharpe ratio - which measures the amount of return generated per unit of risk when investing in an asset or type of other investments. According to Markowitz's methodology, the linear equations are used to determine the best portfolio, but this traditional method works best when the number of stocks and the size of the search space are both small. When there are a lot of stocks and large searchable space, special techniques, such as GAs, must be used. Compared to other optimization methods, GAs work by simulating evolution and natural selection on a computer starting with a random population. Additionally, we require an adaptive function to choose good individuals and reject bad ones in order to optimize. Genetic algorithms, in contrast to other optimization techniques, have the following advantages:

- GAs work with the variable's code, not directly on the variable.
- Most of the optimization techniques normally search from a single vertex, while GAs always operate on a set of vertices (optimal points), this is an advantage of GAs that increases the chances of reaching the comprehensive optimal, and avoids premature convergence at the local point.
- GAs evaluate the objective function to serve the search process, so it can be applied to any optimization problem (continuous or discrete).
- GA is a subclass of probability algorithms, and their fundamental operations are based on their capacity to incorporate randomness into the processing flow.

The paper will help answer the question: "Should genetic math be applied to the creation of an effective stock portfolio

for southeast Asian markets?" To answer that question, the author will study, learn and apply the processes of acquisition to a portfolio of asset classes with a wide range of asset classes with a level of assets risks and ratios that vary to select and create a potential stock portfolio with high profitability criteria with the right level of risk.

II. THEORETICAL BASIS

Yang [1] compares three approaches from genetic algorithms, medium variances, and Bayes methods to improve portfolio efficiency with a sample of MSCI (Morgan Stanley Capital International) datasets of Total Return on Equity of Canada, France, Germany, Japan, the United Kingdom, and the United States include European stocks, bonds, and bonds based on the value of the U.S. dollar between January 1975 and December 2004, taking the risk-free rate of return as the T-bill interest rate of three months. The problem is that the portfolio has a minor standard deviation, and out-of-sample returns also have a significantly higher average value than the standard medium variance portfolio strategy and the Bayes approach. Portfolio weighting using genetic algorithms is less unbalanced and fluctuates much less over time than the standard average method and Bayes method. Furthermore, the author has stated that the algorithm is a model that combines historical information and future uncertainty to significantly improve the accuracy of the average estimate, helping to improve the model's performance by overcoming computational difficulties when approached by the Bayes method

Lin [2] also reports that adopting genetic algorithms would provide optimal value for creating a portfolio. The author asserted that the genetic algorithm could solve the corresponding optimization problems because existing traditional methods cannot be effectively addressed. Moreover, the study based on a team of 40 sample companies collected from the Taiwan market was used to demonstrate the proposed method with the probability of hybridization and random mutations.

Sefiane [3] applied genetic algorithms to optimize a portfolio of five stocks with data including portfolio-wide average returns and portfolio variances for five years from 2007 to 2011. By running the data on Matlab software, the author has produced the result of five proportions of investment in five stock codes and selected a hybrid by one point, two points through the stage of three hybrids. At the end of the research process, the author commented that this problem achieves exceptionally effective results by shortening the calculation time to get an investment solution for the whole portfolio. Dubinskas [4] also evaluate the genetic algorithm method for data of 18 stock codes made from Lithuanian businesses listed on the official list of NASDAQ OMX Baltic companies in 2013 planned portfolio to be built including four businesses representing different sectors. Research indicates that optimizing the portfolio by adopting an algorithmic approach generates four times more returns than portfolios built using a defined or random programming method. Along with high returns, the systematic risk assessment of the portfolio analyzed by genetic algorithms is higher than the portfolio optimized by defined and random programming. However, the authors commented that the portfolio's

performance optimized by algorithmic genetics might exceed market performance. Moreover, the author also concludes that a research paper needs to examine several cycles to look for more reliable conclusions, emphasizing the application of genetic algorithms methods during a market downturn.

In addition, Cheong et al. [5] also implement genetic algorithms to support portfolio optimization based on investor information, which is to build portfolios by selecting institutionalized stocks or foreign investors invest more than other stocks. Through data obtained from the Korea Securities Computer Corporation (KOSCOM), specifically the top 90 Kospi 200 companies in terms of market capitalization from September 1, 2007, to May 30, 2014, and through the analysis process, the author commented that long-term information outperforms medium- and short-term information on the Korean stock market. The weight varies when using genetic algorithms how it affects portfolio performance. In particular, the study results add to the behaviors and patterns of investors that can be used to devise investment strategies. Investors build portfolios according to their risk-return level on the average variance framework, and relying on the portfolio strategies of other confident investors can enhance portfolio performance. However, the author also notes that institutional investors anticipate higher returns and lower risks on the Korean stock market, while foreign investors only consider portfolio risk.

Liu et al. [6] shows that genetic algorithms produce results that provide a more reliable portfolio in the same risk and without the need to introduce or mention each country's data. Liu et al [6] argues about the time series length of each stock on the construction of the portfolio and improve the algorithmic efficiency in fundamental stock analysis. With a fairly comprehensive sample of data, including the closing price of 2317 stocks on the Chinese market from February 20, 2016, to February 16, 2017, there are 250 trading days. The author agrees with the researchers above that genetic algorithms have optimized portfolio strategies. Sharpe ratios are relatively high, markedly improved along with an increase in the number of iterations, meaning that the ability to achieve excess returns increases gradually [7]. Furthermore, the author also compared two other methods, the random method and the K-mean algorithm. Their results indicate that with the increase in risk, the rate of profitability when using genetic algorithms increases, indicating the effectiveness of genetic algorithms.

In general, after consulting and researching research articles, the application of genetic algorithms to selectively and creating an optimal portfolio is agreed and encouraged by many authors because the effectiveness of the algorithm is persuasive when going through the analysis process to create an expected profit level. The standard deviation and deviation are in line with the expected level. Therefore, the expansion direction of future studies is to be able to conduct on a broader scale, a long time to test the appropriate level of an optimal category with the criteria of limiting risk, achieving the expected or highest level of profitability.

III. RESEARCH METHOD

A. Data

The data used in this study includes trading histories such as stock codes, trading months and closing prices provided at the DataStream system. The subjects selected in the study data are stocks listed on the stock exchanges of Vietnam, Thailand, Indonesia, Philippines, Malaysia, and Singapore with the following characteristics:

- Shares listed at least two years before the time of inclusion in the portfolio
- The stock must be traded during the study sample selection period

The data includes 180 stock codes, of which in Vietnam there are 30 company codes in VN30 and 30 companies with the largest capitalization in 5 countries, the month of trading started from 07/2018 to 04/2021

B. Method

Genetic mathematics is a technique of computer science that predicts the behavior and reactions of humans and organisms. Migration algorithms can be applied in the financial sector by forecasting profits, stock prices, portfolio optimization, and determining trading rules and pricing options. Genetic mathematics includes transformation modalities, including selection, hybridization, and mutation. Identifying individuals in the current generation retained in the next generation is called the selection process. The random combination of two different individuals, using the things available in the previous generation passed on to the next generation, is hybridization. Randomly changing the structure of the individual, and transforming into new individuals is called the process of mutation [8].

The author uses a programming language called Python, which runs on the Jupyter Notebook tool to build a research process, a computer-language method, also known as computer-language code used to replace a string of characters or statements briefly. These codes are technically valuable in terms of information technology. The change in this code does not affect the values and results involved, nor does it explain any economic significance. The code used in the article is inherited from many different authors whose research papers agree with this research paper. The code is only intended to support the function and give the study results. The author has also changed the code to match the author's research direction. The study focuses on variables in profitability, risk, and allocation levels accordingly and delivers the most optimal portfolio outcome. The research process will be as follows:

The prerequisite for implementing the algorithm, the libraries are inserted into python language to help support the calculation of significant data sources such as numpy, pandas, functools. Code:

```
import numpy as np
import pandas as pd
from functools import reduce
```

Step 1, import the data of a country of 30 companies, specifically code as follows. The author takes the example of how Vietnam runs. Code:

```
files=['VIETNAM.csv']
dfs=[]
for file in files:
temp=pd.read_csv(file)
dfs.append(temp)
stocks = reduce(lambda left,right: pd.merge(left,right,on='Date'), dfs)
print(stocks.shape)
stocks.head()
```

In the Step 2, the profit is measured through the historical transaction values. The closing price equal to the average of 1 to 33 months, is takes the timeline of 04/2021 as the standard of calculating profitability. The formula used is the profit margin stated by the author in sector 2, section 2.1.3.2, specifically the total return of the stock plus the dividend paid and divided by the original price of the stock. Here, we assume the percentage of dividends paid is not in companies. Code:

```
def hist_return(months):
idx=[]
df=pd.DataFrame()
for mon in months:35
temp=(stocks.iloc[0,1:] - stocks.iloc[mon,1:]/(stocks.iloc[mon,1:]
idx.append(str(mon)+'_mon_return')
df=pd.concat([df, temp.to_frame(). T], ignore_index=True)
df.index=idx
return df
hist_stock_returns=hist_return([3,6,12,24,33])
hist_stock_returns
```

In Step 3, identify the gene or, in other words, encode the problem. In this step, the author will use a binary sequence of n-gene lengths (with n being the number of securities included in the category) as chromosomes to represent a category with n securities to study. Each gene represents the appearance or absence of a stock code, which these genes are regulated in alphabetical order. Code:

```
gene = np.random.rand()
Gene import time
def gen_mc_grid(rows, cols, n, N):
np.random.seed(seed=int(time.time()))
layouts = np.zeros((n, rows * cols), dtype=np.int32)
# layouts_cr = np.zeros((n*, 2), dtype=np.float32)
positionX = np.random.randint(0, cols, size=(N* n* 2))
positionY = np.random.randint(0, rows, size=(N*n*2))
ind_rows = 0
ind_pos = 0
while ind_rows < n:
layouts[ind_rows, positionX[ind_pos] + positionY[ind_pos]*cols] = 1
if np.sum(layouts[ind_rows, :]) == N:
ind_rows += 1
ind_pos += 1
if ind_pos >= N*n*2:
print("Not enough positions")
Break return layouts
def gen_mc_grid_with_NA_loc(rows, cols, n, N,NA_loc):
np.random.seed(seed=int(time.time()))
layouts = np.zeros((n, rows * cols), dtype=np.int32)
layouts_NA= np.zeros((n, rows * cols), dtype=np.int32)
for i in NA_loc:
layouts_NA[:,i-1]=2
positionX = np.random.randint(0, cols, size=(N* n* 2))
positionY = np.random.randint(0, rows, size=(N*n*2))
ind_rows = 0
ind_pos = 0
```

```
N_count=0
while ind_rows < n:
cur_state=layouts_NA[ind_rows,positionX[ind_pos]+positionY[ind_pos] *
cols]
if cur_state!=1 and cur_state!=2:
layouts[ind_rows, positionX[ind_pos] + positionY[ind_pos] * cols]=1
layouts_NA[ind_rows, positionX[ind_pos] + positionY[ind_pos] * cols] = 1
N_count+=1
if np.sum(layouts[ind_rows, :]) == N:
ind_rows += 1
N_count=0
ind_pos += 1
if ind_pos >= N*n*2:
print("Not enough positions")
Break return layouts,layouts_NA
gen_mc_grid(9, 9, 180, 90)
gen_mc_grid_with_NA_loc(9, 9, 180, 90,range(10))
```

Step 4, gather the number of shares in the portfolio and randomly assign the capital allocation ratio, small parts of the total capital specified for each share, to set the investment allocation weighting. A stock portfolio will include fractional or decimal values of all stocks so that the sum of the values is not greater than 100%. Simply put, our portfolio has 30 stocks; the author will randomly create 30 variables corresponding to the proportion of investment in 30 stocks with a total capital of 1 unit. Code:

```
def chromosome(n):
ch = np.random.rand(n)
return ch/sum(ch)
child=chromosome(30)
print(child,sum(child))
```

The Step 5 is the first step in the genetic algorithm to initiate populations. The process is quite simple by creating a population of chromosomes, in which each chromosome is a long binary vector n-gene randomly generated. We need to calculate the probability of the securities number that allow research in the portfolio. Having a portfolio with many securities will not be highly effective in terms of objectives. That probability is measured as follows:

$$P = n/(\text{pop_size})$$

in which n is the number of securities included in the resulting portfolio, pop_size is the number of securities of the whole population. At that time, the initialization process was roughly described as in each gene of chromosomes in the population that generated a random number of realities in the passage [0, 1]. When $r < p$, the stock code appears in the category, i.e., the value of that gene is equal to 1. On the contrary, the gene is zero that stock code will not appear in the portfolio. Code:

```
n=30
pop_size=180
population = np.array([chromosome(n) for _ in range(pop_size)])
print(population.shape)
print(population)
```

Step 6, the author will calculate the target function stated in sector 2 is the Sharpe ratio, taking this ratio as a measure of the performance of the entire portfolio, in the calculation formula, this ratio depends on the variable is a risk-free interest rate, the author will default this ratio to 2%.

$$\text{eval}(vi) = \text{Sharpe ratio} = (E(R_{\text{port}}) - r_f) / \delta p$$

To be able to calculate the Sharpe ratio, calculate the following small components: Calculate the average profit, standard deviation and variance of past stock returns. Code:

```
# First of all, entering and re-universalizing the profit rate calculated in step 2
print(hist_stock_returns.info())
cols=hist_stock_returns.columns
hist_stock_returns[cols]=hist_stock_returns[cols].apply(pd.to_numeric,errors
='coerce')
print(hist_stock_returns.info())
# Calculate the variance of the historical profit, so that it can be easy to
calculate, the author will put the variance of the stock itself by zero
cov_hist_return=hist_stock_returns.cov()
print(cov_hist_return)
for i in range(30):
cov_hist_return.iloc[i][i]=0
cov_hist_return
# Calculating average historical returns
mean_hist_return=hist_stock_returns.mean()
mean_hist_return
# Calculate the standard deviation of historical profits
sd_hist_return=hist_stock_returns.std()
sd_hist_return
# Calculate the expected return rate of the category
def mean_portfolio_return(child):
return np.sum(np.multiply(child,mean_hist_return))
mean_portfolio_return(population[0])
# Calculate the variance of the category
def var_portfolio_return(child):
part_1 = np.sum(np.multiply(child,sd_hist_return)**2)
temp_lst=[]
for i in range(30):
for j in range(30):
temp=cov_hist_return.iloc[i][j] * child[i] * child[j] * child[j]
temp_lst.append(temp)
part_2=np.sum(temp_lst)
return part_1+part_2
var_portfolio_return(population[0])
# Calculate the Sharpe ratio of the category
def fitness_fuction(child):
return (mean_portfolio_return(child)-rf)/np.sqrt(var_portfolio_return(child))
fitness_fuction(population[31])
```

The step 7 is a pretty important step in the genetic algorithm. The author will filter the stocks with the highest Sharpe ratio calculated in Step 6. In this step the author defaulted to a selective probability of 0.3, and the author selected the first three stocks in the category to consider the target function of the research paper. Code:

```
def Select_elite_population(population, frac=0.3):
population=sorted(population,key=lambda x:
fitness_fuction(x),reverse=True)
percentage_elite_idx = int(np.floor(len(population)* frac))
return population[:percentage_elite_idx]
print(wool(Select_elite_population(population, frac=0.3)))
Select_elite_population(population, frac=0.3)
[fitness_fuction(x) for x in population] [:3]
```

Step 8 is mutating the individuals in the category. It can be said that this is a function that improves the individual more and more healthily than the first life. Especially in this process, the author will randomly select two stocks in the list of 30 stocks to conduct the transformation, and the following computer code will perform the following mutations. Code:

```
def mutation(parent):
child=parent.copy()
n=np.random.choice(range(30),2)
while (n[0]==n[1]):
n=np.random.choice(range(30),2)
```

```
child[n[0]],child[n[1]]=child[n[1]],child[n[0]]  
return child  
mutation(population[1],population[1])
```

Step 9, at this step the stock codes will be intersected through real-value investment proportions. In the hybrid task, the author uses the arithmetic hybrid method to bring the most optimal effect. Code:

```
def Arithmetic_crossover(parent1,parent2):  
    alpha = np.random.rand()  
    child1 = alpha * parent1 + (1-alpha) * parent2  
    child2 = (1-alpha) * parent1 + alpha * parent2  
    return child1,child2  
Arithmetic_crossover(population[2],population[3])
```

Step 10 is the step that helps create a generation of stock codes that come with a more potential weighting perform mutation processes or cross-exchange based on probability. The author defaulted to the probability of mutation as 0.4 and hybridization as 0.6. In the final stages, the probability of mutation will be reduced to 0.1, and hybridization will increase to 0.9. The sum of these two probabilities is always equal to 1, and it should be noted that the probability of hybridization always needs to be greater than the probability of mutation because mutations need to be limited, not always mutations to individuals with good character and adaptability to the habitat or in other words to survive in the category. The input of this process will be the sum of the stocks with the appropriate proportion of investment allocation. The output will be the next generation with a more suitable gene level. Code:

```
def next_generation(pop_size,elite,crossover=Arithmetic_crossover):  
    new_population=[]  
    elite_range=range(wool(elite))  
    while wool(new_population) < pop_size:  
        if wool(new_population) > 2*pop_size/3:  
            mutate_or_crossover = np.random.choice([0, 1], p=[0.9, 0.1])  
        else:  
            mutate_or_crossover = np.random.choice([0, 1], p=[0.4, 0.6])  
        if mutate_or_crossover:  
            indx=np.random.choice(elite_range)  
            new_population.append(mutation(elite[indx]))  
        else:  
            p1_idx,p2_idx=np.random.choice(elite_range,2)  
            c1,c2=crossover(elite[p1_idx],elite[p2_idx])  
            chk=0  
            for gene in range(30):  
                if c1[gene]<0:  
                    chk+=1  
                else:  
                    chk+=0  
            if sum(range(chk),0)>0:  
                p1_idx,p2_idx=np.random.choice(elite_range,2)  
                c1,c2=crossover(elite[p1_idx],elite[p2_idx])  
                new_population.extend([c1,c2])  
            return new_population  
    elite=Select_elite_population(population)  
    next_generation(180,elite)[:3]  
    elite=Select_elite_population(population)  
    next_generation(180,elite,Arithmetic_crossover)[:3]
```

Step 11 is a repeat of the entire process until the stocks in the portfolio do not change in terms of maximum profit and minimum risk or the number of fixed iterations selected by the author is 40 iterations. The author ordered that the expected return of the category would be greater than 20% and that the risk through variance calculations must be less than 5%. The loop will stop at the 40th round if that condition is met. If it

does not meet, the study will perform through many subsequent loops so that 43 searches for the appropriate proportion for the 43. Stock codes suitable for the portfolio's great purpose achieve maximum profitability with a reasonably limited level of risk. Code:

```
n=30  
pop_size=180  
population = np.array([chromosome(n) for _ in range(pop_size)])  
elite = Select_elite_population(population)  
iteration=0  
Expected_returns=0  
Expected_risk=1  
while (Expected_returns < 0.2 and Expected_risk > 0.05) or iteration <= 40:  
    print('Iteration:',iteration)  
    population = next_generation(180,elite)  
    elite = Select_elite_population(population)  
    Expected_returns=mean_portfolio_return(elite[0])  
    Expected_risk=var_portfolio_return(elite[0])  
    Print('Expected returns of {} with risk of {}'.format(Expected_returns,  
Expected_risk))  
    iteration+=1  
    print('Portfolio of stocks after all the iterations:\n')  
    [print(hist_stock_returns.columns[i],':',elite[0][i]) for i in list(range(30))]  
    # The ratios will in turn give results combined with the profit corresponding to  
    each stock code included in the portfolio  
    print('Portfolio of stocks after all the iterations:\n')  
    [print(hist_stock_returns.columns[i],':',elite[0][i]) for i in list(range(30))]  
    print("\nExpected returns of {} with risk of  
    {}'\n'.format(Expected_returns, Expected_risk))  
    fitness_fuction(elite[29])
```

After this process, result will generate the weight distribution of the stocks included in the portfolio and the expected return and risk level of the entire category most suitable after undergoing the mutation and hybrid loops.

IV. RESULTS

The study used data from six different countries in Southeast Asia to create six portfolios with varying rates of return and risk. Our findings, as seen in Fig. 1, show that Vietnam, with the top VN30 stock portfolio, has produced the highest expected profit result among the six countries with an incredible rate of approximately three times the expected profit margin of 60.23%. Followed by Indonesia reaching 53.13% and the third place is Thailand with a profit rate exceeding the target of 42.76%. However, accompanied by high profitability is a risk that is also a worrying risk when bringing the highest profitability among the six countries considered in Southeast Asia. Vietnam ranked 2nd in terms of portfolio risk at 4.6%, however, significantly the risk of the portfolio of 30 companies in the Indonesian market accounted for 6.04%, reaching the highest risk level of 4.04% reaching the highest risk level. However, these findings failed to meet the author's initial risk expectations. So it can be commented that when comparing the top 30 companies in the stock market with the stock codes reaching the largest capitalization in each country, Vietnam's portfolio gives positive results and is worth investing more than the Indonesian portfolio with higher profits and lower risks. However, does the Vietnamese category produce the best results? The saying "The higher the profit, the greater the risk" is an immovable rule when it comes to investing; everyone has the price of that action, and paying the desired price for a high profit, the higher the risk.

When it comes to investing, any investor wishes to own a portfolio with stock codes that not only bring high returns, but risk must also be an acceptable variable. When it comes to risk, the study results indicate that all five categories meet the standard deviation expectations that the category brings except for one category that does not meet the expected risk requirements of 30 companies in the Indonesian market mentioned above. However, when it comes to profitability, there are only five categories that bring positive results and exceed the expectations of the author: Vietnam, Thailand, Indonesia, Philippines, and Singapore; Only the Malaysian portfolio reached 19.46% of the profit margin, but in return for the risk that the portfolio overcomes only accounts for nearly 1%, an extremely difficult to figure, the fact that the figure of 19.46% is still an adequate number and if we convert all the capital distributed into stock codes less than 1% into the Stocks with higher allocations can still raise the value of the profitability of the whole portfolio but also mean that the risk will increase.

In general, only four over six markets met both in terms of profitability and risk expectations of the author: Vietnam, Thailand, Philippines, and Singapore. On the other hand, when the author sets an expectation of a return of 20%, regardless of the risk of the whole category, five categories meet the requirements, in order of declining profits: Vietnam, Indonesia, Thailand, the Philippines and Singapore. When the author considers only the expected risk of the portfolio of 5%, which means setting the risk level more important than the expected profit level, five categories meet the requirements presented in incremental risk: Malaysia, Singapore, Thailand, Philippines and Vietnam. Therefore, it is difficult to expect a portfolio with high returns with a lower level of risk. Our findings are consistent with the risk and return trade-off.

To be able to provide detailed statistics of six categories in six Southeast Asian markets, the author uses the Sharpe ratio after the optimal portfolio allocation results have produced the same results with the same data on closing prices with the timeline from 07/2018 to 04/2021 of the 30 companies with the largest market capitalization in each country has produced a result. Sharpe's ratio declined, led by Malaysia with 19.81, Singapore with 15.07, Vietnam with 12.67, Thailand with 9.33, Indonesia with 8.46 and Philippines with 6.9 (see Fig. 2). The Sharpe ratio is a ratio that represents the premium value of the portfolio that an investor will receive per unit of risk. The smaller this ratio, the smaller the risk premium, and vice versa. The larger the ratio, the greater the risk premium.

Fig. 1. Portfolio expected return and portfolio risk of Asian market

Fig. 2. Sharpe ratio of Asian market

Fig. 3. Optimal portfolio of Vietnam market

The results showed that although Vietnam has the highest profitability and Malaysia offers relatively low profits investing in the Malaysian market still preserves much more profitability than other highly profitable categories. On the other hand, the Philippines market, as analyzed in the above subsection on the level of profitability and risk that the market brings, with the profitability brought although higher than 20% of the expected profit rate of the author. However, the risk of this market is very high, reaching 4.51%, overwhelmed the risk in the Thai market (4.37%). Therefore, when calculating the Sharpe ratio, the Philippines is a market where the adjusted profit above the risk level is much less competitive than the Thai market.

For Vietnamese stocks, After 40 iterations, the model has found an optimal solution for profitability and risk limitation, resulting in the allocation of investment capital into stocks in the VN30 basket. Surprisingly, in the stocks with the historical data levels used as research, there were five stocks with an allocation of over 5% respectively: VPB, PDR, NVL, CTG and FPT with weights of 6.01%, 5.95%, 5.51%, 5.50% and 5.48% respectively. The top five stocks in the allocation table belong to the real estate, technology and banking sectors. However, there are three stocks whose portfolios give relatively low allocation results: BVH, VHM and MWG, 1%, 1.42% and 1.50%, respectively (refer Fig. 3).

For Thai stocks, as can be seen from Fig. 4, the allocation of over 5%, four stocks invested quite a lot in the category: COM7, KTC, CPF and DELTA, respectively. The allocation levels are 7.03%, 6.93%, 6.29% and 6.2%, respectively. In particular, according to the research, we can see that com7 stock code is a company based in Thailand with the business of operating information technology products. This is a company in the form of distributing branded technology products. KTC is a company that serves credit card services and provides personal or business loans. CPF is an agricultural and food

corporation specializing in producing the world's largest feed and shrimp. DELTA is an exporting company and a manufacturer of electronics and a flexible power supply. However, in the portfolio, a stock with a fairly low allocation of less than 1% is BBL. This is an operating bank headquartered in Bangkok, Thailand. In general, capital flows are evenly distributed, and no assets are excluded from the stock. This is the leading group of stocks in terms of market capitalization and high liquidity, so the proportion of allocation is evenly arranged is also an inevitable factor.

Fig. 4. Optimal portfolio of Thailand market

This is a reasonably particular category for Malaysian stocks because of the profitability and risk that the portfolio generates. Compared to the profitability that the portfolio brings is the lowest of the six velvet research markets. This is also the category with a respectable risk of less than 1%. Five times smaller than the author expected. Moreover, it can be said that although it does not meet the original target set by the author in terms of profitability, with a risk result of only 0.88%, generating a profit of 19.46% of the whole portfolio is a very positive result. The study results have shown the results of the distribution of the proportion of capital investment evenly in stocks. Above the allocation of 5% of the proportion of investment in the portfolio, the result of 4 companies: PMET, TPGC, TLMM and WPHB, with capital allocated of 6.86%, 6.22%, 5.94% and 5.39%, respectively. Most of the above companies are in the form of manufacturing products in aluminum, medical, other services in telecommunications and transportation. However, two stocks are allocated investment levels of less than 1% in the portfolio: PETR (0.88%) and DSOM (0.48%) as evident from Fig. 5.

The results of the research paper in the Indonesian market showed that with the segment of the allocation density of over 5%, there are five stock codes such as EMTK, TBIG, SMMA, TPIA and MEGA with the following proportions as follows 7.39%, 6.8%, 6.78%, 5.62% and 5.28% respectively (see Fig. 6) TBIG and EMTK are two companies specializing in telecommunication technology and the second-largest media company in Indonesia. SMMA specializes in the comprehensive, integrated financial sector, including banking, insurance, asset management and security. TPIA is the leading petrochemical production company using world-class advanced factories. Finally, MEGA is a domestic bank in Indonesia. There are three stock codes: SMGR, BRIS, and ASII, with an allocation of 0.99%, 0.93%, and 0.66%, respectively. SMGR is a state-owned company specializing in domestic cement production, BRIS is a state-owned Islamic bank of Indonesia, ASII is a large corporation specializing in supplying

automobile and motorcycle products bearing the brand of Toyota, BMW, Isuzu, Peugeot are the largest in Southeast Asia.

Fig. 5. Optimal portfolio of Malaysia market

Fig. 6. Optimal portfolio of Indonesia market

For the Philippine market, the author used data from the 30 companies with the highest market capitalization to review and research to deliver fairly consistent attribution results. The results show that there are quite a few companies allocated a proportion of investment above 5%, such as EMP – the largest spirits company in the world with a staggering 7.24%, followed by stock codes such as ACEN, UBPA, AGI, HVN, LTG, FGEN, TEL with allocations of 6.85%, 6.31%, 6.26%, 6.19%, 6%, 5.97% and 5.44% respectively as seen in Fig. 7. Among them are companies in electricity production, solar energy, real estate, multi-sectors, serving telecommunication services. However, there are still five companies with an investment capital allocation of less than 1% in the list, including the following stock codes AEV, JGS, SECB, SMC, and ALI. These are primarily multidisciplinary companies in consumption, air transport, and banking.

Fig. 7. Optimal portfolio of Philippine market

Fig. 8. Optimal portfolio of Singapore market

In the Singapore Stock Exchange, the author used 30 companies listed on the stock exchange with a high market capitalization, and more than half of the portfolio was stock codes in the top straits time index, which is considered a benchmark index for the Singapore market calculated by Singapore Press Holdings, Singapore Exchange and FTSE Group. Moreover, the study results worked when there was no stock code with an investment allocation ratio of less than 1% in this category, which explains that any stock code that appears in the portfolio is highly appreciated and has great capital investment potential. Although the highest allocation in the portfolio has not reached 6% compared to other countries, the even distribution between stocks is very high and homogeneous. The following image shows three stock codes above the 5% allocation: SCIL, FLEX and OCBC, respectively. The proportion is 5.7%, 5.5% and 5.3%, respectively. In particular, SCIL is an urban development and energy company, and FLEX specializes in manufacturing the third-largest multinational electronics in the world. OCBC is a stock code in the banking sector (see Fig. 8).

V. CONCLUSION

The content of the study is to address and examine the theoretical foundations of portfolio management based on Markowitz's portfolio theory and theories of genetic algorithms such as definitions and cycles contained in the algorithm to establish the portfolios of six different markets in Southeast Asia. The author uses the Python programming language to interpret and assist in producing results and following the steps contained in the genetic algorithm. Based on theory and related studies, the author has obtained very positive results on allocating stocks included in each category with the corresponding profitability and risk level.

The result consists of four categories that meet the author's expectations: the categories in the markets of Vietnam, Thailand, Philippines, and Singapore. The two categories alone

are pretty positive in terms of results, namely Malaysia and Indonesia. Although Malaysia has not met the profitability, the risk ratio of less than 1% is a very potential figure. An immovable rule in investing is that the higher the return on their assets, the higher the risk-taking bravery they need. Therefore, for the portfolio of 30 stocks from the Indonesian market with outstanding portfolio results, there is still a level of risk that needs to be accepted, and there must be a trade-off.

Considering the Sharpe ratio of the categories, topped by the 30 companies with the largest market capitalization in Malaysia with 19.81% of the profitability that can be achieved per unit of risk. Although the profitability of this market is not satisfactory to the author, this is still a category worth seriously considering and invests. Ranked second is Singapore, with a Sharpe rate of 15.07%. Thirdly, the Vietnamese market with a not-so-modest figure of 12.67. Ranked fourth in Thailand, the country of golden pagodas reaching 9.33% of the risk compensation level of the whole category. The fourth market among the six countries in Southeast Asia is Indonesia, with a research rate of 8.46% and the Philippine market of 6.9%. After the above statistical step, the significance level is realized when both categories are not satisfactory in terms of profitability, and the expected risk is Malaysia and Indonesia. The Sharpe rate in the Malaysian market is higher than in Indonesia.

Abstract—Alzheimer's disease (AD), also referred to simply as Alzheimer's, is a chronic neurodegenerative disease that usually starts slowly and worsens over time. It is the cause of 60% to 70% of cases of dementia. In 2015, there were approximately 29.8 million people worldwide with AD. It most often begins in people over 65 years of age as it affects about 6% of people 65 years and older, although 4% to 5% of cases are early-onset Alzheimer's which begin before this. In 2015, researchers have figured out that dementia resulted in about 1.9 million deaths. Continuous efforts are made to cure the disease or to delay its progression. Brain imaging is one of the hottest areas in AD research. Techniques like CT, MRI, SPECT, and PET assist in disease detection and help in excluding other probable causes of dementia. Imaging helps to perceive the intended cause of the disease as well as track the disease through its course. This paper applies Image processing and machine learning techniques combined to MRI brain images to help in detection of AD and classify the case either to MDI or Dementia.

Keywords—Alzheimer detection; brain scanning techniques; MRI scanning; image processing; machine learning

I. INTRODUCTION

The most common early symptom of AD is the short-term memory loss or in other words the difficulty in remembering recent events. As the disease advances, symptoms can include problems with language, disorientation (easily getting lost), mood swings, loss of motivation, not managing self-care, and behavioral issues [1, 2]. As a person's condition declines, they often withdraw from family and society. Gradually, bodily functions are lost, ultimately leading to death [3]. Although the speed of progression can vary, the average life expectancy following diagnosis is three to nine years [4, 5].

The cause of Alzheimer's disease is poorly understood. About 70% of the risk is believed to be genetic with many genes usually involved [1, 6]. Other risk factors include a history of head injuries, depression, or hypertension. The disease process is associated with plaques and tangles in the brain [6]. A probable diagnosis is based on the history of the illness and cognitive testing with medical imaging and blood tests to rule out other possible causes [7]. Initial symptoms are often mistaken for normal ageing. Examination of brain tissue is needed for a definite diagnosis. Around the world, the current challenge in Alzheimer's disease is to search certain therapeutic technique that can detain or arrest the disease progression. Neuroimaging can act as a good biomarker used extensively in drug trials. Brain imaging is also helps in

diagnosis of AD at its early stage. The clinical studies in AD require heavy cost and thousands of patients are generally incorporated for the accuracy of assessment. Both in academic and industrial studies, the prime focus is on the use of significantly fewer subjects exposed to treatment [8]. The computed tomography (CT), magnetic resonance imaging (MRI), Single-photon emission computed tomography (SPECT) and positron emission tomography (PET) scanning techniques are totally non-invasive and rely on the methods offering molecular diagnostics. These techniques are also extensively used in drug trials. Thus, brain imaging offers a robust and efficient tool and is considered as a biomarker for detecting AD in its prodromal stage.

The remaining of this paper is organized as follows: In Section II is discussed a comparison between different brain scanning techniques. In Section III, an overview of AD detection in literature is presented. Section IV presents the theory. Section V demonstrates the proposed approach, whereas Section VI demonstrates the experimental work and the results achieved. Finally, the paper is concluded in Section VII.

II. BRAIN SCANNING TECHNIQUES

The neuroimaging is a powerful biomarker for understanding the pathology of Alzheimer's disease and its progression. Following are the main different techniques widely used in this area:

MRI scan in AD detection: Magnetic resonance imaging (MRI) scan stand upon the principle of nuclear magnetic resonance. The nucleus of hydrogen atom (proton), residing inside the brain tissue as water or fat, becomes excited with radio wave pulse in a magnetic field. When the pulse is turned off, the proton emits radiofrequency signal and return to its native energy level. Depending upon a combination of different pulses and gradients, a sequence of signals are made and cumulatively form a tissue specific map of the brain [9].

CT scan in AD detection: Defused cerebral atrophy with enlargement of the cortical sulci and ventricular space are the primary criteria for computed tomography (CT) scan diagnosis of AD. Generally, diameters of third and lateral ventricles as well as the bifrontal and bicaudate diameters are linearly measured to evaluate the extent of atrophy. Research reveals that the volume of third and lateral ventricles is increased in AD than control [10]. Scientist have pinpointed that there is a positive correlation between brain atrophy and

cognitive loss [11]. Dilated peri-hippocampal fissure forms hippocampal lucency or hypoattenuation in the temporal area medial to the temporal horn and it is a good radiologic marker for AD detection by CT.

PET Scanning in AD detection: Positron emission tomography (PET) scan is a robust, sensitive, powerful, noninvasive technique quantify cerebral blood flow using metabolic property of brain tissue and binding property of amyloid beta plaque. This technique is essential for accurate diagnosis, evaluation of disease progression and assessment of drug response [12, 13]. In AD, at baseline, PET scan can show relation with decline in mini mental state examination score [14]. A major limitation of PET is it is very expensive.

SPECT Scanning in AD detection: Single-photon emission computed tomography (SPECT) is a noninvasive technique uses photon emitting property of radio nuclei with half-life of 6 to 12 hours. This scan depicts a clear 3D image of brain indicating regional cerebral blood flow. Number of studies with SPECT reveals a positive correlation between severity of dementia and temporoparietal hypofunction [15, 16]. Bilateral temporoparietal hypoperfusion shows 82% positive predictive value for AD [17]. A major limitation of PET is it is very expensive. Fig. 1 shows the four different brain scanning techniques.

Fig. 1. Different brain scanning techniques, from left to right: MRI scan, CT scan, PET scan, SPECT scan.

III. LITERATURE REVIEW

Many researchers have studied the detection of AD. These studies usually follow two main approaches: the analysis of biomarkers and the examination of patients' decreasing cognitive abilities. The first approach yields reliable results in the detection of AD in its moderate and advanced stages, albeit still performing insufficiently in the early stages of the disease [18]. The second approach has gained more attention in recent years, since, in clinical practice, it has shown promising results in the early detection of AD [19, 20]. Furthermore, when compared to the first approach, the analysis of the decline of cognitive abilities represents an inexpensive and noninvasive alternative. In 2012, Ali El-Zaart and Ali A.Ghosn [21] have proposed a new method for image thresholding (bimodal and multimodal thresholding). Their segmentation method was based on between-class variance and using Gamma distribution. Authors stated that their approach solved the problem of non-symmetric histogram of images by using Gamma rather than Gaussian distribution. They then confirmed that the experimental results obtained by testing their approach showed a good efficiency and satisfying segmentation results, but they mentioned nothing about the accuracy rate or the impact of their segmentation results on the AD automatic detection. Fig. 2 demonstrates the segmented results obtained from that work.

Fig. 2. Original MRI images and segmented Results by El-Zaart and Ghosn approach [21].

Siavash Fashtakeh suggested a research idea in the same year [22]. The idea was based on applying pattern recognition techniques to structural MRI images and then uses automatic classifiers to detect AD in its early stages. ADNI database was used in this study. Brain tissue categorization into white matter (WM), grey matter (GM) and cerebrospinal fluid (CSF) was held first followed by customized tissue probability maps created for bias correction. SVM was used then for feature reduction and feature selection. As a future work, the author mentioned some trials about developing better classifier using Neural Network for automate classification. Although the paper contains detailed explanation of the steps and the dataset used, all the results discussed by Fashtakeh research are expected in future! In 2013, Herrera et al [23] have used Discrete Wavelet Transform (DWT) for feature extraction, then Principal Component Analysis (PCA) for feature reduction. Researchers have confirmed that the experimental study showed that the use of dimensionality reduction in this problem led to a worse classification accuracy. The main conclusion of their study accordingly was that all available information is important to achieve a good classification performance. They also confirmed that due to that fact the computational cost of classifiers training will be very large, but the results would be worthy. They then confirmed that their system using SVM without feature reduction showed promising results, but they did not write a clear accuracy rate. S. K. Aruna and S. Chitra [24] two years later used the OASIS MRI brain dataset to compare different machine learning approaches. The researchers firstly used Gabor filter with four different orientations and GLSM to extract features, then they normalized and fused the features. They then used SVM with different kernels to compare between the effectiveness of features obtained by Gabor, GLCM, and the fused features. Authors finally confirmed that their fused features achieve better accuracy than the features obtained by both Gabor and GLCM; however, nothing about the accuracy rates of AD detection was mentioned in their article. In the same year Moradi et al [25] have used SVM and LDS classifiers to detect AD from MRI brain images, with and without feature selection, and compared all the results obtained in all cases. Authors confirmed that LDS classifier with feature selection led to the best results with accuracy rate of 74.74% which was the highest accuracy rate achieved by their work. Bolurchi et al [26] have published the most recent work conducted in this area in 2018, as they used 3D MRI brain images to improve the accuracy rates of automatic AD detection and they assured

that they were successful as they used three different feature extractors (PCA, PDF, and contrast homogeneity) with respect to state-of-art, and they fused the features extracted from the three key slices together. Furthermore, they adopted and compared three different classifiers (decision tree, K-NN, and SVM). Authors finally confirmed that SVM achieved the better detection accuracy rate which reached 88.1%. Fig. 3 demonstrates the MRI preprocessing steps.

Fig. 3. Preprocessing steps of Bolurchi et al, 3D image (left), key slices (middle), feature detection (right) [26].

IV. THEORY

There are mainly three differences between healthy and non-healthy brain images which are: Severely enlarged ventricles often result in changes in the shapes of them, extreme shrinkage of cerebral cortex often results in changes in the outer shape of the brain, and extreme shrinkage of hippocampus [27] (see Fig. 4). Among those three different signs of abnormality this paper limits the automatic detection on the first sign which is the enlargement in ventricles as an obvious abnormality sign that proved to be the most promising sign to detect AD automatically from brain MRI images. Two approaches are used here for AD detection: Image thresholding approach and deep learning approach. The following subsections explain the steps of each approach in details.

Fig. 4. Comparison of a normal aged brain (left) and the brain of a person with Alzheimer's (right). Characteristics that separate the two are pointed out.

V. PROPOSED APPROACH

This work adopts two different approaches to detect Alzheimer from brain MRIs and then combine them together to get a hybrid approach. The following subsections explain the steps of every approach.

A. Image Thresholding

Some image processing steps were conducted to get the MRIs classified to either sick or normal case based on certain threshold. Fig. 6 represents the steps of the image thresholding approach.

The data in ADNI database are stored in dicom files, so firstly the dicom files were converted to normal images. After

the dicom file is converted to png image, this data is an open source which can be found in ADNI website [28]. First, a color space conversion takes place to convert the RGB images to grayscale images. Otsu's threshold [29] is then applied to the grayscale images. Otsu's method is roughly a one-dimensional, discrete analog of Fisher's Discriminant Analysis. It automatically calculates a certain number (Threshold) based on image color analysis. The idea is that it applies color clustering-based image thresholding to convert the image from grayscale image to binary image. The algorithm uses a bi-modal histogram to exhaustively search for the threshold that minimizes the intra-class variance (the variance within the class), defined as a weighted sum of variances of the two classes. Otsu shows that minimizing the intra-class variance is the same as maximizing inter-class variance. Fig. 5 shows a sample dicom file.

Fig. 5. Sample Dicom file.

Fig. 6. Image processing phases and steps.

The Algorithm I shows the main steps of the Otsu thresholding method.

Algorithm.1. Otsu Algorithm [29]

- 1) Compute Histogram and Probabilities of each Intensity Level
- 2) Set up Initial $\omega_i(0)$ and $\mu_i(0)$
- 3) Step through all Possible Thresholds $t=1, \dots, \text{Maximum Intensity}$
 - Update $\omega_i(t)$ and $\mu_i(t)$
 - Compute $\sigma^2 b(t)$
- 4) Desired Threshold corresponds to maximum $\sigma^2 b(t)$

Fig. 7 shows image before and after applying Otsu Thresholding.

Fig. 7. Axil: The original image (left), the Otsu based threshold image (middle), the dilated image (right).

A morphological image processing is then held to fill the gaps in the ROI (brain ventricles). After wards the brain is then cropped by pixel aggregation. Once the brain image is cropped the ventricles region can be cropped easily as it is in the middle of the image. The ratio of white to black pixels is calculated and the brain is then classified to either normal or sick (with AD).

B. Deep Learning

Convolutional Neural Networks (CNN) is then adopted to extract features automatically from the Original MRIs, and then classify the cases. It is mainly composed of five layers: the input layer, the output layer and three layers in between. Where, the first layer contains 16 filters, the second one is composed of 32 filters, then the third layer is composed of 64 filters. Fig. 8 shows the components of the CNN followed by a detailed explanation.

Every layer takes the feature map and enters it to three different components which are Rectified Linear Units (ReLU function), Batch normalization, and Max pooling. ReLU function converts every fraction to 0 and forward the integers as it is to the batch normalization. Batch normalization then normalize the input it received by subtracting the batch mean and dividing it by the batch standard deviation. Max pooling component uses down sampling to reduce the number of features in its input feature map. Following is the Algorithm II of batch normalization transform.

Algorithm.2. Batch normalization transform

Input:

- Values of x over a mini-batch: $\beta = \{x_1, \dots, m\}$
- Parameters to be learned: γ, β

Output:

- $\{y_i = BN_{\gamma, \beta}(x_i)\}$

Mini-batch mean:

$$\sigma_B^2 \leftarrow \frac{1}{m} \sum_{i=1}^m (x_i - \mu_B)^2$$

Normalize:

$$\ddot{x} \leftarrow \frac{x_i - \mu_B}{\sqrt{\sigma_B^2 + \epsilon}}$$

Scale and shift:

$$y_i \leftarrow \gamma \ddot{x}_i + \beta \equiv BN_{\gamma, \beta}(x_i)$$

Fig. 8. Layers of CNN.

C. Hybrid Approach

In this phase, a combination between Otsu thresholding and CNN approaches was adopted to study the results of a hybrid approach. This time the CNN's input layer takes the output of the Image thresholding approach rather than the original MRI. In other words, the input taken by the CNN is the thresholded binary image of the brain ventricles. This required less computational cost and time as a lot of features are eliminated from the input images entering the input layer of the CNN. Fig. 9 shows the combination flow of the two approaches.

Fig. 9. The hybrid approach (Image Thresholding + CNN).

VI. EXPERIMENTAL RESULTS

ADNI Database was used to test and validate this work. Researchers and collectors of ADNI confirmed that when significant abnormalities are seen on the screening MRI scan, such as a hemispheric infarction, the participant is excluded. Additionally, sites are notified by email if a radiological finding that is not normal for age is identified by the MRI QC team [30].

The following tables show the results obtained by Image thresholding, CNN, and the hybrid approach respectively. The tests were conducted using the 3D MRI images, i.e., Axial, Sagittal, and Coronal.

As it can be observed from Tables I, II, and III, CNN achieved the highest accuracy rate in case of Axial scanning

direction. It can also be seen that the Axial direction is the best in AD detection whatever the approach adopted. However, CNN takes more time and computational cost to detect the disease; it outperforms the results of image processing and the hybrid approach concluding that deep learning approaches are much better in such a field. The preceding fact tells that all features are important for automatic AD detection and that feature reduction is not a preferred solution for lowering time and cost. Nevertheless, it must be mentioned that surprisingly the hybrid approach outperforms CNN in case of coronal brain scanning direction.

TABLE I. RESULTS OBTAINED BY IMAGE THRESHOLDING APPROACH

MRI	Accuracy rate
Axial	76%
Sagittal	68%
Coronal	71%

TABLE II. RESULTS OBTAINED BY CNN APPROACH

MRI	Accuracy rate
Axial	90%
Sagittal	85%
Coronal	71%

TABLE III. RESULTS OBTAINED BY THE HYBRID APPROACH

MRI	Accuracy rate
Axial	81%
Sagittal	70%
Coronal	75%

VII. CONCLUSION AND FUTURE WORK

Three different approaches for automatic AD detection from MRIs were adopted in this work: Otsu thresholding, CNN, and a hybrid approach between them. The three approaches have achieved promising accuracy rates compared to literature. A comparative study was also conducted and proved that CNN outperforms image thresholding and even the hybrid approach in terms of accuracy rates. At the same time, image thresholding methodologies require less time and computational cost. However, by comparing the accuracy rates, CNN worth its computational time and cost. ADNI brain MRI Database was used for the testing process. 3D MRIs were adopted for the validation.

Multi-Modal Medical Image Fusion Using Transfer Learning Approach

Ms. Shrida Kalamkar, Dr. Geetha Mary A
School of Computer Science and Engineering
Vellore Institute of Technology, Vellore, Tamil Nadu, India

Abstract—Multimodal imaging techniques of the same organ help in getting anatomical as well as functional details of a particular body part. Multimodal imaging of the same organs can help doctors diagnose a disease cost-effectively. In this paper, a hybrid approach using transfer learning and discrete wavelet transform is used to fuse multimodal medical images. As the access to medical data is limited, transfer learning is used for feature extractor and save training time. The features are fused with a pre-trained VGG19 model. Discrete Wavelet Transform is used to decompose the multimodal images in different sub-bands. In the last phase, Inverse Wavelet Transform is used to obtain a fused image from the four bands generated. The proposed model is executed on Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) datasets. The experimental results show that the proposed approach performs better than other approaches and the significance of the obtained fused image is measured using qualitative metrics.

Keywords—Image fusion; discrete wavelet transform; computer vision; inverse wavelet transform

I. INTRODUCTION

The process of fusing multiple images of different imaging modalities to obtain an image with a large amount of information for increasing the clinical applicability of medical images is multimodal medical image fusion [1]. Medical Imaging techniques like Magnetic Resonance Imaging (MRI) give the human body structural characteristics. In contrast, Computed Tomography (CT) provides cross-sectional images from within the body, and Positron Emission Tomography (PET) is provided soft tissue. Single-photon Emission Computed Tomography (SPECT) provides 3D images of different human body organs[1], [2]. Different imaging techniques provide different characteristics and information about the same part of the human body. The purpose of the fusion is to obtain better contrast and fusion quality. The result of the fusion should meet the following conditions [3]:

- 1) The newly obtained fused image should preserve the original information of source images without any information loss [3].
- 2) The newly obtained fused image should not introduce any inconsistencies or artefacts, and
- 3) Should not add misregistration and noise in the newly fused image.

Medical Image Fusion finds its applicability in various diagnostic problems. CT and MRI images of the skull can be fused, providing doctors with both structural and cross-

sectional information about the skull. This can help in identifying more clearly any skull-based tumors or diseases[4], [5]. Similarly, MRI and ultrasound images can be fused to confirm vascular blood flow. Many reputed medical institutes use very expensive image fusion tools to fuse multiple medical image modalities to diagnose images. Therefore, there is a need to develop a low-cost model for fusing such modalities of images that can benefit small clinics and hospitals [6]–[8]. Recently Deep learning architectures have become more successful for image processing due to the availability of many public datasets and optimization techniques. Deep neural networks have their role in various medical-related applications. Deep networks can be trained for specific clinical applications with the intended dataset, fast computing system, and a huge volume of data. Pre-trained networks can also be used for medical image processing towards specific clinical applications[9], [10]. This paper focuses on the survey and development of a novel transfer learning and wavelet-based technique for multimodal medical image fusion.

The contributions of the paper are stated as follows:

- 1) This paper reviews the different multimodal image fusion techniques in the spatial domain, transfer domain and deep learning domain.
- 2) Discrete wavelet transform (DWT) is used initially, which samples the approximation coefficients and detail coefficients at each level.
- 3) To handle the issue of limited multimodal medical images, a transfer learning approach based on the VGG19 Framework for any modality of a medical image without a training set is proposed.

The contents of the paper are organized as follows. Section II elaborates on the image fusion methods and the need for transfer learning in multimodal medical image fusion. Section III gives information about related research in the field. The problem of image fusion for multimodal medical images using the transform domain approach and VGG19 transfer learning framework and the detailed methodology has been described in Section IV. Section V illustrates experimentation details; datasets used, Fusion metrics and performance analysis used for evaluating the proposed methodology, qualitative metrics, and related comparative analysis in all three domains. Section VI portrays the concluding remarks and pointers to extend the current research work.

II. BACKGROUND

The rapid growth of medical imaging technologies such as computed tomography (CT), magnetic resonance imaging (MRI), positron emission tomography (PET) and single photon emission computed tomography (SPECT) has provided us much richer information on the physical condition[8], [11].

Table I briefly overviews different medical image modalities used to treat a disease.

TABLE I. DIFFERENT MEDICAL IMAGING MODALITIES

Sr.No	Medical Image Modality	Methodology of taking an image	Type of image obtained
1	CT Scan[7], [8], [12]	Uses X-ray equipment to take images from within the human body from different angles.	Cross-sectional images of all types of body tissue and organs
2	MRI Scan[7], [8], [12]	Detailed images from within the human body using magnetic and radio waves.	Structural Characteristics of the human body are obtained. Gets Anatomic and contrast details between normal and abnormal tissues.
3	SPECT Scan[7], [8], [12]	Uses nuclear medicine for therapeutic and diagnostic procedures.	The body's temperature, blood flow details, etc., are obtained.
4	PET Scan[7], [8], [12]	It uses a radioactive drug to give information on how tissues and organs function.	Sometimes detect disease before it is detected using other imaging tests. It Delivers details about the area of disease.

In literature, image fusion can be carried out in three ways:

A. Pixel Level Image Fusion

In this mode of fusion, the original information in the source images is directly combined without extracting the relevant features [13]. Different Algorithms like the Color space model, Statistical Algorithms, multiresolution decomposition algorithms, and radiometric algorithms can be used to perform pixel-level fusion. Fig. 1 shows an overview of pixel-level image fusion.

Fig. 1. Pixel-level image fusion.

B. Feature Level Fusion

Feature level fusion, features from the input images using some feature extraction algorithms are extracted to perform the fusion. A region-based fusion approach is used in this type of fusion[14]. Recently, transfer learning algorithms have proven to work well for extracting features from images. Fig. 2 shows an overview of feature-level image fusion.

Fig. 2. Feature-level image fusion.

C. Decision-level Fusion

Compared to pixel-level and feature-level fusion, decision-level fusion is accurate and supports real-time data fusion. The main disadvantage of this type of fusion is the high loss of information[10]. Algorithms include voting, Bayesian inference, evidence theory, and fuzzy integral [15].

III. RELATED WORK

There are many different methods used in the medical field to fuse different modalities in medical images. A detailed review of multimodal medical image fusion is extensively covered in [4] Medical Image Fusion methods are divided into spatial domain, transform domain, and deep learning domain shown in fig 3.

Fig. 3. Image fusion domains.

Table II shows a list of different algorithms in all three domains and systematically reviews different image fusion techniques in all three domains. The algorithms in the spatial domain were popular among the researchers. But spatial domain methods create spatial and spectral distortion of fused images. Hence, researchers used transform domain methods to perform a fusion of images for better fusion results[16]. The fusion methods in the transform domain transform the source image into the frequency domain and then perform reconstruction operations. The disadvantage of the transform domain is that it generates noise in images during fusion processing. With the advancement in deep learning technology, image fusion methods based on deep learning were introduced recently.

TABLE II. MEDICAL IMAGE FUSION METHODS

Domain	Description	Fusion Method	Advantages	Disadvantages
Spatial Domain[1]	Different fusion rules are applied to pixels in the source image.	<ol style="list-style-type: none"> 1. High Pass Filtering 2. Principal Component Analysis 3. Saturation Method of Hue Intensity 4. Minimum and Maximum selection method 5. Brovey Method 6. Average Method 	Simple Method. It can be combined as a part of the frequency domain to generate new research methods.	Spectral and Spatial Distortion of Fused Image
Transform Domain[1]	Based on multiscale transform (MST) theory. It transforms the source image from the time domain to the frequency domain. low and high-frequency coefficients are obtained	<ol style="list-style-type: none"> 1. Pulse Coupled Neural Network (PCNN) 2. Discrete Wavelet Transform (DWT) 3. Nonsampled Contourlet Transform (NSCT) 4. Nonsampled Shearlet Transform(NSST) 	Good structure and avoids distortion	Generate noise in image during fusion
Deep Learning[17]	Aim at learning feature hierarchies. Features from higher levels combined with lower-level features. Spatial and Transform Domain-based image fusion methods fail in automatic feature extraction and generation of fusion rules.	<ol style="list-style-type: none"> 1. Convolution Neural Network (CNN) 2. U-Net 3. Stacked Auto-encoders(SAE) 4. Deep Boltzmann Machine(DBM) 	Extract the relevant features from the image automatically	Some deep learning models neglect the spatial and temporal topologies of the multimodal data

IV. PROPOSED METHODOLOGY

A. Problem Formulation

We formulate the task of fusion of features from multiple modalities of images as a multimodal medical image fusion problem at the feature level. Several algorithms extract the features of interest from an image, ignore irrelevant features, and eventually apply rules to fuse the important feature during image fusion. These rules play an important role or are the key concept in the fusion process. The selection of proper fusion rules is crucial, resulting in a better fusion process. It is impossible to develop a generic fusion rule for all fusion applications. A more feasible approach in medical image fusion is to develop a new image fusion method that can merge the features extracted from different images into a single fused image.

B. Proposed Methodology for Multimodal Medical Image Fusion

Our proposed work aims to develop a hybrid approach by integrating the structural details provided by CT images with soft tissue details provided by MRI images to get a unique fused image. We have proposed a multimodal medical image fusion based on a blend of Discrete Wavelet Transform and transfer learning VGG19 architecture, which uses the concept of CNN.

The DWT of an image is calculated by passing it through a series of filters, i.e., low pass filter, and then through a high-pass filter to get the approximate and detailed features.

VGG networks are image style transfer methods based on features extracted from the content, style, and generated image. The VGG19 uses the ImageNet dataset for feature extraction and is a pre-trained network. This architecture of VGG19 can be effectively utilized in VGG19-based multimodal image fusion. Fig. 4 graphically represents the proposed CT-MRI medical image fusion architecture.

The following algorithms describe the methodology used for image fusion.

Algorithm 1: Generation of co-efficient from a medical image using DWT.

Input: CT and MRI image
Output: Approximate and detailed co-efficient (LL,LH,HL,HH)

DWT(image, DWT):

1. Decompose CT image using DWT to generate detail and approximate co-efficient.
2. Decompose MRI images using the DWT to generate detail and approximate co-efficient.
3. Pass this co-efficient to VGG19 architecture for fusion.
4. Repeat the function on image 2.

Algorithm 2: Fusion of generated co-efficient using VGG19

Input: Detailed and Approximate co-efficient from CT and MRI images
Output: Fused Image

FUSION(LL,LH,HL,HH):

1. Convert all images to YCbCr format
2. Transfer all images to PyTorch tensors
3. Perform fuse strategy
4. Reconstruct fused image given RGB input images
5. Return fused image

Fig. 4. Proposed CT-MRI Medical Image Fusion Architecture.

In this paper, we have used multimodal medical images, i.e., CT and MRI, the source images given as input to the pre-trained VGG19 model. Initially, we used the Discrete Wavelet decomposition technique of the transform domain to decompose the source images, i.e., CT and MRI images, to generate approximate coefficients of the handcrafted features.

CT images are decomposed to generate LL1 coefficient and horizontal, vertical, and diagonal coefficients, i.e., LH1 (horizontal), HL1 (vertical), and HH1 (diagonal). Similarly, MRI images are decomposed to generate LL2 coefficient and horizontal, vertical, and diagonal coefficients, i.e., LH2 (horizontal), HL2 (vertical), and HH2 (diagonal), as shown in Fig. 5 and Fig. 6.

Later the features from lower-level coefficients, i.e., LL1 and LL2, Horizontal coefficients, i.e., LH1 and LH2, vertical coefficients, i.e., HL1 and HL2, and diagonal coefficients, i.e., HH1 and HH2 of CT and MRI images, respectively are extracted and fused using VGG19 model.

LL, LH, HL, and HH bands are obtained after VGG19 on the input coefficients. The LL band has essential information of an original image. The LH, HL, and HH bands have horizontal, vertical, and diagonal information.

Finally, the frequency sub bands LL, LH, HL, and HH are combined using VGG19 architecture to generate the fused image after applying inverse discrete wavelet transform (IDWT)

Fig. 5. Wavelet transform of MRI image.

Fig. 6. Wavelet transform of CT Image.

V. EXPERIMENTAL RESULTS ON CT AND MRI IMAGES

Different fusion algorithms based on spatial, transform, and deep learning domains are used to compare the performance of the VGG19-based medical image fusion.

Spatial Domain methods like Principal Component Analysis (PCA), LPCA, and FCMPCA. Transform domain methods like Standard Wavelet Transform (SWT), Dual-Tree Complex Wavelet Transform (DTCWT), and Non-Subsampled Contourlet Transform (NSCT) are analyzed. Fusion is employed in the wavelet transformation of both CT and MRI images. Wavelet analysis provides a self-adaptive and

localized analysis, which is applicable to the time domain and frequency domain. This analysis can focus on any details of the time domain and frequency domain. Multi-scale decomposition of the image based on DWT extracts low-frequency information, as well as horizontal, vertical and diagonal directions of the high-frequency details.

In the VGG19 transfer learning method, fusion is done by applying DWT to CT and MRI images. Both these images are then decomposed into four sub-bands. The sub-bands labelled LH1, HL1 and HH1 represent the detail images co-efficient while the sub-band LL1 represents the approximation image.

A. Evaluation Metrics

1) *Peak Signal to Noise Ratio (PSNR)*: PSNR can be defined as the difference between x and y.

$$PSNR \text{ in dB} = 10 \log_{10} \frac{255^2}{\sqrt{\sum_x \sum_y (x-y)^2}} \quad (1)$$

PSNR is calculated using the two source images and the fused image.

$$PSNR_{avg} = \frac{1}{2} (PSNR(IM_1, FI) + PSNR(IM_2, FI)) \quad (2)$$

Where,

- IM_1 -> Image 1,
- IM_2 -> Image 2,
- FI -> Fused Image

A higher value of PSNR indicates better quality of the fused image.

2) *Structural Similarity Index (SSIM)*: It contains the structural information present in the images. The loss of structural information leads to distortion of images.

$$SSIM(x,y) = \frac{(2\mu_x\mu_y + C_1)}{(\mu_x^2 + \mu_y^2 + C_1)} \alpha \frac{(2\sigma_x\sigma_y + C_2)}{(\sigma_x^2 + \sigma_y^2 + C_2)} \beta \frac{(\sigma_{xy} + C_3)}{(\sigma_x\sigma_y + C_3)} \gamma \dots (3)$$

Where,

- μ_x and μ_y are the mean of the images x and y and represents the luminance of the image.
- σ_x and σ_y are the variances. It represents the contrast of the image.
- σ_{xy} is the covariance. It illustrates the correlation between images.
- α , β , and γ - Adjust the relative significance of the above terms. The stability of the metric is C_1 , C_2 , and C_3 - constants that maintain the metric's strength.

Average SSIM is calculated as:

$$SSIM_{avg} = \frac{1}{2} (SSIM(IM_1, FI) + SSIM(IM_2, FI)) \quad (4)$$

Where,

- $SSIM_{avg}$ -> Average SSIM

- $SSIM(IM_1, FI) \rightarrow$
SSIM between source image 1 and fused image
- $SSIM(IM_2, FI) \rightarrow$
SSIM between source image 2 and fused image

The range of SSIM values is between 0 to 1; 1 indicates a perfect match between the reconstructed image and the original image.

The higher the value of SSIM better is the fused image.

3) *Mutual Information (MI)*: In MI, how much information from two input source images (X, Y) is transferred to the fused image is calculated. The formula is as follows:

$$MI = I(x,f) + I(y,f) \quad (5)$$

$$I(x,y) = \sum_{y \in Y} \sum_{x \in X} p(x,y) \log \frac{p(x,y)}{p(x)p(y)} \quad (6)$$

Where,

- $p(x)$ and $p(y)$ - the edge probability density function of the two images,
- $p(x,y)$ - the joint probability density function of the fused image and the source image X, Y.

Higher the MI value, more information is transferred from the original images to the fused image.

4) *Entropy (EN)*: Information content in the image by taking values between 0 and 8.

$$EN = - \sum_{i=0}^{L-1} p_i \log_2 p_i \quad (7)$$

Where,

L - number of grey levels and is a probability density function for each grey value i.

B. Experiment and Evaluation on the Group of MRI-CT Images

CT and MRI data were used in this experiment of fusion. The evaluation metrics used in this experiment have been discussed in the above section. The dataset used for this experimentation is available in The Whole Brain Atlas repository hosted by www.harvardmed.edu. All the source images are registered, which is the prerequisite for fusion. The source images are of spatial resolution $256 \times 256 \times 3$.

We have conducted detailed experimental studies on different CT and MRI test images. The evaluation metrics used in this paper are PSNR, SSIM, MI and EN. The fusion results have been compared with both wavelet-based and neural network-based fusion techniques. Table III below presents the evaluation index data of different methods of MRI-CT fusion.

The performance of the multimodal medical image fusion methods of both wavelet-based and neural network-based fusion are evaluated using four qualitative metrics such as EN, MI, PSNR, and SSIM.

Deep learning techniques perform automatic and near-accurate feature extraction, so the Convolutional Neural Network algorithm achieves the best Entropy (EN), i.e., the amount of information contained in fused images is the largest.

Our proposed DWT+VGG19 algorithm performed best on the PSNR and SSIM evaluation indicators. It can measure a large amount of structural information present in the images. High PSNR means a good quality image and a minor error introduced to the image. Also, the higher the value of SSIM better is the fused image. Hence our proposed algorithm for medical image fusion outperforms the other wavelet-based and neural network-based algorithms in the quality of the image.

The MI and Entropy metrics show that wavelet-based algorithms have poor performance if high noise is present in images. In future, we will use VGG19 architecture with averaging and maximum fusion rules and fuse the detailed contents.

TABLE III. EVALUATION INDEX DATA OF DIFFERENT METHODS OF MRI-CT FUSION

Fusion Methods	MRI-CT evaluation metrics			
	PSNR	SSIM	MI	EN
GFF	31.16	0.49	3.43	6.80
MSA	35.07	0.48	3.92	6.38
NSCT+SR	29.56	0.48	3.13	6.89
NSCT+PCNN	31.23	0.50	5.01	6.74
NSCT+LE	31.61	0.49	3.29	6.80
NSCT+RPCNN	31.68	0.50	4.42	6.77
NSST+PAPCNN	32.92	0.49	3.23	6.84
DWT	31.97	0.43	1.98	6.59
DWT+WA	30.98	0.49	4.75	6.30
U-Net	26.42	0.32	2.22	5.13
CNN	28.96	0.48	3.08	7.01
Proposed model	40.63	0.67	2.88	4.93

VI. CONCLUSION

Deep learning for multimodal medical image fusion has been a recent research topic. Many researchers are focusing on using deep learning in the fusion of different modalities of images. This paper majorly discusses the following points.

1) Image fusion methods in spatial, transform, and deep learning domains are discussed in this paper.

2) Automatic feature extraction using Deep learning models leads to the generation of the most compelling features, eventually improving model accuracy.

3) The VGG19 transfer learning method proposed in this paper can achieve multimodal medical image fusion. This method can effectively achieve image fusion and help in medical diagnosis. It can help in improving the accuracy of medical diagnoses.

4) Experimental results on CT-MRI data show that the proposed transfer learning method achieves state-of-art performance in terms of qualitative evaluation metrics.

The Optimal Route Selection Model of Fresh Agricultural Products Transportation Based on Bee Colony Algorithm

Qingqing Ren

Hainan Vocational University

College of Economics and Management, Haikou, 570100, China

Abstract—In order to optimize the distribution route of fresh agricultural products and reduce the distribution cost, the optimal route selection model of fresh agricultural products transportation based on bee colony algorithm is constructed. After establishing the transportation road network model of fresh agricultural products and analyzing the transportation road information, the transportation road network zoning is realized by the dynamic zoning method of transportation road network based on spectral clustering algorithm, taking the unblocked area and congested area as the zoning purpose. Based on the traffic zoning information, the transportation route optimization model of fresh agricultural products with time window is constructed. Solved by bee colony algorithm to obtain the distribution route of fresh agricultural products with the lowest distribution cost and the highest customer satisfaction. The experimental results show that the model can choose the fresh agricultural products distribution route with the lowest distribution cost and the highest customer satisfaction under the two working conditions of smooth traffic and congestion.

Keywords—Bee colony algorithm; fresh agricultural products; transportation; optimal route selection; road network model; spectral clustering

I. INTRODUCTION

Fresh agricultural products refer to primary products such as fresh fruits that can be sold directly on the shelf without further production. At present, fresh agricultural products mainly include fresh vegetables, fruits, flowers, eggs, milk, raw poultry, aquatic products and fresh meat products. These kinds of products occupy a major position in fresh agricultural products, which are traditionally called the three fresh products - fruits and vegetables, meat and aquatic products [1].

Facing the high demand of fresh agricultural products market, the problem to be solved is to reduce the operating cost in the material distribution process as much as possible on the premise of ensuring customer satisfaction. According to the existing research and exploration results, the logistics industry of fresh agricultural products has broad prospects, but the current situation is still relatively lagging behind. The development of the logistics industry related to the distribution of fresh agricultural products is still unbalanced, which needs to be further improved and explored [2]. It is the mission of all kinds of fresh agricultural products logistics parties to do a good job in the transportation and distribution of fresh agricultural products. This requires the promotion and

combination of new electronic data tools and logistics industry to further narrow the gap between logistics. Therefore, for fresh agricultural products, we should not only pay attention to the “quality” and “freshness” distribution of fresh agricultural products, but also make full use of information and communication technology and Internet platform, and let the Internet deeply integrate with the sales of fresh food [3]. To solve various problems in the distribution of fresh agricultural products, we need to start with the vehicle route planning between the distribution of fresh agricultural products. At the same time, doing a good job in the route planning between the distribution of fresh agricultural products is also of great significance for solving the obstacles of material sharing and symbiosis between urban and rural areas [4].

The key to material sharing is to do a good job in logistics distribution. More exploration directions in the distribution mode of fresh agricultural products focus on the transportation of fresh agricultural products between urban and rural areas [5]. Joint distribution is a widely adopted logistics distribution method. In brief, it means that the goods distribution orders of multiple companies are distributed and transported by a special logistics company. The logistics company reasonably arranges the distribution time and the transportation path of each order according to the goods demand of different orders and the characteristics of its own means of transportation, so as to achieve the same effect as much as possible [6]. In foreign countries, crowdsourcing platforms are usually established to create relevant information databases to provide basic support for the whole distribution activities. It can exchange information between distribution centers, customers and merchants, so as to maximize distribution revenue and optimize efficiency. In terms of product logistics and distribution, Marcus Bowles studied the application possibility of nanotechnology in the logistics management of the circulation of fresh agricultural products [7]. Omar Ahumada and Rene Villalobos proposed a stochastic tactical planning model for the production and distribution of fresh agricultural products based on the distribution climate and the information of customers changing at any time, which reduced the uncertainty encountered by the fresh agricultural products industry when equation ting growth and distribution plans. As a consumable, the final value of fresh agricultural products depends on the product quality at the time of delivery, including perceived taste, freshness, etc. While the transportation costs, labor and other costs consumed in the

whole distribution process affect the final profit and benefit of fresh agricultural products. Therefore, how to reasonably select the distribution mode on the basis of balancing many factors is the top priority, and many factors are interrelated. A good game between various influencing factors is very important for goods suppliers and final consumers to achieve a win-win situation.

Combined with the above background and research foundation, in order to improve the customer satisfaction and transportation cost of fresh agricultural products transportation and distribution, this paper constructs a model of optimal transportation route selection for fresh agricultural products based on bee colony algorithm, and verifies its effectiveness through experiments. The reason for choosing the bee colony algorithm is that it does not need to know the specific special information of the problem to be optimized, and its ability to solve multivariable function optimization problems is excellent. It can choose the fresh agricultural product distribution route with the lowest distribution cost and the highest customer satisfaction, providing a more valuable reference method for the industry to improve service quality and operational efficiency.

II. RELATED WORKS

In order to optimize the calculated effect of the path planning scheme in the logistics industry, experts and scholars in the industry have carried out a lot of relevant research. Y. In order to explore the impact of the free trade zone on regional logistics services, Gong et al. selected the adjacent area of a free trade zone in Chongqing as the research object, and used SWOT model to analyze the impact of the free trade zone on international logistics business. Combined with genetic algorithm, an international logistics route planning model is designed. The experimental results show that the model effectively reduces the time consumption of international logistics business [8]. S. O. Ekici et al. found that logistics performance is a key indicator to determine the operating efficiency of the logistics industry. Therefore, they used the enhanced naive Bayesian network and partial least squares method to build a path planning model that considers logistics performance. The experimental results show that the logistics transportation route designed with this model has higher customer satisfaction than that designed with traditional optimization methods [9]. D. T. Xiao's research team believes that the current agricultural product logistics in Heilongjiang Province is relatively inefficient due to the constraints of climate, transportation, supporting facilities and other factors, so it combines convolutional neural network algorithm to build Heilongjiang agricultural product transportation route planning algorithm. After testing, it is found that the transportation cost of the transportation route designed by this model is 15.9% lower than traditional methods [10]. 10. Zhao et al. found that the circulation efficiency of agricultural products in Liaoning Province is insufficient, and some agricultural products have suffered great losses after reaching the transportation destination. Therefore, the author team put forward a series of suggestions on improving transportation efficiency on the basis of understanding the logistics status of local fresh agricultural products [11]. 10. Huang et al. established a real-time and accurate cold chain logistics management system to solve the

problems of loose circulation, inaccurate information transmission, untimely processing, and serious loss of fresh agricultural products in the traditional cold chain logistics management mode of agricultural products. In this system, the e-commerce platform is combined with the cold chain logistics network, and the physical real-time emergency management mode of the cold chain of agricultural products is divided into the sub mode of "production warehouse+cold chain", the sub mode of "e-commerce+cold chain express+smart cabinet" and the sub mode of "cold chain storage+new retail chain". The test results show that the performance evaluation score of emergency management of fresh agricultural product transport enterprises has been significantly improved after using this system [12].

To sum up, although people have carried out a lot of research to improve the logistics transportation efficiency of all kinds of goods before, most of them only consider one aspect of improving logistics services, such as cost time, customer satisfaction, etc. And few of them consider multiple logistics transportation goals. This research hopes to optimize the cost of agricultural product transportation and customer satisfaction at the same time, which is also the scientific contribution of this research.

III. OPTIMAL ROUTE SELECTION MODEL OF FRESH AGRICULTURAL PRODUCTS TRANSPORTATION BASED ON BEE COLONY ALGORITHM

A. Transportation Network Model of Fresh Agricultural Products

According to the characteristics of the road network description of fresh agricultural products transportation, the road network model shall meet the following requirements:

- 1) Description of geometric characteristics and topological structure of fresh agricultural products transportation network. It includes the location, physical connection, number of lanes, length, width, curvature and intersection of fresh agricultural products transportation roads.
- 2) Expression of basic modeling unit of fresh agricultural products transportation network. The traffic organization remains unchanged as the principle of road network modeling, that is, the number of lanes in the modeling unit remains unchanged, the lane attributes remain unchanged, and the connectivity relationship between lanes remains unchanged.
- 3) Description of transportation lanes of fresh agricultural products and topological relationship between lanes. It describes the connectivity of lanes between different basic modeling units, including clarifying the upstream and downstream lanes of each turn, the connectivity of adjacent lanes, etc.

According to the above analysis, the transportation network of fresh agricultural products can be described as a layered network including sub sections, sub section nodes, directed sub sections, lanes and lane connectors. The road network model is divided into two parts: physical layer and logical layer. The graph is used to represent the physical layer Ω_q of the road network model. It is a non-empty set of vertices and edges.

$\Omega_q = (\Gamma, C)$ is the sub segment node set of $\Gamma = \{\Gamma_j\}$. Ω_q representing the endpoint of the sub segment. C is the sub segment set of $C = \{c_j = [\Gamma_p, \Gamma_q]\}$, Γ_p and Γ_q are the two endpoints of the sub segment c_j . Based on the physical layer of the model, the logical layer $\Omega_l = (\Gamma, \partial, Ka, \Omega_{ka})$ of the model is defined to express the logical connectivity of fresh agricultural products transportation network. Among them, ∂ is the directed sub section, which represents the sub sections with different traffic flows. Based on the directed sub section, the lane elements are described, such as the directed sub section where the lane is located, the number of lanes in the driving direction, lane width, etc.

Based on the above theory, the first layer of the basic road network for the transportation of fresh agricultural products is composed of basic modeling units, including two elements: sub sections and sub section nodes. At the same time, on the basis of sub sections, the sub sections are divided into different directional sub sections according to the traffic flow direction; the second layer refines the lane description based on the first layer, including two elements: carriage lanes and lane connectors for fresh agricultural products. The structure of fresh agricultural products transportation network is shown in Fig. 1.

Fig. 1. Schematic diagram of road network.

B. Dynamic Zoning Method of Transportation Network Based on Spectral Clustering Algorithm

In the transportation network model of fresh agricultural products constructed in Section 2.1, the dynamic zoning method of transportation network based on spectral clustering algorithm is used to partition the transportation network of fresh agricultural products. The zoning is mainly to ensure that the transportation of fresh agricultural products can reasonably select the operation path and avoid the traffic congestion area, so as not to increase the transportation cost of fresh agricultural

products, but also avoid excessive transportation time of fresh agricultural products and customer dissatisfaction.

Spectral clustering algorithm is a new research hotspot in the field of machine learning in recent years. It is based on the theory of spectral graph. Its essence is to transform the clustering problem into the optimal partition problem of graph, use the similarity relationship between data points to establish a similarity matrix, obtain the multi feature vectors of the matrix, and use them to cluster different data points. Compared with other algorithms, spectral clustering algorithm is simple, easy to implement and not easy to fall into local optimal solution, which is very suitable for many practical problems. The algorithm has been applied to image segmentation, speech recognition, computer vision, text mining and other research fields. Traditional clustering algorithms such as k-means algorithm and fuzzy clustering algorithm do not involve the connection relationship of graph in clustering. Spectral clustering algorithm can realize the segmentation of graph well and cluster a variety of spatial data in this paper. And the zoning research of urban road network needs to consider the connection relationship and distance of traffic flow, signal cycle and actual road network at the same time, so it is appropriate to use spectral clustering method.

Combined with the zoning principle of fresh agricultural products transportation network and the attributes of road intersections, this paper determines the relevant factors for constructing the spectral clustering similarity matrix, and selects the three factors of traffic flow saturation, signal cycle, geographical location of the intersection and the road connection relationship matrix for road network zoning. The first two indicators reflect the actual traffic flow attributes of the intersection, corresponding to the traffic flow saturation principle and the signal cycle principle, and the latter index reflects the topology attribute of the intersection, corresponding to the distance principle.

The traffic flow saturation BH of fresh agricultural products transportation network can be calculated by equation.

$$BH = \frac{CL}{TX} \tag{1}$$

Where, CL and TX are the traffic flow on the fresh agricultural products transportation road respectively. The actual traffic capacity, signal cycle and geographical location of the intersection can be obtained through actual investigation.

In this paper, the NJW algorithm in the k-way division criterion of spectral clustering algorithm is used for dynamic zoning of road network. According to the specific analysis process of NJW multi-channel spectral clustering algorithm and combined with the relevant factors of road network zoning, the specific steps of road network zoning based on spectral clustering algorithm are as follows:

1) Combined with Fig. 1, calibrate the topological structure of fresh agricultural products transportation network and the number of each intersection and road. JX and DL are the intersection and road in the study area.

2) Calculate the similarity matrix Bc . Standardize the original data of the three factors of traffic flow saturation, signal period and intersection geographical location of the road network model shown in Fig. 1, then calculate the similarity between nodes, and calculate the intersection similarity matrix Bc in combination with the road connection relationship matrix.

$$Bc_{ij} = \begin{cases} \exp\left(-\frac{\|y_{s_i} - y_{s_j}\|}{2\rho^2}\right) & i \neq j \\ 0 & i = j \end{cases} \quad (2)$$

Where, ρ is a parameter selected by people in advance. The larger its value is, the more significant the classification effect is. y_{s_i} and y_{s_j} represent the traffic factors of the i th and j th intersections respectively.

3) Calculate the Laplace matrix lp covering the transportation and traffic information of fresh agricultural products.

$$lp = JH^{-\frac{1}{2}}(lp \cdot JH)^{-\frac{1}{2}} \quad (3)$$

Where JH is the diagonalization matrix obtained from matrix Bc .

4) Calculate the first maximum eigenvalues tz_n and the corresponding traffic information eigenvector \mathcal{X}_n of the Laplace matrix lp . The transportation information of fresh agricultural products can be obtained, and the corresponding eigenvectors are arranged according to the order of eigenvalues to form a matrix ν .

5) Transform the row vector of the characteristic vector matrix ν of fresh agricultural product traffic information into the unit vector to obtain the matrix Ψ .

6) Regard each row of matrix Ψ as a data point in three-dimensional space, and K clusters are obtained by K-means algorithm.

7) Through step 6, the classification results of the best intersection are obtained, the classification results are visually displayed, and appropriate zoning adjustments are made according to the actual situation.

According to the above steps, the zoning results combined with the road network flow can be obtained. When the zoning results cannot meet the traffic flow performance of each road network area after zoning, the road network zoning needs to be adjusted according to the real-time data of traffic flow.

C. Establishment of the Optimal Route Selection Model for The transportation of Fresh Agricultural Products

Combined with the transportation traffic information of fresh agricultural products, the optimal route selection model of fresh agricultural products transportation is constructed, and the model is solved by bee colony algorithm to obtain the optimal route of fresh agricultural products transportation.

D. Description of Transportation Problems of Fresh Agricultural Products

The vehicle routing optimization problem of fresh agricultural products studied in this paper is to consider a distribution center. The distribution center uses multiple transportation vehicles for collaborative distribution. All vehicles start from the distribution center and distribute in the area composed of multi customer distribution nodes. The location of each distribution node is determined, the demand of each distribution node is known, and the distribution service to all customer distribution nodes is completed within the time window required by each customer. All vehicles eventually return to the distribution center.

A single distribution center is set to deliver goods to the k th customer (or distribution node). The freight volume of the j th distribution traffic route is Υ , the time window is $[FH_j, KH_j]$. The unloading time is αt_j , the delay cost per hour is s_j , and the average speed and shortest distance between customers and between distribution centers and customers are u_{ji} and e_{ji} respectively; n trucks can be used to transport goods, including m_q trucks in group q , with a loading capacity u_q , a driving cost g_q of per vehicle per kilometer, a waiting cost s of per hour, overtime allowance dr and baggage allowance r of per hour respectively; The vehicle must return to the original distribution center on the same day, and the demand point of P vehicle distribution of group q is expressed as m_{qp} .

IV. CONSTRUCTION OF OBJECTIVE FUNCTION

Compared with foreign countries, the domestic cold chain transportation of fresh agricultural products is still in the primary stage, but it has also achieved some results in the development of relevant distribution system and technology (Huang et al. 2020). Through the above analysis, it can be seen that distribution is an important part of the cold chain logistics system. Optimizing the distribution route helps to improve the efficiency of cold chain logistics. Due to the lack of scientific and reasonable planning for the distribution route of fresh agricultural products, it is difficult to meet the daily needs of customers in time. Considering the characteristics of distribution cost, distribution time and fresh agricultural products, an overall optimization model of distribution route with time window is established to minimize the distribution cost.

A. Customer Satisfaction

The delivery target customers of fresh agricultural products are required to receive their products within the specified time period. If they exceed the time period or deliver them in advance, they may be rejected or accept certain punishment measures as compensation. Therefore, only by timely delivering fresh agricultural products to customers according to the time window specified in the order can we meet the requirements of customers, improve the satisfaction with the

distribution service of fresh agricultural products, and the online sales of fresh agricultural products can be more accepted by the market [13].

If t_j represents the arrival time of the means of transport and j represents the logistics node number, then $FH_j < t_j < KH_j$. FH_j and KH_j are the earliest and the latest starting time of the distribution service respectively. In the actual distribution process of fresh agricultural products, if the fresh agricultural products are delivered just at the distribution time point required by the customer and look at the time window immediately, the customer satisfaction will reach the maximum, that is, the optimal solution is realized; If the fresh agricultural products are not stuck when they are delivered, and the time is not at the time point required by the customer, that is, the goods may be delivered in advance or the goods may be in a timeout state when they are delivered, namely, the time window can be accepted. At this time, the customer's satisfaction with the service quality of distribution cannot be met [14].

Customer satisfaction can be expressed as a function of fuzzy reservation time. For customers, when the service start time is t_j , the customer satisfaction function can be expressed as:

$$g_j(t_j) = \begin{cases} 0 & t_j \leq FH_j \\ [0.7(t_j - FH_j) / (FH_j^e - FH_j) + 0.3] & FH_j \leq t_j \leq KH_j \\ 1 & FH_j^e < t_j < KH_j^e \\ [0.7(KH_j - t_j) / (KH_j - KH_j^e)] + 0.3 & KH_j^e \leq t_j \leq KH_j \\ 0 & t_j > KH_j \end{cases} \quad (4)$$

Where, FH_j^e and KH_j^e are the earliest and the latest time window of the reservation in turn.

When driving to position i after completing the transportation task j of fresh agricultural products, the waiting time of the distribution vehicle at position i can be expressed as:

$$\varpi_j(t_j) = t_i - t_j - t_{ji} \alpha t_j \quad (5)$$

Where, t_{ji} represents the travel time of the distribution vehicle from customer j to customer i ; $\varpi_j(t_j)$ represents the waiting time of the distribution vehicle at the customer i when the starting time is t_j ; t_i and t_j are the time taken for the delivery vehicles to arrive at the customer i and j destinations respectively.

B. Loss of Fresh Agricultural Products

Different from other products, fresh agricultural products are perishable, and the fundamental value of fresh agricultural products lies in whether they reach the freshness and quality satisfactory to customers. Even if the current means and methods of transportation can improve the temperature in the

transportation process and achieve constant temperature distribution, the final value of fresh agricultural products will continue to decrease with the extension of distribution time in the overall distribution process because the degree of decay of fresh agricultural products is closely related to the length of distribution time; as for the loss degree of fresh agricultural products, generally speaking, it consists of three stages: high value (freshness is the highest after picking) to acceptable value (loss of certain freshness after a period of time, but customers can finally accept) to invalid value (complete decay and damage, which cannot be accepted or eaten by customers). On the whole, fresh agricultural products cannot be delivered when they are obtained, placed an order, and then delivered to customers. More often, fresh agricultural products will be delivered within the stage of acceptable value, resulting in the loss of fresh agricultural products [15].

On the one hand, fresh agricultural products are lost due to the increasing time from the distribution center to the destination, that is, the distribution time has lost fresh agricultural products. The relevant variables are: when the value of vehicle state y_{hk}^v is 1, it means that the vehicle k of distribution center v serves customers h ; when the value of y_{hk}^v is 0, which means that the vehicle k does not provide customer h service. The loss cost at this time is:

$$D_1 = \sum_{k=1}^k \sum_{h=1}^{m+v} \sum_{v=m+1}^v \gamma f k_h y_{hk}^v \beta_2 t_h^k - \gamma f k_h y_{hk}^v \beta_2 t_{h-1}^k \quad (6)$$

Where, f represents the unit price of fresh agricultural products; k_h represents the quantity of fresh agricultural products ordered by the customer h ; β_2 represents the loss rate of fresh agricultural products during transportation; t_h^k represents the time when the vehicle k arrives at the customer h ; t_{h-1}^k represents the time from vehicle k to customer $h-1$.

On the other hand, fresh agricultural products will be unloaded when they arrive at different distribution points in the distribution process. At this time, the opening of the transportation vehicle for unloading will produce internal and external air convection and change the internal air temperature, so as to accelerate the corruption speed of fresh agricultural products and the loss of fresh food in the loading / unloading process. The relevant variables are: when the value of y_{hk}^v is 1, it means that the vehicle k of distribution center v has delivered to point h ; if the value of y_{hk}^v is 0, it means that the vehicle k has not delivered to point h . The loss cost at this time is:

$$D_2 = \sum_{k=1}^k \sum_{h=1}^{m+v} \sum_{v=m+1}^v f \gamma k_h y_{hk}^v \beta_2 (O_h^k) \quad (7)$$

Where O_h^k is the loading and unloading time of vehicle k at distribution point h .

Then the loss cost D of fresh agricultural products in the process of distribution is the sum of equations (6) and (7).

C. General Model Construction

To sum up, in order to build the model, when the values of the vehicle state judgment variables a_{jqp} , a_{jqp} and a_{jiqp} are 1 during introducing the transportation of fresh agricultural products. It means that the vehicle k passes through the distribution point (j, i) , and when the value of a_{jiqp} is 0, it means that the vehicle k does not pass through the distribution point (j, i) ; when the value of a_{jqp} is 1, it means that vehicle k serves customer j ; when the value of a_{jqp} is 0, it means that vehicle k does not serve customer j .

The following models are established:

$$\begin{aligned} \text{Min}W = & \sum_{j=0}^k \sum_{i=0}^k \sum_{q=1}^n \sum_{p=1}^{m_q} e_{ji} f_q a_{jiqp} + \sum_{q=1}^n \sum_{p=1}^{m_q} (\varpi o_{qp} * r + d\varpi o_{qp} * r) \\ & + s_j * s \sum_{j=1}^k \max(t_j - \alpha t_j, 0)(\alpha t_j - t_j, 0) + \Upsilon DBH \end{aligned} \quad (8)$$

The constraints are:

$$\frac{\Upsilon}{k} \sum_{j=1}^k g_j(t_j) \geq 80\% \quad (9)$$

$$\sum_{j=1}^k f_j a_{jqp} \Upsilon \leq u_q \quad (10)$$

$$\sum_{q=1}^k \sum_{p=1}^{m_q} a_{jqp} \Upsilon = 1 \quad (11)$$

$$\sum_{j=1}^k a_{jiqp} = a_{jqp}, i = 1, 2, \dots, k \quad (12)$$

Where, equation (8) is the objective function, which means that the distribution cost of fresh agricultural products is the smallest. Equation (9) is the constraint of customer satisfaction, which means that the average value of customer satisfaction should be more than 80%. Equation (10) is the vehicle loading capacity constraint. Equation (11) is used to ensure that customers only complete the distribution by the P th vehicle of group q . Equation (12) represents the only constraint on the vehicle arriving at a customer, that is, each customer has and only one vehicle to serve him. ϖo_{qp} represents the driving time of the P th vehicle in group q , and $d\varpi o_{qp}$ represents the overtime time of the P th vehicle in group q . e_{ji} represents the shortest distance between transportation

logistics nodes of fresh agricultural products. s is the hourly waiting cost of the vehicle, and s_j is the delay cost of the j th hour.

D. Solving the Optimal Transportation Path of Fresh Agricultural Products based on Artificial Bee Colony Algorithm

Artificial bee colony algorithm is a new intelligent optimization algorithm proposed by Karaboga in 2005. In the artificial bee colony algorithm, the optimal food source is obtained through the cooperation and role transformation of leading bee, following bee and reconnaissance bee. The location of the food source corresponds to the possible solution of the optimal route for the transportation of fresh agricultural products. The income of the bee colony in the food source represents the fitness of the optimized problem [16].

At the beginning of the algorithm, the initial population M with solutions will be generated randomly, and each solution Y_j is a B -dimensional vector. Then, lead the bees to remember the optimal solution and search in the neighborhood of the food source. After initialization, three kinds of bees search circularly. The search equation is as follows:

$$u_{ji} = y_{ji} + \delta_{ji} y_{ji} - \delta_{ji} y_{ji} \quad (13)$$

Where, u_{ji} is the candidate food source and represents the candidate solution of the optimal transportation path of fresh agricultural products; $\mu \in \{1, 2, \dots, M\}$, $i \in \{1, 2, \dots, B\}$ are generated randomly and unequal. δ_{ji} is a random number uniformly distributed on $[-1, 1]$. The leading bee adopts the greedy criterion to compare the search solution of the optimal route of fresh agricultural products transportation with the previous optimal solution. If the search solution of the optimal path is superior to the previous optimal solution, replace it; on the contrary, it remains unchanged. The probability of following bees to choose food source is:

$$\sigma_j = \xi_j \delta_{ji} / \sum_{j=1}^M \xi_j \delta_{ji} \quad (14)$$

Where, ξ_j is the fitness of the j th solution. If a food source remains unchanged after circulation, the food source will be abandoned, and the corresponding leading bee will become a reconnaissance bee, and the solution will be updated through the following equation:

$$\eta_j^i = \eta_{\min}^i + \text{rand}(0, 1)(\eta_{\max}^i - \eta_{\min}^i) \sigma_j \quad (15)$$

Where, η_j^i is the i -th dimensional component of the new food source, which represents the component information of the new path during the transportation of fresh agricultural products; η_{\max}^i and η_{\min}^i are the maximum and minimum values of the i -th dimensional component respectively.

The classical artificial bee colony algorithm adopts the real number coding method for the transportation path coding of fresh agricultural products, which is obviously not feasible in the distribution route optimization of fresh agricultural products. Distribution center demand is decentralized, so the coding method needs to be reconsidered. In this study, if the natural number coding method is adopted for the demand point, a feasible transportation path of fresh agricultural products can be expressed as $(0, \mathcal{G}_{11}, \mathcal{G}_{12}, \dots, \mathcal{G}_{1m}, \mathcal{G}_{21}, \mathcal{G}_{22}, \dots, \mathcal{G}_{2v}; \mathcal{G}_{n1}, \mathcal{G}_{n2}, \dots, \mathcal{G}_{nu})$. The transportation route of this fresh agricultural products means that the first vehicle starts from the distribution center and returns to the distribution center after reaching the demand point $\mathcal{G}_{11}, \mathcal{G}_{12}, \dots, \mathcal{G}_{1m}$; The second vehicle starts from the distribution center and returns to the distribution center after reaching the demand point $\mathcal{G}_{21}, \mathcal{G}_{22}, \dots, \mathcal{G}_{2v}$. The m -th vehicle starts from the distribution center and returns to the distribution center after reaching the demand point $\mathcal{G}_{n1}, \mathcal{G}_{n2}, \dots, \mathcal{G}_{nu}$. If there are 3 vehicles and 9 demand points and the food source is $y = 023601789045$, it means that the first vehicle starts from the distribution center and returns to the distribution center after reaching demand points 2, 3 and 6. The second vehicle starts from the distribution center and returns to the distribution center after reaching demand points 1, 7, 8 and 9, and the third vehicle starts from the distribution center and returns to the distribution center after reaching demand points 4 and 5.

Fig. 2. Food sources before and after exchange.

Since a new food source coding method is adopted in the artificial bee colony, the update of the candidate food source location (transportation path of fresh agricultural products) cannot adopt the mode of equation (15). In this study, by exchanging two neighborhood points in the food source (fresh agricultural product transportation path) are randomly exchanged to obtain the candidate food source. It is illustrated by 9 demand points and 3 vehicles. Fig. 2 shows the food sources before and after the exchange. It can be seen that the candidate food sources can be obtained by exchanging the third and sixth points. The change of food source before and after exchange is small, so many excellent characteristics of food source before change can be maintained; At the same time, the

random location exchange increases the diversity of food source selection and avoids falling into local optimization and failing to obtain the global optimal solution of the transportation path of fresh agricultural products [17].

The fitness function is obtained by transforming the objective function of the established transportation route selection model of fresh agricultural products. Since the objective function pursues the minimization of cost and the maximization of customer satisfaction, its reciprocal is taken and transformed into the fitness function of artificial bee colony algorithm:

$$\zeta = 1 / \min W = 1 / \left[\text{Min} W = \sum_{j=0}^k \sum_{i=0}^k \sum_{q=1}^{m_j} e_{ji} f_q a_{jup} + \sum_{q=1}^{m_j} (\varpi o_{ap} * r + d \varpi o_{ap} * r) + s_j * s \sum_{j=1}^k \max(t_j - \alpha t_j, 0)(\alpha t_j - t_j, 0) + DBH \right] \quad (16)$$

The specific steps of using artificial bee colony algorithm to solve the optimization of cold chain logistics distribution route of fresh agricultural products are as follows:

1) Generate a certain number of food sources, that is, the initial solution of the transportation path of fresh agricultural products. The initial solution is allocated to each leading bee, and the fitness of the transportation path of each fresh agricultural product is calculated;

2) Set the maximum number of iterations, cycles and the cycles of each solution;

3) Leading bees search the neighborhood of the transportation path of fresh agricultural products, generate new solutions of the same scale, and compare the fitness of the old and new solutions. If the fitness of the optimized new solution for the transportation path of fresh agricultural products is greater than that of the old solution, the new solution will replace the old solution, otherwise the old solution of the transportation path of fresh agricultural products will remain unchanged [18].

4) Following bees choose the transportation path of fresh agricultural products with probability σ_i , and conduct the neighborhood search to generate a new solution and calculate its fitness. Select the maximum fitness value of the new solution and compare it with the fitness value of the old solution. If the fitness of the new solution is greater than that of the old solution, the new solution will replace the old solution, otherwise the old solution will remain unchanged [19].

5) Judge whether the number of iterations reaches the maximum value [20-21]. If it is the maximum value, the optimal solution of the transportation path of fresh agricultural products will be output, that is, the distribution route of fresh agricultural products with the lowest distribution cost and the highest customer satisfaction will be obtained. If not, skip to step (3) and continue the iteration [22]. So far, the transportation route optimization model for fresh agricultural products has been built, and the steps for calculating the transportation route are shown in Fig. 3.

Fig. 3. Flow chart of transportation route optimization model for fresh agricultural products.

V. RESULTS AND ANALYSIS

In order to test the effectiveness of the model established above, aiming at the model, this paper will take 18 order information about the distribution process of fresh agricultural products in a city's fresh agricultural products distribution center on a certain day as the research object for analysis and comparison [23-24]. The total transportation cost is 644.1 yuan [25]. Get the optimal transportation route scheme by inputting the data into the program written in Python language.

The basic information of each distribution node is shown in Table I.

TABLE I. COORDINATE NODES OF DISTRIBUTION POINTS

Distribution node code	Abscissa/m	Ordinate /m
1	19	16
2	17	10
3	21	11
4	20	14
5	26	15
6	23	11
7	26	18
8	16	16
9	17	13
10	15	19
11	18	18
12	24	14
13	20	19
14	23	13
15	12	12

Relevant parameter settings are shown in Table II.

TABLE II. RELATED PARAMETER SETTINGS

Parameter name	Parameter value
Vehicle transportation cost (yuan / vehicle / time)	2.2
Vehicle running speed (km / h)	70
Normal salary of driver (yuan / hour)	17
Overtime pays for drivers (yuan / hour)	30
Vehicle waiting cost (yuan / hour)	20
Customer delay fee (yuan / hour)	110

Under the condition of smooth traffic, the path results optimized by the model in this paper are shown in Fig. 3.

Fig. 4. Path results of 10 vehicles.

The calculation results show that under the use of 10 vehicles, the optimal feasible solution obtained after operation is 1-10-9-1-7-1-8-11-1-12-1-13-1-2-1-14-5-1-15-1-4-6-1-3-1. The transportation time of each vehicle is relatively average, which does not cause excessive use of some vehicles, and the transportation time of each vehicle is not long, which is basically about 12 hours, which can maintain the freshness of fresh agricultural products. From the above results, it can be seen that the model constructed in this paper can effectively reduce the distribution cost and meet the customer satisfaction needs. Table III shows the specific results.

TABLE III. ROUTE DELIVERY RESULTS OF 10 VEHICLES

Vehicle code	Route	Journey time/h	Delay waiting/min	Transportation cost / yuan
1	1-10-9-1	12	0	33
2	1-7-1	12	0	23
3	1-8-11-1	11	0	34
4	1-12-1	11	0	35
5	1-13-1	9	0	44
6	1-2-1	10	0	32
7	1-14-5-1	12	0	21
8	1-15-1	11	0	54
9	1-4-6-1	12	0	22
10	1-3-1	12	0	11

As shown in Table III, after the model in this paper is used and fresh agricultural products are transported, the delayed waiting time of the distribution target is 0, and the total transportation cost is 309 yuan, saving 335.1 yuan.

In the case of traffic congestion, after the model in this paper is used, the time-sharing diagram of path optimization is shown in Fig. 4. Among them, the straight line represents the current solution and the wavy line represents the optimal solution. It can be concluded from Fig. 4 that the distribution cost is optimized from 644.1 yuan to about 350 yuan.

Fig. 5. Time sharing diagram of route optimization in this model under traffic congestion conditions.

In the two working conditions, the test results of customer satisfaction rate are shown in Fig. 5.

Fig. 6. Test results of customer satisfaction rate under two working conditions.

As shown in Fig. 6, in the two working conditions of smooth traffic and traffic congestion, after the use of the model in this paper, the customer satisfaction is greater than 95%, and the satisfaction is high.

VI. DISCUSSION

Combined with the research content of this paper, the suggestions to improve the matching effect of fresh agricultural products are as follows:

A. Accelerate the Construction of Agricultural Products Logistics Infrastructure

The rapid development of agricultural products logistics is inseparable from infrastructure construction. All regions make reasonable planning and purposeful construction according to the actual situation. The following suggestions are mainly put forward:

1) *Cold storage construction:* The temperature in the cold storage is mainly adjusted according to the different types of agricultural products. The construction of cold storage in cities is closely related to the distribution of agricultural products. The characteristics of fresh agricultural products determine that the cold storage in cities must reach a certain scale in order to ensure that agricultural products are not damaged. Only by investigating the output, types and distribution of urban agricultural products, planning the layout and optimizing the location can we promote the development of agricultural products logistics.

2) *Construction of distribution center:* The main purpose of distribution center is to distribute to customers at various points, which plays a vital role in the impact of distribution. The distribution cost is directly related to the number of urban distribution centers. There are few distribution centers, resulting in high distribution cost and long distribution distance, and the decay rate of fresh agricultural products is high. Reasonable planning and uniform distribution of distribution centers is an effective measure to effectively reduce the loss in distribution.

3) *Transformation and upgrading of cold chain transport vehicle:* The cold chain transport vehicle is mainly used for the distribution of agricultural products. Whether the cold chain equipment on the vehicle is advanced or not will also affect the cost. At present, many cold chains transport vehicles in China are refitted through ordinary vehicles. The technical level is relatively backward and the distribution cost is high, which cannot be compared with developed countries. Therefore, it is necessary to introduce advanced cold chain transportation technology from developed countries and upgrade cold chain transportation vehicles.

B. Expand the Scope of Green Channel

At present, the transport channel of fresh agricultural products has been expanded to all parts of the country, and the varieties that meet the requirements are given free passage. However, in order to increase taxes, some local governments have not strictly implemented the government documents, which has caused some obstacles to the circulation of fresh agricultural products. In view of the green channel of agricultural products, we should still strive to do a good job in the following aspects.

1) We will continue to implement the policy of exemption and reduction for fresh agricultural products that meet the requirements, and expand this scope to every region and every toll road.

2) Due to the large number of social vehicles, when the agricultural product transport vehicle passes through the toll station, it needs to stop and accept the inspection of the security personnel. It can be released only if there is no problem, resulting in longer transportation time and higher loss rate of agricultural products. Therefore, it is necessary to build a set of security inspection system, which can automatically check whether the products loaded in the vehicle meet the transportation requirements of agricultural products, shorten the vehicle transportation time and effectively ensure the quality of agricultural products.

3) Individuals take advantage of the preferential policy of agricultural product transportation and borrow the green channel to cause some obstacles to the implementation of security inspection personnel. It needs to build a set of credit system and integrate such people into the integrity system, so as to ensure the smooth transportation of agricultural products.

C. Make Full use of Information Technology to Build a Network Information Platform for Cold Chain Distribution

The particularity of fresh agricultural products determines the importance of its distribution link. The optimization of the distribution route of cold chain logistics for fresh agricultural products is to effectively avoid the deterioration and decay of agricultural products and reduce economic losses. Logistics distribution is an important part of the cold chain system, which has high requirements for the timeliness and fresh-keeping function of distribution. In the information age, in order to optimize the cold chain logistics transportation system, we need to make full use of advanced information technology, effectively connect all links of logistics distribution, monitor the status of logistics distribution in real time, and realize the intelligent management of logistics distribution. Through the construction of corresponding network information platform, the collection, sorting and feedback of logistics information are managed in an integrated way, so as to grasp the transport status of fresh agricultural products in real time and improve the safety and freshness of fresh agricultural products. In the implementation of distribution management, big data and other technologies are used to automatically manage logistics transportation and improve the level of distribution management. The one-stop cold chain logistics distribution includes the whole process from production to sales of agricultural products. The intelligent management of the whole service process through the application of information technology can avoid the disadvantages of traditional logistics distribution and meet the optimization requirements of the cold chain logistics distribution route of fresh agricultural products.

VII. CONCLUSION

In recent years, with the continuous development of logistics industry and the increasing variety and output of fresh agricultural products, higher requirements are put forward for cold chain logistics distribution. In the cold chain logistics system, distribution is a very key link, which has high requirements for transportation technology and transportation environment. However, compared with developed countries, China's cold chain logistics started late, the technology is not

mature, the cost of fresh produce distribution is still high, and the corresponding preservation equipment is not perfect. Once the food goes bad or rots, it will seriously affect the surrounding environment. People's income is increasing, and the demand and quality requirements for fresh agricultural products are increasing. In order to better meet people's needs, we must take effective strategies to optimize the distribution route of cold chain logistics of fresh agricultural products. When optimizing the distribution route, we can make full use of information technology to build a network information platform for cold chain distribution; strengthen the implementation of relevant policies to provide a good environment for the development of cold chain logistics; optimize the supply chain of fresh agricultural products and build a large distribution center; strengthen alliances of fresh produce-related organizations to promote the long-term stable development of China's cold chain logistics industry. In this context, this paper constructs the optimal route selection model of fresh agricultural products transportation based on bee colony algorithm, and verifies its application value in experiments. However, due to the limitation of personal energy, this study failed to select more data to verify the model performance of the design, which is also the key point to be noted in the follow-up study.

Abstract—A computer application that can detect, track, identify or verify human faces as of an image or video capture utilizing a digital camera is Face Recognition (FR). Few challenges like low-resolution images, aging, uncontrolled pose, illumination changes, and poor lighting conditions are not tackled even though huge advancement has been created in the Face Detection and Recognition (FDR) domain. Utilizing the Modified Tiny Face Detection (MTFD) and Fuzzy Interference System - Convolutional Deep Neural Network (FIS-CDNN) classifier, a Face Recognition System (FRS) was proposed here to tackle all complications. Primarily, Gamma correction - Based Histogram Equalization (GBHE) technique is utilized to augment the image's input in the pre-processing phase. The MTFD was employed to detect the face. Following that, the features are extracted. The Improved Chehra (IC) landmark extraction method was employed to retrieve the landmark features. And finally, the Geometric Features (GFs) are extracted. Later, the Gaussian - centered Spider Monkey Optimization (GSMO) Algorithm was employed to choose the vital features. To recognizing the face, the chosen features are fed into the FIS-CDNN classifier. When analogized to the prevailing models, it is concluded via the experiential outcomes that higher accuracy was attained by the proposed method.

Keywords—Gamma correction - based histogram equalization (GBHE) technique; modified tiny face detection method (MTFD); Improved Chehra (IC) landmark extraction method; Gaussian-based Spider Monkey Optimization (GSMO) Algorithm; fuzzy interference system-convolutional deep neural network (FIS-CDNN) classifier

I. INTRODUCTION

Since the face contains numerous important details, it is a vital part of the human body for recognizing each individual [1]. This is what led to Human FR being a significant subject in the artificial intelligence field. Owing to their respective pixel data computation, the query face image is harmonized with the template face image in the facial database for the FR, which is the process of recognizing persons [2]. Without using any further equipment, humans have the natural ability to recognize faces in a scene [3]. Additionally, a complex computer vision problem with a variety of aspects is the automatic FR [4]. In every practical aspect of our lives, it has been recognized as a developing field owing to the wide utilization of this technology. The areas where various applications correlated to this field are currently used widely such as defense, surveillance, banking, media field, social media platforms, fraud identification, e-commerce, trade, diagnostics, space

science, research, genomics, bioinformatics, cyber security, internet of things and education [5]. Face Detection, face alignment, face matching and face representation are the four main steps of FRS. Face matching seeks to create a classifier to recognize distinct faces while extracting useful features to differentiate face images as of distinct people is the aim of face representation. The facial landmarks are obtained by the face alignment. Face Detection aims to return the face's position, if they exist.

Some specific conditions still make extremely accurate identification results impossible despite recent advancements in FR. This is typically the case when there is a lack of high-quality data, such as when face images are taken in uncontrolled environments (FR in the wild), where there are numerous variations that can affect facial images, including resolution, background, expression, pose, illumination and occlusions [6]. A critical issue viewed here is the feature's robustness retrieved from face appearance descriptors to tackle these problems. In recent years, a lot of attention was received by deep learning approaches to FR. A turning point was reached when neural networks for facial Feature Extraction (FE) were introduced [7].

Numerous prominent techniques for FE have been developed up to this point, like Scale Invariant Feature Transform (SIFT), Histogram of Oriented Gradients (HOG), Local Binary Pattern (LBP) etc. [8]. When these features are compared to the tested photographs, the person can be recognized or not. Unfortunately, as there are so many difficult and variable parameters in FD and identification as well as poor evaluation techniques, choosing the optimal facial recognition algorithm is a very difficult procedure [9]. Additionally, redundant features were engendered and struggled to handle high dimensions [10].

A. Problem Definition

Numerous approaches to resolving the FRS issue can be found in prevailing research procedures. Still, there is space for improvement. The following list includes the issues with the prevailing approaches:

- The prevailing approach focuses solely on brightening the images with the issue of locating a face in a hazy image. Thus, it has an impact on the recognition rate.

- Another difficulty for the FR system is the ageing process, which reflects the modifications in the face appearance / texture over a time.
- All the issues like age, expression, illumination, position and occlusion invariants were not addressed by most prevailing works. High recognition performance was attained by the prevailing presented pose invariant FR. However, when age, light, resolution and occlusion were all constant, it was unable to identify faces.

B. Limitations of Existing Works

Mohd Najib Mohd Salleh, Noureen Talpur and Kashif Hussain [27] exhibited Adaptive Neuro-Fuzzy Inference System (ANFIS) is an efficient estimation model not only among neuro-fuzzy systems but also various other machine learning techniques. ANFIS suffers from limitations that halt applications in problems with large inputs; such as, curse of dimensionality and computational expense. Different limitations such as curse of dimensionality, interpretability of rules, and parameter training are the major hurdles that need to be overcome for the implementation in problems with larger number of inputs. This is the reason, ANFIS is often integrated with additional techniques for input selection, rule reduction and parameter tuning, which again increases the complexity of the designed model. Various structural and parameters optimization techniques have been proposed in literature; however, there is enough room of improvement in ANFIS architecture so that applications in larger problems can be achieved easily.

A novel method of FR was proposed in this paper to tackle all the above-mentioned issues. The paper is framed as: the associated work regarding the proposed FR is analyzed in Section II. The concise discussion about FR is displayed in Section III. The proposed system's performance is analyzed in Section IV. The paper is concluded in Section V.

II. LITERATURE SURVEY

Shokoufeh Mousavi et al.[11] presented a Distinctive Landmark - centered FR (DLFR) system to diminish the issues. Grounded on the number of key points acquired as of a modified SIFT together with the most idiosyncratic face's landmark region, novel features were generated. The weights for the features were optimized by a slightly altered genetic algorithm. A Support Vector Machine (SVM) classifier was utilized to classify the weighted features. The experiential outcomes exhibited higher efficacy than the prevailing papers. However, for SVM, a large number of data was not appropriate.

Xue Lv et al. [12] introduced a deep learning algorithm for the application of an FR model. For the face image's stimulation transformation along with crop pre-processing, an Optimized Multi-task Cascaded Convolutional Network (OMTCNN) algorithm was utilized. To diminish the FR's computational complexity in the embedded system, a lightweight FR algorithm grounded on Convolutional Neural Network (CNN) was developed, which was denoted as Lightweight CNN (LCNN). Finally, to build the multi-core embedded FRS, OMTCNN and LCNN were combined. The outcomes demonstrated that better performance was exhibited

by OMTCNN in determining face identity. However, owing to the utilization of diverse datasets for training and testing, the developed system's accuracy was missed slightly.

Fanny Spagnolo et al. [13] developed a hardware architecture grounded on a real-time cascade classifier along with a resource-limited model to perform object detection. To accomplish the FD task along with integrating with an entire heterogeneous embedded system, architecture was tailored grounded on a Xilinx Zynq-7000 FPGA-centered System-on-Chip. The experiential outcomes exhibit that a high frame rate was significantly attained by the accelerator than other benchmark competitors however occupied much fewer resources.

Serign Modou Bah and Fang Ming [14] suggested a model tackling a few issues hampering FR accuracy to elevate the LBP codes by merging the LBP with augmented image processing schemes like Contrast Adjustment, Bilateral Filter, Histogram Equalization (HE), Image Blending and so on. Thereby, the overall FRS accuracy was elevated. The experiential outcomes exhibit that it was an accurate, reliable and robust model for FRS. Long histograms were engendered by this LBP that result in retarding the developed system's recognition speed.

Rameswari et al.[15] developed an automated access control system utilizing FR. The HOG was utilized to retrieve the features. The output was engendered by analogizing the face function that contained a classifier named SVM to classify the face encoding. To make the system more effective, Radio Frequency Identification (RFID) sensor together with an Infra Red (IR) sensor was implemented. The authority to the campus management was offered by engendering a webpage. The prevailing models were outperformed by the experiential outcomes. But, the HOG computation speed was tardy.

Bouchra Nassih et al. [16] demonstrated an efficient 3D FR approach named GD-FM+RF grounded on Riemannian geometry's Geodesic Distance (GD) along with Random Forest (RF). The GD between the points of 3D faces' specified pairs' was computed by employing the Fast Marching (FM) algorithm. To analyze the class separability, the Principal Component Analysis (PCA) algorithm utilized the retrieved features offered by the geodesic facial curves. Later, the input to the RF classifier was these features. Finally, the recognition rate was elevated along with attained most promising outcomes analogized to the benchmark models. However, while utilizing PCA, the information might be lost.

Yassin Kortli et al. [17] exhibited an implementation grounded on the Advanced RISC Machines Cortex-A9 processor utilizing the OpenCV library. Grounded on a hybrid ARM-Field Programmable Gate Array (ARM-FPGA) platform, a co-design was developed. Here, the FPGA processed the traditional hardware Visible Light communication (VLC) architecture. Optimized hardware VLC architecture was engendered to respect the real-time constraints. It was processed subsequently to comprehend the second Hardware / Software (Hw/Sw) co-design. The experiential outcome exhibited that a high speed was provided by the optimized hardware VLC architecture when analogized

to the conventional non-optimized framework. The developed system's architecture was more complex.

Masoud Muhammed Hassan et al. [18] exhibited an FR approach grounded on the fusion of Gabor-centered FE, Fast Independent Component Analysis (FastICA) and Linear Discriminant Analysis (LDA). To make the uniform face images, it was converted to grayscale and resized. Later, the Gabor, FastICA and LDA methods were utilized to retrieve the facial features as of the aligned face. To recognize the individual's identity, the nearest distance classifier was utilized. Thus the developed model's efficacy was illustrated by the outcomes, especially under the Cosine distance measure. However, more time consumption along with the high computational cost was the model's major drawback owing to the utilization of '3' sophisticated FE schemes.

Lizzie D'cruz and J. Harirajkumar [19] suggested one-shot learning on the Siamese CNN (SCNN) for FR. Here, the employee attendance was entered in the My Structured Query Language (MySQL) database. For uploading the database, Apache Physiology together with Chronic Health Evaluation (APACHE) Web Server was the application programmable interface employed. Utilizing Send Mail Transfer Protocol (SMTP), get well soon messages were sent to absent employees via Gmail. Better performance was observed by the system with accurate FR along with testing '12' images successfully. However, more memory was requisite by the system to collect the data.

Hao Yang and Xiaofeng Han [20] designed an FR attendance system grounded on real-time video processing. A control group together with an experiential group was comprised in this experiment. Traditional fingerprint check-in was utilized by the control group and real-time video processing was utilized in the experiential group. Two universities were chosen as of a province and a similar number of students were chosen for the experiment, which was then collected, counted and analyzed in the experiment, application space. This may develop FR's prospects along with final issues in the actual check-in. The video FRs' effective performance was exhibited by the experiential data. Owing to the extraction of redundant features, the system was still challenging to offer accurate recognition.

Chaoyou Fu et al. [21] developed integrated large-scale visible data's huge identity information into the joint distribution. Additionally, to ensure their identity consistency, a pairwise identity-conserving loss was imposed on the engendered paired heterogeneous images. As of the noises, immense new distinct paired heterogeneous images with a similar identity could be engendered. To train the HFR network, identity consistency along with identity diversity properties permitted the engendered images via a contrastive learning mechanism. Thereby it yielded both domain-invariant as well as discriminative embedding features. The positive pairs and negative pairs regarded here were the engendered paired heterogeneous images and the images acquired as of diverse samplings. On '7' challenging databases that belong to five Heterogeneous FR (HFR) tasks, encompassing Sketch-Photo, Profile-Frontal Photo, Thermal-Visible and ID-Came,

superior performance was attained by the model. Nevertheless, it was more expensive.

Alireza Sepas-Moghaddam et al. [22] presented a CNN grounded a deep Face Expression Recognition (FER) solution, named CapsField incorporated with an extra capsule network that employed dynamic routing to study hierarchical associations between capsules. The spatial features as of the facial images were extracted by CapsField, which learned the angular part-whole relations for a chosen set of 2D sub-aperture images offered from each Light Field (LF) image. Owing to its capacity in learning inter-view along with intra-view relations available in an LF image, the outcomes exhibited that when analogized with benchmark LF-centered FER, a superior performance. However, the system was susceptible to over fitting.

Weipeng Hu et al. [23] introduced an algorithm to explore the cross-modal image's potential domain-invariant Neutral Face (NF) representations by utilizing Dual Face Alignment Learning (DFAL). Feature-level Face Alignment (FFA), Image-level Face Alignment (IFA), as well as Cross-domain compact Representation (CdR) were the '3' effective components included in the model. To encode features for both VIS NF images as well as non- NF images, Teacher-Encoder CNNs (TeEn-CNNs) together with Student-Encoder CNNs (StEn-CNNs) were designed initially. By executing the feature level alignment between non- NF and VIS NF the FFA was brought in to learn NF representations. To restore face images, StDe-CNN was engendered to decode features secondarily. By imposing image-level alignment, an NF image was reconstructed by IFA's design. The DFAL approach's effectiveness on '3' challenging Near-Infra Red and VISual (NIR-VIS) databases was illustrated by the experimental outcomes. However, the position and orientation of input were not decoded by CNN.

Jae Young Choi and Bum Shik Lee [24] demonstrated a "Gabor Deep CNN (GDCNN) ensemble" method for FR applications. Distinct along with multiple Gabor face representations were effectively applied as inputs during the GDCNN's training and testing phases. GDCNN ensemble construction as well as GDCNN ensemble combination were the '2' parts comprised in the generated GDCNN ensemble. The experiential outcomes demonstrated that significantly a better FR performance was attained by the approach than the conventional approaches that were grounded only on grayscale or color face images as input illustration. However, more time was acquired by the system owing to the deep learning characteristics of Neural Networks (NN).

Hua Yang et al. [25] designed a Weighted Feature Histogram (WFH) method of Multi-Scale Local Patches (MSLP) utilizing Multi-Bit Local Binary Descriptors (MBLBDs) for FR. Using an MSLP Generation (MSLPG) method, the local patches were extracted to attain multi-scale information. To extract MBLBDs, the MBLBD learning (MBLBDL) method was engendered to diminish the binary descriptors' quantization information loss. To project Pixel Difference Vectors (PDVs) into the MBLBDs in each local patch, a learning mapping matrix along with multi-bit coding rules were engaged in MBLBDL. To discover a set of robust

weights for each patch, the Robust Weight Learning (RWL) method was employed to incorporate the MBLBDs into the final face representation. The outcomes as of experiments performed on face datasets exhibited that benchmark recognition performance was attained by WFH and a Coupled WFH (C-WFH).

Harish Sharma, Garima Hazrati, Jagdish Chand Bansal [28], Spider monkey optimization (SMO) algorithm is a recent addition to the list of swarm intelligence based optimization algorithms. The update equations are based on Euclidean distances among potential solutions. The algorithm has extensively been applied to solve complex optimization problems. SMO is applied to solve optimal capacitor placement and sizing problem in IEEE-14, 30 and 33 test bus systems with the proper allocation of 3 and 5-capacitors. SMO is used for the synthesis of sparse linear arrays. The amplitudes of all the elements and the locations of elements in the extended sparse subarray are optimized by the SMO algorithm to reduce the side lobe levels of the whole array under a set of practical constraints. The SMO has also been used to synthesize the array factor of a linear antenna array and to optimally design an E-shaped patch antenna for wireless applications. SMO is a meta-heuristic technique inspired by the intelligent foraging behavior of spider monkeys. The foraging behavior of spider monkeys is based on the fission-fusion social structure.

Features of this algorithm depend on social organization of a group where a female leader takes decision whether to split or combine. The leader of the entire group is named here as the global leader while the leaders of the small groups are named as local leaders. With reference to the SMO algorithm, the phenomenon of food scarcity is defined by no improvement in the solution. Since SMO is a swarm intelligence based algorithm, each small group should have a minimum number of monkeys. Therefore, at any time if a further fission creating at least one group with less than the minimum number of monkeys, we define it as the time for fusion. In SMO algorithm, a Spider Monkey (SM) represents a potential solution. SMO consists of six phases: Local Leader phase, Global Leader phase, Local Leader Learning Phase, Global Leader Learning phase, Local Leader Decision phase and Global Leader Decision phase.

III. PROPOSED FACIAL RECOGNITION SYSTEM

For the efficient recognition of the human face, a novel FIS-CDNN Classifier is proposed in this paper. The face is detected initially in this system together with extracting the features and landmarks. Subsequently, the features are chosen. Finally, the face is classified utilizing the FIS-CDNN classifier. Fig. 1 illustrates the proposed model's block diagram.

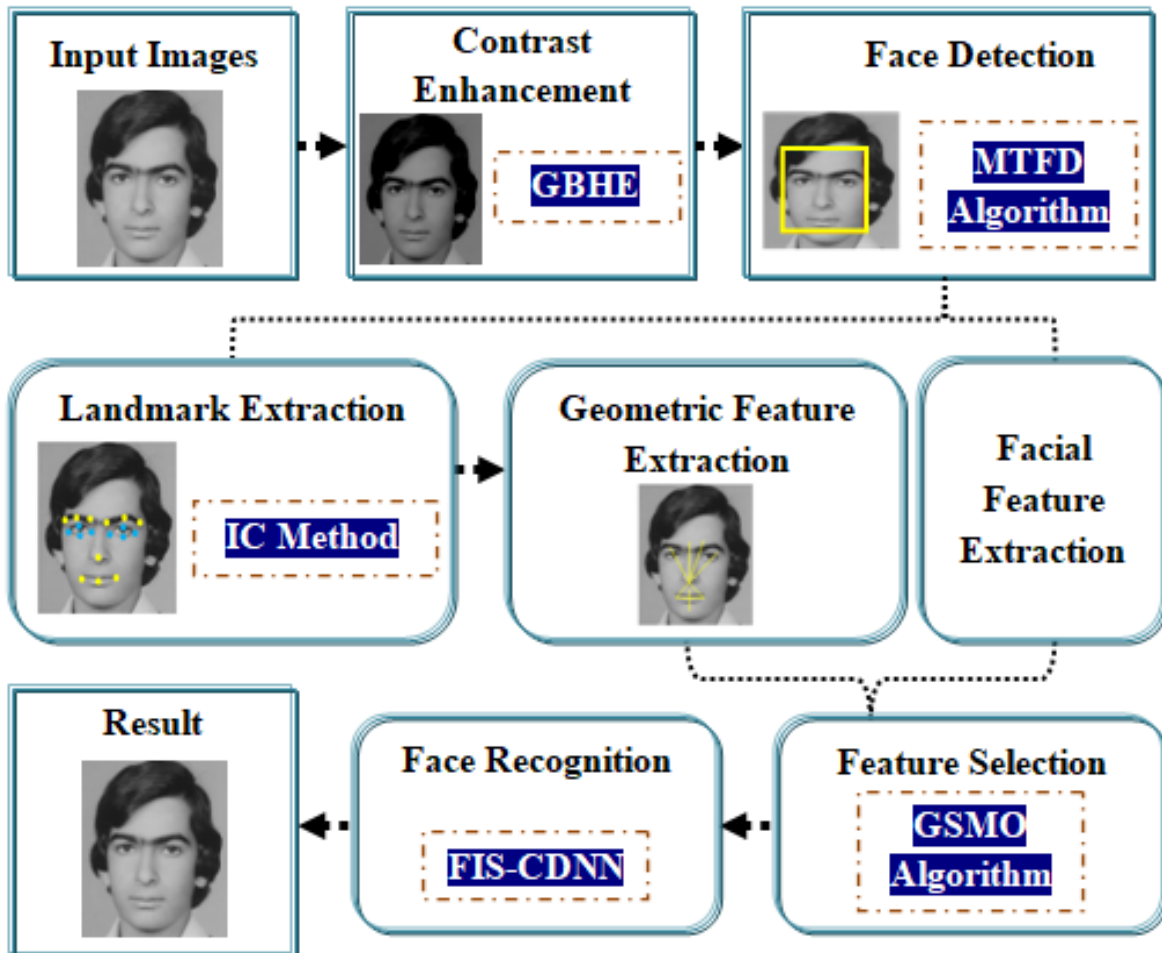

Fig. 1. Block diagram of the proposed methodology

A. Contrast Enhancement

Since the image's quality is low, the face Image (I) is taken as an input and pre-processed in the FRS. By the contrast enhancement technique of Gamma correction-centered Based Histogram Equalization (GBHE), the lower quality is elevated. To augment contrast, HE is a methodology for fine-tuning image intensities. The comparative frequency of various gray levels occurring in the image was represented by the histogram of an image. However, the histogram may bear the intensity saturation issue during the contrast enhancement. So, to control the intensity value, Gamma correction was utilized in this methodology to solve the intensity saturation issue.

A nonlinear operation utilized to encode and decode luminance in the image is Gamma, which is expressed as:

$$G_I = ZI^\xi \quad (1)$$

Where, the positive constants are illustrated as Z and I , the gamma correction's output is denoted as G_I , and the gamma value is represented as ξ . Here, the input image's pixel is mapped into the associated pixel of a prepared output image. It is defined as Histogram, which can be expressed as:

$$I_{pre} = \frac{P_{i(G_I)}^{no.oc}}{n(P)} \quad (2)$$

Where, the number of occurrences of a particular pixel with intensity in G_I is denoted as $P_{i(G_I)}^{no.oc}$, the pre-processed image is notated as I_{pre} , the number of pixels is symbolized as $n(P)$ and the image's range of gray level is $[0, L-1]$.

B. Face Detection

The most prominent step in the proposed methodology is face detection. Utilizing the MTFD, the face is extracted by eliminating the unwanted parts from I_{pre} . The Tiny Face Detector is utilized to perform facial extraction on images by implementing the ResNet101 algorithm. In the scale-invariant stage, cosine similarity is utilized rather than Euclidean distance. If '2' similar documents are far distant by the Euclidean distance (owing to the document's size), there may be still a probability of oriented each other as the cosine similarity is having benefits. This is the advantage of cosine similarity.

The input image is shifted into ResNet101 initially. For detecting the face utilizing a pre-trained Artificial Neural Network (ANN), the features are extracted along with amassed in numpy arrays. It expressed the extracted face features as:

$$Q_n = \{Q_1, Q_2, Q_3, \dots, Q_N\} \quad (3)$$

Where, the number of extracted features is represented as Q_n . By image scale and resolution, the facial extraction

process is affected. Between the input image and extracted feature, the similarity score A is computed as:

$$A = \frac{Q_n * I_{pre}}{\|Q_n\| \|I_{pre}\|} \quad (4)$$

The extracted features for FD are valid if the score is identical for extracted features and the input image. The face is not detected otherwise. F denotes the detected face.

C. Feature Extraction

The informative data regarding the face is obtained with the aid of FE. The key features like SIFT, HOGs, Speeded-Up Robust Features (SURF), Binary Robust Independent Elementary Features (BRIEF), LBP, Gabor Feature, Shape, and edge are retrieved as of the face detected region F . The extracted features E_n are expressed as:

$$E_n = \{E_1, E_2, E_3, \dots, E_N\} \quad (5)$$

1) *SURF*: It is a fast along with robust algorithm comprising of '4' main parts that are Integral image generation, Fast-Hessian detector, Descriptor orientation assignment and Descriptor generation. By utilizing the integral image for extracting interest points, it is centered on a Hessian-matrix approximation. By applying an approximate Gaussian and derivative scale-space representation, it operates under the entry of integral images. E_1 implies the SURF and the integral image F_Σ can be signified as:

$$F_\Sigma = \sum_{x=0}^{x \leq p} \sum_{y=0}^{y \leq q} F(x, y) \quad (6)$$

Where, the input image after integral image representation is modeled as $F(x, y)$. For smoothening and space scale representation, a Gaussian filter is also applied. In the pyramid, the scale representation is implemented. For the extraction of the interesting point E_1 , the box filter's size doubled the sampling intervals owing to the usage.

2) *SIFT*: Robustness to illumination, scale and transformation was shown by SIFT. Grounded on specific steps like extremes of scale space detection, determining the feature point's position, feature points direction along with engendering feature descriptors, the features are extracted. To smooth the images, diverse scales of the Gaussian function were utilized by SIFT algorithm. Stable features are chosen along with regarded as a candidate as of the smoothened image. Further, by utilizing the Harris operator, the corner points around the candidate are computed as:

$$E_2 = g(F, S_1, S_2) * F(x, y) \quad (7)$$

Where, the output extracted features are noted as E_2 , the Gaussian function is given as $g(F, S_1, S_2)$, the Integral

Length Scale (ILS) is demonstrated as S_1 , the scale for the corner point is denoted as S_2 , the input image with pixel coordinates are symbolized as $F(x, y)$. If the threshold is lower than the corner points, the corner points are outstanding to represent the object.

3) *LBP*: A model of retrieving textual features F as of the face detected image F is the LBP, which is a non-parametric operator describing an image's local spatial structure in binary information. Classification, detection and reorganization are the three steps performed by this. The face image's centre pixel is observed as a threshold value along with analogized with the neighbouring pixels. It is denoted as '1' if the neighbouring pixel's value is superior to the threshold value. Otherwise, it is mentioned as 0. An 8-bit value was obtained by merging all these outcomes. Then, the local texture feature's (E_3) LBP value was obtained as:

$$E_3 = \sum_{i=0}^{u-1} T(P_{(i) \in F} - P_{(c) \in F}) 2^i \quad (8)$$

$$T(P_{(i) \in F} - P_{(c) \in F}) = \begin{cases} 1 & P_{(i) \in F} \geq P_{(c) \in F} \\ 0 & P_{(i) \in F} < P_{(c) \in F} \end{cases} \quad (9)$$

Where, the central pixel value is represented as E_3 , the neighboring pixel value is proffered as $P_{(i) \in F}$, the threshold function is modeled as T , the number of pixels in the neighbor of $P_{(c) \in F}$ is notated as u and the centre pixel is signified as $P_{(c) \in F}$.

4) *HOG*: The gradient structure features E_4 is captured by utilizing HOG. Descriptor blocks, block normalization, Orientation binning as well as Gradient computation are the '4' steps involved here. For each pixel, the face image's gradient is computed. The pixel value's magnitude and direction in each block are computed utilizing the gradient. As the image's few parts might show a slight vanish, block normalization is implemented to oversight the image's brightness. Normalization is employed in specific parts to diminish that. The mathematical representation is exhibited as:

$$E_4 = \frac{v}{\|v\|^2 + \sigma} \quad (10)$$

Where, the constant value to avert deviation is σ , the non-normalized vector is signified as V . Conclusively as of the normalization operation, the HOG features are derived along with obtaining the features E_4 .

5) *BRIEF*: A general-purpose feature point descriptor amalgamated with arbitrary detectors is named BRIEF, which can be notated as E_5 . Detection, descriptor and descriptor matching were '3'

steps incorporated. By smoothing the image utilizing a Gaussian filter, the BRIEF commenced averting the descriptor from being sensitive to high frequency. Then, the random pair of pixels was chosen by the BRIEF around the targeted region. Comparisons may occur between utilizing these pixels. The value of 1 is assigned to the corresponding bit if the initial pixel is found to be brighter compared to the second pixel. Or else it is found 0.

$$E_5 = \begin{cases} 1 & F(a) \leq F(b) \\ 0 & F(a) \geq F(a) \end{cases} \quad (11)$$

Where, the two selected points are notated as a and b .

6) *Shape*: The face image's geometric properties were referred to by the shape feature that is utilized to describe the image content. Grounded on the shape boundary information or boundary plus interior elements where the area, parameter and circularity are deemed as key features, the shape features are extracted. It could be computed as:

$$E_6 = \sum_{x,y} F(x', y') \quad (12)$$

Where, the output of the face's shape feature is represented as E_7 , the input face image with the extreme pixels is notated as $F(x', y')$.

7) *Edge*: The input image's edges E_7 is identified by the Canny algorithm. By utilizing noise removal, differentiation, non-maxima suppression, double thresholding and edge tracking. The edge features are acquired as of the image. These images are smoothed initially and gradients ensure the image's edges are taken. By computing the magnitude together with gradients of directions, the points which are not at the maximal are suppressed in the non-maxima suppression. By employing thresholds namely upper threshold and lower threshold in double thresholding, the strong along with weak edges are identified. The edge tracking is aided in determining the final edges. '2' thresholds namely the upper threshold (h_{high}) and lower threshold (L_{low}) are taken in the tracking. The edges E_8 are classified as strong edge (S_{edge}), weak edge (W_{edge}) and non-edge (U_{edge}) along with deciding the concerning gradients under three conditions that are:

$$E_7 = \begin{cases} S_{edge} & \text{if } F(t, v) > L_{low} \\ W_{edge} & \text{if } L_{low} < F(t, v) < h_{high} \\ U_{edge} & \text{if } L_{low} > F(t, v) \end{cases} \quad (13)$$

Where, the gradient in the gradient direction is proffered as $F(t, v)$.

D. Landmark Extraction

Utilizing the Improved Chehra (IC) landmark Extraction method, the face's landmark is extracted as of F . By training a cascade of regressors, this discriminative facial deformable model was obtained. For extracting the Face appearance, the Chehra method utilized PCA in normal. A drawback here is the original features turn into Principal Components (PC) after implementing PCA on the dataset. The linear combination of original features is the PC. As original features, PCs are not readable and interpretable; also it took more time for executing multiclass datasets. So, LDA is employed in the Face appearance stage rather than this.

For facial region extraction, 49 facial landmark points were computed by the Chehra model on the whole facial image. The face image's 10 regions computed following the landmark detection are the forehead region, right eye region, right face region, lower nose region, left eye region, entire eye region, lip region, left face region and upper nose region. For facial appearance, FE has been executed by utilizing LDA after obtaining the blocks.

LDA is a feature diminution technique grounded on supervised linear transformation. It does so in a way that elevates the ratio between the intra-class scatter $\mathcal{S}_{int ra}$ and the inter-class scatter $\mathcal{S}_{int er}$ when projecting a high-dimensional feature vector onto a low-dimensional space. For multiclass l , the scatters are determined as follows:

$$\mathcal{S}_{int ra} \in F = \sum_{i=1}^l \sum_{\Omega \in F} (X_{\Omega} - \mu_i)(X_{\Omega} - \mu_i)^T \quad (14)$$

$$\mathcal{S}_{int er} \in F = \sum_{i=1}^l (\mu_i - \mu)(\mu_i - \mu)^T \quad (15)$$

Where, the average landmark point in i^{th} class is represented as μ_i , the Ω^{th} instance in i^{th} class is indicated as X_{Ω} . The best projection is then computed along with maximizing the ratio between the projected samples' intra-class scatter matrix and inter-class scatter matrix. It is defined as:

$$X^{best} = \arg \max(X) \frac{|X^T \mathcal{S}_{int er} X|}{|X^T \mathcal{S}_{int ra} X|} \quad (16)$$

Where, the best projection point is denoted as X^{best} , the sample point is denoted as X . For further process, the projects are taken as landmark features.

E. Geometric Feature

The face's GF is extracted as of the X^{best} in this phase. The utilization of the distance between the facial landmark points as features is allowed owing to the facial geometry's invariance to the illumination. Hence, the feature utilized here

is the distance between landmarks. The GFs like height, width, length of chin, eyebrows, nose, mouth etc. are extracted. The extracted GF is expressed as:

$$G_n \in X^{best} = \{G_1, G_2, G_3, \dots, G_N\} \quad (17)$$

Where, the number of extracted GFs is signified as G_n . The extracted facial together with GFs is amalgamated and the output can be expressed as:

$$\lambda_n = G_n \cup E_n \quad (18)$$

Where, the combined features are represented as λ .

F. Feature Selection

For elevating the proposed facial detection system's learning accuracy, the features are chosen as of λ_n utilizing the GSMO Algorithm after FE. A meta-heuristic method named SMO is motivated by the clever foraging behavior of spider monkeys. The Fission-Fusion Social Structure (FFSS) serves as the base for the foraging habits of spider monkeys. The group's social organization is in such a way that the female leader makes a decision on whether to split or combine the group. In cases of food scarcity, a female creates mutable smaller groups as well as typically serves as the swarm's Global Leader (GL). Availability of food as of a specific territory is the factor upon which the group sizes rely. A direct proportionality is identified between the size and food availability. The GL deemed here is the entire group's leader and the smaller group's heads are named the Local Leaders (LLs). The variation between the current position and positions engendered at random is averaged out to update the leader position. For a specific issue, a random position is engendered within a predetermined range. As a result, the research proposed the alteration to quicken convergence and boost reliability. The updating stage uses the Gaussian Mutation Technique rather than the Convergence rate.

The number of monkeys deemed here were the extracted features. With the uniform distribution, each Spider Monkey (SM) is initialized as:

$$E_i \in \lambda_n = E_{\min(j)} + \Omega(0,1) \times (E_{\max(j)} - E_{\min(j)}) \quad (19)$$

Where, E_i represents i^{th} SM, the lower and upper limits in j^{th} dimension are indicated as $E_{\min(j)}$ and $E_{\max(j)}$, the random number distributed uniformly in the range of $[0,1]$ is signified as Ω .

The following '6' steps are followed by an algorithm for foraging after initialization. The steps are explained as follows,

a) *Local leader phase (LLP)*: Utilizing the past behaviours of both the LL and the local group members, the SM in LLP shifts its present location. Only when the new location's fitness value is greater than the prior site, the SM's location is updated with the new location. Using the Gaussian

mutation technique E_{ij}^* , the i^{th} SM of the d^{th} local group's location update equation is:

$$E_{ij}^* = E_{ij} + \Omega(G) \quad (20)$$

Where, the j^{th} dimension of i^{th} SM is proffered as E_{ij} , the random Gaussian number is symbolized as $\Omega(G)$.

b) *Global leader phase (GLP)*: Similar to the LLP, but diversely, the swarm updates throughout this phase. Only one randomly chosen solution's dimension is updated here, unlike the LLP. Depending on its probability, which spider monkey will have a probability of being updated is identified.

$$E_{ij}^* = E_{ij} + \Omega(0,1) \times (\mathfrak{R}_j - E_{ij}) + \Omega(-1,1) \times (E_{R_j} - E_{ij}) \quad (21)$$

Where, the GL position in j^{th} dimension is notated as \mathfrak{R}_j . Grounded on the probability that is derived utilizing their fitness, which is computed centered on the classifier's accuracy, the SMs location is updated. The probability of i^{th} SM Φ is calculated as:

$$\Phi = \frac{9}{10} \times \frac{f_i}{f^{\max}} + \frac{1}{10} \quad (22)$$

Where, the fitness of i^{th} SM is illustrated as f_i , the maximum fitness is depicted as f^{\max} . The SM's fitness for the freshly engendered position is then analogized to the old position, and a better position is adopted.

c) *Global leader learning phase (GLLP)*: Here, an SM is updated as the swarm's GL whose position has the maximum fitness value of all the members. The global limit count is elevated by 1 if the position of GL is not updated, representing the number of iterations during which the GLs position was not updated.

d) *Local leader learning phase (LLLP)*: At this point, the group's greedy selection is utilized to update the LL's position. The LL's upgraded position is then coordinated with the previous one. The Local Limit Count (LLC) is then elevated by 1 if the LL position has not been updated.

e) *Local leader decision phase (LLDP)*: In this phase, either by random initialization or by means of collective information as of GLs experience utilizing the equation below, the position of every member in that group is updated if any LL does not become restructured to a specific verge known as LL Limit.

$$E_{ij}^* = E_{ij} + \Omega(0,1) \times (\mathfrak{R}_j - E_{ij}) + \Omega(-1,1) \times (E_{ij} - \mathfrak{S}_{dj}) \quad (23)$$

f) *Global leader decision phase (GLDP)*: LLD and GLD are equivalent. The GL splits the swarm into a lower maximum number of groups if it does not restructure to a specific boundary known as the GL limit. At that point, the LL was chosen by commencing the LL Learning procedure. Additionally, the GL will unite the entire group if the maximal numbers of groups are engendered but the GLs position is not updated. Until enough food is obtained to feed every SM, the procedure is unremitting. Several features are chosen in this method of opting for leaders, which are expressed as:

$$E_n^{sel} = \{E_1^{sel}, E_2^{sel}, E_3^{sel}, \dots, E_N^{sel}\} \quad (24)$$

Fig. 2. Architecture of proposed FIS-CDNN

Where, the number of selected features is denoted as E_n^{sel} . Likewise, utilizing a similar algorithm, the features G_n are chosen. Followed by, it is utilized for choosing features E_n along with obtaining the output G_n^{sel} .

G. Face Recognition

Here, for detecting the human's face, the chosen features E_n^{sel} are fed as input to the FIS-CDNN classifier. To process the image's Red, Green and Blue elements at the same time, a 3D NN was utilized by a Convolutional Deep Neural Network (CDNN). Compared to traditional feed-forward NN, the

number of artificial neurons requisite to process an image is diminished considerably. Normally, for the reason of weight value selection, the classifier suffers from the accuracy issue. The remainder layer comprising the previous training images behavior is deemed in this proposed methodology to solve this issue. The previous training weight values are amassed in the remaining layer. Therefore, the weight selection is very much aided by the remainder layer along with elevating the accuracy. Using the Fuzzy Interference system (FIS), the weight value is initialized in the proposed classifier. Fig. 2 exhibits the proposed system's architecture.

a) *Weight initialization:* By utilizing the five layers, the weights are initialized by the FIS system. The fuzzification process is executed by the first layer, which contains the adaptive nodes. The fuzzified output Ψ_i is:

$$\Psi_i = \nabla_1(\Omega_{\tau_k}) \quad (25)$$

$$\Psi_i = \nabla_2(\Omega_{\tau_j}) \quad (26)$$

Where, the input nodes are notated as ∇_1 and ∇_2 , the weight value acquired as of the previous iteration is symbolized as τ_k and τ_j , the membership function is represented as Ω , which indicates how much given nodes satisfy the quantifier.

The output signals acquired as of the preceding layers are multiplied in the second layer along with the second layer's ϖ_i output is:

$$\varpi_i = \nabla_1(\Omega_{\tau_k}) * \nabla_2(\Omega_{\tau_j}) \quad (27)$$

For normalizing the second layer's output, normalization is executed in the third layer and is expressed as:

$$(\varpi_i)^* = \frac{\varpi_i}{\varpi_1 + \varpi_2} \quad \text{where, } i = 1, 2 \quad (28)$$

Where, the normalized features are specified as $(\varpi_i)^*$. The fuzzy rule's consequent part is executed by the fourth layer that contains the adaptive nodes. Node function has a form:

$$\left(\frac{-}{\varpi_i}\right)^* = (\varpi_i)^* (\varepsilon_i \nabla_1 + \mathcal{G}_i \nabla_2 + \ell_i) \quad (29)$$

Where, the linear adaptive parameters are symbolized as ε_i , \mathcal{G}_i and ℓ_i , defuzzification is proffered as $\left(\frac{-}{\varpi_i}\right)^*$.

Finally, the proposed system's total weight value W is computed in the final layer as:

$$W = \sum (\varpi_i)^* (\varepsilon_i \nabla_1 + \mathcal{G}_i \nabla_2 + \ell_i) \quad (30)$$

b) *Convolution layer:* A specialized sort of linear operation employed for FE is convolution. Here, a kernel is a small array of numbers applied across the input. At each tensor's location, an element-wise product between kernel's each element and the input array is computed. It is again summed to acquire the output value in the output array's corresponding position. By applying multiple kernels, this procedure is recurring to generate an arbitrary number of feature maps representing the input array's diverse characteristics. The given input data's convolution is mathematically expressed as:

$$c = \sum_d \sum_d (E_n^{sel}) (\alpha - d, \beta - d) * W(d, d) \quad (31)$$

Where, the convolution operation's output is signified as c , the weight value in the dimension size $d \times d$ is represented as $w(d, d)$, the input matrix's dimension size is α and β . Each convolution layer is specifically pursued by a non-linear Activation Function (AF) implemented element-wise to the preceding layer's output to permit the network to learn non-linear decision boundaries. ReLu is the activation function utilized in this work. The activation function is mathematically expressed as:

$$R = \max(0, c) \quad (32)$$

Where, the ReLu activation function's output is signified as R .

c) *Pooling layer:* By passing via the AF, the output is obtained, which is again passed to the pooling layer to aggregate the information along with diminishing the representation. The pooling operation's (Δ) result is:

$$\Delta = \frac{c - W}{S} + 1 \quad (33)$$

Where, the kernel's strides are notated as S .

d) *Fully connected layer (FCL):* The final convolution or pooling layer's output feature maps are transferred into a single-dimensional array of numbers, which means typically flattened. By a learnable weight, each input is allied to every output in this layer. The amount of output nodes contained in the final FCL is typically similar to the number of classes. Then, the flattened output is computed as:

$$\Gamma = \Delta - (W(d \times d) - 1) \quad (34)$$

Where, the FCLs output is indicated as Γ .

e) *Softmax layer:* To the softmax activation function, the FCL's output is fed directly into this layer. In the output layer, the activation function is utilized along with normalizing the output real values in the range of $[0, 1]$ as of the last FCL to target class probabilities. The softmax function Γ_{soft} is given as:

$$\Gamma_{soft} = \frac{e^{\Gamma_{\varphi}}}{\sum_{\varphi=1}^h \Gamma_{\varphi}} \quad (35)$$

Where, the FCL output at φ^{th} node is notated as Γ_{φ} , the total number of output nodes is represented as h . With higher accuracy, the faces are recognized by this process. The proposed FIS-CDNN's pseudo code is:

```

Input: selected features  $E_n^{sel}$ 
Output: Recognized face  $I$ 

Begin
Initialize parameters  $c, R, \Gamma$ , layer  $b$ 
Compute weight value
 $W = \sum (\varpi_i)^* (\varepsilon_i \nabla_1 + \vartheta_i \nabla_2 + \ell_i)$ 
For  $b = 1$  to  $n$ 
  while  $b = 1$  ( first round of convolution and pooling layer)
    Compute convolution operation  $c$ 
    Evaluate activation function
     $R = \max(0, c)$ 
    Compute pooling operation  $\Gamma$ 
  End while
End for
Flattening all the layers
Evaluate softmax activation function  $\Gamma_{soft}$ 
End begin
Return  $I$ 

```

IV. RESULTS AND DISCUSSION

The proposed facial recognition system's performance with FIS-CDNN is analyzed in this section. MATLAB (MATrix LABoratory) is the working platform in which the model is implemented. It is a 4th generation programming language with a multi-paradigm numerical computing environment. For rapid along with simple scientific computations and I/O, it is designed particularly.

A. Database Description

FG-NET, collected from a publically available source, is the dataset used in the proposed framework. The dataset for age assessment along with FR across ages is FG-NET. A total of 1,002 images obtained as of 82 people with an age ranging between 0 to 69 and an age gap of up to 45 years were composed in the dataset.

B. Performance Analysis of Classification Method

Grounded on a few quality measures along with prevailing models like Z- Normalization and Moore Penrose-based Deep CNN (ZMP-DCNN) [26], NN, CNN and Adaptive Neuro-Fuzzy Inference System (ANFIS), the proposed FIS-CDNN method's effectiveness is examined here.

TABLE I. A COMPARATIVE ANALYSIS OF THE PROPOSED MODEL AND EXISTING MODEL WITH RESPECT TO TP, TN, FP AND FN

Classifier	TP	TN	FP	FN
FIS-CDNN	1.853659	161.8537	0.146341	0.146341
ZMP-DCNN	1.52439	161.5244	0.47561	0.47561
CNN	1.487805	161.4878	0.512195	0.512195
NN	1.317073	161.3171	0.682927	0.682927
ANFIS	1.402439	161.4024	0.597561	0.597561

Table I summarises the performance analysis of the proposed FIS-CDNN and the prevailing models Regarding True Positive (TP), True Negative (TN), False Positive (FP) and False Negative (FN). The proposed model accurately recognized the face in the outcome named TP. The mismatched face is predicted by the proposed model in the outcome TN. Hence, the proposed model's TP is 1.853659, which is higher than the prevailing techniques. Similarly, 161.8537 is the proposed FIS-CDNN's TN. The face is recognized incorrectly by the model in an outcome named FP. Here, the proposed model's FP and FN are similar at 0.146341. The face is classified more effectively by the proposed model than the prevailing models, which is obtained as of the entire analysis.

Fig. 3. The performance of FIS-CDNN with the existing methods

The proposed FIS-CDNN and prevailing method's performance analysis are illustrated in Fig. 3, grounded on the Accuracy, Precision, Recall along with F-Measure which is defined as the amalgamation of precision as well as recall. The proposed system's higher performance was exhibited by the proposed method's higher value in every metric. The face was recognized by the proposed method with 99.82% Accuracy. It is higher than the prevailing methods and provided better performance. Likewise, 92.68% is the proposed FIS-CDNN's Precision and Recall value. An F-Measure of 16.47% higher than the existing ZMP-DCNN was exhibited by the proposed one.

Fig. 4. The performance of FIS-CDNN with the existing methods

The proposed FIS-CDNN and the prevailing method's performance analysis are depicted in Fig. 4, grounded on Sensitivity and Specificity. The degree of similarity between views of an object that evokes an exact recognition response as of a given subject is Specificity. The capability to classify a test between the True and False positive performance correctly is named Sensitivity. While the ZMP-DCNN attains 99.7%, and CNN attains 99.6%, the proposed model's Specificity is 99.9%, which is superior to the prevailing models. Correspondingly, a higher sensitivity of 18.29% was attained by the proposed scheme than the prevailing CNN.

Fig. 5. The performance of FIS-CDNN in terms of NPV and MCC

The proposed model's performance is demonstrated in Fig. 5, on the basis of Negative Predictive Value (NPV) together with Matthew's Correlation Coefficient (MCC). The proposed model's better performance is proved by higher NPV and MCC. 99.9% is the proposed model's NPV, which is superior to the ZMP-DCNN and all other prevailing models. Likewise, 92.59% is the proposed scheme's MCC.

TABLE II. THE PERFORMANCE OF FIS-CDNN IN TERMS OF FPR, FNR, FRR, FDR

Classifier	FPR	FNR	FRR	FDR
FIS-CDNN	0.000903	0.073171	0.073171	0.073171
ZMP-DCNN	0.002936	0.237805	0.237805	0.237805
CNN	0.003162	0.256098	0.256098	0.256098
NN	0.004216	0.341463	0.341463	0.341463
ANFIS	0.003689	0.29878	0.29878	0.29878

Table II summarizes the proposed FIS-CDNN and the prevailing model's performance analysis, Concerning False Positive Rate (FPR), False Negative Rate (FNR), FRR and FDR. The proposed scheme's higher performance was exhibited by lower values of FPR, FNR and FRR. The proposed model's FPR is 0.002033 and 0.002259 lower than ZMP-DCNN and NN respectively. But, it is 0.002786 higher than ANFIS. Similarly, the proposed methodology's FNR, FRR and FDR are identical along with exhibiting an augmentation by 0.073171. This exposed that it is lower than the prevailing CNN along with other prevailing models. So, it is concluded from the metrics that better performance was exhibited by the proposed model for facial recognition.

Fig. 6. ROC curve of proposed FIS-CDNN and existing model

Fig. 6 exhibits the FIS-CDNN and the existing model's ROC curve analysis. The facial recognition's performance or quality was evaluated by an effective model named ROC. The True Positive Rate (TPR) is plotted against the False Positive Rate (FPR) to engender a ROC curve. The ROC curve illustrates that higher sensitivity together with specificity than the prevailing models like ZMP-DCNN, CNN, NN and ANFIS was exhibited by the proposed model.

V. CONCLUSION

A novel FIS-CDNN classifier was proposed in this work for facial recognition. Pre-processing, FD, facial FE, face landmark, geometric FE, feature selection and classification are all processes involved in the proposed technique. The experimental analysis is performed after all the steps have been completed, and regarding some quality criteria, the proposed

FIS-CDNN's performance is analogized with that of the prevailing approaches. The final outcomes exposed that a 99.82% accuracy rate was attained by the proposed model. Similar outcomes are obtained for all other metrics, including sensitivity, specificity, recall, precision, recall, recall, f-measure, NPV, MCC, FDR, FPR, FNR and FRR by the proposed scheme. The proposed model is therefore found to be significantly more effective than the prevailing approaches for classifying faces grounded on the findings of all metrics. This work will be extended in the future by extracting features as of various head poses employing utilizing advanced models.

Abstract—This paper proposes an Intrusion Detection System (IDS) against Sinkhole attacks in Mobile Adhoc Networks (MANET) with mobile sinks. A sinkhole attack is where a hacked node advertises a false routing update to draw network traffic. One effect of a sinkhole attack is that it may be used to launch further attacks, such as drops or changed routing information. Sinkhole nodes attempt to forge the source–destination routes to attract the surrounding network traffic. For this purpose, they modify routing control packets to publish fake routing information that makes sinkhole nodes appear as the best path to some destinations. Several machine learning techniques, including Decision Tree (DT), K-Nearest Neighbor (KNN), Convolution neural network (CNN), and Support Vector Machine (SVM), are used to do the categorization. Furthermore, the MANET's node's characteristics, particularly speed, are used for feature extraction. Totally 3997 unique samples, including 256 malicious samples and 3604 normal samples are collected. The categorization results demonstrate the accuracy of DT, KNN, CNN, and SVM at 98.4%, 96.7%, 98.6%, and 97.8%, respectively. The CNN approach is more accurate than other methods, at 98.6%, based on the data. After that, Priority, SVM, KNN, and CNN, in that order, each denotes excellent accuracy.

Keywords—Sinkhole; machine learning; MANET; intrusion detection

I. INTRODUCTION

A collection of autonomously placed, wirelessly linked nodes makes up a MANET (Mobile Adhoc Network). Each MANET node acts as a router to send the packet from the source node to the destination node. Massive and frequently used networks are remote ad hoc networks. MANET has no centralized management node; each moveable node is autonomous. The moveable system is allowed to go anywhere they are needed.

It allows the nodes to rapidly enter or go away the network [1]. Nodes are not limited in their ability to communicate with one another. Data loss may occur if the association is created. MANET is often utilized in various industries, including scientific, military, search and rescue, etc. Due to increased network connectivity, cyber-attacks are also rising [2]. Ad-hoc WMN (Wireless Mobile Network) is vulnerable to several attacks because of sharing of the channel, an unstable operating location, constrained mobility of resources, frequently changing device topology, and source limitations

[3]. The detection of anomalies accepts interference from routine system operations. Due to the intermittent nature of system activity, counting standard system output is difficult [4]. The abnormal process detects recent assaults or unexplained with a high rate of false positives. As an attack detection technique, sign-based IDS is defined by looking for distinctive features in network data, such as a sequence of bytes [5]. It only acknowledges known attacks and misses brand-new assaults for which there is no trend. Safe connectivity in MANET is a difficult problem because of the absence of established infrastructure and complicated topology, among other factors. The idea of intrusion detection keeps the balance by using access control and cryptographic techniques. As an automated detection and source of warning, it is presented to stop an attack that has already occurred or is currently ongoing. IDS only find intrusion that sets off an alert since they are passive and do not take any preventive measures [6].

Marti *et al.*, used Watchdog approaches to reduce routing errors and sinkhole nodes in MANET. The scheme was created by the authors using the DSR protocol. The node delivering the traffic watches promiscuously the transmission of the nearby node and route to detect any malicious conduct on the part of that node. The neighboring node will be regarded as acting inappropriately if it disrupts the data flow. The offending node won't be permitted to participate in the next transaction. The watchdog keeps a copy of recently delivered packets, examines each packet it has received and overhears them for similarities [7]. ML was one aspect of AI that was created in the late 1950s. It has grown and changed through time into algorithms that might be machine based and effective sufficient in engineering, medicine, and computer science to address various issues, including sorting, grouping, regression, and optimization. One of today's most popular technologies is machine learning. ML enables workstations to study without personal involvement and respond consequently dynamically. It automatically, appropriately, and efficiently manipulates complicated data to create a model. ML may profit from a generic framework to have a broad approach to enhancing device performance. It has several scientific uses, including data cleansing, noise reduction, picture identification, automatic spam detection, medical diagnostics, and manual data input [8],[9]. According to the most recent research, ML has been used in WSNs to solve several issues.

By incorporating ML into WSNs, complicated issues like reprogramming, manually navigating through enormous amounts of data, and valuable mining information from the facts are avoided. ML approaches are frequently useful in acquiring enormous amounts of data and providing useable data [10]. This thesis' main goal is to provide a strategy for identifying Sinkhole threats using machine learning techniques.

The lack of a reliable security solution that can shield MANETs from routing assaults is their major problem. The required design solutions are not anticipated to lead to resource limitations like battery life and bandwidth. MANETs' ability to "self-organize" can be both a strength and a weakness in terms of security because it leaves opportunities for both passive and active attacks. MANETs have many weaknesses, and some are brought on by their changeable architecture, constrained power source, bandwidth, and scalability.

Because of the weaknesses mentioned above, existing architectures adapted from wired broadband cannot be used directly for MANETs; as a result, a strong security framework must be designed and deployed exclusively on MANETs. Any future QoS-aware security system must work toward achieving availability, integrity, anonymity, identification, and secrecy as security objectives. Individually created security procedures must be used to produce a safe and QoS-aware network [4]. The issue with MANETs is that they are not widely known for providing combined answers to security or QoS-based issues due to their dynamic nature. This research focuses on sinkhole threats through protocol modification to obtain strong security detail without lowering the quality of service in real time.

II. LITERATURE REVIEW

Wireless networks are extremely susceptible to attacks, and hackers can access communication channels. In MANETs, Programme modules that automatically track harmful network activity might be used to keep an eye on attackers. When creating an intruder identification mechanism for MANETs, we must keep certain things in mind [11]. In [9], a geometric-based black hole and grey hole attack scheme detection is examined. According to [10], a secure data fragment is created to detect and prevent a hole in the ground and Sybil attacks on deployed fixed and dynamic nodes, producing high detection and low false-positive rates. Future directions versus DDoS assaults are provided in [11], along with concerns and taxonomy. [12] provides a summary of Sybil's protection methods utilized in online social webs. The intrusion detection systems for MANETs will operate independently of their wired counterparts. The creation of intruder detection systems for MANETs presents various challenges. Non-collaborative intruder monitoring systems use node-level agents to detect and record any unexpected activity [12]. The biggest obstacle is figuring out where the agents are while the nodes move.

Similarly, the nodes housing the intrusion-detecting agents need more processing power, bandwidth, and battery life. However, those services are constrained in MANETs [13]. Several authors have proposed methods to offer the most

suitable answers to an NP-complete problem that involves raising the intruder detection performance with the least amount of resources. There are several intrusion detection architectures available for MANETS [14]. A wide range of assaults is possible, some of which are more devastating in MANETs than in wired networks. The characteristics of these networks prevent the use of conventional methods for identifying attack traffic. Although intrusion detection systems (IDSs) use many different detection methods, anomaly detection is among the most crucial.

Additionally, IDSs based on past attack patterns are less effective if such IDSs are centralized. According to Peterson et al. [15], the detection engine was modified to include a modern Machine Learning approach that recognizes attack traffic live (not to be analyzed and assessed later)[15]. This allowed the IDS rules to be changed instantly. Amouri et al. provide a two-level monitoring approach for spotting rogue nodes in MANETs. The first stage involves the installation of specialized sniffers that operate in promiscuous mode.

Every sniffer uses a decision-tree-based classifier, which generates numbers we apply to every occurrence successfully classified throughout reporting time. The second stage involved sending the categorized instances to the super node that was run on algorithms. Each node being examined establishes the quantities connected to the cumulative fluctuation value of the acquired categorized instances. A workable IDS strategy for wireless sensor networks is the result approach, which has also been expanded [16]. Abd-El-Azim and colleagues proposed MANET's simplified fuzzy-based intrusion detection approach with an automated mechanism using an Adaptive Neuro-Fuzzy Inference System that produces a fuzzy system (ANFIS). The FIS was configured, and this initialization framework was optimized using a genetic algorithm (GA). In the presence of solely blackhole assaults, the network grew by an average of 36% [17]. Soni & Sudhakar recommended the Intrusion Detection Device for the Jamming attack. Depending on time example, the jamming attacker slowly introduced the network packets, quickly increasing their number. The IDS is identified as the attacking node through its unwanted flooding activities, and the attacker's malware is found. The proposed approach continually monitored all network activity, and the harmful node's behaviors were distinct from those of other nodes and did not act normally [18]. Sultana et al. examined the current IDS output when the supposed packet-dropping nodes in a MANET network were present. The reputed intermediate nodes, also known as intermediate bottleneck nodes, lose packets once the number of packets exceeds their handling limits. The effectiveness was calculated using the NS-2 network simulator. The results have demonstrated that the reputational packet-dropping nodes' IDS algorithms' neglect seriously affects network routine [19]. A strategy for cooperative sinkhole identification was put out by Kim et al. in [20].

The sinkhole assault is analyzed, and its characteristics are extracted. The algorithm for sinkhole identification was created to save time and money. When a mobile node receives a route request message with an originator ID matching the receiving mobile node's, it checks the message's sequence

number. The current node recognizes the presence of a sinkhole node. It determines that the route request message originated from the sinkhole node if the sequence number in the route request message is higher than the current sequence number of the mobile node. Therefore, it may be said that the sinkhole node is present in the route path of the request message. On routing protocols like, DSR and AODV, Gagandeep. G *et al.*, [21] concentrated on sinkhole attacks and suggested a Security-aware routing (SAR) method to lessen the effects of a sinkhole assault. SAR executes the message routing security and routing update security processes. Presented by Shafiei *et al.*, [22] is a distributed method of sinkhole attack detection. The MANET's nodes are regarded as reliable nodes. These dependable nodes serve as watchdogs nodes. Each monitoring node includes the local knowledge of the network. Furthermore, A base station is necessary for the detecting operation. Depending on the method of assault, MANET attacks can roughly be divided into two categories: passive attacks and active attacks. [28] [29]. An active assault involves disrupting information, modification, or manufacturing, which impairs the MANET's regular operations [34]. A passive attack exchanges data over the network without interfering with communication. The main taxonomy of MANET security exploits is shown in Table I. Passive assaults include eavesdropping, packet analysis, and traffic monitoring. According to the assaults' domain, the assaults can also be divided into external and internal attacks. Nodes are not a member of a network's domain launch external attacks.

III. PROPOSED WORK

In MANETS, both passive and active assaults are available. The attacker aims to disrupt the network by modifying, injecting, forging, inventing, manipulating, and discarding data packets during an active attack. These assaults qualify as serious assaults. Active assaults include packet dropping and denial of service (DOS) attacks [32]. It may be divided into two categories: internal attacks and external attacks. Compared to external attacks, internal attacks are harder to find. Assaults that are focused, such as malicious packet dropping, routing, sleep deprivation, black hole, gray hole, and rushing attacks. Sinkhole attacks are a novel type of assault that require special attention in MANET [33].

A. Sinkhole Attack

Attacks involving sinkholes are challenging to locate for the reasons listed below. When MANET's regular communication occurs, the sinking node makes numerous attempts to draw in the nearby nodes. With the AODV protocol, data packets are either changed or quietly dropped [23][30]. How the rogue node grows and its sequence number is a mystery. As was already mentioned, the AODV sequence number is utilized to indicate how recent a route is. The malicious node listens on the communication channel and keeps track of each node's sequence number. Following that, it assigns itself the highest sequence number among all nodes in the route and suddenly invades the channel, dropping packets [24][31]. For instance, have a look at Fig. 1. The source node is node 1, while the destination is node 5.

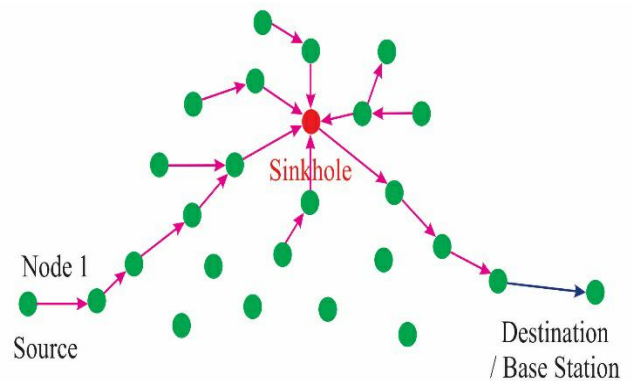

Fig. 1. Sinkhole attack.

B. Support Vector Machine (SVM)

SVM uses a hyperplane, a subset of supervised machine learning, to determine the best classification for each observation in a given data set. SVM is more effective with big datasets and can handle linear and non-linear problems [25]. SVM is incorporated into WSNs to handle various challenges, including congestion control, fault detection, routing, communication, and localization concerns.

Wireless Sensor Networks (WSNs) are susceptible to various software, hardware, and communication-related errors. Given the diversity of deployment scenarios and the limited sensor resources, fault detection in WSNs is difficult [35]. Additionally, the detection must be exact to prevent false alarms and quick to prevent loss. One of the easiest ways to find failure in WSNs appears to be to employ machine learning. Support vector machines (SVMs), a classification technique, are employed in this research to achieve this. SVM is used in our situation to define a decision function based on statistical learning theory [27]. This decision function can be used at cluster heads to find sensors because it is a low-resource procedure.

C. K-Nearest Neighbor (K-NN)

K-Nearest Neighbor is the most well-liked example-based method for regressing and classifying issues (k-NN). K-NN is primarily responsible for defining the distance between the sample being measured and the samples being provided. The many distances, including the Chebyshev distance function, Manhattan distance, Euclidean distance, and Hamming distance, are known in k-NN. The measurements are lowered due to the method's ability to identify the absent samples from the highlighted room. K-NN was first developed by using anomaly detection and data aggregation in WSN applications. An effective defensive mechanism for the WSN is provided by an intrusion detection system (IDS), a proactive network proper security solution. In this paper, we propose a carefully planned edge that needs to perform penetration testing when the WSN confronts a DoS attack [26]. To achieve this, we introduce the kNN in computer vision and the arithmetic optimization technique (AOA) in evolutionary computation. We employ a parallel method to improve the interaction between the population and the Lévy flying strategy to modify the optimization to increase the model's accuracy.

D. Deep Learning with Naïve Bayesian Learning

In WSNs, DL addresses various issues, including anomaly and defect finding, energy harvest, calculating data efficiency, and routing. Deep learning models' security applications, including spam filtering, IDS and malware detection have grown in significance in the design of information safety, categorization, and prediction activities. These numerous operations are designed to build a paradigm that typically distinguishes between "regular" and "malicious" samples, such as assaults and typical packets, based on intelligence. The exponential rise in Deep Learning Model usage compounds the complexity of attack plan tools. The mathematical learning method known as Bayesian learning looks for relationships between the datasets by learning separability using various statistical methodologies. Bayesian learning uses a variety of prior probability distributions and fresh information to assess 8 posterior likelihoods. The probability of $p()$ must be increased if $Y_1, Y_2, Y_3, \dots, Y_n$ represent a sequence of input and returns a mark. Numerous issues with WSNs have been handled using Bayesian learning techniques, such as routing, connection issues, fault prediction, data localization, and aggregation.

E. Convolution Neural Network and Decision Trees

The collections of if but then other rules are used by supervised learning machine learning algorithms, such as DT, to increase readability. DT anticipates a class or objective based on the judging criteria and creates a training model using training data. Decision trees provide various benefits,

including openness, reduced complexity, and thorough examination of decision-making. Different WSN issues, such as mobile devices, data aggregation, connection, etc., are solved using decision trees.

CNN's have been extensively utilized for deep learning (DL). Convolution layers and completely coupled layers make up this system. Sub-sampling layers may occur between these two levels. With multidimensional, locally correlated input data, they can acquire the greatest results from DNNs with properly scaled complexity. Therefore, the immediate use of CNN occurs in DB, where comparatively many nodes and attributes need to be learned.

The identification of harmful content may be done using our technique. This Sinkhole mitigation is established in a network of normal and malicious output stream monitoring nodes. We first explain the total of healthy nodes and cancerous nodes using their processes. This approach creates a tunnel between the communication or packet and the malicious nodes. These are only sent through the tube. (see Fig. 2).

At that point, receive a message that assists in data collecting and follows data out of each moving node. By defining the crucial function, the system's operation may be increased. At that point, eight key characteristics were chosen to create a dataset tagged with the backing of an exceptional hub address. Consequently, six common machine learning classifiers separate the legitimate and harmful data from research samples into two groups.

Fig. 2. Conceptual image for detection process.

IV. RESULTS AND DISCUSSION

The device's effectiveness is evaluated using various mathematical standards and contrasted with the new techniques. The developed standalone system for intrusion detection is tailored to work in the network and data link levels of the TCP/IP paradigm, both using the proposed routing mechanism. Because TCP requires ACKs from the destination, it employs two mechanisms to accomplish its task and is designed to work for UDP traffic. The watchdog examines every node that is close enough to a transmission. Before concluding that the node is acting maliciously, it compares the two variables (the threshold value and the counter). The watchdog algorithm calculates the downtime for the node's delay in forwarding the message if a packet is withheld and compares it to the threshold value.

A. Quality Measures

Metrics used for evaluation include Sensitivity, Accuracy, and precision mentioned in equations 1 to 3. These measurements are measured using four different parameters: true negative (TN), true positive (TP), false negative (FN), and false positive (FP). The percentage of properly categorized documents among all the data is called accuracy. Precision refers to the performance's pertinent proportion. On the other hand, recall is the proportion of correct classifications the algorithm makes for total functional outcomes. Detection Rate (DR), called True Positive Rate, is the proportion of anomalous records accurately recognized as anomalies to all anomaly records (TPR).

$$\text{Accuracy} = \frac{\text{TN} + \text{TP}}{\text{TN} + \text{FP} + \text{TP} + \text{FN}} \quad (1)$$

$$\text{Sensitivity} = \frac{\text{TP}}{\text{TP} + \text{FN}} \quad (2)$$

$$\text{Precision} = \frac{\text{TP}}{\text{FP} + \text{TP}} \quad (3)$$

B. Simulation Results

This work is modeled to detect sinkhole assaults in the Matlab 2019b set with limited nodes. The network protocol, Channel, Computer, and node are combined to create a network topology. In this simulation procedure, many network applications send and receive packets over a network. The simulation execution reaches the principal role and is carried through to the termination stage as packets are created, accepted, and processed. Fig. 3 depicts the nodes' initial positions and the nodes with which they make contact. 48 legitimate nodes and two malicious nodes made up the ad hoc network environment used for this experiment in Fig. 3, 11 sinkhole nodes, are shown as red circles. In contrast, the normal nodes are shown as black circles. Additionally, blue lines connecting the nodes represent the initial connection.

C. Results of Feature Extraction

One of the fundamental ideas in machine learning which directly affects performance is the choice of features. Functions unrelated or loosely connected might negatively affect the device's output. Only any data for a full node are included in the output file's full node information. The provided application is educational. When elements that are not important or provide less information

If characteristics that help with classification are left out, it might choose comparable features. There are several advantages of selecting features, including less over-fitting, shorter preparation times, improved precision, etc. It selected eight key components that enhance the functionality of the system. This includes a sum of distances, number of nodes, minimum speed, maximum speed, fastest direction, average speed, and distance to the destination. This proposed work collected 3604 samples which contain standard and wicked samples (normal 3348 and malicious 256). It creates data that is put together and given the eight selected qualities. The high-volume dataset was produced in an ad hoc network setting to identify sinkhole attacks.

Fig. 3. Position of initial MANET nodes.

D. Classification Results

Fig. 4 shows the classification outcomes using a variety of machine learning techniques, including Convolution Neural Network (CNN), Support Vector Machine (SVM), Decision Tree (DT), and K-Nearest Neighbor (KNN). The green arrays in Fig. 4’s confusion matrix represent genuine values, whereas the red components represent incorrect ones. The target class is often regarded as a positive class for binary assessment. Our primary goal in this article is to locate sinkhole nodes between conventional nodes. Sinkholes are therefore seen as a good class. The top cell displays the true negative, while the bottom one displays the genuine positive, according to the perplexing matrix of Fig. 4 based on true values. The upper one is a false-negative class from red cells, whereas the bottom is a false-positive class. Malicious and normal nodes are included in the two classes used for classification.

Fig. 4. Example confusion matrix of SVM and KNN.

The vertical grey cells show precision and negative predictive values, while the horizontal grey cells show sensitivity. For instance, 192 (or 75.1 percent) of the 256 sinkhole nodes in the SVM approach are accurately detected. However, 64 (24.9%) are incorrectly identified as normal

nodes. In other words, the SVM method’s sensitivity is 75.1 percent. The SVM approach has a 99.6% specificity for identifying the normal node. This indicates that just 16 (0.4 percent) of the 3348 normal nodes are incorrectly diagnosed. Additionally, 92.3% (precision) of the discovered sinkhole nodes in the SVM classifier are in a true condition. The SVM classifier, on the other hand, has an accuracy rate of 97.8%. The overall accuracy value that makes up SVM is the value in the confusion matrix’s lower-right corner cell. Consequently, the findings demonstrate that the accuracy of the SVM, KNN, DT, and CNN techniques are 97.8%, 96.7%, 98.4%, and 98.6%, respectively. Additionally, the classifier’s overall error value is highlighted in red lettering in the lower-right corner.

The input matrix is 8 by 1. Additionally, we employed two convolutional layers with ten 2x2 sizes, stride [1, 1], and padding-free filters. Additionally, we utilized the Tanh and ReLU routines to trigger the layers. Then, correspondingly, 384 and 2 cells are employed in each of the two completely linked layers. Probability is determined, and the final levels are activated using the SoftMax layer

Next, the cross-entropy classification layer is applied while taking into mutually exclusive account classes. Fig. 5 shows the outcomes of the categorization procedure. There are 3000 iterations in the training process. Fig. 5 shows the accuracy and loss value of the training process. The horizontal axis of the ROC curve represents the false positive rate, while the vertical axis represents the true positive rate. In other words, the ROC curve is shown, with the positive class—sinkhole nodes—being considered.

TABLE I. COMPARATIVE ANALYSIS OF VARIOUS METHODS FOR PRECISION IN %

ALGORITHM	EXISTING	PROPOSED
SVM	88.3	92.3
KNN	83.4	89.5
DT	82.4	89.7
CNN	62.4	65.3

Fig. 6. Comparative analysis of different methods for precision.

Table II compares precision values for different classification algorithms in the existing and proposed systems. The proposed system works better in terms of precision. Fig. 6 represents the comparison between existing and proposed work for various algorithms concerning the precision, and the proposed work outperforms when compared to existing algorithms.

Table II compares precision values for different classification algorithms in existing and proposed systems. The proposed system works better in terms of precision. Fig. 7 represents the comparison between existing and proposed work for various algorithms concerning sensitivity, and the proposed work outperforms when compared to existing algorithms.

The work displays the findings of the assessment of several machine learning techniques. The sensitivity of the DT

technique works better than another method, according to the results. The method's sensitivity shows the method's ability to find sinkhole nodes in MANET. As a result, its size signifies the classifiers' potential. The DT classifier has more sensitivity than previous approaches. The accuracy also demonstrates the method's dependability or potential for results.

TABLE II. COMPARATIVE ANALYSIS OF VARIOUS METHODS FOR SENSITIVITY IN %

ALGORITHM	EXISTING	PROPOSED
SVM	72.3	75.1
KNN	60.0	60.2
DT	89.3	91.3
CNN	78.3	80.1

TABLE III. COMPARATIVE ANALYSIS OF VARIOUS METHODS FOR ACCURACY IN %

ALGORITHM	EXISTING	PROPOSED
SVM	93.2	97.8
KNN	92.3	96.7
DT	92.1	98.4
CNN	92.3	98.6

Table III compares accuracy values for different classification algorithms in existing and proposed systems. The proposed system works better in terms of accuracy. Fig. 8 represents the comparison between existing and proposed work for various algorithms concerning accuracy, and the proposed work outperforms when compared to existing algorithms.

The SVM approach, for instance, has a precision rate of 92.3%. Additionally, the specificity demonstrates how the classifier recognizes a typical node. The accuracy of the CNN approach is 98.6%, which is greater than that of other methods, according to the findings and it has been shown in Fig. 8.

V. CONCLUSION

A network layer assault that mimics routing protocols is called a sinkhole attack. A training dataset is necessary to train models in any training mode to identify sinkhole assaults using machine learning. Real-world situations or exams for categorization can serve as training datasets. The experimental data may be described as a function with a goal value and a descriptive function. 3604 unique samples, both benign and malicious, were gathered for this paper. It creates a dataset that is labeled and composed of eight chosen characteristics. Support Vector Machine (SVM), K-Nearest Neighbor (KNN), Decision Tree (DT), and Convolution Neural Network (CNN) are some of the machine learning techniques used in the classification. SVM, DT, and CNN denote excellent accuracy

in the following priority. The effectiveness of our technique motivates us to extend this work to tackle the constraints and simulation mentioned in a 3D ad hoc network.

Abstract—Wireless Ad-hoc Network is characterized by a decentralized communication scheme with self-configuring nodes which has witnessed a wide range of practical wireless applications. However, this characteristic also results in various security threats in vulnerable wireless environment irrespective of presence of various routing protocols. Review of existing literatures shows that there is very less emphasis towards securing Dynamic Source Routing (DSR) while majority of solutions uses encryption-based operation. Therefore, this manuscript introduces a novel non-encryption-based scheme called as Friendly Group Architecture which intends to identify the presence of selfish node followed by presenting a method to promote the secure cooperation of it. The complete modelling is analytically designed using probability-based computation and dynamic thresholding. The simulation outcome carried out in MATLAB exhibits that it outperforms existing system with respect to energy, overhead, and security.

Keyword—Wireless Adhoc network; selfish node; DSR; reactive; security

I. INTRODUCTION

A wireless adhoc network is basically a decentralized form of network system where the devices are connected via wireless medium without any dependencies of infrastructure [1]. The decision of routing is undertaken by all the individual wireless nodes carried out dynamically using a routing protocol [2][3]. They can be stated as a self-configuring network with dynamic capabilities. There is no restriction of mobility for such device as the links changes frequency with other connected devices. While doing so, the elementary challenge is to prepare each wireless node to manage information that is demanded for a proper connection [4][5]. This give rises to more challenges as there is a need to forward the data packet to almost all the nodes which comes in the vicinity of its transmission zone. Apart from this, another challenge will be to maintain a required proportion of overhead under control for better routing performance [6]. Although, each nodes is aware of its own data transmission performance but they have no much idea about the demands of others. Apart from this, the dependencies of limited channel capacity are another impediment towards data transmission. Wireless adhoc network is always under a constant threat of attackers owing to its spontaneously changing topology. All the security threats that are present in conventional network

are also applicable in wireless ad-hoc network with respect to authentication, confidentiality, integrity, privacy, etc. [7]-[9]. Owing to such security threats, there are an increasing occurrences of intrusion events e.g., inferior monitoring of routing, denial of service attack, injection of counterfeited message, eavesdropping, etc. Essentially, there are two types of routing scheme widely deployed i.e., proactive and reactive protocols. It is found that proactive protocols are (e.g., optimized link state routing, destination sequence distance vector) are more prone to get compromised compared to reactive schemes (e.g., adhoc on-demand distance vector, dynamic source routing). A closer look into existing approaches also showcase that majority of the security scheme is carried out over reactive protocols and currently more research is also dedicated towards securing proactive protocols. However, there are less studies being carried out securing a variant of reactive protocol i.e. Dynamic Source Routing (DSR) to construct on-demand routes while forwarding request of node using source routing. The significant advantage of DSR is its independence from forwarding table update beacon periodically. The overhead is significantly controlled using cache information of route in DSR. However, majority of the security threat in DSR arises from its incapability to repair broken links while lack of updated cache information accelerates to this problem further more. DSR protocol is more prone to flooding attack and it could result in higher delay during connection set up compared to other proactive protocols. Apart from this, DSR protocols is actually meant for static environment and environment with low mobility to some extent [10][11]. They are not suitable for handling communication with higher degree of mobility.

1) *Motivation behind the study:* With the number of application rising towards the usage of ubiquitous computing, it is necessary that such forms of application should be smart enough to identify threat. However, adoption of sophisticated mechanism may significantly assist in threat detection but at the cost of computational and network resources. Adoption of DSR protocol offers beneficial networking perspective but their mechanism of inherent source routing makes the nodes more vulnerable towards its identity. This is the prime motivational factor to carry out the study towards improving DSR protocol in order to incorporate a capability to perform

secure routing operation in presence of routing misbehavior event in wireless adhoc network.

2) *Study contribution*: Apart from this, it is also seen that irrespective of various studies towards securing wireless adhoc network, there is no benchmarked model which can ascertain this fact. Therefore, the proposed system presents a novel scheme called as Friendly Group Architecture, which uses a simplified analytical model using probability theory exploits the selfish node to promote selfish node cooperation. The study contributes towards a novel modelling of securing DSR protocol by identifying selfish node as well as promotes cooperation of selfish nodes in presence of unknown malicious environment. The core idea of this framework is to balance the security, resource, and overhead demands to enhance DSR protocol in wireless adhoc network. Therefore, the study contribution is as follows:

- The proposed model is developed on the basis of an adversarial model whose information is not predefined with the other normal nodes in network.
- The model presents friendly group architecture which uses both normal and selfish node to participate in data forwarding process.
- The proposed technique introduces a unique incentive allocation scheme which is allocated to all the nodes on the basis of their undertaken action.
- The incentive policy is meant for promoting selfish node to achieve gain if they choose to forward data as a normal node.
- The proposed model is capable of resisting majority of the routing misbehavior in wireless adhoc network with better data transmission performance being noted.

The organization of this paper is as follows: Section II discusses about the existing literatures where different techniques are discussed for detection schemes used in power transmission lines followed by discussion of research problems in Section III and proposed solution in IV. Section V discusses about algorithm implementation followed by discussion of result analysis in Section VI and discussion in Section VII. Finally, the conclusive remarks are provided in Section VIII.

II. RELATED WORK

This section briefs of existing approaches towards security in wireless adhoc network especially emphasizing on the work carried out using routing protocols. The work of Almazok et al. [12] have presented an optimized version of DSR protocol using bio-inspired approach as well as time scheduling with main focus on routing performance. Study towards similar direction of improving routing performance is also carried out by Berri et al. [13] where a statistical modelling has been carried out using state of links. Study towards anomaly detection is carried out by Chugh et al. [14] where a zone-driven data forwarding scheme has been introduced. Existing study has also discussed about the resistivity techniques against selfish node using reputation based DSR protocol considering the mobility aspect of it as witness in work of

Delgado et al. [15]. Hadi et al. [16] have further presented a work which can enhance the detection performance of selfish node under mobility environment using on-demand routing scheme. Study of Liang et al. [17] have presented a DSR scheme by filtering the optimal path for routing to offer more reliable data delivery performance. The work of Mohan Priya et al. [18] have presented a secured DSR scheme in order to resist a specific form of attack i.e. black hole attack. Study towards selfish nature of vehicular network system is investigated by Shan et al. [19] considering static and dynamic nature of the node over multiple environments of communication. The work carried out by Shan et al. [20] has presented a discussion about influence of energy dissipation towards selfish behaviors in mobility environment. Exclusive study towards securing mobility environment is carried out by Srivastava et al. [21] where digital signature is used for authenticating the participating nodes. Azam et al. [22] have studied about various authentication scheme over vehicular adhoc network while work of Faisal et al. [23] have presented a detection of identity attack in wireless adhoc network considering received signal strength. Farahani [24] have used k-nearest method for computing reputation in order to resist black hole attack over mobility environment. Im and Lee [25] have presented a secure covert communication system over two hop adhoc network. Mahmood et al. [26] have studied the issues associated with existing security scheme over vehicular adhoc network and concludes that there are still many issues which require attention in conventional scheme. Naresh et al. [27] have used group key agreement for securing cluster-based communication in adhoc network. Usage of blockchain is reported in work of Ran et al. [28] where on-demand data transmission scheme is used considering QoS constraint. Siddiqui et al. [29] have presented a security approach for resisting wormhole and blackhole attack considering adhoc network integrated with an Internet-of- Security. Wu et al. [30] have presented a secure authentication scheme using key exchange protocol over vehicular adhoc network. Hence, it can be noticed that there are some dedicated investigations towards securing wireless adhoc network. The next section briefs about the issues associated with existing system of secure routing scheme in wireless adhoc network.

1) *Limitation and research gap*: The prime limiting factors of existing security techniques are mainly associated with the core emphasis on adopting sophisticated technique to identify abnormality in routing. The techniques are either based on data forwarding or it's based on high-end resource dependent security technique. Another significant limiting factor is that the solution of problem space is more concerned about singular form of attack. Such methodologies make the system non-applicable in different attack scenario. Hence, there is potential research gap between rising of dynamic adversaries and existing problem solution, which is highly symptomatic to specific event. Hence, they cannot be deployed over the scenario which calls for presence of multi-attacker or attackers launching dynamic strategies of attack in wireless adhoc network. Apart from this, there is a still a gap between security solution resiliency and its dependencies towards resources.

III. RESEARCH PROBLEM

The unaddressed problems explored after reviewing the existing system are as follows:

- There are very few potential implementations towards securing DSR protocol over uncertain condition of intrusion in wireless adhoc network.
- Majority of the existing security approaches are based on authentication on priorly known information of the attacker and they are highly specific for attackers.
- The fact that attacker could exhibit dynamic behavior is out of scope of any existing implementation work in wireless adhoc network.
- Existing security approaches doesn't offer much balance between data transmission performance and security performance at a same time.

Therefore, the problem statement arrived from the above points is "Developing a novel secure data transmission scheme considering the dynamicity of attacker behaviors and harnessing malicious node to secure communication in wireless adhoc network is challenging task".

IV. RESEARCH METHODOLOGY

The core target of the proposed system is to introduce friendly group architecture in order to secure DSR protocol in wireless adhoc network. The secondary objective of this architecture is also to ensure better resource management along with overhead reduction. The term 'friendly' is stated as this architecture offers identification of selfish node and uses them in order to perform data dissemination in uncertain communication environment in presence of uncertain intruder's strategy. Fig. 1 highlights the proposed architecture.

A closer look in Fig.1 shows that proposed DSR implementation scheme is classified into two functionalities i.e., identification of selfish node followed by secure participation of selfish node. In initial operation, all the response-based beacons are analyzed in order to compute probability of cooperation as well as intrusion. These two parameters are further used for computing two empirical forms of trust i.e., degree of conformity which is about data forwarding operation and degree of non-conformity which is about rejecting all possibilities of forwarding data (followed by dropping packet). Further conditions are designed to finalize the trust value from its third type i.e., degree of vagueness in trust, which is about incapability of a node to decide if the other node is regular or selfish node. Finally using dynamic thresholding, selfish node is positively identified. The next round of operation is to further assess the probability of attacker identity for the selfish node followed by another dynamic thresholding in order to allocate incentives. All selfish nodes that comply with proposed secured DSR protocol will be allocated a measurable incentive in order to promote selfish node cooperation. The proposed system ensures that under no circumstances, the selfish nodes once identified as positive attacker will be able to initiate attack next time. The next section discusses algorithms.

Fig. 1. Proposed friendly group architecture.

V. ALGORITHM IMPLEMENTATION

This section discusses about the algorithm design and its implication towards developing friendly group architecture with an implicit focus on identification of a selfish node and ensuring participation of a selfish node securely. The novelty of the algorithm implementation is that it exploits the selfish node to participate in data forwarding process even after positively identifying it as a selfish node. This is completely different from any existing system which either isolates the selfish node or takes countermeasure of its non-participation. However, the core idea of this algorithm is to incorporate security in DSR protocol using retaliation-based concept within the node properties. The discussion of the algorithms is as follows:

A. Algorithm for Identification of Selfish Node

This algorithm is responsible for performing positive identification of a selfish node assuming that it doesn't have any previously fed information about its presence. The steps of the algorithm are as follows:

Algorithm for Identification of Selfish Node

Input: n (number of nodes)

Output: n_s (identified selfish node)

Start

1. For $i=1:n$
 2. $n_{ad} \rightarrow n_t(\text{RREP})$
 3. n_t computes d_c and d_{nc}
 4. If $d_{nc} > d_c$ & $d_{nc} > T_1$
 5. $n_s = \text{declare } n_{ad} \text{ as selfish node}$
 6. If $(p_c = p_a)$
 7. compute d_v
 8. If $d_v > T_2$
 9. $n_s = \text{declare } n_{ad} \text{ as selfish node}$
 10. End
 11. End
-

The algorithm takes an input of n (number of nodes) which after processing yields an outcome of n_s (identified selfish node). Considering all the nodes n in simulation area (Line-1), the adjacent node n_{ad} forwards the route response beacon RREP to the transmitting node n_t after the former receives the route request message from latter (Line-2). Upon receiving this beacon, the transmitting node n_t computes degree of conformity in trust d_c as well as degree of non-conformity of trust d_{nc} (Line- 3). For a regular form of node, the frequencies of d_{nc} value should reduce or stop which is not the case of malicious form of node. This is because the malicious node could have opted for initially forwarding the regular response in order to increase its individual trust value. In such case, it could become quite impossible for the transmitting node to decide if the adjacent node is regular node or malicious node. Hence, the computation of d_c and d_{nc} assist in this regard in the form of mathematical expression as follows:

$$\begin{aligned}d_c &= p_c / p_c + p_a \\d_{nc} &= p_a / p_c + p_a\end{aligned}\quad (1)$$

In the above expression (1), μ_1 and μ_2 represents probability of cooperation (forwarding data) or probability of intrusion respectively. For any discrete value of p_c and p_a , it's easier to find the case of vulnerability where in such case $d_{nc} \gg d_c$. However, if the attacker chooses to increase its trust value by cooperating than in such case, $p_c = p_a$ which will result in $d_c = d_{nc}$ (Line-6). This similar value of degrees will lead to failure of decision of nodes about the regularity and malicious nature. The proposed system considers a primary threshold T_1 which is assigned by user to be compared with d_{nc} (Line-4) to determine its malicious nature (Line-5). However, in case of Line-6, the proposed algorithm further computes degree of vagueness mathematically as follows:

$$d_v = (\lambda \cdot P_1) / (P_2 \cdot P_3) \quad (2)$$

In the above expression, the variables λ , P_1 , P_2 , and P_3 represents network coefficient, $(p_c \cdot p_a)$, $(p_c + p_a)^2$, and $(p_c + p_a + 1)$ respectively. This mathematical expression is used only in the condition stated in Line-6. After the d_v value is obtained, its is further compared with secondary threshold T_2 to ensure that d_v should be always within T_2 limit (Line-8) otherwise, the monitored adjacent node is termed as malicious node (Line-9). It should be noted that proposed algorithm represents selfish node as malicious node. For regular environment, the value of d_v should be reduced and its value is fixed by user based on the application it deploys. Hence, using a simplified probability concept, proposed system can easily identify selfish node n_s .

B. Algorithm for Secure Participation of Selfish Node

This algorithm is a continuation of the previous algorithm which detects the selfish node. The prime basis of this algorithm are two folds viz. i) a selfish node will not introduce any form of attack in the preliminary level and will choose to cooperate. As selfish node will not be aware of security protocol running, this is the best way to get them latently introduced within the network, gain trust, and introduce attack, ii) selfish node also participate in data forwarding process; however, they do it with malicious intention. Hence, the above two properties can be harnessed to exploit the data

forwarding capability of selfish node as a complimentary to regular node for seamless secure data transmission. However, this operation is strictly monitored on the basis of threat computation for such selfish node and until and unless they are within a permissible limit, the selfish nodes are allowed to propagate data. The success factor of this algorithm completely depends upon how positively the first algorithm works. Apart from this, a second level of controlling is offer, by allocating incentives to the nodes based on their adopted steps of action, the proposed algorithm offers secure participation of selfish nodes. The operational steps of the proposed algorithm are as follows:

Algorithm for Secure Participation of Selfish Node

Input: n_s (selfish nodes)

Output: S_p (secure participation)

Start

1. **For** $i=1: n_s$
 2. compute $paid$ of n_s
 3. **If** $paid > T_3$
 4. Allocate $I_1 \rightarrow n_s$
 5. **Else**
 6. $S_p = \text{Allocate } I_2 \rightarrow n_s$
 7. **End**
 8. update S_p , d_v , d_c , and d_{nc}
 9. **End**
-

This above stated algorithm takes the input of n_s (selfish nodes) from prior algorithm which after processing ensures an outcome of S_p (secure participation). This algorithm considers all the n_s (selfish nodes) (Line-1) followed by conditional assessment to check if the probability of attacker paid is greater than tertiary threshold T_3 (Line-3). It should be noted that proposed system performs computation of $paid$ using same expression as that of p_a as seen in prior algorithm. If the $paid$ value is found to be more than T_3 than it will represent positive presence of many numbers of selfish node. Knowing that fact that a selfish node will need to comply with the proposed secure DSR protocol and hence, its actions will be controlled by allocating an incentive I_1 , which are computed based on their trust value. The incentive I_1 will state allocating of increasing number of profits for selfish node as long as they assist in forwarding data. However, there is also a possibility that the selfish node violates proposed secure DSR protocol and executes its own malicious code. In such case, the malicious node's action is public-ally flagged as a malicious node to all other regular node and in such case; it fails in further data forwarding process to other non-victim regular node. Hence, the selfish node has no other option but to assists in data forwarding or else they will need to isolate themselves from the current network itself (Line- 4). On the other hand, if $paid$ value is found to be lower than tertiary threshold than they are allocated an incentive of I_2 . It should be noted that $I_2 > I_1$, which is strategically designed to ensure participation of selfish node (Line-6). All the other variables are further updated and this updated information is shared among all the neighboring nodes (Line-8).

It is to be noted that prime contribution of the proposed secured DSR protocol is basically in the formulation of the incentives which directly control the actions of all nodes on the basis of their actions viz. i) data forwarding, ii) data dropping, iii) raising a notification about intrusion, and iv) introducing intrusion. It could be seen that first two actions could be exhibited by both regular node and selfish node whereas the discrete action of third and fourth could be only exhibited by regular node and selfish node respectively. Hence, on the basis of dv value computation, observing its trend, and comparing with the threshold value. In this process, there is also a likelihood that a regular node could generate false alarm and hence the proposed system introduces an inclusion of penalty factor which is computed for every decision of alarm generated by the regular node. Although, there is a possibility of few instances of false alarm by regular node, but more the regular node updates its variable (Line-8), the occurrences of such false alarm reduces down and network becomes more accurate to capture the event of intrusion. Apart from this, a non-inclusion of conventional cryptography approach is one big advantage of proposed system which not only makes the proposed DSR protocol to offer security but also leverages the data transmission performance in wireless adhoc network.

VI. RESULT ANALYSIS

This section discusses about the implementation of the proposed system discussed in prior section using MATLAB. The simulation environment consists of randomly distributing 500 nodes in 1000x1000 m² area with 3000 simulation rounds. The assessment of performance is done using 4 evaluation parameters i.e., overhead, battery usage, identification of selfish node, and consistency in selfish node cooperation. The outcome of proposed system is compared with current work of Delgado et al. [15] termed as DRSR and conventional DSR protocol.

Fig. 2 highlights the traffic overhead reduction which is computed as proportion of control message that lacks application contents. Owing to possession of stale route information, DSR protocols exhibits higher traffic overhead in case of unnecessary cooperation by selfish node, which is avoided to a large scale in DRSR scheme which uses allocation of reputation value for establishing communication. However, DRSR considers static nodes which further doesn't scale up when the iteration is incremented. Proposed system, on the other hand, ensures all its routing decision on the basis of computed probabilities of trust. This ensures higher generation of reliable links causing higher reduction of traffic overhead.

Fig. 3 highlights the battery saving where proposed system excels better energy saving compared to proposed system. Both existing system of DSR and DRSR make use of highly iterative mechanism to find the routes with more emphasis over the destination node proximity and not much into ascertaining the reliability of neighboring node. This is the reason that both the existing schemes doesn't have much significantly different outcomes of battery saving. On the other hand, proposed system has highly structured computation of links, where thresholding, updating operation,

and computation of threat probability are spontaneous causing efficient and secure route. This leads to significant energy saving.

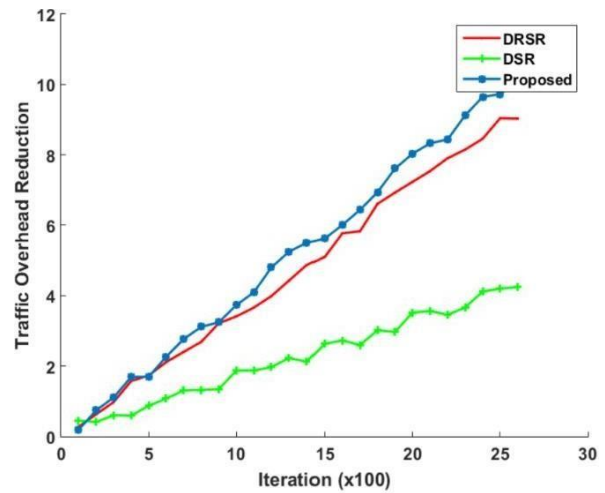

Fig. 2. Analysis of traffic overhead reduction.

Fig. 3. Analysis of battery saving.

Fig. 4. Analysis of identification of selfish node identity.

Fig. 4 highlights the positive identification of selfish node. It should be noted that proposed system uses three different forms of thresholds in order to confirm the identity of selfish node and therefore, although the trendline of proposed system is lower than existing system, but still the outcome is reliable to consider in presence of uncertain and dynamic environment. This is because, existing DSR and DRSR system showcase higher identification rate as its attackers are well defined in its environment and hence this outcome is not applicable for uncertain intrusion environment.

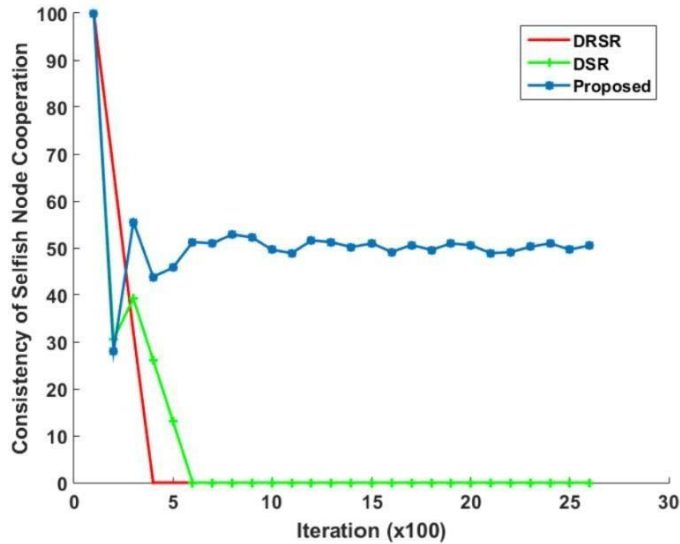

Fig. 5. Analysis of consistency of selfish node cooperation.

Fig. 5 highlights the consistency of the selfish node cooperation. In this case, it is proved that existing system doesn't support selfish node cooperation, where amending the conventional DSR in proposed system logic entails that selfish node has no other choice but to participate in data forwarding process in proposed friendly group architecture. A closer look into the graphical trend shows that proposed system has superior consistency with an increase of iteration. This is because of the fact that proposed algorithm performs spontaneous updates which not only reduces the effort to compute degree of vagueness in trust but it also increases degree of conformity of trust resulting. Allocation of dual form of incentives either forces the selfish nodes to participate till it drains its energy or it isolates the selfish node if the probability of attacker identity is found to be highly significant. Although, this may cause selfish node slightly bypassing the security in preliminary level (0-less than 5 round), however, it soon obtains its consistency and hence proposed system offers more reliable outcomes with respect to selfish node cooperation.

VII. DISCUSSION

From the previous section, it is quite evident that proposed scheme offers better performance in contrast to existing routing schemes. There are multiple points to be highlighted for this perspective of outcomes which are as follows:

- Overhead control is one of the potential contributions of proposed scheme. A closer look into the friendly

architecture in joint collaboration with incentive policy states that proposed system carry out its operation on the basis of three different forms of trust scores. This computation is carried for each group in friendly architecture using probability-based conditional logic. Hence, there is much less effort implied by proposed scheme towards trust computation whereas existing DRSR scheme is required to iteratively compute trust score. This fact doesn't suit well in presence of dynamic environment leading to higher traffic overhead in DRSR. At the same time, the higher score of traffic overhead in DSR is accounted for its increasing memory allocation to retain source information.

- From the resource consumption viewpoint, the only operation proposed scheme does are dual fold viz. i) trust computation by neighborhood monitoring and ii) allocation of incentives using conditional logic. The complete operation requires lesser memory, is faster, and is always updated causing better resource retention performance of proposed system with increasing iteration. This is not the case with DSR or DRSR or any other existing scheme briefed in Section II.
- From the security perspective, the proposed scheme emphasized on identification of selfish node on the basis of presented trust computation. The granularity in the trust computation is further ensured by progressive assessment of conditional logic based on dynamic thresholding. This causes uniform performance of selfish node identification over increasing iteration. However, existing scheme e.g. [12]-[25] considers highly sophisticated computation while scheme [26]-[30] offers highly iterative scheme that captures attacker only if attack definition is well defined. Hence, the inconsistency arises in selfish node identification with increasing iteration witnessed with dynamic topology.
- One of the major contributions of the proposed scheme is its prevention technique where the positively identified selfish node is forced to cooperate in network. It is also quite fair enough to ascertain that at certain point of time, such selfish node could violate too. However, there are very less chances for this as if the selfish node chooses to violate, its information have already been updated in hop table of all its neighboring nodes. In such case, selfish node will fail to initiate a new attack in different group. Apart from this, the neighborhood monitoring is a continuous process which is also responsible of capturing any form of anomaly in behaviour of selfish node causing routing misbehaviour.

VIII. CONCLUSION

The presence of intruder in wireless adhoc network is quite challenging to be explored even by the most potential intrusion detection system. Existing studies carried out considers the predefined information about the attacker doesn't find its applicability over dynamic form of network.

Apart from this, there was so significant security work being carried out considering DSR protocol. These challenges are addressed in current study with following contributions: i) a novel analytical framework of Friendly Group Architecture which promotes the regular node to perform seamless data transmission as well as promotes selfish node for secure cooperation, ii) every actions of selfish nodes are preemptively computed in order to find out its next step of actions and accordingly allocation of incentives are carried out, iii) the proposed model is completely independent of any apriori information of an attacker and hence it can be widely applicable for resisting majority of attacks, iv) the proposed model offers a well-balance between traffic overhead, energy consumption, and security.

Abstract—Skin diseases are a group of diseases affecting people of all ages, commonly caused by fungi, bacteria, parasites, viruses, and infections. The disease's main symptoms are usually itching all over the skin. Many patients are often underestimated and embarrassed to consult directly with doctors, which in the end, ignores the symptoms of skin diseases. Since they usually have imprecision symptoms, examining skin diseases is complex and challenging. Recently, many efforts have been made to utilize artificial intelligence approaches for diagnosing various diseases based on the patient's condition. This paper aims to develop a novel fuzzy-based medical expert system based on unprecise existing symptoms. The system uses the specialist Doctor's knowledge (dermatologist) to diagnose and provide the patient's severity level for the disease. We have done numerical experiments using 100 (one hundred) test problems to evaluate the performance of the developed system by comparing the result with the recommendations of doctors (dermatologists). It shows that this system succeeds in all tests with an accuracy value of 95.6%. Thus, this system is very beneficial to support doctors in the assessment of skin diseases.

Keywords—Artificial intelligence; expert system; fuzzy logic; skin disease

I. INTRODUCTION

The skin is the human body's largest organ [1]. Bacteria, viruses, or fungi have usually caused several types of diseases. The statistics indicate that skin diseases are common in half the adult population [2]. In Indonesia, patients with skin diseases are 62.8% men and 37.2% women. With details of the age group 11-20 years 31.4%, in the age group 21-30 years 19.3%, in the age group 31-40 years 14.6% with 76 cases, in the age group 41 -50 years 11.3%, in the age group 51-60 years 7.5%, and the age group > 60 years 3.1%, and the last one in the age group < 10 years 12,8% [3]. Treating skin disease reduces the most negligible effect of disrupting a patient's life quality. Doctors and paramedics often see patients with severe skin diseases without proper treatment. Many patients are often underestimated and embarrassed to consult directly with doctors, which in the end, ignores the symptoms of skin diseases.

Correctly diagnosing a skin disease is essential to patient-centered care. It requires knowledge and thoroughness from expert doctors, but doctors have limitations in consulting with patients because of the tight schedule and many patients. In addition, patients are sometimes embarrassed to consult directly with the Doctor. Many patients underestimate this skin disease, which in the end ignores the symptoms of skin

disease.

The treatment therapy given to patients is usually done by giving medicine. Providing the appropriate drugs and the proper dosage is critical for skin disease medication and requires the standard knowledge of pharmacology. Inappropriate or improper dosage would become health problems, such as increased side effects, treatment failure, and resistance [4].

Recently, as computers have become popular, many researchers have developed technology in the form of artificial intelligence that imitates an expert's ability (based on expert knowledge) to make decisions. Expert systems use an expert's knowledge to solve some of our real-life activities, including Interpretation, Prediction, Diagnosis, Design, Planning, Monitoring, and so on [5]-[6]. In medical science, expert systems have been adopted to help doctors and specialists diagnose and get appropriate advice on several medical problems, such as Teeth and Gums, Shortness of Breath in Infants and Children, Eye Diseases, breast cancer, neck pain, and Anemia Diseases. With this expert system, even ordinary people can solve complex issues that usually can only be solved with the help of experts [7].

Each year we see almost ten billion Google Searches related to skin, nail, and hair issues. Two billion people worldwide suffer from dermatologic issues, but there's a global shortage of specialists. While many people's first step involves going to a Google Search bar, it can be challenging to describe what you see on your skin through words alone. Patients consider skin disease a common disease because there is no information about the causes and indications of the disease known to the patient [8]. Many patients experience the adverse effects of skin disease without realizing it, so experts in diagnosing kidney disease are needed. However, because the time specialists have is very limited and the number of patients is large, it is difficult for patients to consult a specialist. It causes patients and specialists to have difficulty conveying information about skin diseases. Therefore, people need an expert system that helps to analyze skin diseases [5].

Another essential issue in diagnosing skin diseases is vague symptoms. Examining skin diseases becomes complex and challenging. Since Zadeh introduced it in 1965, fuzzy logic has been successfully applied for various applications, mainly in control. This 'fuzzy' boom has generated strong interest from researchers in developing new fuzzy-based technology for various applications. Prior to the theory of fuzzy logic, we know as crisp logic, which has a value of true

*Corresponding Author.

and false explicitly [9]. Otherwise, Fuzzy logic is logic that has a value of vagueness or ambiguity (fuzziness) between true and false. In fuzzy logic theory, a value could be true and false simultaneously. People unfamiliar with fuzzy logic would have thought that fuzzy logic is very complicated and unpleasant. However, once people know it, they will be interested and newcomers to studying fuzzy logic [10].

This research aims to develop a novel fuzzy-based medical expert system for diagnosing skin diseases. Based on the imprecise patient's symptoms, the system can produce output depending on the fuzzy inference system's situation. This fuzzy logic-powered system would be an application tool that makes it easier to figure out what might be going on with your skin. By answering your symptoms, the system gives the skin disease diagnosis with a certain confidence level. The AI model analyzes this information and draws from its knowledge to provide you with possible matching diseases. Moreover, it will also show you the severity level and give answers to common questions. The tool is not intended to provide a diagnosis nor be a substitute for medical doctors.

In this study, we used Matlab to develop the system because it is easy to run, performs information retrieval, and assists in calculations. The fuzzy approach is adopted to

calculate drug compatibility and types' value. Paramedics and doctors can also use the system to recommend medicine. Numerical experiments using 100 (one hundred) datasets have been conducted to evaluate the effectiveness of the systems. The results are compared with those of the expected results by experts (doctors). It is shown that the system is effective and helps doctors diagnose skin diseases.

We organize this paper into five sections. The literature review of the medical expert system is given in the next section. The third presents a straightforward design of the proposed approach. The numerical experiments and the comparative results are described in the fourth section. Finally, conclusions are drawn in the last session.

II. LITERATURE REVIEW

Several researchers have reported the uses of various Artificial Approaches for medical problems. In the following Table I, several recent AI approaches for various skin diseases are presented.

Based on the above information, it can be seen that most of the previous approaches used a deterministic process. In this research, a novel technique called the fuzzy expert system is developed to diagnose skin disease.

III. MATERIALS AND METHODS

This research has several stages of designing an expert system for skin diseases. The process starts with collecting literature studies. Then the second stage is identifying system requirements. The third stage is developing knowledge-based and compiling a membership function to determine the maximum and minimum value of the weight value of each symptom. Next is the development of the system stage. Finally, experiments are done to evaluate the functional system and compare the results with those of experts. The design of the system process in this study is illustrated in the following Fig. 1.

Fig. 1. The design of the system.

A. Symptom and Disease Datasets

This study used 10 (ten) types of skin diseases and 23 (twenty-three) symptoms. The data are given by an expert who is a skin doctor. The types of conditions and the symptoms are presented in Tables II and III. Each sign of the disease will have a weight value. We summarize the weight symptom value of the disease in Table IV.

TABLE II. SKIN DISEASE DATA

Code	Skin Disease
D01	Crustose Impetigo
D02	Bullous Impetigo
D03	Neurodermatitis
D04	Cellulitis
D05	Scabies
D06	Candida Cutis
D07	Herpes Zoster
D08	Furuncle
D09	Tinea Versicolor
D10	Tinea Cruris

TABLE III. SKIN DISEASE SYMPTOM DATA

S1	S2	S3
Spots appear in the groin area and anus	A rash appears on the facial area	A red rash in the groin area, underarm skin, and breast folds

S4	S5	S6
Swelling of the skin in the lymph area	Reddish skin blisters on the lower legs, arms, abdomen, or face	Red spots or whitish lesions
S7	S8	S9
Itchy patches on the wrists, arms, ankles to the genitals or anus	There is a lump	There is a bull that can make wounds
S10	S11	S12
Have sores that itch	There are red spots	Feeling itchy
S13	S14	S15
Very itchy, like burning	At night itchy	Feel itchy when sweating
S16	S17	S18
On one side of the body appears blisters	There is a brownish-yellow scab around the wound as a result of an irritated wound	Skin feels dry, thick, and scaly
S19	S20	S21
Smooth scaly skin	Fever	Headache or Feeling Dizzy
S22	S23	
Pain in the spine	Rash spots on the surface of the skin	

TABLE IV. SYMPTOM WEIGHT VALUES FOR THE DISEASES

Diseases	Symptoms	Weight Value (Percent)
Crustose Impetigo (D01)	S02	30%
	S04	10%

	S15	20%

B. Fuzzy Rules

To map the inputs to output, we define several fuzzy rules based on the information given by experts. The fuzzy rules are usually in the form of IF-THEN, made by experts or doctors. The defuzzification process converts the fuzzy output from the system inference engine into a definite value to determine the diagnostic results) [9]. An overview of tree- structure of the expert system on skin diseases is given in the following Fig. 2.

Fig. 2. The tree structure of the system.

C. Fuzzy Logic Controller

The concept of fuzzy logic was then successfully applied to a controller by Zadeh. Recently, it has been used for many applications in our daily life. Thousands of electronic products in the market have adopted the concept of fuzzy logic, ranging from washing machines to high-speed trains. It has been reported that the advantages of fuzzy logic in the sense of performance, simplicity, low cost, and productivity [21]

There are three steps passed before obtaining the crisp value. The processes of fuzzy are as follows:

- Fuzzification is the process of transforming crisp input values into linguistic values, which are usually presented in the form of fuzzy associations with a membership function respectively.
- An interference System is a reference for explaining the relationship between the variables of input and output variables that are processed and the resulting shaped fuzzy. To illustrate the relationship between inputs and outputs, the "IF-THEN" is used.
- Defuzzification is a process of changing the form of fuzzy variables into the data bound (crisp) that can be transmitted to the control equipment.

The step-by-step fuzzy logic process is shown in Fig. 3. The raw input is crisp. The Fuzzification process produces the fuzzy value, which is then calculated by the membership function. Later, the defuzzification process converts it back to the crisp value, as shown in Fig. 3.

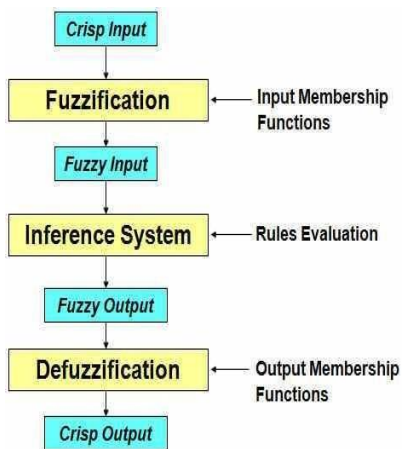

Fig. 3. Step-by-step fuzzy logic approach.

1) *Fuzzy membership function*: Unlike traditional Crisp Logic, such as Binary Logic, where variables may only take on true and false values represented by 1 or 0, the variables in fuzzy logic may have a truth value in the range of 0 and 1 [22]. The value called membership value explains the degree of truth. Here, the fuzzification process transforms the symptom density value into a linguistic variable using a membership function. The function represents the membership degree of the input variable, denoted by the symbol $\mu(x)$, in the interval between 0 on the information given by experts. For this research, we used fuzzy symptoms membership functions, as shown in Table V. We also used criteria and density values for each symptom criterion in this research. The data was obtained from a dermatologist with a practice permit, as shown in Table VI.

TABLE V. MEMBERSHIP FUNCTION OF THE SYMPTOMS

Symptom		Symptom		Symptom	
S01		S09		S17	
S02		S10		S18	
S03		S11		S19	
S04		S12		S20	
S05		S13		S21	
S06		S14		S22	
S07		S15		S23	

TABLE VI. THE DENSITY VALUES OF THE SYMPTOMS

Code	Symptom	Criteria	Density Value
S01	Spots appear in the groin and anus area	- Pink spots without freckles	40
		- Pink spots with freckles	55
		- Bright red spots with freckles	70
		- Bright red patches with flaky or scaly spots	82
		- Dark red or black patches with flaky or scaly spots	90
S02	A rash appears on the facial area	- A red rash resembling a wound with nodules filled with clear fluid	78
		- A brownish, crusty rash with nodules filled with clear fluid	85
S03	A red rash in the groin area, underarm skin, and breast folds	- Red rash and red, cracked, dry plaques	75
		- A red rash with pus-filled bumps and red, well-defined plaques	85
S04	Swelling of the skin in the lymph area	- Significant red swelling that feels rough and painful	74
		- Significant red swelling that feels rough and contains pus or blood	88
S05	Reddish skin blisters on the lower legs, arms, abdomen, or face	- The pink skin blisters feel swollen and warm and look shiny	65
		- Red skin blisters that are swollen and inflamed (painful)	78
		- Red skin blisters with bubbles filled with fluid or pus	85
S06	There are red spots or whitish lesions	- Pink lesions	63
		- Red lesions	78
		- Whitish patches	85
S07	There are itchy patches on the wrists, arms, ankles, genitals, or anus	- Itchy patches with red or darker than the surrounding skin	65
		- Itchy patches feel rough and scaly and thick	77
		- Itchy patches with open sores that can lead to infection	85
S08	There is a lump	- The bumps are red and not hard	50
		- Red bumps that are inflamed and hard-filled with pus	74
		- White bumps like a pile of pus, and around the lump is red	85
S09	There is a bull that can make wounds	- There are several bullies in certain body parts	65
		- There are many red bullies like hives that feel itchy	85
S10	Have sores that itch	- The wound is starting to itch	65
		- Burns that feel hot and itchy	78
		- Burns that feel hot, very itchy, and scaly	85
S11	There are red spots	- There are some small red nodules	60
		- There are rashes and red skin blisters filled with clear fluid	77
		- There are nodules and red, inflamed skin blisters filled with clear fluid	85
S12-	Feeling itchy	- itchy	60
		- a bit itchy	78
		- very itchy	85
S13	Very itchy, like burning	- itchy like burning	60
		- a bit itchy, like burning	78
		- very itchy, like burning	85

Code	Symptom	Criteria	Density Value
S14	At night itchy	- itchy at night	60
		- a bit itchy at night	78
		- very itchy at night	85
S15	Feel itchy when sweating	- itchy when sweating	60
		- a bit when sweating	78
		- very itchy when sweating	85
S16	On one side of the body appears blisters	- Red blisters that start to become inflamed and itchy	70
		- Red blisters are painful, itchy, and filled with fluid	83
		- Red blisters that fill with fluid and break into crusts	88
S17	There is a brownish-yellow scab around the wound as a result of an irritated wound	- Yes	85
		- No	0
S18	Skin feels dry, thick, and scaly	- Dry skin	60
		- Skin feels dry and flaky	78
		- Skin feels dry, thickened, and scaly	85
S19	Smooth scaly skin	- Yes	85
		- No	0
S20	Fever	- Low	35 C - 36 C
		- Normal	36,1 C - 37,5 C
		- High	37,6 C - 38 C
S21	Headache or Feeling Dizzy	- Feeling sick at one point	65
		- Like spinning	78
		- Feels floating or head feels heavy	85
S22	Pain in the spine	- Feel pain	65
		- Feel a bit of spinal pain	78
		- Feel very of spinal pain	85
S23	Rash spots on the surface of the skin	- Rash of pink spots	65
		- A rash of bright red spots that start to become inflamed	78
		- A rash of red, inflamed spots that feels rough	88

IV. THE NUMERICAL EXPERIMENTS AND RESULTS

We develop a fuzzy-based expert system for diagnosing kidney diseases using MATLAB R2020a and run on PC Processor Intel® Core™ i3-7020U. For the experiments, we used 100 (one hundred) test problems from the Abdoel Moeloek National Hospital in Lampung. We compared the results of the system with those given by the Doctor.

This system first displays questions from each symptom according to the closest symptom. After selecting the related symptom, the system will show a selection of symptom criteria. Finally, the diagnostic results will be displayed. After choosing the symptoms, the system will present the results as illustrated in Fig. 4.

The system's output will be the diagnostic results and its confidence level. We compared the results with those given by the expert (dermatologist) and the system in Table VII. These results show that the system succeeds in diagnosing the patient's

disease for all tests. It can analyze the conditions precisely the same as given by experts.

Fig. 4. User Interface of the system.

TABLE VII. COMPARATIVE RESULTS BETWEEN EXPERTS AND SYSTEM

		Predicted by the System									
	Type of Disease	D01	D02	D03	D04	D05	D06	D07	D08	D09	D10
Actual by the expert	D01	5	0	0	0	0	0	0	0	0	0
	D02	0	12	0	0	0	0	0	0	0	0
	D03	0	0	8	0	0	0	0	0	0	0
	D04	0	0	0	13	0	0	0	0	0	0
	D05	0	0	0	0	13	0	0	0	0	0
	D06	0	0	0	0	0	13	0	0	0	0
	D07	0	0	0	0	0	0	13	0	0	0
	D08	0	0	0	0	0	0	0	2	0	0
	D09	0	0	0	0	0	0	0	0	13	0
	D10	0	0	0	0	0	0	0	0	0	8

TABLE VIII. NUMERICAL EXPERIMENT RESULTS

Disease	Problem	Expert	Status	System		
				Very Mild	Mild	Severe
D01	5	Expert	Very Mild	0	0	0
			Mild	0	1	0
			Severe	0	0	4
D02	12		Very Mild	0	0	0
			Mild	0	6	0
			Severe	0	0	6
D03	8		Very Mild	0	0	0
			Mild	0	2	0
			Severe	0	1	5
D04	13		Very Mild	0	0	0
			Mild	0	6	0
			Severe	0	0	7
D05	13		Very Mild	0	0	0
			Mild	0	6	0
			Severe	0	0	7
D06	13		Very Mild	0	0	0
			Mild	0	5	0
			Severe	0	0	8
D07	13		Very Mild	0	0	0
			Mild	0	6	0
			Severe	0	0	7
D08	2		Very Mild	0	0	0
			Mild	0	0	0
			Severe	0	0	2
D09	13		Very Mild	0	0	0
			Mild	1	4	1
			Severe	0	2	5
D10	8		Very Mild	0	0	0
			Mild	0	3	0
			Severe	0	0	5

Next, for each test problem, the system also provides the severity level for each patient. Table VIII shows the comparative results of experts and the developed system on the disease severity for the patients. Based on these results, we calculate the system's accuracy in determining the patients' disease severity, as shown in Fig. 5.

Fig. 5. Expert diagnostic test chart and system.

The above results show that the system's accuracy in determining the severity level of the patient's disease is 95.6%. It shows that this system is effective in diagnosing skin disease. Thus, the system is very beneficial to support doctors in assessing skin diseases.

V. CONCLUSION

The diagnosis of skin diseases is a difficult task. There is always some possibility of misdiagnosis that leads to miss treatment. This research presents a fuzzy expert system to examine skin diseases based on patient symptoms. The system gives information about the type of disease with confidence based on the existing symptoms and how to handle them. The system's output will be the type of disease and its attributes, namely very mild, mild, and severe. We had several experiments to evaluate the system's performance using 100 test problems and compared the results with those given by the expert (dermatologist). The result shows that the system succeeds in all of the tests. Thus, this system is very beneficial to supporting doctors in the assessment of skin diseases.

ACKNOWLEDGMENTS

The authors express their deepest gratitude for using the facilities of the Basic Computing Laboratory, Department of Computer Science, and the University of Lampung to support this research and for the willingness of dr. Hendra Tarigan Sibero, Sp.KK, M. Kes. who has contributed his practical knowledge to this skin disease expert system. A "Fundamental" research Grant supported this research.

Dual U-Net with Resnet Encoder for Segmentation of Medical Images

Syed Qamrun Nisa Author¹, Amelia Ritahani Ismail^{2*}

Department of Computer Science-Kulliyyah of Information and Communication Technology,
International Islamic University Malaysia, P.O. Box 10, 50728, Kuala Lumpur, Malaysia

Abstract—Segmentation of medical images has been the most demanding and growing area currently for analysis of medical images. Segmentation of polyp images is a huge challenge because of the variability of color depth and morphology in polyps throughout colonoscopy imaging. For segmentation, in this work, we have used a dataset of images of the gastrointestinal polyp. The algorithms used in this paper for segmentation of gastrointestinal polyp images depend on profound deep convolutional neural network architectures: FCN, Dual U-net with Resnet Encoder, U-net, and Unet_Resnet. To improve the performance, data augmentation is performed on the dataset. The efficiency of the algorithms is measured by using metrics such as Dice Similarity Coefficient (DSC) and Intersection Over Union (IOU). The algorithm Dual U-net with Resnet Encoder obtains a higher DSC of 0.87 and IOU of 0.80 and beats the other algorithms U-net, FCN, and Unet_Resnet in segmentation of gastrointestinal polyp images.

Keywords—Segmentation; Medical Images; Deep Convolutional Neural Network; FCN; U-net; Unet_Resnet; Dual U-net with Resnet Encoder

I. INTRODUCTION

Image segmentation is one of the most widely and effectively used techniques for image analysis. Image analysis is a method of extracting data from images by analyzing the features within an image. There are a variety of image processing techniques that are used for image analysis, including edge detection, image preprocessing, and image segmentation[1]. The fundamental purpose of image processing is to improve the image or extract relevant information from the images[2]. Segmentation is a crucial yet challenging aspect of image processing for image analysis. Image segmentation techniques are now evolving in a faster and more precise approach[3]. Segmentation is the technique of splitting digital images into several segments to improve image quality.

Segmentation of medical images, as an emerging medical image processing method, has made a significant contribution to long-term medical treatment. For analysis of images in medical, segmentation is performed to locate the area of interest[4]. Before an illness could be diagnosed, medical images must go through numerous processes. Initially, images are gathered, then the pre-processing is performed and after that data must be stored in memory. That demands a significant memory space and a processing time. It is required to process images in medical applications in order to find relevant information[5].

Polyps in the gastrointestinal are abnormal growths of cells in the stomach and colonic mucosa. This abnormal growth occurs gradually and, in most instances, it does not create symptoms till it achieves a significant magnitude[6]. One of the most common causes of gastroenterology is a polyp, which could develop into colorectal cancer[7]. Nonetheless, cancer is preventable and treated, if polyps are diagnosed early[6]. Segmentation of gastrointestinal polyps is a challenging process because of the variation in color intensity and form of gastrointestinal polyps in colonoscopy images. Various techniques have been developed in order to achieve accurate segmentation[8].

In this work, we have applied Deep Convolutional Neural Network algorithms including Dual U-Net with Resnet encoder, U-Net, Unet_Resnet, and FCN to do segmentation on the images of gastrointestinal polyps gathered from the dataset of 'Kvasir-SEG'. The performances are evaluated by using the metrics: Dice similarity coefficient and Intersection over Union. Also, the comparison of these algorithms of segmentation is performed on the bases of metrics.

The rest of the paper is structured as follows: Section II discusses the works related to our study; Section III gives overview of architecture of Dual U-Net with Resnet encoder; Section IV explains the design of methodology for this work; Section V presents the result and discussion; Section VI gives conclusion and presents the future work.

II. RELATED WORK

Medical images are crucial and assume a fundamental part in monitoring and diagnosing the status of a patient's wellbeing[9]. For clinical investigation, diagnosis, and treatment planning, medical imaging including X-Rays, Computed Tomography (CT), Positron Emission Tomography (PET), Ultrasound, and Magnetic Resonance Imaging (MRI) are utilized to provide a clear depiction of the interior of the body[10]. The use of medical imaging techniques has expanded in recent years as a result of technological advancement[11]. Medical images have rich properties, these are images that include a massive amount, high resolution, and complicated features[12]. These medical images are utilized and saved for diagnostic and research purposes on a regular basis[13].

Image analysis is described as a process of extracting quantitative information from images by measuring objects within them. Image analysis has proven particularly valuable for industrial and scientific applications due to its capacity to

*Corresponding Author.

process digital images and objectively analyze parameters such as distance, size, color, number of particles, and so on without affecting the sample[14]. For image analysis, the major image processing approaches used are pre-processing, edge detection, compression, and segmentation. Pre-processing of images often entails eliminating low-frequency background noise, leveling the intensity of individual particle images, and erasing or improving data images before the computational processing. Image compression is a type of data compression in which the original image is encoded with a few number of bits The aim of image compression is to eliminate the image redundancy and store or transmit data in a more efficient manner[1]. Edge detection is a technique for detecting the boundaries of objects or regions that are closely related. The discontinuity of the object is identified using this technique. The edge detection technique is mostly used in image analysis to identify areas of an image where there is a large fluctuation in intensity[15]. Image segmentation is one of the primary phases of image processing where each image is partitioned into several parts, each of which contains some type of information[16].

Image segmentation is an important step in analyzing an image. Image segmentation is the first step in analyzing and extracting information from images[17]. Image segmentation is an image processing technique that partitions an image into contiguous parts[18], that is commonly used to detect objects and borders in images such as lines, and curves[19]. The various segmentation techniques for image segmentation are edge detection, thresholding method, region-based segmentation, clustering-based segmentation[20], and deep neural network-based segmentation[21]. Segmentation of medical images is an essential phase in the examination and evaluation process. For medical images, segmentation is performed to identify and extricate characteristic regions. The purpose of the segmentation of medical images is to identify the tumor location, detect the lesion and other abnormalities, help in treatment planning prior to radiation treatment[22], and help in improving the quality of medical images[4].

Banerjee, et al. [23], proposed an algorithm that clusters pixels into four sections depending on their intensity. This approach employs a thresholding mechanism with one global threshold and two local thresholds. The new aspect of this procedure is the automated establishment of three thresholds based on inherent features of the image. The global threshold is calculated by comparing the neighborhood of the image's localized parts. The global threshold divides pixels into two sets of groups, which are then used to determine the local thresholds. For evaluation of the efficiency of the proposed algorithm, the resulting images are compared to Berkeley's dataset benchmark image. The results are visually examined to determine the region identified by the proposed algorithm. All the regions mentioned in the benchmark images are successfully identified by the proposed algorithm.

Cao, et al. [24], proposed an algorithm for segmentation of the sequence of CT images of the whole heart. They have developed two improved segmentation algorithms based on traditional region-based and edge-based segmentation algorithms and then the improved algorithms are implemented

to the whole heart CT sequence images for segmentation. The evaluation of the proposed segmentation algorithm is based on three features in this study: the algorithm's efficiency, subjective evaluation of whole heart image segmentation, and the deviation method, in which the Jaccard and Dice coefficients are used to evaluate the segmentation results of the whole heart CT images. The results of the two improved segmentation algorithms are contrasted with the manual segmentation results, the improved algorithms of segmentation demonstrate superior efficiency in terms of reliability and accuracy of CT image segmentation of the whole heart.

Substantial advancement has been accomplished in recent years in establishing more productive and precise segmentation algorithms for the medical image in machine learning[25]. The machine learning field has been overpowered with a variety of deep learning-based techniques. Deep learning-based techniques such as Recurrent Neural Networks (RNNs), Artificial Neural Networks (ANNs), and Convolutional Neural Networks (CNNs) are efficient in image segmentation[26]. Convolutional Neural Network (CNN) works well on medical image challenges, convolutional plays an important role in performance in CNN in image analysis techniques such as segmentation and classification[4]. In a deep neural network, Convolutional Neural Network has several architectures. AlexNet, VGG, FCN, SegNet, Resnet, and U-Net are some of the architectures of Convolutional Neural Networks[27]. AlexNet, VGG, and Resnet are widely regarded as the most prevalent architecture that successfully performs image classification and image recognition tasks[28].

A Fully Convolutional Neural Network (FCN) is a segmentation method that can make a prediction on the bases of pixel-by-pixel using the image's ground truth and directly output the label map. The objective of FCN is to extract significant feature maps and restore them to the labels of the image. The capability to identify features is the fundamental cause of FCN's effectiveness in image segmentation, object detection, and classification. FCN can function effectively only if a sufficient amount of training datasets is accessible. Data gathering is costly in the realm of medical imaging. Furthermore, there are several other aspects that affect data availability, such as privacy, regulation, and ethical concerns[29]. Without enough availability of dataset, FCN provides less accurate results[30] and results in inaccurate segmentation of small organs[31]. As a consequence, FCN has been enhanced to U-Net in order to conduct medical image segmentation, which performs effectively with a relatively small amount of training dataset[29]. SegNet is another architecture of CNN for the segmentation task of images, this architecture has significant features of memory and efficient performance[32]. However, during the training phase, U-Net exhibits a faster processing speed[33], and also U-Net performs better compared to the SegNet[34].

U-Net is among the most widely used architectures of deep Convolutional Neural Networks for segmentation tasks of medical images[35]. The downsampling (contracting path), and the upsampling (expensive path) are the primary components of the U-Net network[36]. The U-Net architecture is shown in Fig. 1.

Fig. 1. The architecture of U-Net [37].

Fig. 1 depicts the architecture of U-Net which comprises of a contracting path/downsampling (left side) and an expansive path/upsampling (right side). The convolutional network design is followed throughout the downsampling path. It consists of two 3x3 convolutions, each of which is accompanied by an activation function, a rectified linear unit (ReLU), and a 2x2 pooling with stride 2 for downsampling. The number of channels gets doubled during downsampling. The upsampling or expansive path comprises of 2x2 convolutional that reduces the feature channels, a concatenation with the correspondingly cropped feature map from the contracting path, and it also has two 3x3 convolutional layers, each of which is trailed by Rectified Linear Unit activation function. At the final layer, a 1x1 convolutional layer is utilized to map the features to the necessary number of classes[37]. The U-Net architecture has sparked a lot of attention in medical image segmentation, and various variants have been developed based on it[31].

In [38], the authors developed a 3D U-Net, a convolutional neural network technique, for whole heart segmentation. The proposed algorithm comprises two 3D U-Net architectures, the first part of architecture locates the bounding box around the heart and the second part of architecture is to perform the segmentation. This algorithm is evaluated on 20 3D CT images. The dataset of 20 2D CT images is partitioned into two sets: 15 training images and 5 validation images. Because of less dataset, the augmentation procedure is utilized to increase the amount of dataset for training to increase the performance. The performance of the algorithm is calculated by using the Dice coefficient. The mean dice score of 89% is obtained by the proposed model for the whole heart segmentation.

In [39], the authors proposed a U-net segmentation architecture for the CT images of lungs. The dataset presented includes lung cancer thoracic computed tomography (CT) scans with depicted lesions. For the ground truth, manual segmentation for lung parenchyma was performed prior to the experiment. Cropping of images is conducted after manual segmentation to remove details that are not relevant for their analysis. The network’s performance is evaluated by the dice

coefficient index. They have achieved a 0.9502 dice coefficient for the segmentation.

III. ARCHITECTURE OF DUAL U-NET WITH RESNET ENCODER

The architecture of Dual U-Net with Resnet encoder is illustrated in Fig. 2.

Fig. 2. Architecture of dual U-Net with resnet encoder.

Fig. 2 depicts the architecture of Dual U-Net with Resnet encoder. This architecture consists of two U-net: U-NET 1 and U-NET 2, and an encoder Resnet_50 sub-network. In U-NET 1, the application of Resnet_50, ASPP, and decoder block differentiates the Dual U-Net with Resnet encoder from U-Net. An element by element multiplication is carried out between the results of U-NET 1 with the input of the same network. In U-NET 2, the main distinction between U-Net and Dual U-Net with Resnet encoder is the use of ASPP. The first encoder in Dual U-Net with Resnet encoder purposes pre-trained Resnet_50, while the encoder in U-NET 2 was created from the beginning. The encoder U-NET 2 performs two 3x3 convolution operations, each of which is followed by a batch normalization. An activation function Rectified Linear Unit (ReLU) is applied, which is accompanied by a squeeze and excitation block, significantly improving the integrity of the feature maps. Max-pooling is applied after that with a stride2 and 2x2 window to minimize the spatial dimension of the feature maps. In the architecture, two decoders are used in Dual U-net with Resnet encoder. In the decoder, the input feature is subjected to a 2×2 bi-linear up sampling in every block,

which increases the dimensionality of the maps of input feature. The appropriate skip connections now concatenate feature maps from the encoder with the result feature maps. Only the skip connection of the encoder in U-NET 1 is utilized in the first decoder, while the skip connection from U-NET 1 and U-NET 2 encoders is utilized in second decoder. After concatenation, two 3×3 convolution is performed again, each accompanied by batch normalization and a rectified linear unit activation function. A squeeze and excitation block is then applied. Finally, a convolutional layer is applied with a sigmoid function that produces the mask.

IV. METHODOLOGY

Fig. 3 illustrated the flowchart of the method utilized in this work. The methodology design for this work is divided into the following four stages: research design, data collection and data processing, experimental setup, and performance analysis.

A. Research Design

The first step is to measure and evaluate the previous research that has been investigated using the terms ‘segmentation’, ‘medical images’, ‘polyp image segmentation’, ‘deep convolutional neural network’, and ‘U-net’. To identify the problem statement and determine the approaches that have been used, a literature review is required. This section gives an overview of the segmentation of images and identifies the various image segmentation approaches and algorithms, along with their merits and limitations, that have been presented for medical image segmentation using deep convolutional neural networks.

B. Data Collection and Data Processing

This section explains the process for the collection of a dataset. The dataset for this study is gathered from the ‘Kvasir-SEG <https://datasets.simula.no/kvasir-seg/>’, which contains Gastrointestinal Polyp images. Once the data is gathered, every image of gastrointestinal polyps is examined for the ground truth. The dataset of gastrointestinal polyps includes 1000 images and corresponding 1000 masks.

Fig. 3. Illustrates the flowchart of the methodology.

The dataset of gastrointestinal polyp images is partitioned into a training set, a validation set, and a testing set. The training set includes 80% of a dataset which is 800 images, the validation set contains 10% which is 100 images, and the testing set contains 10% which is 100 images. Once the partition of the dataset is done, augmentation of data is performed to the 800 images of the training set, increasing the total number of images in the training dataset up to 13600. For this work, we have used four algorithms of the deep convolutional neural network: Fully Convolutional Network (FCN), U-net, Unet_Resnet, and Dual U-net with Resnet encoder to illustrate the segmentation of an image dataset.

C. Experimental Setup and Performance Analysis

This experiment is conducted on RTX 2060 GPU with 6 GB of RAM, and python 3.9 software framework with Tensor flow 2.5. All the segmentation algorithms used in this work are trained for 50 epochs.

Image segmentation algorithms such as Unet_Resnet, FCN, U-net, and Dual U-net with Resnet encoder will be compared on the basis of performance. The performance of these algorithms for image segmentation is measured by using the Intersection over Union (IOU), and Dice Similarity Coefficient (DSC).

V. RESULT AND DISCUSSION

The dataset from the ‘Kvasir-Seg dataset’ of a Gastrointestinal Polyps includes 1000 images of polyps and corresponding 1000 masks. Dataset is partitioned into 80% (800 images) of the training set, 10% (100 images) of the validation set, and 10% (100 images) of the testing set. After the dataset partitioning, data augmentation is implemented to the 800 images of the training set, which increases the dataset of training images to 13,600 images which will help in improving the accuracy rate. After that, the algorithm for segmentation is performed on the gastrointestinal polyp dataset. In this work, we have implemented Unet_resnet, U-net, FCN, and Dual U-net with Resnet encoder to conduct segmentation on images of gastrointestinal polyps.

The performance of the algorithm for segmentation of the images on the gathered dataset is described in this work. Performance of the algorithm is evaluated by, Intersection Over Union (IOU), Dice Similarity Coefficient (DSC) Recall, and Precision. Jaccard index commonly referred to as Intersection Over Union (IOU), is utilized to quantify the percent of overlap between the predicted image and the mask image. To calculate Intersection Over Union, the formula is as follows

$$\begin{aligned} \text{IOU} &= \frac{|X \cap Y|}{|X \cup Y|} \\ &= \frac{|X \cap Y|}{|X| + |Y| - |X \cap Y|} \end{aligned} \quad (1)$$

Dice Similarity Coefficient quantifies the percentage of similarity between the predicted image and the mask image. The Dice similarity coefficient (DSC) is calculated by using the formula described below.

$$\text{DSC} = 2 \times \frac{|X \cap Y|}{|X| + |Y|} \quad (2)$$

Precision calculates the percentage between the accurate prediction and the overall prediction. The following is the precision formula:

$$\text{Precision} = \frac{\text{TRUE POSITIVE}}{\text{TRUE POSITIVE} + \text{FALSE POSITIVE}} \quad (3)$$

The quantity of predictions that the algorithm predicted accurately is True Positive, and the total number of predictions is calculated by the formula's denominator.

Recall describes the number of accurate predictions to total observations made by the algorithm. The following is the recall formula.

$$\text{Recall} = \frac{\text{TRUE POSITIVE}}{\text{TRUE POSITIVE} + \text{FALSE NEGATIVE}} \quad (4)$$

True positive is the number of accurate predictions which is recognized by the algorithm, the formula's denominator shows the true positive as well as the number of positives that the algorithm falsely predicted as negative.

A. Results

The deep convolutional neural network algorithms: Dual U-net with Resnet encoder, Unet_Resnet, U-net, and Fully Convolutional Network (FCN) are used in this work to do the segmentation of the image dataset of gastrointestinal polyps. The performance of these algorithms is calculated by the Intersection over Union (IOU), and Dice Similarity Coefficient (DSC) as shown in equation (1) and equation (2) respectively. Both the metrics, Dice Similarity Coefficient and Intersection Over Union, ranges from 0 to 1. Fig. 4 illustrates a few of our results with Unet_resnet, Dual U-net with Resnet encoder, FCN, and U-net.

Fig. 4. Results of FCN, U-NET, Unet_Resnet, and Dual U-net with Resnet encoder.

Fig. 4 depicts the results of the segmentation of gastrointestinal polyp images using four algorithms. Table I shows a comparative study of the performances of these four algorithms.

Table I compares the performances of four algorithms based on Dice similarity coefficient (DSC) and Intersection over Union (IOU). As shown in the performance table FCN achieves less result than U-Net, while Unet_Resnet achieves a

better result than U-Net. Dual U-net with Resnet encoder has achieved higher DSC and IOU than the other three algorithms.

TABLE I. THE PERFORMANCE OF ALGORITHMS

Algorithm	Dice Similarity Coefficient (DSC)	Intersection Over Union (IOU)
FCN	0.8393	0.7243
U-NET	0.8528	0.7458
Unet_Resnet	0.8603	0.7570
Dual U-net with resnet encoder	0.8715	0.8042

VI. CONCLUSION

In this work, deep convolutional neural network algorithms; U-Net, FCN, Unet_Resnet, and Dual U-net with Resnet encoder, are proposed to do segmentation of images of the gastrointestinal polyp's dataset from the Kvasir-SEG. The dataset collected from Kvasir-SEG is divided into three sets that are training set, validation set, and test set. Augmentation is applied to the training dataset, which increases the number of images in the dataset, and helps to improve the performance. The performance of the four algorithms of segmentation proposed in this work is evaluated by using the Intersection Over Union (IOU) and Dice Similarity Coefficient (DSC) metrics. Dual U-net with Resnet Encoder achieved DSC and IOU of 0.8715 and 0.8042 respectively. The result of the Dual U-net with Resnet encoder is compared with the other three algorithms, FCN, U-Net, and Unet_Resnet. FCN attained a DSC of 0.8393 and IOU of 0.7243. U-Net obtained DSC of 0.8528 and IOU of 0.7458 and Unet_Resnet acquired DSC of 0.8603 and IOU of 0.7570. The comparison result clearly shows that Dual U-net with Resnet Encoder outperforms the other three segmentation algorithms for gastrointestinal polyp images. In addition, future work will concentrate on enhancing the segmentation algorithm so that more accurate results will be achieved, and segmentation will be performed on various medical image datasets.

Abstract—This study demonstrates the utilization of rapid machine learning modelling in an essential case of the real estate industry. Predicting office rental price is highly crucial in the real estate industry but the study of machine learning is still in its infancy. Despite the renowned advantages of machine learning, the difficulties have restricted the inexpert machine learning researchers to embark on this prominent artificial intelligence approach. This paper presents the empirical research results based on three machine learning algorithms namely Random Forest, Decision Tree and Support Vector Machine to be compared between two training approaches; split and cross-validation. AutoModel machine learning has accelerated the modelling tasks and is useful for inexperienced machine learning researchers for any domain. Based on real cases of office rental in a big city of Kuala Lumpur, Malaysia, the evaluation results indicated that Random Forest with cross-validation was the best promising algorithm with 0.9 R squared value. This research has significance for real estate domain in near future, by applying a more in-depth analysis, particularly on the relevant variables of building pricing as well as on the machine learning algorithms.

Keywords—Random forest; decision tree; support vector machine; rapid prediction modelling; office rental price

I. INTRODUCTION

Now-a-days, real estate is becoming more digital, automated, and integrated. The fusion of industry 4.0 and digital 4.0 includes connected buildings, wearable technology, data management for buildings and infrastructure, and smart cities. The transformation of the real estate industry was improved due to the advancement in data science technologies such as analytic technologies [1]. The analytic technologies mentioned include Computational Statistics, Artificial Intelligence (AI) and Machine Learning. Machine learning is a sub-field of AI that can learn and re-learn from data exploration and inferences. Nowadays, these analytic technologies have successfully transformed the real estate industry to discover various opportunities, particularly by developing prediction applications that involve fundamental tasks that uncover hidden patterns, unknown correlations, and preferences [2]. Despite opportunities, some challenges appeared, including gaining adequate skills instantly that involves varying knowledge of AI concepts, mathematics, programming, and computer technologies. Thus, rapid software is useful to them and at the same time benefits the

expert in accelerating the preliminary analytic tasks.

Considering real estate markets in general, office building markets are more synchronized in terms of exposure to macro-effects and performance of the real estate within the market. The heterogeneity of the office markets makes them more complex to analyse [3], [4]. It can be challenging to understand the market, for which the property's price might be determined on the market, but it may not always equate with the valuation of property in the market [5]. Office markets often relate to good investment opportunities since it draws much capital but with a substantial return [6]. Despite being a well-established investment industry, it has a highly complex market structure due to the lack of a central marketplace and the individuality of each building.

Numerous econometric models have been proposed to predict the office market performance, especially the rental property market. These include office market econometric models [5], and the hedonic regression model [6]. Sadly, limited success was achieved in finding a reliable and consistent model to predict rental property market movements over a five-to-ten-year time frame [7]. It was expected that lacking market data can be the main problem to fault the unreliability of prediction model. Based on the preliminary statistical analysis, the collected data of office rentals has a few problems of variance insufficient, imbalance with very skewed data distribution and most of them are having low dependencies to the target data (dependent variable) to be relied by the prediction model in generating high accurate results.

Acknowledging the advantages of artificial intelligence computing approach that able to learn and redevelop knowledge to self-improve the output target from the given data, the used of machine learning technique in solving issues of real estate industry has started to begin. Even with low-association dataset, machine learning with the intelligent and leaning ability, will use mathematical and heuristics projection to self-improve their performances continuously during the training stage. Despite the wider used of machine learning in various domains of problems, there is still limited work that can be found for the real estate industry. This research attempted to fill the gap by focusing on the flexible and rapid modelling machine learning approach for office rental prediction problem.

This research was funded by NAPREC under grant number 100-TNCPI/GOV 16/6/2 (027/2021).

The contributions of this paper are two-fold. First, it demonstrates the use of AutoModel RapidMiner for the office rental price prediction model as a rapid modelling in the preliminary research activities. Second, it presents a comparison of results between two machine learning training approaches (split, cross-validation) that developed with manual model in RapidMiner and provides discussion on the significant findings in the context of office rental domain.

This paper is organized as follow. The next section II presents the literature review of rapid modelling machine learning and the state-of-the-arts of research for office rentals prediction. The methodology of research is given in section II followed with the results and discussion in section IV. The last section V provides the conclusion remarks.

II. LITERATURE REVIEW

A. Rapid Modelling of Machine Learning

Rapid modelling has been a long-time concern by researchers to solve real-world problems, mainly when complex computing techniques are required. In machine learning, to support rapid modelling, several tools have been introduced, and the most popular is script programming with Python or R programming languages [7]. Although this two-scripting language is considerably easy to utilize with their built-in programming libraries, they still need some help for a non-computing expert who never learns to program.

Graphical User Interface (GUI) based rapid modelling is easier than programming to implement machine learning. To date, some of the popular rapid tools are Weka [8] and RapidMiner [9]. Automated machine learning (AML) [10], [11] is a promising module in Weka and RapidMiner. Auto-WEKA is the AML in Weka, while AutoModel is the one provided in RapidMiner. AML helps to accelerate the modelling tasks by optimizing the machine learning pipelines from the input variables (features selections) step, algorithm suitability selection and hyper-parameters optimal setting. Literature on research that used Auto-WEKA is more available than AutoModel RapidMiner. Thus, focusing on Auto-Model RapidMiner for this study can provide additional benefits to the AML scholarly, mainly to inexpert data scientists in various domains.

B. Office Rent Predictions with Machine Learning

A number of researchers have used machine learning in the real estate or property industry. Researchers in [12] presents the real estate opportunities with machine learning technique modelling. It was reported that one of the advantages of machine learning is for assisting the stakeholders in making important decisions related to commercial or office building. A significant of finding has been presented by researchers in [13] that used machine learning technique to estimate the warehouse rental price. More interesting, by utilising social media web scraping technique, the collected data were analysed with machine learning prediction algorithms and hedonic modelling to monitor the building rental prices in Shenzhen, China [14]. To ensure the development of holistic smart building control effectively, researchers in [15] have utilised deep reinforcement learning, a recent advance method of machine

learning. Internet of Things (IoT) is the main elements of smart building hence researchers in [16] introduced an algorithm named as Random Neural Network (RNN) to make used the IoT data to predict the consumption of energy of the smart building. Random Forest machine learning for forecasting shop rents in Guangzhou, China. To conduct mass appraisal in an urban residential area where commercial properties are available, researchers in [17] used multiple regression and random forest as the proposed methods. Similarly, the performances of random forest and multiple regression has been reported from the research findings in [18]. How the neighbourhood environment can influence peer-to-peer accommodation when using random forest is the finding reported in [19]. It seems that random forest is very promising, and it is also one of the suggested algorithms from AutoModel used in this research together with Decision Tree [20] and Support Vector Machine [21]. To the best of our knowledge, rapid modelling on office rental prediction has not been reported yet in the current literature. This research filled the gap by presenting the precise steps and the comparison of results.

III. METHODOLOGY

A. The Dataset

The dataset used in this study is a collection of office rentals from the year 2015-2021 in Kuala Lumpur, Malaysia. Table I shows the set of features of developing the machine learning prediction model. This study uses 21 attributes or features as independent variables for office rental prediction.

TABLE I. FEATURES OF THE OFFICE RENTAL PREDICTION MODEL

Office Rent Determinants	Description
Building Appearance and Design	Physical building appearances and Design
Building Age	Age of Building
Amenities and In-house Services	Amenities and Services Provided by the building
Occupancy	Occupancy rate
Distance to the city centre	Distance to the city centre
Building Frontage	Building allocation towards the main road
Neighbourhood Characteristics	Surrounding areas
Traffic Condition	Traffic Condition (Congested, Free)
Nearest Public Transport	Availability of Public Transport
Transaction Date	Date of Transactions
Floor Level	Rented Floor Level
Rentable Area	Area of premises being rented
Tenancy Duration	Lease duration by the tenant
Service Charge	Service Charge towards the building's occupants
Employment Rate	Employment rate by year
Inflation	Inflation by year
Gross Domestic Product (GDP)	Gross Domestic Product by Year
Finance, Insurance and Real Estate (FIRE)	Business purposes of building
Green Certificate	Green Certification of the building
MSc Status	MSc Certification of the building
Building Grade	Office Building Grading

B. Machine Learning Rapid Modelling Framework

Fig. 1 presents the rapid modeling framework used in this research. On the pre-processing data that was ready to be read in RapidMiner, AutoModel was firstly executed. The purpose of executing AutoModel is to get suitable machine learning algorithms for the dataset and the optimal hyper-parameters. The suggested machine learning algorithms are Generalized Linear Model, Deep Learning, Decision Tree, Random Forest, Gradient Boosted Trees and Support Vector Machine. The six sets of experiments can be described as listed in Table II. Table III is the optimal hyper-parameters setting suggested by the AutoModel.

Fig. 1. Machine learning rapid modeling framework.

TABLE II. DESCRIPTION OF EXPERIMENT SET

Experiment set	Algorithm	Training
1	Decision Tree	Split
2	Random Forest	Split
3	Support Vector Machine	Split
4	Decision Tree	CV
5	Random Forest	CV
8	Support Vector Machine	CV

TABLE III. ALGORITHMS SELECTION AND OPTIMAL HYPER-PARAMETERS

List of Algorithms	Maximal Depth	Number of Trees	RBF	C	Error Rate
Decision Tree	15	NA	NA	NA	10.7%
Random Forest	20	7	NA	NA	26%
Support Vector Machine	NA	NA	0.050	1000	43.5%

As listed in Table III, the lowest error rate for the Decision Tree can be achieved for the office rental dataset if the maximal depth of the tree is 15. maximal depth defines the maximum level of the tree minus 1. AutoModel has identified that the worst error rate was achieved if the maximal depth was set to 2. Random Forest has additional hyper-parameters as it is an advancement of Decision Tree. Besides maximal depth, Random Forest has number of trees. Imagine a forest that consists of more than one tree. AutoModel suggested that the optimal values for the number of trees and maximal depth were 20 and 7, respectively. The worst error rate achieved was 42.9% at 140 trees and two maximal depths. Support Vector Machine has Radial Basis Function (RBF) Kernel and C value. The C parameter instructs the SVM optimization to avoid misclassifying each training example. The kernel function is used to transform the data, increasing its dimensional. This enhancement causes the data to be split with a hyperplane with a significantly greater probability and establishes a minimal prediction probability error measure [22]. The configuration of optimal parameters suggested by Auto Model for the Support Vector Machine algorithm is at RBF = 0.050, C = 100, and 43.5% error rate.

C. Training Approaches

AutoModel used a split training approach that allowed the researcher to look at another training approach, namely the cross-validation approach. Therefore, based on the AutoModel findings, manual machine learning modelling in RapidMiner was developed to compare the three machine learning algorithms with the optimal setting but with different training approaches; split and cross-validation (CV). Fig. 2 presents the RapidMiner process for split training, while Fig. 3 presents the CV approach.

Fig. 2. Split approach.

The “Split Data” operator is a custom operator for splitting a dataset into training and testing datasets [23]. To configure the parameter in the split approach, the researcher will specify the ratio of all partitions. The sum of all partitions’ ratios should be equal to 1. As for this study, the 0.8:0.2 ratio was used for setting the partitions. Therefore, the training and testing datasets constructed from the original dataset were 80% and 20% of the data, respectively. The next step is to include the algorithms in the office rental price prediction model by connecting all nodes from the chosen parameters.

Fig. 4, Fig. 5 and Fig. 6 present the manual modelling process for the tree algorithms with split training. The Split Data operator can be changed to Cross Validation operator for implementing CV on each model.

Fig. 3. Cross-validation approach.

Fig. 4. Decision tree with split training.

Fig. 5. Random forest with split training.

Fig. 6. Support vector machine with split training.

D. Performances Metric

In developing the office rent prediction model, this study deployed two (2) performance measurements, namely the Coefficient of Determination “R²” and “Root Mean Square Error”. R-Squared is a statistical metric that indicates the

proportion of the variation explained by the independent variables for the dependent variable. The greater the R-squared, the better the model matches the dataset under consideration. R-Squared may be calculated mathematically as Equation (1).

$$R^2 = 1 - \frac{\sum(y_i - \hat{y})^2}{\sum(y_i - \bar{y})^2} \quad (1)$$

The metric of root means square error (RMSE) is a common way to calculate a model’s error in quantitative data prediction. *E* is no absolute good or bad error level but can be identified based on the dependent variable. Generally, the range from 0 to 1000 is classified as small, but if the range is from 0 to 1, it is classified as no longer being small. In evaluating the model, the smaller the value of the root mean square error the better the model has produced [24]. Equation (2) is to calculate root means square error.

$$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (y_i - \hat{y}_i)^2} \quad (2)$$

IV. RESULTS AND DISCUSSION

A. Machine Learning Prediction Results based on Split Approach

Table IV compares the prediction results generated by the three different algorithms using the split approach. The “observed value” indicates the actual value/the raw rental data acquired. The prediction value indicates the value generated after considering the optimal parameters, processes, and factors involved.

TABLE IV. SPLIT-DATA PREDICTION RESULTS

Observed Value	Prediction		
	Decision Tree	Random Forest	Support Vector Machine
RM24.53	RM29.20	RM42.67	RM37.50
RM27.55	RM31.89	RM34.60	RM37.57
RM24.58	RM35.47	RM27.37	RM41.53
RM19.85	RM22.42	RM43.09	RM43.80
RM21.37	RM35.47	RM29.06	RM41.58
RM21.98	RM32.45	RM26.52	RM39.48
RM76.84	RM77.47	RM73.72	RM63.35
RM28.00	RM28.72	RM37.16	RM34.77
RM29.85	RM23.97	RM35.37	RM41.99
RM21.37	RM36.28	RM28.44	RM38.78

An extensive result of the prediction with details is provided in the prediction chart, as shown in Fig. 4, 5 and 6. The prediction chart depicted in Fig. 4 to 6 was analysed from the triangle patterns and the diagonal line. The diagonal line indicates the real data/actual office rent values while the triangle patterns indicates the prediction generated by the algorithms used in this study. The accumulated pattern at the diagonal line shows a good prediction. In contrast, the deviated pattern from the line showed less accuracy in predicting the rent and was considered a prediction outlier. The illustrated chart demonstrated that Random Forest (Refer Fig. 8) provides the best predictions can be seen through the

high accumulation of the triangle patterns to the diagonal line. In comparison, Decision Tree algorithms also provide a good prediction, as illustrated in Fig. 7. The prediction chart for Support Vector Machine, however, depicts scattered triangle patterns which indicate high frequencies of outliers when predicting office rents, as seen in Fig. 9. To justify Random Forest algorithms as the best predictor, this study employed another approach in Machine Learning called Cross-Validation.

B. Machine Learning Prediction Results based on CV Approach

Table V lists some of the prediction results generated by each algorithm using the CV approach. An extensive result of the prediction with details is provided in the prediction charts, as shown in Fig 10 to 12.

TABLE V. CROSS-VALIDATION PREDICTION RESULTS

Observed Value	Prediction		
	Decision Tree	Random Forest	Support Vector Machine
RM24.53	RM29.20	RM46.34	RM22.42
RM27.55	RM31.89	RM34.89	RM39.57
RM24.58	RM35.47	RM31.37	RM41.53
RM19.85	RM22.42	RM43.09	RM35.47
RM21.37	RM35.47	RM29.06	RM41.58
RM21.98	RM32.45	RM26.52	RM39.48
RM76.84	RM77.47	RM73.72	RM63.35
RM28.00	RM28.72	RM37.16	RM34.77
RM29.85	RM23.97	RM35.37	RM28.72
RM21.37	RM36.28	RM23.97	RM38.78

Fig. 7. Prediction chart of decision tree (split).

Fig. 8. Prediction chart of random forest (split).

Fig. 9. Prediction chart of support vector machine (split).

Fig. 10. Prediction chart of decision tree (CV).

Fig. 11. Prediction chart of random forest (CV).

Fig. 12. Prediction chart of support vector machine (CV).

The prediction charts of each algorithm with the CV approach demonstrate that Random Forest provides the best predictions can be seen through the high accumulation of the triangle patterns to the diagonal line. In comparison, Decision Tree algorithms also provide a good prediction, as illustrated in Fig. 4. However, the prediction chart for the Support Vector Machine depicts scattered triangle patterns, which indicate high frequencies of outliers when predicting office rents.

C. Performances Comparisons

Table VI compares the performances of each algorithm concerning the training approaches. Overall, the result shows that the CV approach provides better results with a higher R² correlation value and lower RMSE value than the split data approach. The Random Forest algorithm outperformed other algorithms regarding office rental price prediction value. It has generated the most accurate prediction compared to the decision trees and support vector machine. The accuracy of prediction generated by random forest was supported through the observation of the RMSE value. The lowest RMSE values generated by random forest justified a lower error rate when predicting a model evaluation; the smaller the value of root means square error, the better the model produced.

TABLE VI. MACHINE LEARNING ALGORITHMS COMPARISONS

Algorithms	Split		CV	
	R ²	RMSE	R ²	RMSE
Decision Tree	0.852	80.663	0.876	61.294
Random Forest	0.883	75.695	0.906	51.859
Support Vector Machine	0.479	155.465	0.725	120.738

V. CONCLUSIONS

This paper presents the review and findings of using machine learning algorithms for real data of office building rent in Bandar Kuala Lumpur, Malaysia. The rigorous steps for rapid machine learning models initiated with AutoModel preliminary findings were given in this paper. The suggested setting from AutoModel has been used to improve the machine learning by using the suggested split training with cross-validation technique. The performances of all machine

learning algorithms can be improved with the cross-validation technique. However, the findings from this study are limited to the tested datasets and therefore require further investigation for different types of problems. Notably, this study provides new knowledge on the application of machine learning in analyzing real estate data, particularly on rental values of the office building. By exploring the machine learning methods, this study will greatly assist future research in solving problems involving prediction and forecasting real estate data.

Abstract—Due to the linked various matching categories, news article categorization are a rapidly increasing field of interest in text classification. However, the low-reliability indices and ambiguities related to frequently used province classifiers restrict success in this field. Most of the existing research uses traditional machine learning algorithms. It has weaknesses in training large-scale datasets, and data sparseness often occurs from short texts. Therefore, this study proposed a hybrid model consisting of two models, namely the news article classification and the outlier detection model. The news article classification model used a combination of two deep learning algorithms (Long Short-Term Memory dan Convolutional Neural Network) and outlier classifier model, which was intended to predict the outlier news using a decision tree algorithm. The proposed model's performance was compared against two widely used datasets. The experimental results provide useful insights that open the way for a number of future initiatives.

Keywords—News article classification; machine learning; outlier detection

I. INTRODUCTION

Digital or online news is a form of contemporary news where editorial content is distributed over the internet as opposed to published via print or broadcast. News or information contained in online news portals allows errors to occur in grouping/classifying news. For example, news is categorized in the infotainment category, while based on the content of the news or the words contained in it, the news should be categorized in the politics category. Journalists and news monitoring companies (media monitoring companies) often face problems identifying topics in a very large number of news articles around the world [1]. Errors in categorizing or classifying information/news can also occur because the method used is still manual by reading the entire article to find the main topic. This method requires large resources and requires the reader's ability to extract the topic of a news/information document [2]. This fact shows a discrepancy between the news category (or context) and the news content, or the meaning discussed or the news topic (as content) in categorizing or classifying news.

The increase in online news makes it difficult for internet users to access the content they are interested in, so it is necessary to classify news (text) so that it is easily accessible [3]. Coupled with the ever-growing volume of news corpus on the World Wide Web (WWW), it also creates problems in text classification, especially news article classification [4].

Readers can receive much information on the online news portal. Sometimes, they take it for granted without any selection of information. On that basis, much of the current information media classifies the categorization before dissemination to the general public. This classification is useful to make it easier for people to find the desired information. The classification of news articles often suffers from ambiguity due to the various categories that fit and the weak reliability performance of most classification systems used, resulting in low efficiency [5]. Therefore, automatic news (text) classification needs to be developed because manual work is no longer effective. If it is done automatically, people will not be asked to think about which category the news belongs to [2]. The ability to classify texts (news) into certain categories is very helpful in dealing with information overload [6]. Multilabel text classification is an activity to categorize text into one or more categories [7].

Recurrent Neural Network (RNN) is one of the most popular architectures used in Natural Language Processing (NLP) because the recurring structure is suitable for processing text with long variables [7]. Meanwhile, the Long Short-Term Memory (LSTM) was developed to solve the exploding and vanishing gradient problems that can be encountered during traditional RNNs training. Classification of online news texts using LSTM was utilized in this study because the LSTM structure is a complete series or cannot be cut since cutting text document structure changes the meaning of the sentence. Word embedding was used as an input feature in the LSTM before classifying the text. Apart from RNN/LSTM, Convolutional Neural Network (CNN) has also achieved excellent results in the NLP field. CNN can be combined with word vectors in topic classification and semantic analysis to achieve good results [8]. The CNN input matrix only extracts the word vector matrix from the word detail level and ignores the overall semantic feature expression from the text breakdown level, which leads to an incomplete representation of text features and can affect the accuracy of text classification [9].

This study aims to evaluate how extractive summary of the text (news content) and context (similarity of words and relationships between words) can help filter important information from the text either for readers or consumption models in classifying online news in English. The word embedding method is used to represent words in vector space in content-based and context-based representations. The method used in content-based representation is Latent

Semantic Analysis (LSA) and Singular Value Decomposition (SVD), while in context-based representation, the technique used is Word2Vec. In addition to the classification performance of news articles, outlier detection is also the focus of this research since outlier detection is very closely related to the text classification process [10]. Outliers are abnormal patterns or events that do not match the expected events or patterns [11]. Outlier detection is used to detect news that does not fit the category of news articles. The research results are expected to be used by news management agencies on online news portals to classify news articles according to their categories and filter or block if they are found to contain outliers. In addition, automatic news/information categorization is very important for handling multi-label news article classification in online portals [6].

The remainder of this work is structured systematically. The second section provides brief overviews of text classification (or news article categorization) approaches. The research approach for the experiments is presented in Section III. The outcomes of the experiments are reported in Section IV, while the conclusion is presented in Section V.

II. RELATED WORKS

Relevant research related to text classification has been carried out in previous studies in accordance with the process of classifying texts or online news articles, including:

- The research of Stein et al. [12] analyzed presentation text (i.e., GloVe, word2vec, and fastText) with a combination of classification models (i.e., fastText, XGBoost, SVM and CNN) for hierarchical text classification (HTC) using the RCV1 dataset. The analysis results showed that fastText was a classification method that provided very good results as word embedding, although the amount of data provided was relatively small. The precision, recall and F1 measure values were 0.920, 0.922, and 0.920, respectively. In contrast, our study focuses on deep learning to classify news articles based on their categories and machine learning for outlier detection.
- Shao et al. [13] experimented with the word2vec and doc2vec features for a clinical text classification task and compared the results with the traditional bag-of-words (BOW) feature. Learning showed that the word2vec feature performed better than the BOW-1-gram feature. In combination sets that were larger than six modalities (i.e., acupuncture, biofeedback, guided imagery, meditation, tai-chi and yoga), BOW-1,2-gram had better performance compared to the other feature extraction, with an area under curve (AUC) value of 0.91 and an accuracy of 0.85 specifically for the guided imagery. Meanwhile, in the smaller individual modality set, word2vec performed better compared to the other feature extraction, with AUC values between 0.80-0.93 and accuracy values between 0.82-0.86. The dataset used by Veterans Affairs (VA) electronic medical records (EMR) was stored in the Veterans Administration Informatics and Computing

Infrastructure (VINCI) database. In contrast, this research only utilized word2vec in feature extraction.

- Research by Yan et al. [14] proposed the LSTM2 model for document classification consisting of repLSTM for the adaptive data representation process and rankLSTM for the integrated learning ranking process. In repLSTM, the supervised LSTM was used to study document representation by inserting label documents. In rankLSTM, the order of document labels was rearranged according to the semantic tree, where the semantics were compatible with and conformed to LSTM sequential learning. The word embedding used was BoW, and the dataset was taken from Bio (10C), email and News. The model achieved F1 Measure results of less than 75% in document classification tasks [14]. Meanwhile, the research in the article builds the news article classification model using LSTM+CNN.
- Gao et al. [9] proposed a text feature that combined the word2vec neural network model and the Latent Dirichlet Allocation (LDA) document topic model. Word2Vec and LDA represented the matrix model. The feature matrix was entered into a CNN for convolution pooling, and text classification experiments were performed. The experimental data come from the Sogou corpus text classification lab with 8,000 documents from sports, military, tourism, finance, IT, real estate, education, entertainment, and eight categories of 1000 experiments. The experimental results suggested that the proposed matrix model had a better classification effect than the traditional text classification method based on word2vec and CNN. At the level of text classification accuracy, the recall rate and F1 of the three evaluation indicators increased by 8.4%, 8.9% and 8.6% [9]. The similarity between the previous and current studies is that both use Word2Vec and LDA in feature extraction.
- Other research conducted by Yuan et al. [15] proposed a weighted word2vec, adding an attention mechanism to the LSTM model for emotion classification. After the text information was encoded into the word vector by word2vec, the weight matrix was combined with TFIDF to form the LSTM input. The dataset used is English data set and Chinese data set. The English dataset is an IMDB film review set consisting of 25,000 movie data, positive and negative values of 12,500 texts each. The Chinese dataset was collected from the hotel review corpora (Chn Senti Corp.) with 6000 data where the positive and negative values were 3,000 texts each. The experimental results showed that this method had a precision, recall and F1 measure of 0.87, respectively [15]. In contrast, the research in the article builds the news article classification model using LSTM+CNN.
- Subsequent research by Wang et al. [14] investigated label embedding for text representation and proposed a label-embedding attentive model. The model

embedded words and labels in the same merged space and measured the compatibility of word-label pairs to attend to document representation. The learning framework was tested on five datasets (i.e., AGNews, Yelp Review Full, Yelp Review Polarity, DBPedia and Yahoo! Answers Topic) and clinical text applications. The investigation results indicated that the proposed LEAM (Label-Embedding Attentive Model) algorithm required much lower computational costs, and achieved better performance compared to CNN, LSTM, Simple Word Embeddings-based Models (SWEM) and bi-directional blocks self-attention network (Bi-BloSAN). Following predictive performance [16], F1 and micro mean area was 0.91 and macro average was 0.88 under the ROC (AUC) curve, and precision at n (P@n) was 0.61. In contrast, the research in the article builds the news article classification model using LSTM+CNN. The similarity between the previous and current studies is the use of ROC (AUC) curve to evaluate the model.

- Sun & Chen [17] designed a short text classification method based on word vectors and the proposed LDA topic model by considering the combined weighting factors of grammatical categories and high frequency topic words. In this method, Gibbs sampling was used to train the LDA topic model based on the weight of the part of speech. The model was exercised using the word vector *Wor2vec* and vectorized with high frequency topics. Then, the extended text feature was tested. After expanding the feature, the SVM algorithm was used to classify the extended short text, and the classification results were evaluated using Precision (83.6), F1-score (84.4), and recall (85.4). The dataset was taken from the news corpus provided by Sogou Lab, which consisted of a total of 6,000 titles after being extracted, divided into six categories: computer, health, sports, tourism, education and military. Each category had 1000 essays, which was less than 200 words and belonged to text data short [17]. The similarity between the previous and current studies is that both used *Word2Vec* and LDA in feature extraction, but the algorithm used in classification was different.
- Xu et al. [18] proposed a new topic-based skip-gram neural language model to study topic-based word embedding for indexing biomedical literature with CNN. Topic-based skip-grams utilized textual content with topic models, for example, LDA, to capture topic-based precise word relationships and then integrated them into distributed word embedding learning. The combination of topic-based Skip-grams and multimodal CNN architecture outperformed advanced methods in indexing biomedical literature, annotating clinical records, and general textual dataset classification. The performance of the model was measured using the F1 score with a value of 82.7% [18]. In contrast, the research in the article builds the news article classification model using LSTM+CNN.
- In this study, we present a new active learning method for text categorization. The main goal of active learning is to reduce labeling effort without compromising classification accuracy by intelligently choosing which samples to label. The proposed method selects an informative sample set using the posterior probabilities provided by a set of multi-class SVM classifiers, and these samples are then manually labeled by an expert. The datasets used are public datasets in the text category (TC), namely Reuters-21578 document (R8), 20ng dataset and WebKB collection. Word embedding used was TFIDF. The accuracy of each dataset varies where R8, 20ng and WebKB had values of 83.33%, 43.79% and 53.07%, respectively [19].
- Verma [3] compared four very prominent algorithms for news classification, namely Naïve Bayes (NB), SVM, Random Forest and Multi-layer Perceptron (MLP) Classifier. Compared to the other approaches, Naïve Bayes is likely to be a better approach to serve as a text classification model because of its homogeneity. The paper proposed news classification by comparing four classifiers in which several different types of news have been classified, such as business & finance, sports, politics & policy, criminal justice, and health [3]. In contrast, the research in the article builds the news article classification model using LSTM+CNN.
- Next, Azan et al. [20] analyzed the performance of the classification algorithm using the Scopus dataset. In text classification, classification and feature extraction from documents using the extracted features were the main problems in reducing performance of different algorithms. The performance of classification algorithms such as NB and K-Nearest Neighbor (K-NN) showed a better improvement using Bayesian boost and bagging. Data preprocessing and cleaning steps were induced on the selected data set, and class imbalance issues were analyzed to improve the performance of the text classification algorithm. The overall accuracy of NB and KNN was 71.11% and 78.67%, respectively. The experimental results showed that KNN's performance was better than NB's [20]. Our study builds the news article classification model using LSTM+CNN, while the previous research builds the model using a machine learning algorithm.
- Wongso et al. [2] analyzed the suitable algorithm to classify news articles in Indonesian automatically. The dataset was retrieved using a web crawling method from www.cnnindonesia.com. The document first underwent several text preprocessing methods (i.e., lemmatization and stop word removal), followed by applying feature selection (i.e., term frequency-inverse document frequency (TF-IDF) and singular value decomposition (SVD) algorithms) and classification algorithms for Multinomial Naive Bayes, Multivariate Bernoulli Naive Bayes, and Support Vector Machine. The test results suggested that the combination of TF-IDF and Multinomial Naive Bayes Classifier gave the

highest results compared to the other algorithms, with a precision of 0.9841519 and a recall of 0.9840000. The results outperformed previous similar studies that classified Indonesian-language news articles with an accuracy of 85% [2]. The previous research builds the model using a machine learning algorithm, while the current study builds the news article classification model using LSTM+CNN.

- Fagbola et al. [4] evaluated the accuracy and efficiency of the computational time of Kolmogorov Complexity Distance Measure (KCDM) and Artificial Neural Network (ANN) for large-dimensional news article classification problems. Dataset used by British Broadcasting Corporation (BBC) News. The dataset consisted of 2225 news articles in five categories: politics (417), sports (511), entertainment (386), education and technology (401) and business (510). Porter's algorithm was used for words stemming after tokenization and deletion of stop words, and Normalized Term Frequency-Inverse Document Frequency (NTF-IDF) was adopted for feature extraction. Experimental results showed that ANN performed better in terms of accuracy while KCDM produced better results than ANN in terms of computational time efficiency [4]. The similarity of the previous study with the current study is that both utilized BBC dataset to evaluate the model. Nevertheless, the algorithm used in the feature extraction is different.
- Sunagar & Kanavalli [21] dealt with the complexities involved in the text classification process. The experiment was carried out with the implementation of the RNN+LSTM+Gated Recurrent Unit (GRU) model. This model was compared with RCNN+LSTM and RNN+GRU. The model was tested using the GloVe dataset. The accuracy and recall obtained from the models were assessed. The F1 score was used to compare the performance of the two models. The hybrid RNN model had three LSTM layers and two GRU layers, while the RCNN model contained four convolution layers and four LSTM levels, and the RNN model contained four GRU layers. The weighted average for the hybrid RNN model was found to be 0.74, RCNN+LSTM was 0.69, and RNN+GRU was 0.77. The RNN+LSTM+GRU model showed moderate accuracy in the initial epoch, but the accuracy slowly increased as the epoch increased. In contrast, the research in the article builds the news article classification model using LSTM+CNN.

Several related studies (review papers) on text classification suggest that machine learning algorithms are generally used for text classification combined with word embedding models. Text classification using a deep learning method that combines RNN/LSTM and CNN is still limited. In this study, we proposed a hybrid modeling (RNN/LSTM + CNN) with a word embedding feature (i.e., Word2vec + LSA/SVD) for news text classification and coupled with a model for outlier detection using machine learning algorithms, especially the decision tree algorithm.

III. METHODOLOGY

The hybrid model developed in this study consisted of two models, namely a classification model using a deep learning algorithm (i.e., RNN/LSTM+CNN) and an outlier detection model using a machine learning algorithm (i.e., decision tree). LSTM-CNN was used to classify news articles based on Word2Vec-based context and LSA/SVD-based content. The outlier detection model was intended to predict which news was an outlier. Before the dataset was ready to be used for modeling, the dataset needed to be processed in several stages, such as text processing, data sharing into training and testing data, and feature extraction (word embedding) contained in news texts. After the data was ready to be used, the data was used for model training, which was then employed for data testing to validate the prediction results of the two models. In general, the hybrid model developed is presented in Fig. 1.

Fig. 1. Hybrid model framework

The classification results from the LSTM+CNN model was used as input in the outlier detection process. There would be errors (outliers) from the classification results generated by the model. For example, if a news item had topic A, the model might predict the probability that the news would be classified as topic B. Specifically, the use of the term “topic” in the research referred to content. Later, each news item would be labeled as an outlier or not an outlier. Furthermore, if topic A is at number 0.4, then there will be an error of 0.6. Once the error calculation result was obtained, the root mean square error (RMSE) for the entire dataset could be calculated. Sample/raw data that had an error of more than the RMSE would be categorized as an outlier. The outlier labeling enabled us to build an outlier classification model.

A. Text Preprocessing

The stages of text preprocessing news articles from raw data to ready-to-use data consisted of four stages (as presented in Fig. 2), namely deletion of symbols and numbers, tokenization, deletion of stop words, and lemmatization. The removal of symbols and numbers was done because symbols and numbers did not have a special meaning that was correlated with the topic of the news. Then, tokenization was done to break sentences or paragraphs in the news into chunks of words so that the model could read them. Furthermore, words with no meaning, such as subject (I, he, she, etc.), were

removed to reduce noise in the data. Finally, lemmatization was used to reduce the word form to its simplest form, such as “eating” to “eat”.

Fig. 2. Stages of text preprocessing

B. Feature Extraction

The news text that had been cleaned was not yet fully usable by the model. Feature extraction was used to extract information from the text. The feature extraction stages are presented in Fig. 3. This research used two extraction methods, namely context and content-based information/news extraction. The Word2Vec model was used to extract context-based information. Each word from the text processing above was converted into a 100-dimensional vector. A window of value 5 was used to obtain the vector, meaning that five surrounding words would be used to understand the context of a word in the paragraph. The results of the Word2Vec model were vectors with dimensions of 100, with the number of vectors as many as the number of words contained in the training data.

Fig. 3. Stages of feature extraction

The method used to extract content-based news was the SVD model. This model broke down the matrix of words obtained from the text processing results into three matrices, namely a matrix containing the relationship between news and words, a matrix containing the relationship between news and topics, and information containing the relationship between topics and words. The matrix used was the relationship matrix between topics and words so that each word had a vector containing information about its relationship to the topics. After obtaining two types of vectors from the results of Word2Vec and SVD, the two outputs were combined into one vector. This vector was called the embedding vector, which represented one word.

C. Hybrid Model of LSTM+CNN Architecture

Fig. 4 presents the architecture of the classification model of the Hybrid model using two deep learning algorithms (i.e., RNN/LSTM+CNN).

Fig. 4. Hybrid model architecture

Embedding vector from feature extraction was used in LSTM-CNN modeling as an embedding layer. When there was news used as model input, every word in the news would be transformed into the corresponding embedding vector. Then, the embedding vector became the LSTM input layer. The LSTM cells used were 64 cells. The output of each LSTM cell would be used as the CNN input layer, with a filter size of 100, a kernel size of 2, and a ReLU activation function. The CNN output matrix was inserted into the max pooling layer to reduce noise in the output. After the noise in the output was reduced, the output, which had been converted into a 1-dimensional vector in the flattened layer, can be input to a fully connected neural network (NN). Here, we use 2 NN layers, where the first layer had 16 nodes and the ReLU activation function, while the second layer had the number of nodes corresponding to the number of topics in the data. The softmax activation function was used in the second layer to obtain the output in the form of the probability of each topic (content).

D. Model Evaluation

The ROC curve provides a graphical representation of the performance of the classifier. The ROC curve was generated by calculating and plotting the TPR against the false positive rate (FPR) for a single classifier at various thresholds. The TPR and FPR equations are presented in equations 1 and 2.

$$TPR = \text{Sensitivity} = TP / (TP + TN) \quad (1)$$

$$FPR = 1 - \text{Specificity} = FP / (FP + TN) \quad (2)$$

Where TP is the number of true positives and FN is the number of false negatives. TPR is a measure of the probability that an actual positive event will be classified as positive. FP is the number of false positives and TN is the number of True Negatives. FPR is a measure of how often a "false alarm" will occur or how often an instance of a true negative will be classified as positive.

Visualization of ROC curve uses AUC. The higher the AUC score, the better the classifier performs for a given task. ROC curve with AUC score is presented in Fig. 5.

Fig. 5. ROC curve with AUC score

The classification category based on the ROC Curve value is shown in Table I [22]. In general, an AUC score of 0.6 - 0.7 indicates poor classification performance (failure), 0.7 - 0.8 is considered acceptable, 0.8 - 0.9 is considered very good and more than 0.9 is considered extraordinary. Model category based on ROC curve value [23] is presented in Table I.

TABLE I. MODEL CATEGORY BASED ON ROC CURVE

Accuracy	Category
0.90 – 1.00	Excellent Classification
0.80 – 0.90	Good Classification
0.70 – 0.80	Fair Classification
0.60 – 0.70	Poor Classification
0.50 – 0.60	Failure Classification

IV. EXPERIMENTAL RESULT

A. News Classification

The architecture used to build the model with the AGNews dataset consisted of: (1) Embedding matrix (the result of extracting content and context information that was carried out in the previous stage) with input size = 100; (2) LSTM with 64 nodes = 64; (3) CNN with parameters: filter = 100, kernel = 2, number of strides = 1, padding = valid, activation function = Relu; (4) Pooling; (5) Flatten; (6) Dense hidden layer with number of nodes = 16 and activation function = Relu; (7) Dropout rate = 0.5; (8) Dense hidden layer with the number of nodes = 4 (according to the number of targets) and the activation function = softmax. Meanwhile, the hybrid architecture model for the BBC News dataset, which were points 1 to 7, was the same as the AGNews dataset. The difference between the two dataset was in point 8. The dense hidden layer was used in BBC News with five nodes (according to the number of targets). This step was done to achieve the best set of hyperparameters by performing hyperparameter tuning.

The next step was the model fitting. This stage conducted model training, which would be stopped if there was no increase in the accuracy value in data testing for 10 iterations (epochs). The modeling results were then stored (Table II).

TABLE II. HYPER PARAMETERS

Layer (type)	Output Shape	Param #
Embedding_2 (Embedding)	(None, 100, 104)	6533800
Lstm_2 (LSTM)	(None, 100, 96)	77184
Conv1d_2 (Conv1D)	(None, 97, 100)	38500
Global_max_pooling1d_2 (GlobalMaxPooling1D)	(None, 100)	0
Flatten_2 (Flatten)	(None, 100)	0
Dense_4 (Dense)	(None, 10)	1010
Dense_5 (Dense)	(None, 4)	44

Total params: 6,650,538

Trainable params: 6,650,538

Non-trainable params: 0

After the hybrid model was built using training data with hyperparameter tuning, the model was evaluated using the confusion matrix (CM) and ROC curve. The test results after 235 iterations showed a loss value of 0.2818, accuracy of 0.9065, test loss of 0.28183448, test accuracy of 0.90653336. The CM on the model with the AGNews dataset suggested that the data had been predicted correctly for each actual label, as shown in Table III.

TABLE III. CM OF AGNEWS DATASET

Accuracy 90.65					
Confusion Matrix	Label	World	Entertainment	Sport	Business
	World	6620	232	373	256
	Entertainment	65	7250	45	73
	Sport	199	83	6703	595
	Business	219	62	602	6623

The evaluation model using the CM on BBC News is presented in Table IV.

TABLE IV. CM OF BBC NEWS DATASET

Accuracy 0.85						
Confusion Matrix	Label	Entertainment	Tech	Politics	Business	Sport
	Entertainment	64	2	1	14	0
	Tech	2	52	0	6	0
	Politics	0	2	49	12	0
	Business	3	2	5	76	0
	Sport	1	0	1	5	76

The accuracy of the test on the AGNews dataset was 91%, the ROC curve value was 0.9832 and the training validation had a loss value of 0.1146 and an accuracy of 0.9611 (96.11%). The results of accuracy in training, testing and validation as well as the ROC curve value suggested that the model had good performance. The ROC curve for AGNews is presented in Fig. 6.

Fig. 6. ROC curve of the AGNews dataset

The ROC Curve of the BBC News dataset is presented in Fig. 7.

Fig. 7. ROC curve of the BBC News dataset

The ROC curve showed the visualization between TPR and FPR. The classifier that provides the curve closer to the top left corner (perfect classifier) exhibits better performance. The closer the curve is to the 45-degree diagonal of the ROC space, the less accurate the classifier is.

TABLE V. PERFORMANCE EVALUATION OF TWO DATASET

Model	Class	Precision	Recall	F1-score	Support
AG News	World	0.93	0.88	0.91	7481
	Entertainment	0.95	0.98	0.96	7433
	Sport	0.87	0.88	0.88	7580
	Business	0.88	0.88	0.88	7506
Accuracy				0.91	30000
Model	Class	Precision	Recall	F1-score	Support
BBC News	Entertainment	0.91	0.79	0.85	81
	Tech	0.90	0.87	0.88	60
	Politics	0.80	0.78	0.82	6
	Business	0.67	0.88	0.76	86
Sport	1.00	0.92	0.96	83	
Accuracy				0.85	373

The model was trained and tested against two datasets, namely the AGNews and BBC News datasets. The results of the model evaluation showed that the LSTM+CNN hybrid model had excellent accuracy (as presented in Table V) and ROC AUC scores.

B. Outlier Detection

The first step in outlier detection is processing error data. At this stage, the prediction results of the error model will be collected into 1 (one) separate data frame consisting of test topics and train topics. The magnitude of the error is calculated through the equation: $error = 1 - \max(x_i)$, $i \in \{1,2,3,4\}$, where x_i denotes the highest probability score that the model assigns. In this formulation, each prediction error can be calculated by the magnitude of the error, so that the RMSE error data can be calculated. The size of the RMSE dataset error was 0.93. Fig. 8 shows error data train, while Fig. 9 shows error data test on the AGNews dataset.

Fig. 10. Error data test on BBC News

To predict whether a news item is an outlier, two types of systems were designed. In the first system (Fig. 11), the outlier classifier model was installed separately from the LSTM+CNN hybrid model. As for the second system (Fig. 12), the meta-modeling principle was used, namely the outlier

classifier model using the prediction results of another model (the LSTM+CNN hybrid model for this case) to determine whether a news item is an outlier news or not. Decision tree models were used in both systems to determine which system had the best performance in determining outliers.

Fig. 11. The First Model of the classification of news outliers

Fig. 12. The second model of the classification of news outliers

C. Validation Model

Validation models of the two classification models are presented in Fig. 13. Fig. 13 shows that system 2 is far superior to system 1. In system 1, the ROC AUC score was only around 0.5-0.6, meaning that the model predictions were not much different from the random prediction results. However, in system 2, the ROC AUC score could reach 0.8 - 0.9, indicating that by obtaining input from the probability prediction results of the LSTM-CNN hybrid model, the outlier classifier model can properly determine whether a news item is an outlier news or not.

Fig. 13. Comparison of outlier news classifications

D. Comparative Study

Table VI is a comparison of previous research related to news article classification. The results of the performance evaluation of training and testing of the developed hybrid model showed better results. Based on the ROC curve, the hybrid model developed is in the excellent classification category. This can prove that the hybrid model with RNN/LSTM+CNN architecture and feature extraction Wor2Vec+LSA/SVD can be utilized as a good method for classifying sequential text. Furthermore, the hybrid model developed can perform news outlier detection well. The last two approaches in Table VI are the current research results (presented in bold).

TABLE VI. COMPARISON WITH PREVIOUS RESEARCH

Word Embedding	Text Classification Strategies	Dataset	Result

V. CONCLUSION

In this study, we developed a hybrid model consisting of two models: the news classification model (news categories) and the outlier classification model. The news classification model employed a deep learning algorithm (i.e., LSTM+CNN) based on the context and content of a news story. Meanwhile, the outlier classifier model was intended to predict which news is an outlier. The datasets used for modeling were AGNews and BBC News. The Word2Vec model was used to extract context- and content-based news using the SVD model. Our results on AGNews showed an accuracy of 0.91 with a ROC curve score of 0.97, while BBC News had an accuracy value of 0.86 with a ROC curve score of 0.96. These results suggested that the hybrid model had excellent accuracy and ROC AUC scores.

The process of labeling news included the detection of outliers. The predicted data from the LSTM-CNN model was used and tested with two types of models. First, the outlier classifier model was installed separately from the LSTM-CNN hybrid model. The second model used the meta-modeling principle, namely the outlier classifier model using the prediction results of another model (LSTM-CNN hybrid model). The algorithm used in the outlier classification model was a decision tree. Of the two models tested, the second model was far superior to the first model. In the first model, the ROC AUC score was only around 0.5-0.6, which indicated that the model predictions were not much different from the random prediction results. However, in the second model, the ROC AUC score could reach 0.8 - 0.9, meaning that by obtaining input from the probability prediction results of the LSTM-CNN hybrid model, the outlier classifier model could properly determine which news item was an outlier, with accuracy values of 0.71 and 0.92 for BBC News AGNews, respectively.

The drawback of the results of this study is that the proposed hybrid model did not reach maximum accuracy. The sample used in the dataset to evaluate the performance of the model is still limited, causing the model to have difficulties learning the vocabulary used in classifying news articles based on their categories. This situation may lead to overfitting. Furthermore, the model only tested news articles in English. Further research is needed to develop the proposed hybrid model, combined with other deep learning algorithms and more dataset samples, to obtain optimum model performance. The performance of the developed model also needs to be tested using news articles other than in English, such as Indonesian, Mandarin, Arabic and other languages.

Abstract—Histological grading quantifies the tumor architecture and the cytology deviation of breast cancer against normal tissue. Nottingham Grading System grades the breast cancer classification and allots tumor scores. Mitotic detection is one of the major components in the Nottingham Grading System. Using a conventional microscope is time-consuming, semi-quantitative and has limited histological parameters. Digital scanners scan the tissue slice into high-resolution virtual images called whole slide images. Deep learning models on whole slide images provide a fast and accurate quantitative diagnosis. This paper proposes two deep learning models namely Faster R-CNN and YOLOv5 to detect mitosis on WSI. The proposed Deep Learning models uses 56258 annotated tiles for training/testing and provide F1 score as 84%. The proposed model uses a web-based imaging analysis and diagnosis platform called CADD4MBC for image uploading, Annotation and visualization. This paper proposes an end-to-end web based Deep Learning detection for Breast Cancer Mitosis.

Keywords—Nottingham grading system; breast cancer biomarker; whole slide image; mitosis; faster R-CNN; YOLOv5

I. INTRODUCTION

Histological grading system is used to evaluate the behavior and prognosis of breast cancer on Hematoxylin and Eosin (H&E) stained images which quantifies the tumor architecture and the cytology deviation of the breast cancer tissue against the normal tissue. The grading also provides a degree of differentiation in the morphological assessment of breast cancer. As clinical stages are unable to provide early as well as developed lymph-blood meta stages information, Bloom and Richardson defined a histological grading system. This system allotted tumor scores between 1-3 based on individual components such as mitotic nuclei, nuclear pleomorphism, and tubule formation [1]. Their grading system was not accepted as a routine procedure for breast cancer grading classification due to the inconsistent issue in grading [2].

Elston-Ellis modified the Bloom and Richardson system and called their grading system as Nottingham grading system (NGS). NGS is accepted globally as a guide for grading breast cancer classification due to its semi-quantitative assessment of three morphological components such as a number of mitotic figures in the most active area called a high-power field, the size and shape of nuclear variation in tumor tissue against small regular uniform cells (Nuclear Pleomorphism) and the percentage of tumor tubule formation [3]. Hence the detection of mitosis is the major component of NGS. Mitosis is a cell duplication process that divides the cell into two cells which are genetically identical. The rapid and irregular mitosis cell count decides the tumor grading and the selection of tumor treatment options.

Histological grading on glass tissues using conventional microscopes is time-consuming which also has a limited evaluation of histological Parameters and semi-quantitative properties which is subject to high inter-observer variability. These limitations are overcome by the advent of digital pathology and Whole Slide Image (WSI) technology. WSI technology uses digital scanners to create high-resolution virtual images of the glass slide. The digitized images are stored as pyramid structures to view and analyze WSI at various Zoom levels (5x - 40x) [4]. Deep learning models performed over WSI virtual images provide fast and accurate diagnoses [5].

This paper proposes 1) Creation of digitized WSI Breast Cancer dataset; 2) performs mitosis annotations on the created dataset by pathologists; 3) develop two deep learning models, namely, Faster R-CNN and YOLOv5 to detect mitosis on WSI. This proposal reduces the difficulties of pathologists such as time consuming and inter-observer variability. The proposed models produce quantitative results. The paper is organized as follows: Section 2 lists the existing works, Section 3 proposes Faster R-CNN and YOLOv5 models and describes the dataset and preprocessing methods used by the deep learning models, Section 4 discusses the implementation/results and Section 5 conclude the summary of the proposed work.

II. LITERATURE SURVEY

MP-Mitdet [6] used a multiphase CNN framework to detect mitosis using the public dataset, namely MITOS 12 [7], MITOS 14, AMIDA 13 [8] and TUPAC 16 [9] with the evaluation parameters as F1 Score 0.74 and precision 0.71. The model performs Mean-Standard normalization as the pre-processing procedure on the different public datasets which are captured by different scanners. Model Mask-RCNN is used for automatic labelling and detection of mitosis. Resnet is used for cell-level classification. The model also proved that deep CNN's performance is better than conventional classifiers such as SVM, Logistic Regression, XGBoost, Random Forest and Navies Bayes.

The Deep Mitosis model [10] adopts three components to detect mitosis using a deep detection model on 205 weakly annotated mitosis. The first component DeepDet produces all possible detection of mitosis, the second component DeepVer removes false positives, and the final component DeepSeg uses RPN to segment the mitosis. They conclude that the model DeepVer reduces the performance and other models produce an F1 Score of 0.38.

Meriem Sebai et al [11] use two datasets ICPR12 & ICPR14 for the localization, classification and segmentation of mitosis. The weakly annotated mitosis dataset i.e. ICPR 14 which has labels only the centroid of mitosis is trained by Mask-RCNN Model [12]. The model segments the mitosis by using the pixel-level annotated mitosis dataset called ICPR12. The model Mask-RCNN is used as a two-stage deep learning framework in which the first stage identifies the centroid of the mitosis and in the subsequent stage detects the instance segmentation of mitosis. This model produces an F1 Score of 0.863 on the 2012 ICPR and achieves an F1 Score of 0.475 on the 2014 ICPR datasets.

De Cai et al. [13] segments mitotic cells by using the deep learning model called Faster R-CNN [14]. This two-stage object detector model first identifies the possible mitotic cells and then the second stage detects the target mitotic cells from the result of the first stage which produces higher accuracy than the single-stage detectors and also reduces the computation time. This model achieved a 0.76 recall value and 0.736 F1 Score on Miccai and TUPAC datasets.

Dan C Cireşan et al. [15] proposed a supervised model called Deep Neural network to detect mitosis on H&E images. This model uses Max Pooling layers as a subsampling layer to classify whether a cell is a mitosis or not. The model is trained and tested by two public datasets namely ICPR12 and ICPR14. In the training datasets, the cells in the H&E images are labelled as mitosis or non-mitosis based on the number of pixels which are closer to mitosis. The training dataset also uses bounding boxes to label mitosis. This model achieved an F1 Score of 0.782.

The research done by Gabriel Jiménez et al [16] suggests two deep learning architectures namely CNN and U-net [17] for mitosis classification and detection in histopathological tissue samples. The images used to evaluate the proposed approaches were obtained from two public datasets from the ICPR-2012 competition and the MITOS-ATYPIA-2014

challenge. Convolutional Neural Network is used for binary classification to classify mitotic and non-mitotic cells. The model got 95% testing accuracy with an F1 score of 94.35%. The model U-net is used for the semantic segmentation of mitosis and produces 0.9 F1 score accuracy.

MiNuGAN [18] automatically segments mitoses and nuclei using conditional generative adversarial networks [19] on the public datasets namely TUPAC16, ICPR14, and ICPR12 Datasets. The model uses 618 annotation files for training and 200 file images for testing with an F1 Score of 0.824.

The limitations in the existing literature are most of the researchers applied deep learning models only on the three public datasets namely ICPR 12, ICPR14 and Tupac in which, ICPR14 and Tupac are weakly annotated (only the mitotic centroids are labelled) and ICPR 12 is a strongly annotated dataset (all the pixels of mitotic cells are labelled). The combined data size of the three datasets is around 7000 only. The less data in deep learning training may produce less accuracy. Another main problem in mitosis detection is to differentiate normal cells from mitotic figures. If the pathologist missed this differentiation causes wrong annotations. The existing works are not providing information about the data collection /annotation of the mitosis dataset.

The above-mentioned limitations are overcome by the proposed system by training the deep learning models on both public datasets and private KMIT datasets. KMIT dataset is a private dataset contains breast cancer WSI, tile images with their respective mitotic figure annotations. CADD4MBC is a web-based deep learning platform developed internally by the authors which is used for uploading WSI/tiles, creating annotations, JSON downloading and visualization of WSI. Thus, the proposed system provides a web-based end-to-end AI mitosis detection which connects pathologists, technicians and hospitals.

III. PROPOSED SYSTEM

A. Dataset Description

1) *Public dataset:* The proposed Deep learning models use three public datasets namely ICPR12, ICPR14, and TUPAC. Mitos Dataset is a public dataset of the mitosis competition held by ICPR in 2012. In each slide, the pathologists selected 10 high-power fields at 40X magnification. This dataset consists of 2994 files of size 512 x 512. After applying augmentation methods such as horizontal flipping and vertical flipping increase the files to 4367. The ICPR 2014 dataset was presented in the MITOS-ATYPIA-14 grand challenge and comprises 2400 files of size 512 x 512 at 40x magnification. Pathologists annotated a total of 1502 centroid pixels of mitosis (weakly labelled).

The TUPAC mitosis dataset contains 73 cases collected from the department of pathology at the university medical Centre in Utrecht, The Netherlands. Each case was represented by one WSI region with an area of 2mm x 2mm. The annotated mitotic figures are accepted by two pathologists and the dataset contains 1552 weakly annotated mitotic figures of the size 512 x 512.

2) *KMIT dataset*: KMIT dataset contains 75 WSI which are collected from Basavatarakam Indo-American Hospital and scanned by Tapadia diagnostics Centre using a Morphile scanner at 40x magnification for the last two years. The dataset contains around 56,000 mitotic figures annotated by pathologists from both hospitals using the CADD4MBC platform and each WSI varies from 8 - 12 GB. The 40X level magnification WSI is divided into several tiles (around 30,000 - 50,000) of size 500 x 500. Each uploaded WSI is divided into several (minimum 100) batches and each batch consist of 150 tiles as shown in Fig. 1.

Fig. 1. Uploaded WSI and the batches of tiles

Each tile is annotated by the pathologists using the drawing tools in the CADD4MBC as shown in Fig. 2.

Fig. 2. Mitosis annotations on tiles

Basavatarakam Indo-American Hospital and Tapadia diagnostics centre annotate around 42,000 tiles for mitotic figures using CADD4MBC platform. This Dataset is increased to 56,258 after applying augmentation methods such as horizontal and vertical flipping. The proposed Deep learning (DL) models use both private and public datasets for training. The summary of the dataset used by the proposed deep learning models is shown in Table I.

TABLE I. DATASET SUMMARY

Dataset Name	Size of Dataset	Image Size	Number of Tiles after Augmentation	Labels	Annotation Type
ICPR 12	2994	512 x 512	4367	Strongly Labelled	CSV
ICPR 14	2400	512 x 512	-	Weakly Labelled	CSV
TUPAC	2650	512 x 512	-	Weakly Labelled	CSV
KMIT Dataset	42,000	512 x 512	56,258	Strongly Labelled	JSON

B. KMIT Dataset Preprocessing

1) *Color normalization*: Hematoxylin and Eosin staining provide a detailed view of the cells in the tissue. Color variations may occur in the image due to the H&E staining affects deep learning predictions and can result in an incorrect diagnosis.

Color normalization provides a uniform standardized staining effect on tissue images. Reinhard color normalization method [20] adjusts the color variations of the input image by comparing the mean color variations between the input image and the standard reference image. After color variation adjustment the input image will be converted back to RGB color space.

2) *Mask generation*: The input files and the respective annotated JSON files are gathered from the CADD4MBC platform and the mask is created by using the ellipse function in the OpenCV library as shown in Fig. 3.

Fig. 3. Generated mask and the respective mitotic figure annotations

The generated mask is used to calculate the area of the ellipse and the semantic segmented points of the mitosis. If the area of the ellipse is very small then the respective annotations are removed as they won't produce good accuracy in deep learning training.

3) *Annotation formats*: The JSON format of the annotations is downloaded from CADD4MBC and are converted into a COCO dataset format and .txt for Faster R-CNN and YOLOv5 model respectively. The COCO annotation format [21] is used and understood by the most popular advanced neural network libraries such as Facebook Detectron-2. The COCO format can be used for object detection for both binary and multiclass detection. COCO dataset format is a combined file of all the annotations (JSON formats). Hence as shown in the Fig 4, all training image annotations are presented in a single file instead of individual JSON files for each annotation and similarly, testing requires only one COCO dataset JSON file.

The YOLOv5 model requires the annotations in a .txt file format. Each line in the .txt file represents one annotation and has [Class, X-center, Y-center, Width, Height] format, where the class number is used for mitosis and the remaining are the bounding box coordinates of the annotations which is shown as [0, 0.221, 0.579, 0.058, 0.058].

C. Proposed DL Models Description

1) *Faster R-CNN*: Object detection networks primarily depend on algorithms which propose regions. The Proposed work uses Faster R-CNN to detect mitotic figures which is the most popular and advanced CNN-based object detection model. Faster R-CNN consists of three components such as backbone network, region proposal network and region of interest pooling.

a) *Backbone network*: In this proposed method, the Resnet-FPN [22] model is used as the backbone for automatic mitosis detection which is a combined model of Residual networks (Resnet) [23] and Feature Pyramid Network (FPN). As the input image is given to the first convolution block of the model then the features are extracted till the last convolution block. This layer-by-layer feature extraction sometimes leads to a gradient vanishing problem which makes it to lose the important features of the original image. The gradient vanishing problem is handled by Resnet by using its skip connections property and by FPN. The main objective of FPN is up sampling the low-resolution features with high-level feature maps (feature maps generated from the previous layers).

b) *Region proposal network (RPN)*: Region Proposal network takes feature maps generated by FPN as input. RPN generates anchor boxes by using two parameters such as scales and aspect ratio. After generating anchor boxes there will be a possibility of many boxes which do not contain any object inside them. Region proposal network is mainly used for localizing and classification of the anchor box which are performed by the bounding box regression layer (anchor deltas convolution) and the bounding box classifier layer. These layers produce four regression parameters such as (x, y, w, h) where (x, y) is the centre, and w and h are the width and height of the anchor box.

c) *Region of interest (ROI) pooling*: The main issue in object detection is each proposal of RPN will be in a different shape. As per the Faster R-CNN architecture after ROI pooling there is a Fully Connected layer which generates a fixed-size feature map from the non-uniform size of input feature maps.

2) *YOLOv5*: YOLOv5 [24] is a single-stage object detector which requires only a single pass to the neural

network and predicts all the bounding boxes. This feature makes YOLOv5 faster than any other traditional detection algorithm.

a) *YOLOv5 consists of three important components*: Cross Stage Partial Network (CSP) [25] is used as a backbone to extract informative features from an input image. CSPNet is used to achieve a good gradient combination and reduce the amount of computation which is achieved by partitioning the feature map of the base layer into two parts and then merging them through a proposed cross-stage hierarchy. PANnet [26] is used as a model neck which generates feature pyramids and scaled up the features.

The YOLOv5 model uses the YOLO layer as the head layer for the final detection of the objects. This layer generates 3 different sizes (18×18 , 36×36 , 72×72) of feature maps (bounding boxes) to achieve optimal prediction. This layer enables the model to handle small, medium, and big objects depending on the size of the objects.

IV. RESULTS AND DISCUSSIONS

The proposed system initially uses three public datasets namely ICPR 12, ICPR 14 and TUPAC to detect mitosis. ICPR 12 contains semantic segmentation of mitosis whereas ICPR 14 and TUPAC contain the centroid of the mitosis. The proposed system uses the Faster R-CNN model to detect mitosis by using the ICPR 12 dataset for training and testing around 2994 tiles and produces an F1 score of 82.1. Subsequently, ICPR 14 and TUPAC datasets are tested by the Faster R-CNN model which is tested on around 900 tiles to detect mitosis. From tested results, the false positives are removed by comparing the centroid annotations of mitosis in ICPR 14 and TUPAC. The model produces F1 Score as 75% and 84% for ICPR 14 and TUPAC, respectively.

KMIT dataset is created by scanning 75 breast cancer WSI using a Morphle scanner at 40X magnification. The breast cancer tissue slides are collected from Basavatarakam Indo-American hospital, Hyderabad and Tapadia diagnostic centre Hyderabad. After digitizing WSI, each WSI is divided into tiles and on each tile the preprocessing methods such as normalization and resizing are applied. The tiles are annotated on the CADD4MBC platform by the pathologist of both the hospitals. Then masks are generated for the annotated tiles as well as JSON format of the annotations are downloaded from the platform. The JSON annotations are converted into COCO annotation format which is applicable to Faster R-CNN. The model is trained by 45,006 tiles and tested by 11,251 tiles. The model got an F1 score of 77% and the time taken for training is 10 hours 46 minutes

To improve accuracy the proposed system uses the YOLOv5 model which is the fastest object detection model on the KMIT dataset. YOLOv5 model accepts .txt annotations format. After converting JSON format into .txt format, YOLOv5 is trained by 45,006 tiles and tested by 11,250 files. The model produces an F1 score of 84%, and the time duration for training is around 9 hours 12 minutes.

To improve training and testing time YOLOv5 distributed model is applied to the KMIT dataset. This model used 45,006 files for training and 11,251 for testing and produced an F1

score of 84% within 5 hours and 28 minutes. Table II shows the performance of the proposed models, size of training and testing dataset, Evaluation metrics, and the training time of the proposed deep learning models.

TABLE II. PERFORMANCE OF THE PROPOSED MODEL

Dataset Name	Trainin g	Testin g	Model	F1-Score	Recal l	Precisio n	Training Duratio n
ICPR12	3304	1063	Faster R-CNN	85.48	88.91	82.15	49 mins
ICPR14	-	547	Faster R-CNN	81.46	87.89	76.52	-
TUPA C	-	321	Faster R-CNN	82.15	81.56	81.69	-
KMIT Dataset	45006	11251	Faster R-CNN	75.86	73.83	76.86	10 Hrs 46 mins
KMIT Dataset	45006	11251	YOLOv5 (CPU)	84.23	81.62	86.76	9 Hrs 12 Min
KMIT Dataset	45006	11251	YOLOv5 (Distributed GPU)	84.58	82.31	86.42	5 Hrs 28 mins

Fig. 5. Single mitosis detection by faster R-CNN

Single Mitosis Detection using Faster R-CNN model is demonstrated in Fig. 5.

Fig. 6. Mitosis cell detection on tiles by Faster R-CNN

Mitosis cell detection on WSI tiles using Faster R-CNN model is demonstrated in Fig. 6.

Fig. 7. Mitosis detection by YOLOv5 on WSI image

A number of mitoses (as red dots) detection on WSI image through YOLOv5 model is demonstrated in Fig. 7. The Results shows that the proposed deep learning models Faster RCNN and YOLOv5 produces good accuracy than the other models which are mentioned under the literature survey section. The other models use only the public dataset having 8000 tiles with strong/weak annotation and produce an F1 score between 0.3 and 0.7, whereas the proposed system produces an F1 score of 0.84 by trained and tested around 56,000 mitotic annotated tiles.

V. CONCLUSION

Nottingham grading system is a globally accepted system for breast cancer classification and grading the tumor. Detection of mitosis is the major component of NGS. Conventional microscopic mitosis detection is time-consuming, semi-quantitative and subject to inter observability. Digital pathology digitizes the tumor slides as WSI and applying deep learning models on WSI reduces the workload of the pathologist and assists them for quick accurate report generation. The deep learning models Faster R-CNN and YOLO v5 are learned from both the public datasets and KMIT dataset which has 56,258 tiles with annotated mitosis figures. The proposed web-based deep learning models detect mitosis with an F1 score of 0.84. The accuracy can be improved by increasing the size of the Breast Cancer WSI Mitosis dataset and Mitosis annotations to the models.

Abstract—In today's world, it is time to identify the driver through technology. At present, it is possible to find out the driving style of the drivers from every car through controller area network (CAN-BUS) sensor data which was not possible through the conventional car. Many researchers did their work and their main purpose was to find out the driver driving style from end-to-end analysis of CAN-BUS sensor data. So, it is potential to identify each driver individually based on the driver's driving style. We propose a novel compound feature-based driver identification to reduce the number of input attributes based on some mathematical operation. Now, the role of machine learning in the field of any type of data analysis is incomparable and significant. The state-of-the-art algorithms have been applied in different fields. Occasionally these are tested in a similar domain. As a result, we have used some prominent algorithms of machine learning, which show different results in the field of aspiration of the model. The other goal of this study is to compare the conspicuous classification algorithms in the index of performance metrics in driver behavior identification. Hence, we compare the performance of SVM, Naïve Bayes, Logistic Regression, k-NN, Random Forest, Decision tree, Gradient boosting.

Keywords—Compound feature; driver behavior identification; engine speed; fuel consumption; vehicle

I. INTRODUCTION

Every driver has their driving style; therefore, the driver can be identified according to exploration through the driving pattern analysis. It is to be considered as a fingerprint of the driver's manner like acceleration, speed, and braking habits that vary from driver to driver. Driver fingerprinting could lead to important privacy compromises [1]. Today we cannot consider just a vehicle as a modern car, as it is a fully decorated smart device with various functions like multimedia, security system, and different sensors [2]. The sensors were very simple because the driver was informed regarding the features of the engine and the amount of fuel through the magnetoelectric and light display devices [2]. Using state-of-the-art technology in real-time all the microcomputers are communicated with each other through CAN-BUS (Controller Area Network) [3]. To make a car more efficient a good number of technologies are used in the modern engine. To improve engine performance direct injection technology was introduced in the modern car [4]. According to a survey, the researcher predicted that the number of sales of connected cars will reach 76.3 million in the next 2023 [5]. Through state-of-the-art technology, modern engines use less fuel and besides get more power [6].

Most of the cars have partnered with other components which are highly technology-based, such as traffic lights, garage doors, and services [7]. Not only the driving style there is a discount policy on insurance services but also real-time monitoring, maintenance, pathfinding, driving style development, and also consumption of fuel [8]. Vulnerabilities of connected cars will increase the auto-theft which is one of the threats [9]. Top-of-the-range vehicles are targeted by thieves who simply drive off after bypassing security devices by hacking onboard computers [10]. Penny [11] introduced a man-in-the-middle attack or relay attack, to do this radio signals are passed between two devices. Pekaric I et al. (2021) [12] described other attacks such as GPS spoofing and message injection attacks. BMW Connected Drive [13] seamlessly integrates mobile devices, smart home technology, and vehicle's intelligent interfaces into a complete driver's environment. Even though in 2021 they introduced a remote door unlock system through a signal to the driver's door to unlock [13]. CAN-BUS is likely a nervous system used to allow configuration, data logging, and communication among electronic control units (ECU) e.g., ECU is like a part of the body and interconnected through CAN, by which information sensed by one part can be shared with another [14]. Up to 70 ECUs have a modern car e.g., the engine control unit, airbags, audio system, acceleration, fuel unit, etc. [15]. Normally, multi-sensor data is made up of in vehicle's CAN data. The in-vehicle CAN data such as steering wheel, vehicle speed, engine speed, amount of fuel, etc. Several researchers previously proposed a driver identification method based on in-vehicle CAN-BUS data. But direct connectivity is difficult to get data, so onboard diagnostics (OBD-II) is used. (OBD-II, ISO 15765) is a self-diagnostic and reporting capability that e.g., mechanics use to identify car issues, OBD-II specifies diagnostic trouble codes (DTCs) and real-time data (e.g., speed, revolution per minute RPM), which can be recorded via OBD-II loggers from CAN-BUS. Many authors described the problem of CAN-BUS data for identifying the driver [9], [16], [17].

Since this is a big dataset and there are 51 features with 10 labels. Moreover, for analyzing the whole dataset we need more time. To reduce the time complexity we have explained compound feature selection process. In this paper, our objective is to identify driver behavior through telemetric data using machine learning algorithms. We analyze the data in terms of training, testing, and validation to get model accuracy that helps us with driver identification.

There are some significant commercial and personal values of driver identification for insurance, rental companies, personal and tripping regulations as well. The goal of this work is to monitor and maintain unauthorized access.

The paper is organized as follows. We have presented an introduction and literature review Sections I and II as well. The architecture of the proposed system has described in Section III. The discussion of methodology and compound features have existed according to Sections IV and V. Before the conclusion part of Section VII, the results and discussion are mentioned in Section VI.

II. LITERATURE REVIEW

The author [18] uses telemetric data to investigate driver identification and identification accuracy decreases by 15% compared to the method. They use the role of non-public parameters in identifying the driver. Previous work had been done by using car driving simulated [18] data. Investigated the driver's behavior when he follows another car. The features mentioned below are used to observe such as accelerator pedal, car speed, brake pedal, and distance to the next car. Gaussian Mixture Model (GMM) is used to achieve 81% accuracy with 12 drivers and 73% of 30 drivers [18]. Another author [19] analyzes overtaking style for each driver, uses accelerator, and steering data and the accuracy is 85% for about 20 drivers through the Hidden Markov Model (HMM). Some other authors used smartphones to capture driver data. Sensors in the smartphone are- GPS, accelerometer, magnetometer, and gyroscope [20-22]. This data is used for driver profiling and other tasks. An author used an inertial sensor and algorithm was SVM, and k-means methods and got 60% accuracy between two drivers.

In another research, the authors [8, 16], [23-24] acquire data from in-vehicle CAN-BUS via OBD-II. The author [23] uses in-vehicle CAN-BUS sensor data and the accuracy was 99% among 15 drivers. He uses SVM, Random Forest, Naive Bayes, and k-NN methods. Another researcher [9] got 99% accuracy from 51 features of 10 drivers and used Decision Tree, k-NN, Random Forest, and Multilayer Perceptron (MPL). Choi et al. [24] find out the driving detection and driver recognition using both GMM and HMM methods, which are used for analyzing vehicle CAN-BUS data. Kedar-Dongakar et al. [25] recognized the driver classification based on the energy optimization of a vehicle. Based on driving style three types of drivers are classified as aggressive, moderate, and conservative. The author considers the following features for his research work such as vehicle speed, acceleration, torque, acceleration pedal, steering wheel angle, and brake pedal pressure.

Several researches have been going on neural network and deep learning algorithms for a few years back and draw a good impact on driver behavior identification works. Xun et al. [26] introduced Convolutional Neural Network (CNN) and got 99% accuracy for 10 drivers. For driver identification, another paper uses noise-free data and as an algorithm-LSTM-Recurrent Neural Network is used, where it has high accuracy with salient advantages [27].

After reviewing, the difference among this work and the done before.

- For collecting dataset uses specific model's vehicle.
- Specific dataset with different features
- Uses CAN-BUS and public OBD-II.

III. ARCHITECTURE OF THE PROPOSED SYSTEM

The purpose of the proposed system is to identify the actual driver. After capturing the raw data through OBD-II sent to the cloud is shown in Fig. 1. Once completed the engineering knowledge-based mathematical operation like adding, multiplication, and logging of two features then send for prediction based on model accuracy result.

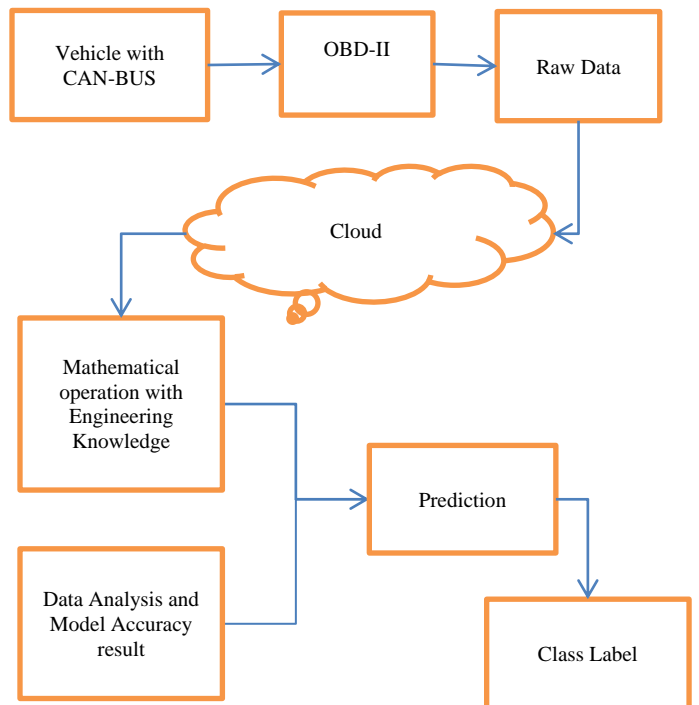

Fig. 1. Architecture of the proposed system

IV. METHODOLOGY

A. Approaches of Methodology

The steps of the proposed system are shown in Fig. 2. Before the classifier's dataset preparation, data preprocessing, feature selection, normalization, and other activities have occurred. Several classifiers are used for comparative analysis with state-of-the-art classifiers to find the best model.

In this connection, we need data on the trips for driver identification. Our model is considered an Oclab driving dataset [28]. This data is used for driver indemnification and personalization based on pattern analysis. KIA motors corporation vehicles in South Korea were performed to collect the data and the experiment has been done since July 28, 2015 [28]. A total of 10 drivers labeled "A" to "J" are included in the trips and cover 23 km length, completing two round trips from 8.00 PM to 11.00 PM [28]. Three types (such as city roads, freeways, and parking lots) of the road are there with

their characteristics. There are a total of 94,401 records with 51 dimensions (51 features) [28]. Not all data is possible to get because there are some limitations of OBD-II identifiers and sensors such as it cannot provide body control status or airbag status even wheel angle rotation status. OBD-II has a limited set of identifiers [29] provided by the manufacturer.

Fig. 2. Step by step process of the work

Among 51 features we have considered two prominent features with around 13,000 samples named Fuel Consumption (FC) and Engine Speed (ES) to make a compound feature. Transform the collected data to our classification model for analysis we follow- feature selection, making a compound feature, scaling, and data processing through state-of-the-art techniques [34]. The sample data are viewed in Eq. (1).

$$X = \begin{bmatrix} X_1^1 & X_2^1 & X_d^1 \\ X_1^2 & X_2^2 & X_d^2 \\ \vdots & \vdots & \vdots \\ X_1^N & X_2^N & X_d^N \end{bmatrix} \quad (1)$$

Where d columns correspond to d variable and N rows correspond to N instances. Fig. 3 shows the histogram of the compound dataset.

Fig. 3. Histogram of the dataset

To improve the dataset several statistical and logical tools are used to overcome the problem. Significantly different data points are removed by outliers [30].

B. Data Visualization and Relationship in a Dataset

a) *Heat-map*: A heat map is a data visualization technique that shows the magnitude of a phenomenon as color in two dimensions [31-32]. The color variation may be by hue or intensity, giving obvious visual cues to the reader about how the phenomenon is clustered or varies over space [38]. We consider a correlogram a clustered heat map that has the same trait for each axis to display how the traits in the set of traits interact with each other. The correlogram is a triangle instead of a square because the combination of A-B is the same as the combination of B-A and so does not need to be expressed twice. Fig. 4 is shown the feature correlation of the compound dataset. The value of correlation can take any value from -1 to 1, based on that-

- Features such as Fuel Consumption, Log FC, Sum, and Mul are having strong positive correlations.
- Fuel consumption and engine speed, engine speed, and Log FC, Log FC, and Log Es have a weak positive correlation.
- Class has a strong negative and weak positive correlation with every feature.

Fig. 4. Correlation among features

C. Pair Plot

A pair plot is a pairwise relationship in a dataset [36]. The pair plot function creates a grid of Axes such that each variable in data will be shared on the y-axis across a single row and the x-axis across a single column [39]. By plotting pair plots, it visualized that most of the classes of each feature overlap with each other. Fig. 5 shows the pair plot of the compound dataset. After analyzing the scatter plot a statistically significant result is shown that non-linear classification models such as k-NN, Decision tree, Random Forest classifier, Gradient boosting classifier, etc. perform better than linear classification models such as logistic regression.

D. Standard Scaler

Standard Scaler comes into play when the characteristics of the input dataset differ greatly between their ranges, or simply when they are measured in different units of measure [37]. Standard Scaler - standardizes a feature by subtracting the mean and then scaling to unit variance. Unit variance means dividing all the values by the standard deviation.

Fig. 5. Pair plot of the dataset

As we see, different scales of data exist in the dataset. Normalization is essential for some machine learning algorithms like k-NN (k-Nearest Neighbor) and SVM [29]. The normalization formulas for integrating data scales are shown in Eq. 2.

$$Z = \frac{(x - \mu)}{\sigma} \quad (2)$$

Here, μ = mean and σ = standard deviation. To evaluate the generalization of the model we have considered K fold cross-validation for low bias and a modest variance [33]. We have used five folds for training and testing the dataset and obtained the mean performance.

In the case of classification application, we have considered supervised machine learning classifiers for performing the metrics named k-NN, SVM, Logistic Regression, Decision tree, Random Forest, and Gradient boosting. The k-NN (k-Nearest Neighbor) is an instance-based traditional machine learning algorithm. Both classification and regression cases k-NN can be used and select the number of neighbors through distance calculation of the query points. Eq. 3 is used to calculate the Euclidean distance between two points.

$$D = \sqrt{\sum_{i=1}^n (X_i - Y_i)^2} \quad (3)$$

SVM stands for Support Vector Machine, used for classification and regression problems. The goal is to find a hyperplane in an N-dimensional space and separately classify the query data point. There is a decision boundary called hyperplane that is used to differentiate the classes. It also creates a margin separator with the nearest observations and it performs better if maximizes the margin. The equation represents the loss function that indicates maximize the margin

$$C(x, y), \text{ Where } Y = f(x) = \begin{cases} 0, & \text{if } y * f(x) \geq 1 \\ 1 - y * f(x), & \text{else } 1 \end{cases} \quad (4)$$

Logistic Regression predicts whether something is true or false. Instead of fitting a line to the data, it fits an “S” shaped “logistic function” and the curve goes from 0 to 1. The following equation is used to calculate the function, also called the sigmoid function.

$$S(x) = \frac{1}{1 + e^{-x}} \quad (5)$$

Naïve Bayes is a classifier based on Bayes’ theorem. It assumes that the presence of a particular feature in a class is unrelated to the presence of any other feature. The naïve Bayes model is easy to build a large dataset and outperforms sophisticated classification methods. The way Naïve Bayes is used to calculating the posterior probability shows in the Eq. 6.

$$P(c|x) = \frac{P(x|c)P(c)}{P(x)} \quad (6)$$

To measure the performance, we have used four indicators named accuracy, precision, F-Measure, and Recall. The computation and the evaluation performance of the classifiers have occurred through the confusion metric. Once the model is generated then the classifier is tested by using a test dataset to check the model's accuracy. Precision indicates how close or dispersed the measurement is to each other. It measures the number of correct positive predictors made. A recall is a metric that quantifies the number of correct positive predictions made out of all positive predictions that could have been made.

The number of FP 's, FN 's, TP 's, and TN 's cannot be calculated directly from this matrix. The values of FP 's, FN 's, TP 's, and TN 's for class i ($1 \leq i \leq n$) are determined as per [35].

The final confusion matrix, which has dimension 2×2 , comprises the average values of the n confusion matrices for all classes. For a binary, i.e. two-class problem, a confusion matrix gives the number of false positives (FP s), false negatives (FN s), true positives (TP s), and true negatives (TN s). From this confusion matrix, accuracy, precision, recall, and $F-1$ score are calculated in the following way:

$$Precision = \frac{TP}{TP+FP} \times 100\% \quad (7)$$

$$Recall = \frac{TP}{TP+FN} \times 100\% \quad (8)$$

$$F_1 - score = \frac{2 \times precision \times recall}{precision + recall} \times 100\% \quad (9)$$

$$Accuracy = \frac{TP+TN}{(TP+FN)+(FN+TN)} \times 100\% \quad (10)$$

Fig. 6 shows the time series of a dataset with a window based on RPM. We have considered time t_0 with the window size of w_1 and t_{0+1} time for the next window and so on. Fig. 9 shows the accuracy of the several models based on time and window size.

Fig. 6. Time series of dataset with window

V. COMPOUND FEATURE

To make the feature compound we consider a general mathematical operation. We have selected two important features among the 51 features from the Oclab dataset. Once we have applied mathematical operations to the selected feature to achieve the compound feature. The compound feature processing method is stated in Fig. 7.

Fig. 7. Preparation of compound feature

From the mathematical operation, we have considered addition, multiplication, and binary logarithm to make the feature compound. Eq. (11), (12), and (13) describe the mathematical operation. Here, $k > 0$, $k \in \mathbb{N}$ and a_k, b_k are two features with the index of k .

Since the value of the features are numerical so we add two features to make a single (Compound) feature is shown in Eq. (11). Eq. (12) is shown for multiplication between two features to build a compound feature. In Eq. (13), another mathematical operation binary log is applied to a single value of two features separately and after that we add them for making compound feature.

$$S = \sum_{k=1}^n (a_k + b_k) \quad (11)$$

$$M = \prod_{k=1}^n (a_k b_k) \quad (12)$$

$$Y_1 = \log_2 a_k, Y_2 = \log_2 b_k \quad (13)$$

We have considered raw features as the first level and the others as are inner level. Fig. 8 shows the level indexing process.

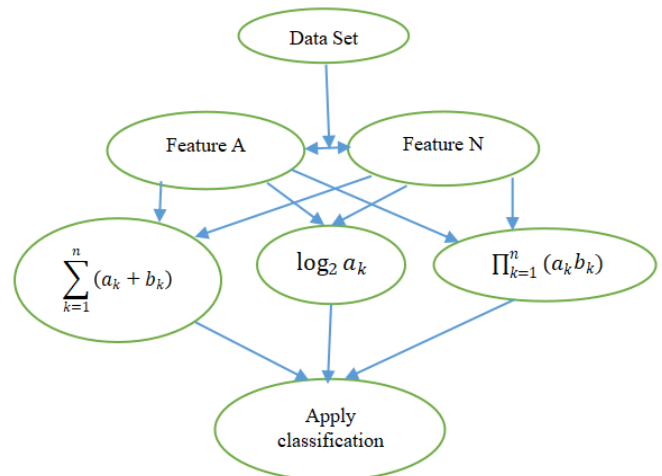

Fig. 8. Inner level processing system

VI. RESULTS AND DISCUSSION

To evaluate the generalization of the model we have considered K fold cross-validation for low bias and a modest variance [33]. We have used five folds for training and testing the dataset and obtained the mean performance.

For the classification of the driver, we have introduced the prominent supervised algorithm named Naive Bayes (NB), Logistic Regression, *k*-NN, Decision Tree (DT), Gradient Boosting (GB), Random Forest (RF), and SVM. Table I shows the result of all classifiers through the confusion metric. Among them, GB shows 83.00 % (highest) and NB performs 65.00% (lowest) accuracy respectively. Mentionable, we have made four compound features from two features among 51 features and considered two drivers among 10 drivers respectively from the Ocslab dataset. The results of non-linear classifiers where GB and RF are given 85.00% and 81.00% accuracy accordingly. Results of confusion metrics are shown in Table II and a comparative analysis of original features vs compound features is visible in Table III. In the Compound feature, GB performs a height accuracy of 85%. Moreover, the ROC curve are shown in true positive in Fig. 10 for all classifiers.

Again we have considered the time series of the drivers' and found out the driving pattern style through the windowing system using the compound dataset. Fig. 9 is representing the accuracy of only two drivers (A, D) and it also represents the W_1 , W_2 , and W_3 accuracy of 75.00%, 78.00%, and 85.00% respectively. In this research, we have figured out linear and non-linear algorithms to calculate the performance. Moreover, according to pair plot analysis, we have decided that non-linear is better than linear analysis. As a result, the model is statistically significant because of the better performance of the non-linear algorithm.

TABLE I. MODEL CLASSIFICATION REPORT

Classifiers	Performance parameters				
		Accuracy	Precision	Recall	F1-Score
Logistic Regression		72.00	76.00	81.00	78.00
	Macro Average	-	71.00	70.00	70.00
	Weighted Average	-	72.00	72.00	72.00

VII. CONCLUSION

In terms of driver identification, the role of machine learning as a cutting-edge technology is immense. Through this work, we found the best model that shows a momentous way to build our proposed anti-theft driving expert system. This research work has presented an in-depth comparison of the performance of seven (7) projecting classifiers in the context of driving behavior identification. As a result, the best and the worst classifiers we have found are GB and NB respectively. This type of result is very effective in developing an online-based anti-theft system. We have executed our experiment with only a few numbers of drivers among ten drivers.

Through online the owner of the vehicle will notify, so there is possibility man-in-the middle attack to another LAN. We will introduce network security to ensure authorized access and overcome the vulnerabilities of the proposed system in the next work.

ACKNOWLEDGMENT

I am grateful to KIA Motor Corporation for the Dataset provided to me.

BrainNet-7: A CNN Model for Diagnosing Brain Tumors from MRI Images based on an Ablation Study

Md Harun or Rashid, Salma Akter, Amatul Bushra Akhi
Dept. of Computer Science Engineering
Daffodil International University
Dhaka, Bangladesh

Abstract—Tumors in the brain are masses or clusters of abnormal cells that may spread to other tissues nearby and pose a danger to the patient. The main imaging technique used to determine the extent of brain tumors is magnetic resonance imaging, which ensures an accurate diagnosis. A sizable amount of data for model training and advances in model designs that provide better approximations in a supervised environment likely account for most of the growth in Deep Learning techniques for computer vision applications. Deep learning approaches have shown promising results for increasing the precision of brain tumor identification and classification using magnetic resonance imaging (MRI). This study's purpose is to describe a robust deep-learning model that categorizes brain tumors using MRI images into four classes based on a convolutional neural network (CNN). By removing artefacts, reducing noise, and enhancing the image, unwanted areas of brain tumors are deleted, quality is improved, and the tumor is highlighted. Several CNN architectures, including VGG16, VGG19, MobileNet, MobileNetV2, and InceptionV3, are investigated to compare or get the best model. After getting the best model, a hyper parameter ablation study was performed on that model. Proposed BrainNet-7 achieved the best results with 99.01% test accuracy and 99.21% test and validation accuracy.

Keywords—MRI image; image pre-processing; transfer-learning; CNN; brainnet-7

I. INTRODUCTION

A brain tumor is one of the tenth most common causes of mortality in men and women regarding the brain or central nervous system, often referred to as the CNS [1]. It is estimated that 40% of all cancer types develop brain cancer as a result of metastasis rather than death from brain tumors [2]. In 2000, June 8 was designated World Brain Tumor Day to raise understanding and educate people regarding brain tumors [3]. If abnormal cells begin to grow unnecessarily in the brain or spinal cord, it is known as a brain tumor. The World Health Organization categorized brain tumors into four groups on the basis of molecular characteristics in 2016 -- I, II, III, and IV [3, 4]. Brain tumor patients have a very low life probability when the tumor is in more advanced phase [5]. Therefore, accurate and timely cancer diagnosis and grade estimation

enhance illness prognosis and treatment options. A neurological examination, imaging, biopsies, and other methods are used to determine the grade and diagnosis of tumors [3, 6]. Doctors use magnetic resonance imaging (MRI) before and after treatment to determine the tumor's shape. As a result, surgical resections can be planned and monitored as the illness develops [7]. Early classification of brain tumor grade plays an important role in successful prognosis [8]. A good contrast enhancement and noninvasive MRI images make it the preferred imaging technique in glioma diagnosis [9]. Radiologists observe and diagnose tumors using the conventional method, it is laborious and time-consuming. Computer-aided medical diagnosis (CAMD) has made great strides with artificial intelligence (AI) and deep learning, which can assist doctors in interpreting medical images within seconds [10]. A dataset's quality and size significantly impact the performance of deep learning technology. Images with high-quality annotations are required for deep learning techniques. However, labelling large quantities of medical images is quite challenging since annotation is a time- and expertise-intensive process [11]. Two significant barriers to deep learning in medical imaging are insufficient imaging data and a lack of annotations from human experts [11]. The above challenges have been addressed and resolved through numerous efforts. A transfer learning strategy can be helpful when there are only a few domain samples for training. Typically, it refined on the architecture that has already pre-trained on a largest, labelled dataset. The transfer of learning knowledge to the target dataset makes network convergence speed faster while maintaining low computational complexity [12].

In this work, we propose a CNN model BrainNet-7, which is fine-tuned network and classifies brain tumor MRI images most correctly. Firstly, use, five pre-trained models, VGG16, VGG19, MobileNet, MobileNetV2, and InceptionV3, are employed in the dataset and then use proposed a CNN model. After in the CNN model a hyper parameter ablation was performed for getting the robust and fine-tuned model. This model is given the best accuracy among all the previous networks (see Fig. 1).

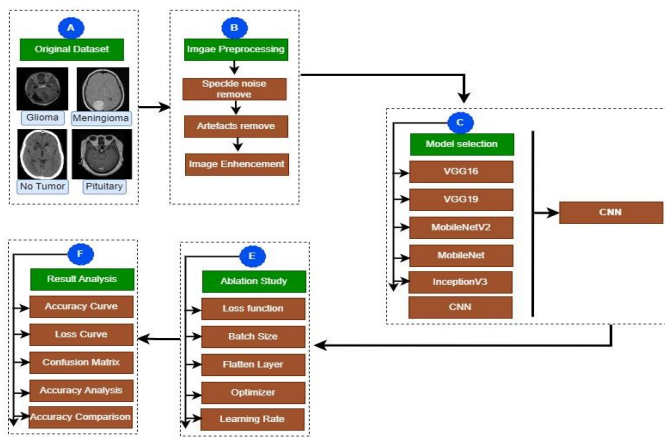

Fig. 1. An overview of the entire classification process.

II. LITERATURE REVIEW

A classification approach was provided by Santhosh and his colleagues to distinguish between normal and abnormal brain tissues. The segmentation of the system was based on threshold and watershed. SVM provided overall classification accuracy of 85.32 percent [13].

Arunkumar and his research associates created a world-class brain tumor classification architecture on the basis on traditional machine vision techniques like Fourier transform image enhancement, completely automated trainable segmentation, histogram-of-oriented-gradients (HOG) feature extraction, and an ANN-based classification model. Size, circularity, and gray-scale average are used to filter out non-ROI brain components and a k-fold-cross validation technique, the constructed model successfully distinguished between normal and pathological brain slices with the accuracy of 92.14%. [14].

A brain tumor categorization algorithm based on brain MRIs obtained from RD-BVH was proposed by Hafeez Ullah and research fellows. Brain MRI slices' intensity, shape, and texture features were retrieved, and the proposed methodology achieved 97% accuracy [15].

An approach for classifying tumors that uses CNN and a genetic algorithm was proposed by Amin Kabir et al. in 2019 [16]. To reduce validation error, the authors used a genetic algorithm. Prior to the CNN architecture, the images were rescaled using data normalization, and they underwent augmentation to achieve perfect rotation. The accuracy was 94.2% using the recommended procedure. The new method, according to the authors, is sufficiently successful to detect tumors.

Biswas et al. in 2021[17] an efficient training feature. The proposed network construction method, known as "Levenberg-Marquardt," offers 95.4% accuracy, 94.58% sensitivity, and 97.83% specificity. Comparatively speaking, this improved result outperforms other current detection methods. Getting great results comes down to two main things: using the right preprocessing steps and a powerful training function.

Brain cancers can be identified and classified from MRI images using a quicker Region-based CNN (faster R-CNN) technique used by Avşar, E. et al. [18]. Their model's accuracy was 91.66% as measured. In study [19], a method for classifying MRI brain cancer was also suggested that uses SVM with grayscale, symmetry, and texture features to get information about features.

Precious et al. [20] propose three optimizers, including ADAM, SGDM, and RMSprop, from whom detection accuracy of 98.1%, 92.5%, and 83.0% is attained. In order to detect tumors, four supervised machine learning classifiers are used once the features have been retrieved using CNN. Discriminant analysis, Naive Bayes, SVM, and KNN classifiers are among the classifiers that are employed. 96.2%, 94.3%, 75.0%, and 96.2% of the classifiers' accuracy were obtained, respectively.

Papageorgiou et al. [21] created the fuzzy cognitive map (FCM) approach to represent model experts. A computationally sophisticated training technique known as the activation Hebbian algorithm was added to the FCM ranking model to enhance its classification capabilities. Medical resources, which included 100 instances, were used to verify the proposed method. For low-grade and high-grade brain tumors, the FCM model correctly diagnosed patients in 90.26% (37/41) and 99.22% (55/59) of the cases, respectively. Comparing the proposed model's results to those of current algorithms like fuzzy decision trees and decision trees, the proposed model's results show a marginally higher accuracy. The same kind of first-hand data was used to compare them, and while they were able to get high accuracy, they couldn't get high memory.

In order to work with 2D (two-dimensional) images, John Schmeelk [22] used a two-dimensional wavelet transform (2D-WT). The comparison of the two transforms on separated elements was covered in depth by the authors. A similar image was also subjected to a comparison of the global qualities offered by the Fourier transform (FT) approach and the wavelet transform. The Gaussian subfield wavelet was chosen for this study because, for some reason, it made it possible to compare it to the Fourier technique.

In our findings we are improving the model and get the high accuracy from the model. In our approach firstly we decrease noise by using various image processing techniques and then we are developed a model which give us the best accuracy and our approach beat all the existing model.

III. DATASET DESCRIPTION

The Brain Tumor MRI dataset has a total of 7022 MRI images analyzed for this research. There are four classes in the dataset: glioma, meningioma, no tumor, and pituitary. There are 1621 images in the glioma class, 1645 images in the meningioma class, 2000 images in the no tumor class, and 1757 images in the pituitary class. All images of this datasets are 512×512 pixels in grayscale presentation. The dataset was taken from the open-source website Kaggle. As shown in Table I, Fig. 2 the dataset is described in detail:

TABLE I. SHOW THE DATASET DESCRIPTION

Name	Description
Total Number of Images	7022
Average Dimension	512 x 512
Color Grading	Grayscale
Data Format	JPG
Glioma	1621
Maningioma	1645
No Tumor	2000
Pituitary	1757

Fig. 2. Brain Tumor MRI dataset containing four classes with various noise and artifacts.

A. Image Processing

There is a lot of noise and artefacts in brain tumor MRI dataset images, so this study focuses on improving the model's accuracy through image processing techniques. Because images are usually filled with noise and artefacts, image processing is the first step in training a deep-learning model. First, a median filter is used to remove noise from this image, then a morphological opening is used to remove artefacts.

B. Remove Spackle Noise

The brain tumour MRI dataset has spackle noise, as previously stated. Median filters are useful for removing spackle noise.

C. Median Filter

Median filter is a well-known order-statistic filter that excels at removing certain types of noise, including Gaussian, random, and salt-and-pepper noise. The image of this step is given in Fig. 3.

Fig. 3. Median filtered images.

The first photo are the original images and the second photo is the output of the median filter.

D. Artifact Removal

In addition to the brain tumour MRI dataset having artefacts, morphological operations are used to remove these artefacts [23]. Various morphological operations can be used for eliminating artefacts, but this study uses morphological opening techniques.

E. Morphological Opening

The kernel size of the filter depends on the operation to be performed. The output of this step is shown in Fig. 4.

Fig. 4. Output of the morphological opening.

The first image are the input images which we get from the median filter and the second photo is the output of the morphological opening.

$$g(j, s) = f(j, s) * u(j, s) + (j, s) \quad (1)$$

Where,

$g(j,s)$ – debase image $u(j,s)$ – multiplicative noise

$f(j,s)$ – original image $\eta(j,s)$ – additive noise

Before diagnosis, removing additive noise from ultrasound images is necessary, but multiplicative noise can be allowed, given in the equation below:

$$g(j, s) = f(j, s) * u(j, s) + \eta(j, s) - \eta(j, s) \quad (2)$$

$$g(j, s) = f(j, s) * u(j, s) \quad (3)$$

F. Clahe

The Clahe technique is used to balance the overall contrast. A further sophisticated version of adaptive histogram equalization is called CLAHE. Clahe was developed to improve the quality of medical imaging of complex structures [24, 25]. The output of this step is shown in Fig. 5.

Fig. 5. Output of the clahe.

The first images are the original images and the second images are the output of the CLAHE.

Let an image size be $M \times M$ and each tile size for image is $m \times m$ then the total number of tiles is calculating as:

$$T = \frac{M \times M}{m \times m} \quad (3)$$

Clip limit $C_L = M_{CL} \times M_{avg}$ is used to construct the histograms for these tiles.

Where,

M_{CL} = normalized contrast limit. M_{AVG} = total pixels average value.

The equation of pixels average is (3):

$$M_{AVG} = \frac{M \times M}{Mg} \quad (4)$$

Where,

Mg = total gray levels Mx and My = total pixels of x and y dimension

$$M_{CP} = \frac{M \sum cl}{Mg} \quad (5)$$

Where,

C_L = the clipped pixel.

$$M_r = \frac{Mg}{M_r} \quad (6)$$

Where,

M_r is remaining number of clipped pixels

clahe formula:

$$I_c(p, q) = T(t(p, q) = \frac{(L-1)}{PQ} \sum_j^K n_j \quad (7)$$

G. Verification

It is possible to lose a lot of image quality when using many image preprocessing algorithms, so various types of geometric analysis like PSNR, SSIM, MSE, and RMSE are performed to determine if the image quality has been compromised.

H. MSE

MSE describes the pixels of the two pictures under comparison as having a cumulative squared error. A value close to 0 indicates acceptable image quality, while the MSE value ranges from 0 to 1. A value of 0 indicates a picture with no noise. Values higher than 0.5 indicate a decline in quality.

$$MSE = \frac{1}{AB} \sum_{i=0}^{r-1} \sum_{j=0}^{n-1} (O(r, s) - P(r, s))^2 \quad (8)$$

Where,

The ground truth image is O , the image which is processed is P and A, B denote the pixels of O and P , and r, s denote pixel rows of p, q .

I. PSNR

Calculating PSNR begins with calculating MSE. PSNR is then estimated using the following formula:

$$PSNR = 10 \log_{10} \left(\frac{Q^2}{MSE} \right) \quad (9)$$

Q is the highest fluctuation in the input image data type. A maximum of 255 pixels is used as image maximum value. Typically, PSNR should be between 30 and 50 dB for an 8-bit image [26].

J. SSIM

SSIM measures the decline in image condition caused by preprocessing processes. In this estimation, 1 indicates "perfect structural similarity" and 0 means "no structural similarity" [9].

$$SSIM(r, s) = \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\sigma_x^2 + \sigma_y^2 + c_2)} \quad (10)$$

Where,

r, s is two image, σ_r^2, σ_s^2 is variance, σ_{rs} is covariance of the images and μ_r, μ_s is the average of two image calculated using the Gaussian window.

K. RMSE

Image quality is measured by RMSE, which compares the original and processed images. RMSE values near 0 indicate good image quality and fewer errors.

$$RMSE = \sqrt{\sum_{j=1}^N (d_{fi} - \frac{d_d}{N})^2} \quad (11)$$

Where, d_{fi} is the different of predict value, d_d is the actual value, N is the Size of the Dataset.

TABLE II. SHOWN PSNR, MSE, SSIM, RMSE

Image	MSE	PSNR	SSIM	RMSE	Image
Image_1	15.17	39.35	0.962	0.13	Image_1
Image_2	13.63	40.66	0.961	0.13	Image_2
Image_3	14.25	42.59	0.964	0.11	Image_3
Image_4	13.13	38.28	0.968	0.12	Image_4
Image_5	12.38	45.47	0.962	0.09	Image_5

In this Table II we are showing some statistical value which proved that our image processing techniques are the best. Image quality is not damaged after image preprocessing.

IV. DATA SPLIT

After analyzing the statistical value of the image, the full dataset is divided into three segments (training set, validation set, and testing set). Three splitting ratios for training-testing data (90:10, 80:20, and 70:30) are often used to evaluate the effect of the overall accuracy of a model is affected by the size of the training-testing data [27]. According to this study, the 70:30 ratio means 70% train sets, 10% validation sets, and 20% test sets.

V. PROPOSED MODEL

As previously said, this research explored with a total of five transfer learning network to identify the ideal network based on accuracy in order to discover the best transfer learning model for the classification issue. Transfer Learning

Model: There are five pre-trained models total—InceptionV3, MobileNetV2, MobileNet VGG16, and VGG19—that are trained on training data and tested on testing data.

A. VGG-16

Simonyan and Zisserman [28] introduced the DCNN model known as VGG16. The model achieving 92.7% top 5 test accuracy in the ImageNet dataset [29]. A VGG16 produced a substantially greater accuracy than a fully trained architecture, according to studies on the efficiency of transfer learning [30]. The kernel may learn more complicated characteristics with the help of the VGG model's enhanced depth. The VGG16 architecture is a convolutional neural network set. It is regarded as one of the best computer vision models to date. VGG16 is unusual in that it only employs 3 x 3 filter convolution layers with a stride 1 and always uses the same padding and maxpool layer with a 2 x 2 filter stride 2. VGG16 has 16 layers. Spatial pooling is achieved in this model by employing five max pooling layers. After a sequence of convolutional layers, three fully connected (FC) layers are added. Finally, there's the softmax layer. In all networks, always set the layers 1 and 2 in the same way.

B. VGG-19

There are 19 layers in the VGG19 model, a variation of the VGG model. The VGG19 model concludes with three additional FC layers, totaling 19 layers with 4096, 4096, and 1000 neurons in each layer. Moreover, five Maxpool layers are included as well as a Softmax layer. It is a characteristic of convolutional layers that ReLU is activated. Non-linearity is included into models using Rectified linear units (ReLU), which increases classification and compute performance. Three layers were built, all of which were entirely interconnected. Finally, there is a softmax function as the model's final layer.

C. MobileNet

The MobileNet model is TensorFlow's first computer vision model designed specifically for mobile applications. MobileNet employs depth-wise separable convolutions. The number of parameters is dramatically reduced compared to a network with regular convolutions of the same depth. As a result, portable deep neural networks have been developed. To generate a depth-separable convolution, two techniques are used.

- In-depth convolution.
- Convolution at the point of interest.

MobileNet, a CNN class that Google freely licenses, is a great starting point for training our ultra-short and ultra-fast classifiers.

D. MobileNetV2

The Google community has suggested MobileNetV2. There are two kinds of blocks in it, and each block has three levels. Each block has 11 convolutional layers with 32 filters in the first, third, and second layers. All layers use the rectified linear activation function (ReLU). In order to prevent non-linearity from corrupting a significant volume of data, longitudinal bottlenecks are essential between layers. There is

a difference between the strides of the two blocks, with block 1 having a stride of one and block 2 having a stride of two.

E. InceptionV3

A new InceptionV3 design aims to reduce the needed computational power by modifying earlier Inception designs. It is possible to decrease the computational cost by regularizing, reducing the dimension, factorizing convolutions, and parallelizing computations.

F. BrainNet-7

The BrainNet-7 has three convolutional layers and one max pool layer for each convolutional layer Fig. 6. There are 3 X 3 convolutional kernels in the model. There is a dropout value of 0.5 in the first block of the convolutional kernel, and 32 in the second block of the convolutional kernel. 'Relu' has been selected as the activation function for the final layer, followed by 'SoftMax'. Using batch size 32 and Adam optimizer, categorical crossentropy was used as a loss function. There is an 0.001 learning rate.

Fig. 6. BrainNet-7 model architecture.

VI. TRAINING APPROACH

For training the models, the batch size is 16, and the maximum number of epochs is 100[31]. During training, Keras' "callback" function was used to store the weights of the best model based on a minimal loss value [32]. Adam has been used as an optimizer at a learning rate of 0.001. Categorical cross-entropy is the defaulting loss function for multiclass challenges [33]. In order to forecast the probability for each class, 'Softmax' activation is used. Since Softmax normalizes all values between 0 and 1, their aggregate always equals 1.

$$\text{Softmax}(y_i) = \frac{\exp(y_i)}{\sum_j \exp(y_j)} \quad (12)$$

VII. ABLATION STUDY

An ablation study is often carried out in CNN-based applications to evaluate the model's stability and performance after deleting or changing various layers and hyperparameters. Using hyperparameter ablation to develop a robust and fine-tuned network in this study.

VIII. RESULT AND DISCUSSION

In this section, several performance matrix are shown as mathematically.

$$\text{ACC} = \frac{TP+TN}{TP+TN+FP+FN} \quad (13)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (14)$$

$$\text{Specificity} = \frac{TN}{TN+FP} \quad (15)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (16)$$

$$\text{ACC} = 2 \frac{\text{precision} * \text{recall}}{\text{precision} + \text{recall}} \quad (17)$$

$$\text{FPR} = \frac{FP}{FP+TN} \quad (18)$$

A. Result of Transfer Learning and CNN Model

Table III shows the training accuracy, test accuracy, validation accuracy, and train, test and validation loss for the five transfer learning models. The CNN model has the highest accuracy, as can be seen in the table.

TABLE III. RESULT OF TRANSFER LEARNING AND CNN MODEL

Model	Train_Accuracy	Train_Loss	Val_Accuracy	Val_Loss	Test_Accuracy
VGG19	96.67	0.22	95.63	0.21	95.24
VGG16	97.77	0.18	96.83	0.12	96.13
Mobile Net	95.43	0.18	94.23	0.28	94.24
Mobile Net V2	95.76	0.25	94.63	0.32	94.59
InceptionV3	76.86	0.421	76.21	0.392	76.21
CNN	97.91	0.15	97.95	0.11	97.95

In this table we are showing the Accuracy of the all model which we employing in this study.

IX. RESULT AND ABLATION STUDY

It is possible to improve classification accuracy by changing several design components to make it more reliable. A total of five studies are run as an ablation study, modifying various BrainNet-7 elements based on the optimized VGG16 architecture.

A. Case Study-1 Changing Flatten Layer

In case study 1, it is shown in Table IV that the flatten layer provides the highest accuracy when it is used. Additionally, global average and global maximum pooling do not provide good accuracy. Flattening the layer gives 96.93% accuracy, while global max and global average pooling give 95.24 and 96.83% accuracy, respectively.

TABLE IV. CHANGING FLATTEN LAYER

Configuration No.	Flatten layer type	Epoch x training time	Test accuracy (%)	Finding
1	Flatten	97 x 5s	97.95%	Highest accuracy
2	Global Max pooling	60 x 4s	95.24%	Accuracy dropped
3	Global Average pooling	54 x 5s	96.83%	Accuracy dropped

B. Case Study-2 Changing the Batch Size

Changing the batch size is the subject of case study two. A batch size of 32 is the most accurate, followed by 32, 64, and 16. When the batch size is 32 the test accuracy is 96.39%.

C. Case Study-3 Changing Loss Function

Case study 3 experiments with changing loss functions and finds that categorical cross-entropy gives the best outcomes, (Table V) 96.93%.

TABLE V. CHANGING LOSS FUNCTION

Configuration No.	Loss Function	Epoch x training time	Test accuracy (%)	Finding
1	Binary Crossentropy	Error	Error	Error
2	Categorical Crossentropy	43 x 5s	98.13%	Highest accuracy
3	Mean Squared Error	96 x 5s	96.82%	Accuracy dropped
4	Mean absolute error	12 x 4s	68.25%	Accuracy dropped
5	Mean squared logarithmic error	45 x 5s	96.83%	Accuracy dropped

D. Case Study-4 Changing Optimizer

Adam optimizer provides the highest accuracy when compared to Nadam, SGD, and ADamax optimizers in case study 4 (Table VI).

TABLE VI. CHANGING LOSS OPTIMIZER

Configuration No.	Optimizer	Epoch x training time	Test accuracy (%)	Finding
1	Adam	97 x 5s	98.41%	Highest accuracy
2	Nadam	44 x 5s	98.13%	Previous dropped
3	SGD	90 x 5s	84.13%	Accuracy dropped
4	Adamax	88 x 5s	90.48%	Accuracy dropped

E. Case Study-5 Changing Learning Rate

In comparison to 0.001, 0.0001, and 0.01, when using 0.01 provide the highest accuracy (Table VII).

TABLE VII. CHANGING LEARNING RATES

Configuration No.	Learning rate	Epoch x training time	Test accuracy (%)	Finding
1	0.01	92 x 55s	98.41	Accuracy dropped
2	0.001	97 x 5s	98.43%	Highest accuracy
3	0.0001	68 x 57s	97.28	Accuracy improved

F. Performance Analysis of Best Model

After executing the ablation study on the suggested BrainNet-7 model, an improvement in classification accuracy is shown on CNN model. A summary of BrainNet-7 final setup is provided in Table VIII.

TABLE VIII. EVALUATED PERFORMANCE OF BEST MODEL

Configuration	Value
Size of images	224 x 224
Epoch	97
Optimizer	Adam
Learning rates	0.001
Batch sizes	16
Activation functions	Softmax
Dropouts	0.5
Momentums	0.9
Accuracy	98.43

G. Performance Analysis and Statistical Analysis

In Table IX show the FPR, FNR, FDR, KC, MCC, MAE and RMSE of the best hyper-tuned CNN (BrainNet-7) model.

TABLE IX. PERFORMANCE ANALYSIS AND STATISTICAL ANALYSIS

Accuracy	FPR (%)	FNR (%)	FDR (%)	KC (%)	MCC (%)	MAE	RMSE
98.43	1.46	2.22	2.59	99.01	88.35	2.09	5.79

Fig. 7. Losses and accuracy curve.

Fig. 7 shows the accuracy and loss curves for the best-performing model. The training curve converges without bumps from the first to the final epoch. Based on the difference between validation and training accuracy curves, there is no evidence of overfitting in the course of training. As with the training curve, the loss curve in figures 6 unites smoothly to the end epoch. The trainings and losses curves indicate that neither overfitting nor underfitting occurred. The confusion matrix is also shown in Fig. 7.

H. Comparison with Existing Work

This section Table X compares the proposed CNN models (BrainNet-7) to classify. The accuracy, reliability and competency of these earlier investigations and our suggested methods are compared in Table VIII.

TABLE X. COMPARISON BETWEEN PROPOSEDMODEL AND PREVIOUS STUDY

Paper	Dataset	Classifier	Accuracy
[13]	MRI	SVM	85.23%
[14]	MRI	ANN	92.14%
[15]	MRI	Machine Learning Classifier	97.00%
[16]	MRI	CNN	94.2%
[17]	MRI	CNN	95.4%
[18]	MRI	Faster-R-CNN	91.66%
[20]	MRI	Machine learning classifier	98.1%
Proposed Model (BrainNet-7)	MRI	Fine-tuned Transfer Learning	98.43

X. CONCLUSION

For training, deep learning systems for tumor identification in medical imaging need massive, annotated datasets. Subspecialty, radiologists often manually annotate images. AI's progress in medical imaging is hampered by unreasonably high related costs (time and expertise). Transfer learning techniques have been studied to train a competitive classifier with the least amount of annotation expense. Transfer learning is a popular technique that allows models to apply the information they have gained on massive datasets to new recognition and classification tasks. This study proposes a system based on a transfer learning model for classifying brain tumor MRI images more accurately which can reduce the death ratio. This experiment uses various preprocessing techniques to remove speckle noise and artefacts from the image. Five transfer learning models have been experimented with in the Brain Tumor MRI dataset. After that, a hyperparameter ablation study is conducted on the best-performed transfer learning model to get the best outcome from the model. The proposed model has been fine-tuned with proper hyperparameters, that's why it gained the highest accuracy.

XI. LIMITATIONS AND FUTURE SCOPE

The suggested CNN models for multiclass classification outperformed traditional classifiers considerably, according to the whole discourse of this work. The dataset for the suggested model is too small—it only contains 7022 images—and the study's major limitation—the leakage of a significant amount of genuine medical data—can be solved in the future. As a result, it is possible to expand the quantity of unprocessed medical photos and assess the performance of the suggested model using real-time medical data in the future. The suggested model of this research does, however, successfully categorize the four types of brain tumor classes in the majority of test instances. It is feasible to make sure that the recommended fine-tuned CNN model is accurate and improved in all areas of diagnosis, despite a few small disadvantages.

Research on Real-time Monitoring of Video Images of Traffic Vehicles and Pedestrian Flow using Intelligent Algorithms

Xiujuan Dong*, Jianping Lan, Wenhuan Wu
School of Electrical & Information Engineering
Hubei University of Automotive Technology
Shiyan, Hubei 442002, China

Abstract—The development of urbanization has brought many traffic problems, among which the delayed feedback of traffic flow and people flow has led to traffic congestion. In order to effectively analyze the traffic flow and people flow on the traffic road, this research proposes a traffic surveillance video image object detection model based on the improved Vibe algorithm, and uses the moving historical image to track the traffic flow and people flow. Finally, the performance analysis of the algorithm shows that the loss rate of the improved Vibe algorithm proposed in the study is only 0.25%, and its detection accuracy reaches 91.25%. The above results show that the use of Vibe intelligent algorithm can significantly improve the detection effect of traffic flow and pedestrian flow in traffic monitoring video, help to improve urban traffic management ability and promote the development of urban modernization.

Keywords—Urban development; object detection; traffic video; Vibe algorithm; visitors flowrate; image filtering

I. INTRODUCTION

Rapid economic development promotes urban development. However, in urban development, the increase in the number of motor vehicles and long-term residents increases the difficulty of traffic control. Therefore, a large number of studies have put forward the concept of intelligent transportation on the existing urban traffic problems. In intelligent transportation, it is believed that the processing of traffic data can be realized by using intelligent algorithms, and the traffic pressure can be relieved by understanding the traffic conditions [1, 2]. In the current research, the emphasis is on the systematic and real-time nature of intelligent transportation, which realizes the traffic management of multiple road sections through its system planning, makes timely traffic diversion through real-time nature, and ensures the convenience of people's travel [3]. With the development of computer technology, intelligent algorithms have been continuously introduced in the monitoring and monitoring of traffic flow and people flow. The purpose is to use the moving target tracking algorithm to grasp the changes of vehicle and people flow in the traffic section in real time, and provide a planning scheme for subsequent sections [4]. However, it has to be admitted that my country's traffic video image traffic flow and people flow monitoring technology started later than foreign countries, and the existing detection schemes are difficult to deal with the increasing traffic problems. In this study, a video image target

recognition model based on the improved Vibe algorithm is proposed, and the tracking of vehicles and human bodies is realized with the help of motion history images, and the real-time monitoring of traffic flow and people flow is realized, in order to relieve urban traffic pressure and speed up China's Urbanization.

The main structure of the article is divided into four parts. In the second part, the development status of urban traffic monitoring technology and image processing technology is analyzed. In the third part, the intelligent algorithm design for traffic vehicle and pedestrian flow monitoring is proposed. In the fourth part, the algorithm performance analysis and monitoring effect test are conducted.

There are two innovations in this paper. First, image processing is carried out for traffic flow and pedestrian flow monitoring videos; the second is to study the further processing of the surveillance video image and target tracking with the aid of only algorithms, which improves the real-time detection capability of the surveillance video.

II. RELATED WORKS

With the continuous progress of urban traffic, the monitoring technology for the detection of urban traffic vehicles and people flow has also become increasingly prominent. In the same way, aiming at the existing urban traffic flow management problems, the research proposes to introduce intelligent algorithms to realize the monitoring and control of vehicle flow and pedestrian flow. In order to further understand the monitoring status of traffic flow, the research status in this field is analyzed. In order to promote the development of urban modernization, Pan S et al. used network tomography to realize the optimization of urban traffic monitoring, and used FIM and multi-agent reinforcement learning methods to help monitors improve the processing capacity and performance of surveillance video. The simulation experiment proves that the proposed scheme can effectively reduce the error of monitoring video processing compared with the traditional scheme [5]. In order to improve the traffic monitoring ability, Rogowski M gained experience from the traffic monitoring of tourists in national parks. In this study, Rogowski M proposed a comprehensive monitoring method. It has been proved by practice that the proposed method can effectively monitor and evaluate tourists [6]. In

*Corresponding Author.

order to monitor the traffic flow, Zhu L et al. proposed a self-organized flow monitoring measure, and finally proved the feasibility of the measure through safety analysis and experimental verification. However, although this research can achieve traffic flow monitoring, it is difficult to extract effective targets from the monitoring video [7]. In order to obtain traffic conditions in low-light environments such as nighttime, Cai X et al. explored light control strategies in traffic monitoring, aiming to use threshold increments to evaluate disability glare, and showed in the final results, research. The proposed light control strategy can reduce the interference caused by glare in traffic monitoring and improve the effect of traffic monitoring [8]. Almeida TD et al. believe that most of the current traffic monitoring systems require high maintenance costs, so in order to improve the effect of traffic monitoring and reduce costs, a community-based decentralized traffic monitoring system is proposed. The traffic conditions of the road sections are analyzed, and the comparative analysis finally confirms that the accuracy of the system proposed by this study can be higher than 90% in multiple scenarios. However, this research is difficult to monitor the rapid growth of traffic flow and people flow in real time [9].

The processing of traffic monitoring is to process the detected video images. In the research of video image processing, a large number of scholars have proposed effective methods. In order to increase the sensitivity and specificity of medical video image processing, Obukhova N et al. proposed a personalized processing method, which uses artificial intelligence technology to realize the visualization of video image data, which is displayed in the result classification. The proposed video image processing method has high accuracy and improves the diagnostic efficiency of medical images [10]. Long C proposed an edge computing framework to optimally group mobile devices into video processing groups, and at the same time proposed an efficient collaborative video processing scheme that can achieve sub-optimal performance with existing detection accuracy. Each parameter is evaluated, and the effectiveness of the method proposed in the study is confirmed in the simulation experiment, and its superiority compared with the baseline scheme is proved [11]. Ragan-Kelley J et al. believed that there was too little work in different stages in image processing to load the results into the corresponding memory and would add extra cost, so the team wrote a high-performance image processing code that implements The simplification of image processing and the ability to use a dedicated image processor to generate effective results finally confirmed the efficiency of the image processing code through experiments. However, the image processing code proposed in the study has some limitations in application, and is difficult to deal with the environment with huge data [12]. In order to detect acephate, Osman MJ et al. proposed an image processing technology combined with an aptamer sensor, using the sensor to obtain the relevant information of the aptamer, and using the image processing technology to achieve colorimetric detection, and finally proved in the experiment the effectiveness of the current method. Although this research can effectively achieve image detection, it uses sensor technology, which is vulnerable to environmental interference [13]. In order to reduce the mite infection in bee farming, Sevin S et al. proposed an image capture device that can automatically focus

detection. The device is compatible with cloud storage and 5G technology, and can distinguish bees from Varroa mites through images, and finally train on samples. The method proposed in the research shows that the method can effectively distinguish between honeybees and Varroa mites [14].

To sum up, with the continuous development of intelligent technology, the research on video image processing in modern technology research is increasing, but in traffic monitoring, there are still few effective processing solutions for monitoring video. For the real-time monitoring of traffic flow and people flow, a monitoring video image processing algorithm based on Vibe intelligent algorithm is proposed to detect the traffic flow and people flow. See Fig. 1 for the structure and flow of research contents.

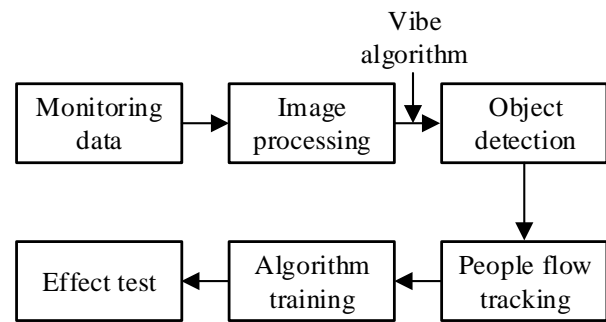

Fig. 1. Workflow diagram.

III. DESIGN OF TARGET DETECTION ALGORITHM FOR TRAFFIC SURVEILLANCE VIDEO IMAGE

A. Traffic Flow and People Flow Detection

In urban traffic video detection, affected by the traffic environment and the natural environment, the monitoring video has significant interference noise. Therefore, in order to accurately monitor the real-time traffic flow and people flow, the video image needs to be preprocessed first [15, 16]. In the research, for image denoising in surveillance video, the method of image filtering is used to extract the target features in the image, and the median filtering method is used to suppress the noise in the image. The basic principle of median filtering is to replace the value in the image with the median value of the region where it is located. One-dimensional median filtering is shown in equation (1) [17].

$$y = med(f_0, f_1, \dots, f_k) \quad (1)$$

In formula (1), it (f_0, f_1, \dots, f_k) represents the sequence value in the one-dimensional sequence; k it represents the sequence length. After filtering, the image needs to be enhanced. In the image enhancement, the research adopts Laplacian sharpening to achieve it. The Laplace calculation method is shown in formula (2).

$$\nabla^2 f(x, y) = \frac{\partial^2 f}{\partial^2 x} + \frac{\partial^2 f}{\partial^2 y} \quad (2)$$

In formula (2), it (x, y) represents the coordinates of a certain point in the image.

The detection of traffic flow and people flow in video images is to find out the moving vehicles and people from the video. The target detection algorithm is used to realize the target selection of continuous video. In the research, the background difference method is used to find the appropriate target. The background difference method is often used in the detection of moving objects such as human bodies and vehicles, which can strip the background area in the video image to obtain moving objects [18, 19]. In the application of the background difference method, the Vibe algorithm is widely used, and its calculation is divided into three steps. The first is background initialization. In the background initialization, the video is initialized through the first frame image, that is, to establish the current video. For the background model, see equation (3).

$$BK_m^0 = f^0(x^j, y^j) | (x^j, y^j) \in N_G(x, y) \quad (3)$$

In formula (3), it $N_G(x, y)$ represents the neighborhood point. After the background is initialized, the foreground image is detected, and the background model established by the background initialization is used to judge whether the subsequent image sequence belongs to the foreground, and the foreground part is separated. The judgment formula is shown in formula (4).

$$f^k(x, y) = \begin{cases} fore & BK > T \\ back & BK \leq T \end{cases} \quad (4)$$

In formula (4), T represents the threshold set according to the experimental environment. When the value of the background model is greater than T that, it is judged as the foreground, and when it is less than, it is judged as the background. In addition, as shown in formula (4), in the selection of the foreground part, the pixel is the selection of points in random. The last step is to update the background model of the image, in order to reduce the error effect of the light intensity on the image [20, 21]. In the process of updating the background model, for any background point, it has a certain probability to update the background model, and randomly selects samples in the updated sample set. After a certain period of time, the probability that the sample value is retained can be expressed as (5).

$$P(t, t + dt) = \left(\frac{N-1}{N}\right)^{(t+dt)} \quad (5)$$

In formula (5), it N represents the number of background models; dt represents the update time; $\frac{N-1}{N}$ represents the probability of not updating at time t . However, the traditional Vibe algorithm is based on the background model. Under the premise of efficient image processing, there is still ghosting phenomenon. The reason is that the algorithm is difficult to accurately detect the slow moving stage. For this reason, in order to solve the ghosting of the Vibe algorithm, the research

introduces the frame difference image of adjacent frames to optimize the effect of foreground detection, as shown in Fig. 2.

As shown in Fig. 2, for the calculation of the frame difference image of adjacent frames will judge the selected first frame image after the background initialization. When the selected image is not the first frame image, the pixel points selected multiple times are filtered out by calculating the adjacent frame difference, and they are eliminated to ensure that no background points appear in the foreground part and reduce the appearance of ghosts. In addition, in the actual traffic situation, when there is sufficient light, pedestrians and vehicles on the road will produce obvious shadows during the movement, and the existence of shadows will be judged as the foreground part during detection, resulting in the failure of foreground detection. To achieve better results, a shadow removal algorithm is proposed in this research. First, the brightness in the video image is modeled, see equation (6).

$$s_k(m, n) = E_k(m, n)\rho_k(m, n) \quad (6)$$

In formula (6), $E_k(m, n)$ represents (m, n) the radiance of the pixel point, and $\rho_k(m, n)$ represents the reflection coefficient of the vehicle or pedestrian to the light. On the basis of brightness modeling, HSV is used to eliminate shadows, and the discriminant function of shadow detection is shown in formula (7).

$$HSV(x, y) = \begin{cases} 1 & \partial \leq \frac{I_k^V(x, y)}{B_k^V(x, y)} \leq \beta \cap (I_k^S(x, y) - B_k^S(x, y)) \leq T_s \cap \\ & |I_k^H(x, y) - B_k^H(x, y)| \leq T_B \\ 0 & other \end{cases} \quad (7)$$

Fig. 2. Image foreground detection.

In formula (7), $I_k^V(x, y)$, $I_k^S(x, y)$, $I_k^H(x, y)$ represent the component of the k th frame image pixel in HSV space; $B_k^V(x, y)$, $B_k^S(x, y)$, $B_k^H(x, y)$ represent the component of the k th frame background pixel in HSV space; ∂ , β represent the judgment parameter; T_s , T_b represent the threshold; when the discriminant function When the value is 1, the position is (x, y) defined as the shadow, and the rest are the target. The improved Vibe algorithm and shadow elimination algorithm are combined to realize the detection of traffic flow and human flow. The detection process is shown in Fig. 3.

As shown in Fig. 3, in the moving target detection, the traffic surveillance video is firstly used as the input for detection, and the HSV shadow removal algorithm is used to eliminate the ghost in the target detection. Image denoising is used to remove noise in video images after target detection. Finally, the contours of moving objects in the video images are extracted to analyze the foreground objects of vehicles and human bodies in the images.

B. Traffic Flow and People Flow Tracking and Early Warning

In actual traffic conditions, different traffic conditions have significant differences in the impact of urban traffic flow and people flow, so after solving the problem of vehicle flow and people flow detection, it is necessary to track the moving target. In moving target tracking, it is necessary to perform feature matching on each frame image in the video, that is, mark each moving target, so as to establish the correspondence between adjacent frame images [22, 23]. In the research, in order to track and identify the moving target, the motion history image is used for module tracking, and H is the pixel intensity in the motion history image. The calculation method is shown in formula (8).

$$H(x, y, t) = \begin{cases} \tau & \psi(x, y, t) = 1 \\ \max(0, H_\tau(x, y, t-1) - \delta) & \text{other} \end{cases} \quad (8)$$

Fig. 3. Detection process of vehicle flow and passenger flow.

In formula (8), τ represents the duration between two frames in the video scene; t represents the time of the target

pixel point; δ represents the decay parameter; $\psi(x, y, t)$ represents the inter-frame difference method. In addition, in the tracking process, the size of the weight of the pixel will affect the stability and reliability of the target detection, and the weight calculation is shown in formula (9).

$$k(x)C = \frac{1}{\sum k(\frac{x_i - x_0}{h})}, \quad \sum_{n=1}^m q_n \quad (9)$$

In formula (9), C represents the normalization coefficient; q_n represents the color distribution probability; h represents the area radius; m represents the total number of pixel points. The normalization coefficient is expressed as formula (10).

$$C = \frac{1}{\sum (\frac{y-x}{h})} \quad (10)$$

Secondly, similarity is used to measure the matching degree between moving target templates, see equation (11).

$$p = \sum_{n=1}^m \sqrt{q_n(y)q_n(x)} \quad (11)$$

In Equation (11), $q_n(x)$, $q_n(y)$ represent the image x axis and y the color distribution probability on the axis, respectively. According to the pixel points in the motion history image proposed by the research, the tracking of traffic flow and people flow is realized, and the method flow is shown in Fig. 4.

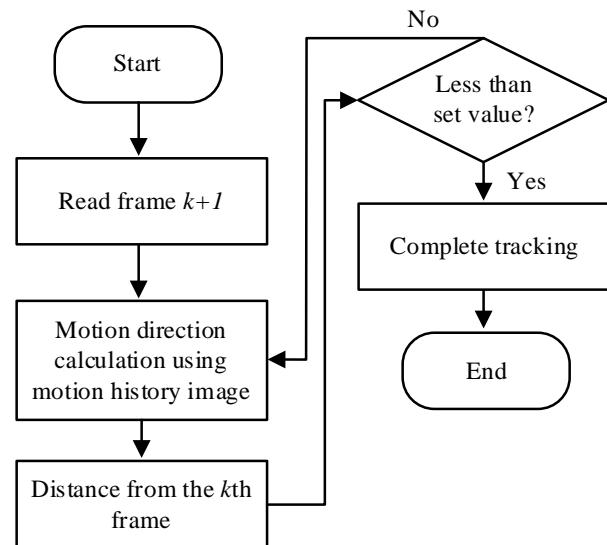

Fig. 4. Tracking process of traffic flow and people flow.

Finally, it is necessary to make a certain early warning in the monitoring of traffic flow and human flow, so as to reduce the incidence of traffic accidents. In the early warning, it is mainly aimed at identifying the distance between the age of the vehicle and the vehicle and between people. A neural network is used for distance monitoring. The distance between cars and cars and between people Z has been expressed since, and its calculation method is shown in formula (12).

$$Z = f * H / y \tag{12}$$

In formula (12), f represents the focal length of the monitoring equipment; H represents the distance from the ground to the particle; y represents the distance from the horizontal contact point of the previous moving target to the vertical distance of the video image. To set parameters for the rear vehicle under monitoring, the distance formula can be updated to formula (13).

$$Z = f * H / y = F * H / Y \tag{13}$$

Formula (13), F represents the equivalent vertical focal length of the rear vehicle in the video image; Y represents the number of pixels at the bottom of the front vehicle and the key position of the image. Through traffic monitoring, it is judged whether there is a possibility of collision between two vehicles, and the time of the vehicles that may collide is estimated. Equation (14) is used to calculate the transformation of vehicles in the image.

$$h = Z_0 / Z_t \tag{14}$$

Equation (14), Z_0 the position of the vehicle detected at the initial time in the image is Z_t expressed, and the position of the vehicle detected at time t in the image is expressed. Considering the speed difference between v vehicles, calculating the collision time between vehicles is shown in Equation (15).

$$G = \frac{Z_0 * a}{v_0^2} \tag{15}$$

In formula (15), a represents the braking parameter. Through the motion detection of vehicle information and people flow information in traffic monitoring video images, the monitoring of traffic flow and people flow and accident warning are realized.

IV. ALGORITHM PERFORMANCE AND APPLICATION TEST

A. Algorithm Performance Analysis

In the research, the performance of the proposed monitoring video image target detection algorithm for traffic flow and people flow is analyzed. The experiment is set up in Intel Core i5-5300, its main frequency is 2.3GHz, the memory is 4GB, and the operation is performed in Windows7. The data set used in the research is the road surveillance video data of a certain urban area on sunny days, cloudy and rainy days and at night. The data is divided into three data sets, which are 70%

training set, 20% test set and 10% application set. , select the training set and test set for calculation training. First, evaluate the loss value of the algorithm through comparative analysis, as shown in Fig. 5.

As can be seen from Fig. 5, the research compares the detection loss rate of the improved Vibe algorithm with the traditional convolutional neural network and A* algorithm. As shown in Fig. 5(a), in the training set, the loss rate of the traditional convolutional neural network during the training process shows a decreasing trend, and after the number of iterations reaches 50, it decreases to near the minimum value. The minimum value of the loss rate is 0.43%. In the training process of the A* algorithm, when the number of iterations reaches 70, the changes of the algorithm begin to gradually stabilize, and finally the loss rate is stabilized at 0.51%. However, the improved Vibe algorithm proposed by the study begins to stabilize after the number of iterations reaches 30, and its loss rate is reduced to 0.25%, which is significantly lower than the other two algorithms. Fig. 5(b) is the test effect in the test set, where the three algorithm changes are consistent with the training set. Secondly, the missed detection rate and the false negative rate index of the three algorithms are analyzed to judge the accuracy of different algorithms in target recognition, as shown in Fig. 6.

Fig. 5. Training and testing of loss rate.

Fig. 6. Test results of missed detection rate and missed report rate.

As can be seen from Fig. 6, with the continuous increase of the confidence, the missed detection rate and the false negative rate of the three algorithms show a decreasing trend. It can be clearly seen that during the training process of the improved Vibe algorithm proposed by the study, the missed detection rate and the false negative rate indicators show a decreasing trend, and show a rapid decline before the confidence level of 0.2, and then gradually show downward trend. It can be seen from the changes of the missed detection rate and the false negative rate indicators of the improved Vibe algorithm that compared with the changes of the FPPI indicators of the

traditional convolutional neural network and the A* algorithm, the improved Vibe algorithm can reduce it to a lower level, and its reduction speed is also significantly higher than the rest of the object detection algorithms. After that, the precision and recall rates of all algorithms in target detection training are analyzed, and the PR curve is used to describe them, as shown in Fig. 7.

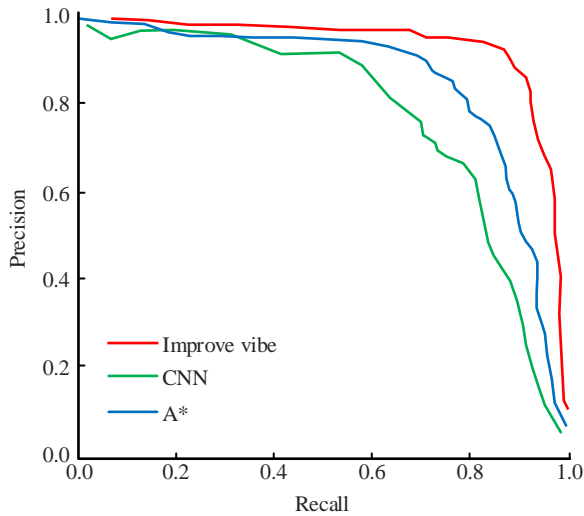

Fig. 7. PR curve comparison.

As can be seen from Fig. 7, in the change of the PR curve, the traditional convolutional neural network is closer to the lower left corner, indicating that the traditional convolutional neural network has a lower detection accuracy than the A* algorithm and the improved Vibe algorithm. In addition, the precision rate and recall rate of the A* algorithm are in the middle position, and the calculated precision rate and recall rate are 87.62% and 89.17%, respectively. The improved Vibe algorithm proposed in the study is closer to the upper right corner, and its precision and recall rates are 91.25% and 93.33%, respectively. Comparing the PR curves of the three algorithms, it can be seen that the improved Vibe algorithm proposed in the study has higher precision and recall rates, and the target recognition and detection effects reflected in data training are more significant.

B. Application Test of Target Detection Algorithm

The monitoring video traffic flow and people flow detection algorithm proposed by the research is applied and practiced, and 10% of the collected traffic data in an urban area is used as a sample for application testing. Firstly, the detection results of traffic flow and people flow under different algorithm models are analyzed, and the real rate is used as the detection index, as shown in Fig. 8.

From Fig. 8, in the detection of traffic condition data, the true rate of the detection model proposed in the study can finally reach 0.98, and it can be known from the changes of its true rate and false positive rate that its highest false positive rate is only 0.06. From the change of the true rate of the detection model under the convolutional neural network, it can be seen that its true rate is only 0.96 at the highest, and its false positive rate reaches 0.11. In addition, the application of the A*

algorithm detection model shows that the changes of its true rate and false positive rate are significantly different from those of the detection model proposed in the study and the convolutional neural network detection model. The highest value of the true rate is only 0.85, while the false positive rate reached 0.26. The reason for the analysis is that the detection performance of the A* algorithm in the detection of traffic data is interfered by many factors, which leads to the suppression of its true rate. Secondly, the detection time required by different models in the detection of traffic flow and people flow is analyzed, as shown in Fig. 9.

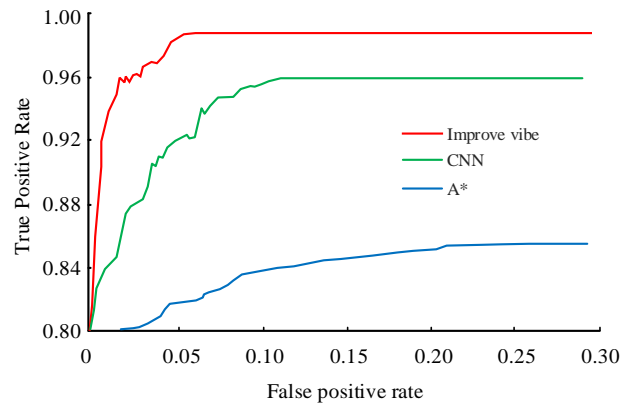

Fig. 8. Real rate test results.

Fig. 9. Comparison of detection time.

It can be seen from Fig. 9 that the average detection time of multiple models in the detection of traffic flow and people flow is within 5s. Among them, the detection time fluctuation of the traditional convolutional neural network detection model is the most significant, and its average time is 3.26s. From the detection time change of this model, it can be seen that with the continuous increase of the number of image frames, its fluctuation frequency continues to increase. The application of the A* algorithm detection model shows that the average detection time of this model is 3.02s, which is a certain reduction compared to the convolutional neural network detection model, and the model has less fluctuation in detection, which is not significantly changed by changes in the number of image frames. Finally, it can be seen from the application results of the detection model proposed in the study

that the average detection time of this model is only 1.83s, and with the continuous increase of the number of image frames, the model detection time has no significant change, which is more efficient than the A* detection model for gentle changes. Then, in order to fully understand the application effect of the human flow and traffic flow detection model proposed by the research, we conduct in-depth exploration by analyzing the renderings of its traffic flow and human flow, as shown in Fig. 10.

As can be seen from Fig. 10, the vehicle flow and people flow detection model proposed by the study can count the flow of vehicles and people, and can distinguish between vehicles and people in detail. At the end of the study, a vehicle collision warning model based on convolutional neural network is proposed, which aims to judge the accident rate during the calculation of traffic flow, and use the receiver operating characteristic curve (ROC) curve to evaluate its warning effect, as shown in Fig. 11.

Fig. 10. Detection effect of traffic flow and pedestrian flow.

Fig. 11. ROC curve comparison.

As can be seen from Fig. 11, the area under the curve of the early warning model proposed by the study is 0.802, which is significantly higher than the standard value of 0.5, and compared with the traditional early warning model, the area under the curve increases by 0.038. The above results show that the proposed accident early warning model can effectively predict the upcoming traffic accident and provide early warning, and is more efficient than the traditional early warning scheme.

V. CONCLUSION

Urban development makes urban traffic show a trend of continuous development. Under this trend, how to monitor and monitor the traffic flow and people flow in the city is very important. In the research, a detection model based on Vibe algorithm is proposed for the traffic flow and people flow information in the traffic monitoring video images, and an algorithm for eliminating vehicle shadows is proposed for the traffic conditions in the video images. Finally, the motion history images are used to detect motion. The target is tracked. The algorithm performance simulation shows that the minimum loss rate of the improved Vibe algorithm proposed by the study reaches 0.25%, and the missed detection rate and the false negative rate are also low. Finally, the application test shows that the detection time of the detection model proposed in the study is only 1.83s, and it can count and distinguish the traffic flow and people flow in the traffic situation. In addition, the ROC of the detection model proposed in the study is in traffic accident warning. The offline area reached 0.802. The above results show that the improved Vibe algorithm is effective in detecting traffic flow and people flow in traffic videos, and the lower detection time indicates that it can realize real-time monitoring of traffic vehicles and people flow. However, the improved Vibe algorithm used in the study does not consider the image quality in different weather conditions. Therefore, in the follow-up work, it is necessary to improve the algorithm's ability to deal with complex environments to ensure that the vehicle flow and pedestrian flow can be monitored in various weather conditions

Abstract—Breast cancer (BC) is considered the most common cancer among women and the major reason for the increased death rate. This condition begins in breast cells and may spread to the rest of the body tissues. The early detection and prediction of BC can help in saving a patient's life. In the last decades, machine learning (ML) has played a significant role in the development of models that can be used to detect and predict various diseases at an early stage, which can greatly increase the survival rate of patients. The importance of ML Classification is attributed to its capability to learn from previous datasets, detects patterns that are difficult to comprehend in massive datasets, predicts a categorical variable within a predefined example and provide accurate results within a short amount of time. Feature selection (FS) method was used to reduce the data dimensionality and choose the optimal feature set. In this paper, we proposed a stacking ensemble model that can differentiate between malignant and benign BC cells. A total of 25 different experiments have been conducted using several classifiers, including logistic regression (LR), decision tree (DT), linear discriminant analysis (LDA), K-nearest neighbor (KNN), naive Bayes (NB), and support vector machine (SVM). In addition to several ensembles, the classifiers included random forest (RF), bagging, AdaBoost, voting, and stacking. The results indicate that our ensemble model outperformed other state-of-the-art models in terms of accuracy (98.6%), precision (89.7%), recall, and F1 score (93.33%). The result shows that the ensemble methods with FS have a high improvement of classification accuracy rather than a single method in detecting BC accurately.

Keywords—Breast cancer; feature selection; classification; machine learning

I. INTRODUCTION

Breast cancer (BC) is the major cause of cancer death among women worldwide. Most recent reports showed a significant increase in patients with BC [1]. Early detection of BC is crucial to increasing the survival rates, lowering the risks of treatments, and decreasing mortality. Cancers are uncontrolled cell divisions that can infect other tissues. BC usually starts in ducts that lead milk to the nipple. Symptoms of BC include changes in the size of one or both breasts, dimpling of breast skin, and a lump in one of the armpits. Breast tumors are classified into two types: benign and malignant. Benign tumors are non-cancerous because they are not diffused into the tissue of the breast surrounding the duct and do not cause harm on one's life. Malignant tumors are cancerous, and their cells spread to the surrounding breast tissue through the duct lining, posing a hazard to one's life.

The traditional approach for cancer diagnosis mainly depends on the experience of medical experts and their visual inspections. However, this type of diagnosis consumes long hours and may be susceptible to human errors[2]. Therefore, an automatic diagnosis system must be developed for the early detection of cancer. In this regard, several studies used machine learning (ML) techniques to develop classification and prediction models for medical diagnosis. ML is a type of artificial intelligence that allows a machine to learn by supplying a collection of facts and gaining knowledge through experience rather than through extensive programming [3].

Classification and prediction are the main techniques used to analyze data in ML. Classification refers to the predictive process of class objects whose label is unknown based on the training samples and predicts a categorical variable within a predefined example. Prediction is the process of determining numerical data that are missing or unavailable for a new observation based on previous information.

Different algorithms for classification, such as (KNN), (SVM), artificial neural networks (ANNs), and (RF) have been applied in several studies to classify BC.

Harikumar et al. [4] used DT and KNN algorithms in the classification of BC. Principal component analysis (PCA) technique was used to select the optimal feature set.

Hiba et al. [5] presented a comparison between the performance of four classifiers: SVM, NB, C4.5, and KNN. These studies mainly aimed to determine whether the classification of data is proper in regard to the efficiency and effectiveness of each algorithm.

Marie et al. [6] reviewed ML models that may predict BC in women and compared their performances. A total of 116 participants were measured for various parameters in the Coimbra dataset: insulin, glucose, resistin, adiponectin, homeostasis model assessment (HOMA), leptin, and monocyte chemoattractant protein-1. They implemented classification algorithms that included logistic regression LR, KNN, SVM, DT, RF, gradient boosting method (GBM), and NB.

Tsehay [7] proposed the KNN model for BC prediction using a grid search approach to find the best hyper-parameter. Then, a comparison was made between the default and tuned hyper-parameters. The results demonstrated that the performance significantly increased when the best parameter

or K value was utilized to train the KNN using the Wisconsin Breast Cancer dataset.

Salehi et al. [8] proposed an ensemble machine for survivability prediction. The main goal was to lower the feature set's size by deleting the more complex features. This machine depended on three basic learners, namely, multi-layer perceptron (MLP), SVM, and DT, based on 25 simple features. The ensemble multi-stage machine was based on a performance investigation using a 10-fold cross-validation (CV) method.

In this paper, we utilized a stacking ensemble model to detect BC. Ensemble learning refers to the training of a set of models instead of a single model and the combination of results using weighted or unweighted techniques [9]. The aim of combining several models is to achieve an improved predictive performance than any single-component model. The solidity of the ensemble limits the dispersion of single-model prediction. Thus, this type of learning contributes to reduction of variance and the generalization error of these models.

The following problems were considered in this article:

Various studies focused on the use of single ML algorithms in BC classification. These studies did not concentrate on the difference in the algorithms' performance in terms of the various data categories in the dataset (i.e., text and numeric). Several algorithms, such as SVM, perform better with text data than numeric data. Other algorithms, such as DT, perform better with text data. Thus, we suggested the ensemble model to aggregate the benefits of different algorithms.

The main contributions of this dataset are summarized in the following points:

We proposed medically intuitive and accurate ML models for BC prediction based on a medical text dataset, and they can be detailed in the following points:

- Survey of the most recent studies in BC classification and prediction;
- We explore the shortcoming of the previous literature and draw the guidelines for future improvements that could overcome these challenges;
- Proposal of a framework for BC classification based on textural features relating to tumor description;
- Framework model is created to solve a binary classification (0 = benign and 1 = malignant);
- Framework included the study of the effect of using FS and ensemble ML models on improving the quality and efficient for Bc classification;
- Comprehensive analysis of popular ML models (single models), such as NB, KNN, linear discriminant analysis (LDA), LR, DT, and support vector classifier (SVC), and ensemble classifiers, such as RF, bagging, AdaBoost, stacking, and voting classifiers;

- Use of feature selection (FS) to reduce data dimensionality and select the optimal feature set;
- Use of various metrics, including accuracy (Acc), specificity (Sp), precision (P), recall (R), F1 score (F1), and area under the receiver operating characteristic (ROC) (AUC) curve, to evaluate our model performance;
- Investigation of the capability of ensemble learning to perform binary classification tasks after the application of data to pipeline preprocessing steps;
- The results showing that the best Acc was achieved by the ensemble model with FS of 98.6%, which can adapt to several types of classification of medical data.

The rest of the paper is organized as follows. Section II discusses the literature review. Section III elaborates the methods and materials. Section IV explains the proposed framework. Section V presents the results. Section VI presents the discussion. Comparing with other works presented in Section VII. Finally, Section VIII concludes the paper.

II. RELATED WORK

Numerous researchers are interested in BC prediction using ML. The related previous works can be divided into two groups: those that used single ML and those that applied ensemble learning. In the following, the two groups will be discussed.

A. The First Group Included Studies that Utilized Single ML

Abdulrahman et al. [10] compared six ML techniques. Their experiment concluded that SVM and RF were the most effective ML classifiers, with an Acc of 97.3% for BC prediction.

R. Karthiga1 et al. [11] proposed a novel strategy of BC diagnosis, which was collected from a visual laboratory, using image analysis and ML techniques. First, they applied image quality enhancement and a region of interest (ROI) selection using the morphological transform process. Then, hot regions, including armpits and neck, were segmented. The image's structural flaws were removed using morphological procedures. The statistical, intensity, and geometric features were extracted from the images of enhanced ROI. Curvelet transform was implemented using the wrapping process. The matrix of gray-level co-occurrence was used to extract textural features from the curvelet coefficients. Various ML techniques were investigated, and the cubic SVM showed the best Acc (93.3%) instead of the limited Acc for SVM.

Shiny et al. [12] proposed a new discriminate ratio for SVM. They compared three of the most common ML algorithms. RF, SVM, and NB have been applied in the original WDBC. The results have shown that SVM exhibited the best performance and an Acc of 97.2%.

Jiande et al. [1] also used the SVM algorithm in addition to KNN, NB, and DT. They utilized gene expression data to classify triple- and non-triple negative BC patients using a ML approach. The implementation of different algorithms

indicated that SVM had the highest performance with an Acc of 90%.

Mücahid et al. [13] suggested a model for the detection of BC using ANN and NB based on age, biomarkers, glucose, body mass index, HOMA, resistin, leptin, adiponectin, and insulin. According to the results, the markers can be used to obtain desirable findings from the classification algorithms; BC was classified with high accuracies of 86.95% and 83.54% with the use of ANN and NB algorithms, respectively.

Milon et al. [14] increased the Acc of the ANN classifier and compared five ML techniques, namely, SVM, KNN, RF, ANN, and LR, for BC prediction. The Acc, sensitivity, Sp, P, negative predictive value, false negative (FN) rate, false positive (FP) rate, F1, and Matthews correlation coefficient were all used to evaluate the study’s performance. The best Acc achieved was by the ANN (98.57%).

Akizur et al.[15] introduced FS as a promising solution for maximizing Acc. FS was focused on to reduce the dimensionality of data and obtain a high level of BC classification Accs The proposed system was based on two stages. First, FS techniques selected 22 features from the WDBC dataset. For BC classification, the ANN with a 15-neuron (15-neuron ANN) classifier obtained an Acc of 96.4%, 99.9% sensitivity, 98.4% P, 1.6% FP rate, and 0.42 s processing time. The proposed 15-neuron ANN classifier achieved a 98.8% classification Acc in the initial experiment, which was performed without FS. The Acc of classification was improved with a median of 0.6% after the application of FS.

Sapiah et al. [16] also focused on improving the Acc. ML algorithms were used along with particle swarm optimization (PSO) for FS. The results indicated that using PSO achieved better performance than their counterparts in terms of Acc. With the use of PSO, NB, KNN, and reduced error pruning (REP) tree obtained accuracies of 81.3%, 66.3%, and 80%, respectively. Without PSO, the accuracies reached 70%, 75.5%, and 76.3%. Thus, the use of PSO increased the Acc of ML algorithms.

B. The Second Group Included Studies that Concerned Ensemble ML

Amal et al. [17] proposed a BC detection method that relies on a bagging ensemble classifier. They used One Rule (OneR) to extract the beneficial features of BC. The results of this method showed that the bagging classifier achieved the best Acc of 92.25% over other single ML classifiers, such as KNN, MLP, and SVM.

Royida et al. [18] proposed a new strategy for enhancing the Acc of BC dataset classification. Hoeffding trees were

used for normal classification, whereas NB was applied to reduce data dimensionality. The results of the proposed model have shown an increase in the Acc to 95.9943%.

Meerja et al. [19] proposed an ensemble model for data BC classification using Bayesian network and radial basis (RB) function, which provided a good classification Acc. Various measurements were used to evaluate the model’s performance. The results have shown that the proposed ensemble method recorded an Acc of 97.42%.

Tina et al. [20] proposed two methods: stacking -voting model and stacking ensemble models with Bayesian methods as base classifiers. In stacking, the model was used with three Bayesian methods, such as NB, hidden NB, and Bayesian network. Six models were created, and their performances were compared. In voting and stacking models, the classifiers were combined by the voting classifier, and three Bayesian methods were used individually with sequential minimal optimization (SMO) as the base classifier and a voting ensemble of REP Tree and RF as meta classifiers. The results revealed that the method using stacking alone and an ensemble of Bayesian methods exhibited the best performance, and NB combinations with LR and SMO gave the best prediction Acc of 97.8%.

Hajar et al. [21] improved the performance of ML techniques to test their classification performances in large BC databases, such as the Surveillance, Epidemiology, and End Results (SEER) database. The KNN, NB, LR, and MLP techniques exhibited low Acc, contrary to the RF and DT, which proved their high performance. Ensemble approaches, such as voting, stacking, bagging, and boosting, were used to increase the performance of single algorithms. Voting techniques provided the greatest improvement and Acc (99.99%) with NB, DT, and RF. For more information about the use of ML models in BC classification, readers are guided to the following surveys [22],[23].

Previous works presented several shortcomings. (1) Several researchers used an insufficient number of features, (2) most of the researchers disregarded FS as the primary algorithm for BC diagnosis, and (3) others focused on the same algorithm in the classification although most of the different types of data require the use of various types of algorithms to be classified. Most algorithms work best on text data and others on numeric data. Thus, combining two types of data using the same algorithm affects the classification performance. Therefore, we suggested the use of ensemble learning and FS to overcome these limitations and improve the Acc and performance for BC classification. Table I shows the characteristic of the reviewed studies.

III. METHODS AND MATERIALS

A. Data Set

In this section, we used the Wisconsin Diagnostic Breast Cancer (WDBC) obtained from UCI ML Repository [24]. This data set was used to detect malignant and benign tumors. All features in the WDBC were extracted from fine-needle aspirate images, which describe the features of the nucleus. The WDBC included the features of 569 patients (357 benign and 212 malignant cases) and 32 attributes in Wisconsin hospitals. Each attribute represents a measurement result. The first and second attributes refer to the identifier number and patient diagnosis status, respectively. The remaining attributes correspond to standard error, mean, and the least of red nucleus features. Table II provides details of the dataset attributes and their description.

TABLE II. DATASET ATTRIBUTES AND THEIR DESCRIPTION

NO	Attribute	Description	Domain value
1	Id	Alphanumeric code is used in a health record system to uniquely identify a patient.	8670 to 912 m
2	Diagnosis	Process of identifying the condition of the disease	0 or 1
3	Radius_mean	Average of distances between the center and points around the perimeter	6.99 to 28.2
4	Texture_mean	Gray-scale value standard deviation	9.73 to 39.4
5	Perimeter_mean	Average tumor size	44 to 189
6	area_mean	Mean area inside the boundary of core tumor	144.1 to 2500
7	smoothness_mean	Local variation's mean in the radius lengths for the measurement of the smoothness of breast cells	0.06 to 0.17
8	compactness_mean	Calculated using the equation $(\text{perimeter}^2 / \text{area} - 1.0)$	0.03 to 0.35
9	concavity_mean	Mean of the degree to which the cell contour is concave	0 to 0.44
10	Concave points_mean	Mean of the quantity of concave contour parts	0 to 0.4
11	symmetry_mean	Mean of similar area of tumor parts that match	0.11 to 0.3
12	Fractal_dimension_mean	Mean for "coastline approximation"-1	0.05 to 0.2
13	radius_se	Error of standard for the average length from the center to the perimeter points	0.11 to 2.88

14	texture_se	Error of standard for the grayscale values' standard deviation	0.38 to 4.88
15	perimeter_se	Error of standard for the tumor perimeter	0.77 to 22
16	area_se	Error of standard for the mean area inside the boundary of the core tumor	6.9 to 543
17	smoothness_se	Error of standard for variations in radius lengths on a local scale	0 to 0.03
18	compactness_se	Error of standard for $\text{perimeter}^2/\text{area}-1.0$	0 to 0.15
19	concavity_se	Error of standard for the degree to which the cell contour is concave	0 to 0.5
20	concave points_se	Error of standard for the quantity of concave contour parts	0 to 0.06
21	symmetry_se	Error of standard for the mean of similar area of matching tumor parts	0.01 to 0.08
22	fractal_dimension_se	Error of standard for "coastline approximation"	0 to 0.04
23	radius_worst	Biggest or worst mean value for the average distance between the center and points on the perimeter	7.94 to 36
24	texture_worst	Biggest or worst mean value for gray-scale value standard deviation	12.1 to 49.6
25	perimeter_worst	Biggest or worst mean value size of the core tumor	50.6 to 251
26	area_worst	Biggest or worst mean value for the mean area inside the boundary of the core tumor	185 to 4255
27	smoothness_worst	Biggest or worst mean value for local variations of radius lengths	0.08 to 0.23
28	compactness_worst	Biggest or worst mean value for $(\text{perimeter}^2 / \text{area} - 1.0)$	0.03 to 1.07
29	concavity_worst	Biggest or worst mean value for the degree to which the cell contour is concave	0 to 1.27
30	concave points_worst	Biggest or worst mean value for the quantity of concave contour parts	0 to 0.30
31	symmetry_worst	Biggest or worst mean value for a similar area of matching tumor parts	0.17 to 0.77
32	fractal_dimension_worst	Biggest or worst mean value for "coastline approximation"-1	0.07 to 0.22

B. Machine Learning

1) *Single machine learning*: In this paper, we used popular classification models to test the capability of data features in the classification of BC; these models included SVM [25]–[28], LDA [29], [30], [31] KNN [32]–[35], LR [35]–[38], DT[39], [40], and NB. The selection of classifiers was based on two main reasons: (1) popularity in medical domains (2) and their diversity in terms of classification structure. Table III shows the selected classifiers and their types.

TABLE III. CLASSIFICATION MODELS

Classifier Type	Classifier Name	Label
Tree based	Decision Tree	DT
Linear-based model	Logistic regression	LR
	Support Vector classifier	SVC
Nonparametric-based model	K-Nearest Neighbor	KNN
Statistical based model	Linear discriminant analysis	LDA
	Naïve Bayes	NB

2) *Ensemble machine learning*: Ensemble classifiers integrate the decision of a set of base classifiers (single classifier) using either weighted or unweighted techniques to obtain a model that outperforms all base classifiers. Table IV describes the ensemble classifiers. Ensemble learning is an initiative technique that simulates the human nature of humans and considers several perspectives before making the final decision [31].

In traditional learning, only a single classifier is used to make the decision and solve a problem, whereas in ensemble learning, several classifiers are used to solve a problem [41]. The two main types of ensemble classifiers include (1) homogeneous classifiers, which use the same classifier such as RF, and (2) heterogeneous classifiers, which use a set of diverse classifiers such as LDA and DT. The sequence of running base classifiers and the decision combination are significant in building ensemble classifiers. Three major kinds of learning and aggregation exist.

First, bagging considers a homogenous classifier in which learning occurs independently (parallel approach). Then, the results are combined using the averaging process as in the following equation $E = (\sum e_i)/n$, where E refers to the final classifier, and e indicates the base classifier (i.e., RF) [42].

Second, boosting is a homogenous classifier that works sequentially (self-learning technique). Boosting works by assigning weights for every classifier (equal weights in the first stage). Then, the weights are updated every iteration based on the classifier performance. The final model is averaged using a weighted average with the following equation $e = ((\sum e_i w_i) / \sum w_i) / n$, where e is the base model, and w is the weight (i.e., AdaBoost, light GBM, GBM, and XGBM). Fig. 1 shows the bagging, boosting, and subspace models [43], [44].

TABLE IV. DESCRIPTION OF ENSEMBLE CLASSIFIERS

Classifier name	Description	Classifiers	Aggregating result technique
RF	Ensemble of DT mode	DT	Majority voting
Bagging	Fits base classifiers on each random subset and aggregates the results (parallel)	LR	Average of five weak classifiers
Boosting	Trains data on a model and then uses the second algorithm to correct errors from the first model (sequentially)	LR	Weighted average of five weak classifier
Voting	Runs several classifiers on all dataset and then outputs class depending on the highest majority voting.	LR, SVC, KNN, and LDA	Soft voting
Stacking	Splits data into several data subsets; each subset runs on different classifiers, and the final results are aggregated.	LR, SVC, KNN, DT, LDA, and NB	Meta model (Level 2 learning)

Fig. 1. Bagging, boosting, and subspace models.

Third, stacking considers heterogeneous classifiers that may run in two different ways, including the following. (1) All data are divided into feature subsets, with each subset running on all classifiers (several diverse classifiers) and a replacement for the selection of the most suitable classifier based on performance. Finally, the most accurate classifier is selected for each subset, and the final ensemble model is created. (2) For the second approach, all data sets are run in all classifiers (level 0); then, a meta learner is used to learn the best combination of predictions from all models. Fig. 2 displays the stacking ensemble model.

Fig. 2. Stacking ensemble learning.

IV. PROPOSED FRAMEWORK

Based on the literature review, it was found that in the majority of the cases disregarded the role of FS algorithm for BC diagnosis. Others focused on the same or single algorithm in the classification although most of the different types of data require the use of various types of algorithms to be classified.

The steps of data pre-processing are as follows:

A. Data Pre-processing

This step aimed to represent data efficiently and improve the quality of the medical data collected. Data processing is

The objective of our proposed work is to construct an ensemble model to aggregate the benefits of different single algorithms until we can come up with an ensemble model which can give the best accuracy. We also use the method of FS that helps for improving the quality and making the process of model more efficient.

This framework is introduced a stacking ensemble classifier for the classification of BC based on tumor features (numeric features). It is a binary classification task in which 0 = benign and 1 = malignant. The model has been evaluated based on the WDBC dataset. As shown in Fig. 3, the proposed framework has several steps. The first step collects the WDBC data and implements the preprocessing steps to improve the

quality of data, including (1) data normalization for data scaling to hasten the training process and (2) data balancing to increase the number of cases in the minority class. The second step uses FS to remove the weakest feature. The third step evaluates the performance of six single ML classifiers (KNN, LDA, DT, NB, SVM, and LR) with and without a FS step for BC classification task. The fourth step builds an ensemble model from a set of single classifiers with and without a FS step and compares its performance with other models that do not use ensemble learning. The tested ensemble models included RF, AdaBoost, bagging, stacking, and voting models.

We proposed a customized stacking ensemble model with high performance and Acc rate based on six optimized basic Classifiers required for ML to resolve several types of problems, such as noisy data, redundancy data, and missing data values, making it suitable for building and training ML mode:

1) *Data normalization*: In this step, we scaled all the data from their original range to be within the range of 0 to 1 through the following equation for normalization. This step speeds up the training processing.

$$y = \frac{(X - \min(x))}{(\text{Max}(x) - \min(x))} \quad (1)$$

2) *Data balancing*: As we mentioned in Section 3.1, WDBC included the features of 569 patients (357 benign and 212 malignant cases). The main problem of imbalanced data is that it affects the performance of ML algorithms. Algorithms, such as DT and KNN, will treat the minor class as not important as the major class and place more concern to the major class. Oversampling and undersampling are the main approaches used to deal with imbalanced data.

Oversampling increases the number of the training set in the minor class, whereas undersampling removes data from the minor class [45]. In this paper, given the shortage of the dataset, we decided to use an oversampling technique known as random oversampling [46]. This technique is used to randomly duplicate training examples in the minor class. The final dataset included 607 patients (357 benign and 250 malignant).

Fig. 3. Proposed framework.

B. Feature Selection

We used recursive feature elimination (REF) for FS. This method is used to reduce the input variable of a model by selecting relevant data only and cutting down the data noise [47].

The REF algorithm is based on filter and removes the weakest feature from our dataset to produce a new subset of features ranked by importance[48]. This process reduced the number of features from 32 to 24.

V. RESULTS

A. Experimental Setup

All experiments were implemented on a PC workstation with an Intel Core i9, two tera hard disks, 32 GB RAM, and Windows 10 64 bit. All ML algorithms were implemented using Python language. Single and ensemble ML models were run using the Scikit-learn library.

All models were trained using 10-fold cross-validation (CV), which is a technique for validating the efficiency of a model in which unobserved testing data are used to evaluate the model performance and ensure the generalization performance of the training models.

We ensured that the training and testing datasets contained no data to prevent the algorithm from memorizing data and giving a better performance in the testing phase without ensuring its generalization capability. Fig. 4 shows the CV process.

B. Evaluation Performance

The effectiveness of ML algorithms was assessed using a set of performance measure parameters. The matrix of confusion, which included true positive (TP), False Positive (FP), true negative (TN), and FN results for actual and predicted data, was created to evaluate the parameters. In our study, we used the following parameters to evaluate terms by their formulas to evaluate our performance study.

The following equations were used to evaluate the comparison study's performance:

Accuracy (Acc): The correct ratio of samples that is classified to the total samples.

$$(Acc) = \frac{(TP+TN)}{(TP+TN+FP+FN)} \quad (2)$$

Specificity (Sp): The relationship between negative examples observed and all other negative examples; shows the rate of projected existence in the presence of BC in all samples.

$$(Sp) = \frac{TN}{(TN+FP)} \quad (3)$$

Precision (P): The division of samples that were positive among all the samples that we anticipated to be positive.

$$(P) = \frac{TP}{(TP+FP)} \quad (4)$$

Recall (R): The rate of the case of positive impression divided by the total positive of cases.

$$(R) = \frac{TP}{(TP+FN)} \quad (5)$$

F1 score (F1): The mean between P and R

$$(F1) = 2 * \frac{P*R}{P+R} \quad (6)$$

Area under the ROC curve (AUC): Measures the performance and how the evaluated model distinguishes between models.

$$AUC = \frac{s_p - n_p + (n_n + 1) / 2}{n_p n_n} \quad (7)$$

C. Experimental Results

Four extensive experiments have been conducted to determine the efficiency of the proposed model using the WDBC dataset. WDBC provided 30 features for 560 patients and summarized the tumor status to determine benign or malignant tumors.

1) Single model

a) *Without feature selection:* In this section, we evaluated six diverse classifiers, including KNN, LDA, DT, NB, SVC, and LR. We carefully selected the most efficient classifier used frequently on the medical side. Table V shows the performance of all models represented by CV Acc, in addition to details about the testing performance in terms of P, R, F1, AUC, and SP.

From Table V, (1) SVC generated the least performance, with testing results of Acc=78.9%, AUC = 77.88%, and F1 = 69.2%, followed by LR with testing performance results of Acc = 92.1%, AUC = 90.49, and F1=87.32%. DT, KNN and NB performances improved by approximately 1%–2%, whereas LDA provided the best performance, with Acc = 98.2%, AUC = 97.97%, and F1 = 97.22%.

b) *With feature selection:* As shown in Table VI, in this section [31], [49], we explored the importance of using the FS technique to improve the ML model performance. In this paper, we used REF for FS. This technique works by fitting a model and then removing the weakest features. This process was repeated until the optimum feature set with 24 features was reached. FS techniques improved the Acc of the developed models by about 3%–6%.

SVC enhanced by about 6% and achieved Acc, AUC, and F1 of 89.4%, 82.71%, and 86.6, respectively. NB, KNN, and LR attained 92.9%, 91.22%, and 91.22%, respectively.

Fig. 4. Process of 10-fold CV.

TABLE V. SINGLE-CLASSIFIER RESULTS WITHOUT FEATURE SELECTION

Algorithm name	Training score %	Testing score %	Acc %	Sp %	P %	R %	F-score %	AUC %
NB	94.06	94.73	94.73	94.87	89.47	94.44	91.89	94.65
SVC	81.75	78.94	78.9	80.7	64.2	75.01	69.2	77.88
LR	91.64	92.10	92.1	92.1	88.57	86.11	87.32	90.49
LDA	96.92	98.24	98.2	98.71	97.22	97.22	97.22	97.97
KNN	94.94	92.10	92.1	92.30	84.61	91.66	87.99	91.98
DT	96.9	92.98	92.9	91.02	83.33	97.22	89.7	94.12

TABLE VI. SINGLE-CLASSIFIER RESULTS WITH FEATURE SELECTION

Algorithm name	Training score %	Testing score %	Acc %	Sp %	P %	R %	F-score %	AUC %
NB	94.505	92.98	92.9	95.8	92.3	92.3	87.8	91.8
SVC	90.54	89.47	89.4	86.3	71.61	85.11	86.6	82.71
LR	92.08	91.2	91.22	95.8	91.8	82.9	87.1	89.4
LDA	96.9	95.6	93.5	95.6	80.80	87.0	93.5	93.9
KNN	94.72	91.2	91.22	95.5	93.01	85.1	88.8	90.3
DT	98.02	93.8	93.8	94.0	91.6	93.06	92.6	93.8

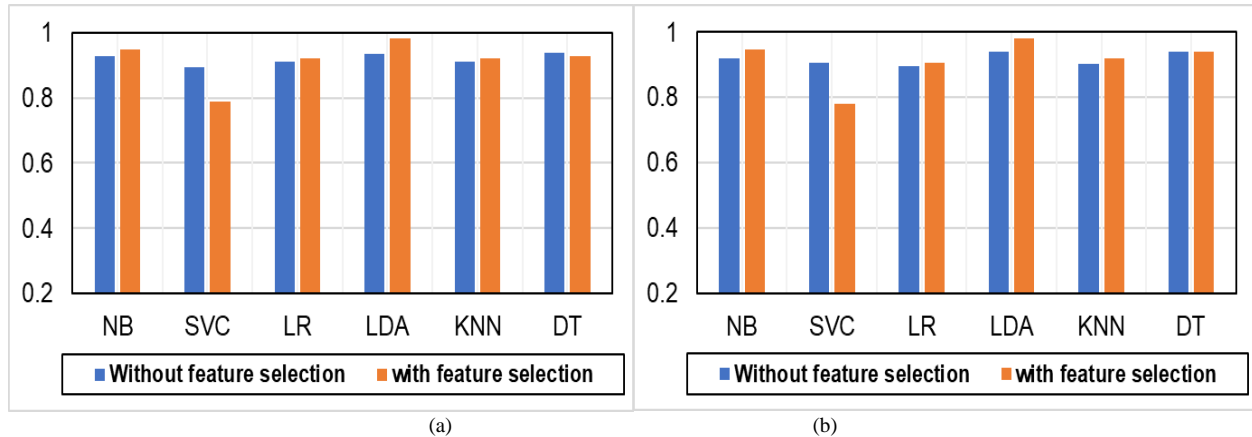

Fig. 5. (a) F-score of single classifiers with and without FS. (b) Acc result of single classifiers with and without FS.

The best performance was obtained by the DT, with Acc = 93.8%, F1 = 92.6%, and AUC = 93.8%. From the previous tables (Tables V and VI), we arrived at the following observations: (1) the use of FS improved the total performance with all classifiers; (2) DT worked better with less features. Fig. 5 compares F-score and Acc result of all single algorithms with and without FS.

2) Ensemble models

a) *Without Feature Selection:* In this section, we investigated the role of popular ensemble models, including voting, bagging, boosting, and RF, and compared them with the proposed stacking algorithm. The proposed stacking algorithm used three diverse classifiers: LDA, DT, and LR. LR was used as a meta classifier at level 2 of learning. These classifiers were selected because their diversity increases their search space and Acc accordingly. Table VII shows the CV Acc and testing performance of the used ensemble models. These results showed that (1) ensemble models improved the results by approximately 2%–4%; RF generated the least

performance with the testing results of Acc = 93.8%, AUC = 92.8%, and F1=91.7%.

This finding may be attributed to the structure of RF, which selected a random subset to run in each branch. The other homogenous classifiers, including bagging and boosting classifiers, achieved better performances, with Acc = 94.3%, AUC = 96.01%, and F1 = 96.5% for the boosting classifier and Acc = 94.73%, AUC = 94%, and F1 = 93% for the bagging classifier. Regarding heterogeneous ensemble classifiers (voting and stacking), stacking provided the best performance, with Acc = 97.2%, AUC = 96.2%, and F1 = 97.72%. The performance improved by about 3%–5% over single classifiers and 1%–2% over homogenous ensemble classifiers.

b) *With Feature Selection:* In this section, we explored the performance after using the FS technique with ensemble classifiers to improve the ML model performance. As shown in Table VIII, the FS techniques improved the Acc of the developed models by about 2%–3%. The RF enhanced by about 3% and achieved Acc, AUC, and F1 of 94.73%, 95.4%, and 92.1%, respectively.

TABLE VII. ENSEMBLE CLASSIFIER RESULTS WITHOUT FEATURE SELECTION

Algorithm name	Training score %	Testing score %	Acc %	Sp %	P %	R %	F-score %	AUC %
RF	96.4	93.85	93.8	97.1	95.1	88.6	91.7	92.8
Bagging	98.5	94.7	94.73	97.14	95.2	90.9	93.0	94.0
Voting	95.9	93.8	93.85	98.5	97.4	86.3	91.5	92.4
AdaBoost	95.7	97.36	94.3	98.5	97.6	95.45	96.5	96.01
Stacking	99.4	98.2	97.2	98.5	97.72	97.7	97.72	96.2

TABLE VIII. ENSEMBLE CLASSIFIER RESULTS WITH FEATURE SELECTION

Algorithm name	Training score %	Testing score %	Acc %	Sp %	P %	R %	F-score %	AUC %
RF	96.7	94.73	94.73	93.64	87.5	97.2	92.1	95.4
Bagging	99.7	95.61	95.6	94.8	89.7	97.2	93.3	96.04
Voting	96.7	98.2	98.2	98.7	97.22	97.22	97.22	94.9
AdaBoost	94.41	95.40	97.7	94.8	89.4	94.44	91.89	94.6
Stacking	97.81	95.61	98.6	94.8	89.7	97.22	96.33	98.1

Fig. 6. (a). F-score of the ensemble classifiers with and without FS. (b) ACC result of the ensemble classifiers with and without FS.

The best performance was obtained from our stacking compared with other studies with F1 score = 96.33%, Acc = 98.6%, and AUC = 98.1%. From the previous tables (Tables VII and VIII), we arrived at the following observations; (1) the use of FS improved the total performance with all classifiers; (2) the combination of FS techniques with diverse stacking model improved the overall performance of the model. Fig. 6 compares F-score and Acc result of all ensemble algorithms with and without FS.

3) *Model evaluation*: We used the Nemenyi critical difference (CD) diagram to calculate the rank of each model [29], [45]; then, we evaluated and compared the performances of all the developed models (stacking, boosting, RF, LDA, and DT) with FS. The diagram in Fig. 7 shows that all algorithms were connected using horizontal lines, and they were ranked from 1 to 5, with rank 1 being allotted for the most accurate model and 5 for the least.

This ranking is equal to the average of ranking results of Friedman’s test. We obtained complete information and explored the role of all features, such as radius_mean, area_mean, etc., in BC classification. This diagram proves that the stacking model achieved the best rank with a value 1.6. We calculated the feature importance with two different

techniques, including information gain and RF. Table IX shows this importance numerically.

Fig. 7. CD between all classifiers with FS.

TABLE IX. RESULT OF THE FEATURE IMPORTANCE WITH INFORMATION GAIN AND RF

Feature Name	Correlation coefficient	RF
radius_mean	0.02537	0.02848

VI. DISCUSSION

We introduced an ensemble ML classifier that can distinguish between malignant and benign BC cells. Our model was examined on the WDBC dataset. Our work faces the contribution of accelerating the training process, using data normalization for data scaling and increasing the number of instances in the minority class by data balancing. One of the main challenges in using FS is to remove the weakest feature in our model.

In order to test how well the suggested model works, we performed four experiments with and without the FS method for both single ML and ensemble ML.

In our research, we found that employing ensemble models with FS resulted in better overall performance across all classifiers. Based on six optimized basic classifiers (LR, SVC, KNN, DT, LDA, and NB), we proposed a customized stacking ensemble model that achieved the best performance and accuracy rate.

VII. COMPARISON WITH LITERATURE

In this section, we compared our proposed models with those of other literature. For fairness of comparison, we conducted this comparison only with studies that used the same dataset.

For example, [50] utilized SVM classifier in their studies to achieve an Acc of 97.47%. Similarly, in [51], a single classifier was utilized, and a classification performance of 96.5% was achieved in terms of Acc when using NB and ANN classifiers. Amrane et al. [52] used KNN and attained an Acc of 97.5%. Although these studies also used the same of classifiers, our results were superior with regard to the use of single classifiers. Such a conclusion can be attributed to the use of FS technique, which was used to extract the most important features. Bazila et al. [53] presented an ensemble known as tree augmented NB (TAN) with a boosting technique, and it achieved an Acc of 94.11%. Haifeng et al. [54] focused on an ensemble SVM learning approach named weighted area under the receiver operating characteristic curve ensemble (WAUCE). Their approach obtained an Acc of 97.68%. Table X summarizes this comparison.

Our proposed ensemble model used a heterogeneous ensemble classifier. This type of ensemble provides a high diversity between classifiers, which increases the overall classification performance. Our study achieved a superior Acc (98.6%) compared with other existing studies. On the other hand, our proposed model did not demonstrate a significant variation in the performance between training and testing. The proposed model can be potentially more stable and trustworthy and be used as an alternative to BC prediction.

TABLE X. COMPARISON OF THE ACC OF VARIOUS METHODS FOR BC CLASSIFICATION (EXPERIMENTS CARRIED OUT ON WDBC)

Ref.	YEAR	Method	Accuracy
[50]	2022	SVM	97.47%
[51]	2021	NB-ANN	96.5%
[55]	2021	KNN	97.15
[4]	2019	PCA with K-NN algorithm	95.6 %
[53]	2018	GBM -TAN	94.11%
[54]	2018	SVM -WAUCE model	97.68 %
[52]	2018	KNN	97.5%
[56]	2016	FS+ANN	97.3%
Proposed Model	2022	Stacking Ensemble ML	98.60%

VIII. CONCLUSION AND FUTURE WORK

In this paper, we proposed ML models for BC classification. We focused on the comparison of Acc when using single-classifier models, such as NB, KNN, LDA, LR, DT, and SVC, and ensemble models, such as RF, bagging, AdaBoost, stacking, and voting models, with and without using FS on WDBC. The key results from the study included the following.

In a single model, the SVC generated the least performance with testing results of Acc = 78.9%, AUC = 77.88%, and F1 = 69.2%. When using FS techniques, the total performance was improved, and SVC enhanced by about 6%,

with Acc, AUC, and F1 of 89.4%, 82.71%, and 86.6%, respectively.

For the ensemble model, we compared traditional ensemble models combining FS techniques with our stacking proposed model. The results of our experiments revealed that the use of the ensemble model and FS improved the Acc of all classifiers. The performance improved by about 3%–5% over single classifiers and 1%–2% over homogenous ensemble classifiers. The results also showed that the best Acc (98.6%) was achieved by the stacking ensemble ML with FS techniques. The proposed model can help cancer specialists to recognize BC.

In the future, we plan to expand our model to handle different types of data using different feature selection methods. We will investigate the role of machine learning models in dealing with time series data. Finally, we can apply classification with deep learning algorithms to investigate the accuracy enhancement of the classification.

A Deep Learning-based Model for Evaluating the Sustainability Performance of Accounting Firms

Cui Hu

Business Big Data College, Chongqing College of Finance and Economics, Chongqing, 402160, China

Abstract—The harmonious and stable development of society is strongly related to the sustainable development of enterprises. In order to better face the challenges of environmental resources, sustainable development must be included in the development focus of accounting enterprises. The research proposes a performance evaluation model based on deep learning, improves RBMs model on the basis of deep belief network (DBN), improves the accuracy of the model through reverse fine-tuning technology, and effectively combines multiple restricted Boltzmann machines (RBMs) and Softmax classifiers to build a modular multi classification model to complete the sustainable development performance evaluation of accounting enterprises. The performance of RBM fine tuning classifier is higher than that of RBM expression and PCA (Principal Component Analysis) expression, which mainly shows the effectiveness and stability of feature extraction. The network output results of test samples are converted into prediction performance evaluation. The model is evaluated by average precision (AP), average recall (AR), and prediction accuracy. The AP, AR, and prediction accuracy of the proposed method are 86.95%, 89.74%, and 88.29% respectively, which are higher than Softmax classifiers, Back Propagation (BP) neural networks, and DBN based Softmax methods, It shows that this method is superior to other algorithms in the application of performance evaluation model for sustainable development of accounting enterprises, and it is feasible and effective, which is of great significance to the establishment of performance evaluation model for the accounting industry.

Keywords—Deep learning; RBM; performance evaluation; classification accuracy; sustainability

I. INTRODUCTION

The sustainable development of enterprises is an important guarantee for a harmonious and stable society [1]. The theory of sustainable development includes equity, commonality, sustainability, coordination, demand, limitation, and inherency [2]. Corporate sustainability can be influenced by resource resources such as corporate culture, human capital, intangible assets and ecological nature [3]. From the perspective of corporate sustainability, its essence is clearly different from the meaning of ecological sustainability, which in depth is the optimal allocation of resources. Enterprise performance evaluation is the basis for measuring the production and operation behaviour of enterprises; therefore, it is positive to construct an enterprise sustainability performance evaluation model [4]. Performance evaluation indicators include the evaluation of non-economic aspects and economic aspects, but the previous economic performance indicators of enterprises are no longer applicable to the concept of accounting standards [5]. Domestic and international research on the

evaluation of corporate sustainability performance has gone through four evaluation stages: cost performance, financial evaluation, strategic performance, and multidimensional synthesis [6]. With the advantages of efficient storage capacity, parallel processing capability, and associative memory, deep learning has now been more widely used in natural language processing technology, speech recognition, image recognition and other information retrieval. Common deep learning evaluation models include Deep Belief Network (DBN), Stacked Autoencoder (SAE), CNN, etc., and have positive application value in evaluation. In order to realize the evaluation and prediction of the sustainable development of enterprises with the help of the deep learning algorithm, on this basis, the research introduces the requirements of the harmonious financial theory and the new accounting standards, constructs the performance evaluation system of the sustainable development of accounting enterprises, and constructs the corresponding evaluation model through the deep learning algorithm. The contribution of the research is to propose a new feature extraction method with stronger feature learning ability, improve the RBMs model on the basis of DBN, improve the accuracy of the model through reverse fine-tuning technology, and effectively combine multiple RBMs and Softmax classifiers to build a modular multi classification model to complete the sustainable development performance evaluation of accounting enterprises. The goal and significance of the research is to provide a more scientific theoretical basis for the evaluation of the sustainable development of enterprises, and provide advice and guidance for the long-term development of enterprises. The research makes up for the phenomenon that the subjectivity of traditional evaluation methods is too strong, and the evaluation methods constructed have merit.

II. RELATED WORK

Sokil addressed the issue of information support and practical assumptions for sustainable development policy implementation through accounting analysis and mathematical analysis of the quadratic correlation and regression dependence of corporate value added on social and environmental cost scales [7]. Fu et al. used a multidimensional big data matrix model for optimization analysis to systematically construct a corporate performance evaluation system and two dimensions to construct a systematic model for the use of enterprise performance information. They applied logistic regression methods for empirical research, providing a theoretical and empirical basis for the division of the demand dimensions of the enterprise performance evaluation system [8]. Jana et al. proposed a

multi-attribute decision method for enterprise financial performance evaluation, applying the new Dombi hybrid operators, which work on parameters have the advantage of good adaptability to complete financial performance assessment through intuitionistic fuzzy methods [9]. Yan Y et al. researchers analysed the performance appraisal management of manufacturing enterprises based on the Analytic Hierarchy Process (AHP) of fuzzy multi-criteria decision making to establish an enterprise performance management evaluation system, and this This exploration can provide a theoretical basis for improving the management innovation ability of manufacturing enterprises, and also has important reference value for expanding the market competitiveness of manufacturing enterprises [10]. Fang H applied the enterprise value management theory to the performance evaluation of university discipline construction members, established a performance value evaluation model, and applied the AHP method and quantitative research methods to costs and the functions achieved were evaluated [11].

Bao through the analysis of many classical methods such as economic value added, key performance indicators, balanced scorecard and current performance evaluation methods, the application analysis shows that the evaluation model is reasonable and the mathematical method is effective [12]. Yang et al. proposed the design of the enterprise environmental performance evaluation system in the new economic situation, according to the basic laws of the new situation theory and big data technology, the evaluation principles and typical index system were applied to the performance evaluation system as a reference, and the experimental results were of reference value for the application of the performance evaluation system in the field of corporate finance, which substantially improved the overall performance of the enterprise[13]. Qi established an enterprise human resource management performance evaluation system, which combined the relevant features of the opposable theory to provide more effective evaluation of enterprise HRM performance, providing a scalable analytical model for enterprise HRM performance evaluation [14]. Xiong et al. researchers evaluated the performance of food cold chain logistics enterprises based on AHP and entropy method, based on the analysis of the current situation, AHP was used to determine the subjective weights and entropy method was used to obtain experts' own weights. Finally, a comprehensive index fusion weight was performed [15]. Cui et al. researchers designed a multi-objective RBM model for training, and experiments showed that the proposed model could effectively improve the data classification accuracy of the heterogeneous network and reduce the loss in the data fusion process [16]. Sun L et al. proposed a gradient-enhanced Softmax classifier based on Convolutional Neural Networks (CNN), which alleviates the gradient disappearance problem in the Softmax classifier and can achieve better results [17]. Pan et al. proposed a novel deep learning network that performs hierarchical feature learning by limiting RBM machines in parallel, and the results demonstrate that the method is able to extract sensitive features for fault detection [18].

As can be seen through the research of domestic and international researchers on corporate innovation and development and performance evaluation models in the context of sustainable development, there are currently more studies that use AHP method for performance evaluation. In terms of building evaluation models based on deep learning, some researchers have proposed using RBM for hierarchical feature learning to improve feature extraction, but there are better methods for feature extraction of evaluation indicators. Therefore, the research will propose a new method of feature extraction with stronger feature learning capability, improve the model of Restricted Boltzmann Machine (RBM)s based on DBN, improve the correctness of the model through reverse fine-tuning techniques, and at the same time effectively combine multiple RBMs and Softmax classifiers to construct a modular multi-classification model to complete the sustainability performance evaluation of accounting firms.

III. RBMs MODULAR DEEP LEARNING MODEL FOR SUSTAINABILITY PERFORMANCE EVALUATION OF ACCOUNTING FIRMS

A. RBMs Modular Deep Learning Models

Because the data type of university performance evaluation is sample data with multiple feature modules, deep learning algorithms have outstanding advantages in performance evaluation. RBM, as a new method of feature extraction, has stronger feature learning capability. The study will improve the model of RBMs based on DBN, improve the correct rate of the model through reverse fine-tuning technique, and at the same time effectively combine multiple RBMs and Softmax classifiers to construct a modular DBN is a concept generation model, which consists of multiple RBMs stacked as in Fig. 1.

Fig. 1. Classic DBN network structure of two-layer RBM

Fig. 1 shows the structure of a DBN network containing two layers of RBM, which is first trained on the parameters of each layer of RBM by a greedy layer-by-layer unsupervised strategy, and then after confirming that all input data have passed through the full RBM network in order for the me

network to obtain useful feature information. Finally, other algorithms such as the Back Propagation (BP) algorithm are used to receive the output data and use it as input data, and the whole network is supervised and adjusted according to the error between the expected and actual output data. At the top is the top layer network for supervised learning, which can become a classifier model such as Softmax depending on the specific practical application.

The RBM is an energy-based model where the visible and hidden layers form a system (v, h) with the energy shown in equation (1).

$$E(v, h) = -\sum_{i=1}^n a_i v_i - \sum_{j=1}^m b_j h_j - \sum_{j=1}^m \sum_{i=1}^n h_j w_{ij} v_i \quad (1)$$

In equation (1), n and m denote the number of neurons in the visual layer and the hidden layer respectively; v denotes the state vector of the visual layer, h denotes the state vector of the hidden layer, a denotes the bias vector of the visual layer, b denotes the bias vector of the hidden layer, and w_{ij} denotes the connection weights of the i neuron in the hidden layer and the j neuron in the visual layer. The writing matrix of equation (1) is shown in equation (2).

$$E(v, h) = -a^T v - b^T h - h^T W v \quad (2)$$

Equation (2) can be understood as an energy function. This function combined with the RBM corresponding to the state (v, h) yields the expression for the distribution of the expression probability generation model as equation (3).

$$p(v, h) = \frac{1}{Z} e^{-E(v, h)} \quad (3)$$

In equation (3), Z is the normalisation factor, i.e. it is the accumulation of the states of all visible and hidden layers, as in equation (4).

$$Z = \sum_{v, h} e^{-E(v, h)} \quad (4)$$

In contrast, for real life and work problems, the RBM network focuses on the marginal fraction of $p(v, h)$, the probability distribution of the input data v $p(v)$, as shown in equation (5).

$$p(v) = \sum_h p(v, h) = \sum_h \frac{1}{Z} e^{-E(v, h)} \quad (5)$$

Given that there are no neurons that play a connecting role between the visual or hidden layers that are connectionless, the individual neurons are seamlessly connected to each other, as in equation (6).

$$\begin{cases} p(v|h) = \prod_{i=1}^n p(v_i|h) \\ p(h|v) = \prod_{j=1}^m p(h_j|v) \end{cases} \quad (6)$$

When given the state of the visual layer v , the probability of finding the hidden layer neuron $h_j = 1$ is given in equation (7).

$$p(h_j = 1|v) = \sigma\left(b_j + \sum_{i=1}^n v_i w_{ji}\right) \quad (7)$$

When given the state of the hidden layer h , the probability of finding the visual layer neuron $v_i = 1$ is given in equation (8).

$$p(v_i = 1|h) = \sigma\left(a_i + \sum_{j=1}^m h_j w_{ij}\right) \quad (8)$$

In equations (7) and (8), $\sigma(x)$ is the Sigmoid function. The essence of the training process of the RBM is the use of learning algorithms to adjust the parameters of $\Theta = (a, b, W)$ through continuous iterative learning, which eventually makes the energy of the entire RBM move towards a gradient that gradually decreases, and finally reaches a state where the energy of the RBM is minimized, i.e., the model reaches a stable state [19]. When the energy of the RBM network is the lowest, it is known that the marginal distribution range of the RBM network is the largest according to the energy conversion formula, and then the parameter Θ needs to be solved for when the value of the marginal distribution is the largest. Based on the expert product system to fit complex high-latitude data, the system can have a more ideal probability distribution in the processing of high-dimensional model data, it can complete the target transformation training of RBM by maximizing the likelihood function, and the calculation expression is equation (9).

$$L(S, \Theta) = \prod_{i=1}^N p(v^{(i)}) \quad (9)$$

In equation (9) $S = \{v^{(1)}, v^{(2)}, \dots, v^{(N)}\}$, $v^{(i)}$ denotes the i th training sample and N is the number of samples. Considering that the function $\ln x$ is strictly monotonically increasing and maximizing $L(S, \Theta)$ and maximizing $\ln L(S, \Theta)$ are equivalent, the objective of training the RBM becomes maximizing the log-likelihood function, as in equation (10).

$$\ln L(S, \Theta) = \sum_{i=1}^N \ln p(v^{(i)}) \quad (10)$$

The gradient ascent method is the most efficient way to maximise the log-likelihood function and it uses an iterative approach to update the parameters as shown in equation (11) [20].

$$\Theta = \Theta + \eta \frac{\partial \ln L(S, \Theta)}{\partial \Theta} \quad (11)$$

In equation (11), $\eta > 0$ is the learning rate. For the training sample S , Eq. (12) is obtained by derivative calculation.

$$\frac{\partial \ln L(S, \Theta)}{\partial \Theta} = \sum_{i=1}^N \left(- \left\langle \frac{\partial E(v^{(i)}, h)}{\partial \Theta} \right\rangle_{p(h|v^{(i)})} + \left\langle \frac{\partial E(v, h)}{\partial \Theta} \right\rangle_{p(v, h)} \right) \quad (12)$$

In equation (12) $\langle \cdot \rangle_{p(h|v^{(i)})}$ denotes the mathematical expectation based on the training samples and $\langle \cdot \rangle_{p(v, h)}$ denotes the mathematical expectation based on the model reconstruction data.

The study constructs a modular multi-classification model by combining multiple RBMs and Softmax classifiers. The model structure is shown in Fig. 2.

Fig. 2. Structural diagram of RBMs based modular deep learning model

The deep learning model designed in the study is a multiple RBMs feature extractor and a top-level classifier. The deep model first extracts different feature module samples using RBMs features, and then classifies various different types of data by the top-level classifier. The structure of the RBMs is contained in dashed lines, which is a modular feature extractor composed of RBMs, where $RBM_s(i)$ is the i th RBM and $i = 1, 2, \dots, L$. Set the input features set to (x_1, x_2, \dots, x_n) , divide them into L feature modules according to the sample characteristics, without considering the sequential nature, the feature modules are noted as (x_1, \dots, x_{n_1}) , $(x_{n_1+1}, \dots, x_{n_2})$, \dots , $(x_{n_{L-1}+1}, \dots, x_{n_L})$, then the

input layer of $n_L = n, i$ feature module is equivalent to the visual layer of the first RBMs of $RBM_s(i)$. The hidden layer of the last RBM is the new feature data, then the input of the top-level classifier is the output reconstruction result of each RBMs. The solid line included in the figure shows one of the network structures of the top-level classifier, with the classifier's first j network output value being \tilde{y}_j , where $j = 1, 2, \dots, K$.

The top layer of the deep learning model requires the addition of a classifier, and the study uses the Softmax classifier. The Softmax classifier is used as a non-linear model

for classification, and it has a high correct classification rate when combined with a deep neural network. The Softmax classifier performs model training through a cost function, and it solves for the optimal parameters of the model through a parametric gradient method [21].

Given the training sample dataset $S = \{(X^{(1)}, y^{(1)}), (X^{(2)}, y^{(2)}), \dots, (X^{(N)}, y^{(N)})\}$, where $X^{(i)}$ is the i sample, the category output values of $X^{(i)}$ are referred to by $y^{(i)}$ and the number of samples is referred to by N . Assuming that the output data contains K categories, the probabilistic classification values are calculated using the hypothesis function approach for $y^{(i)} \in \{1, 2, \dots, K\}$, and $\phi_j = p(y = j|X)$, which defines the hypothesis function of the form shown in (13).

$$h_{\theta}(X^{(i)}) = \begin{bmatrix} p(y^{(i)} = 1|X^{(i)}, \theta) \\ p(y^{(i)} = 2|X^{(i)}, \theta) \\ \vdots \\ p(y^{(i)} = K|X^{(i)}, \theta) \end{bmatrix} = \frac{1}{\sum_{j=1}^K e^{\theta_j^T X^{(i)}}} \begin{bmatrix} e^{\theta_1^T X^{(i)}} \\ e^{\theta_2^T X^{(i)}} \\ \vdots \\ e^{\theta_K^T X^{(i)}} \end{bmatrix} \quad (13)$$

In equation (13), $\theta = [\theta_1, \theta_2, \dots, \theta_K]^T$ is the Softmax classifier model parameter; the expression for the probability value of the sample $X^{(i)}$ being classified as the j class is $p(y^{(i)} = j|X^{(i)})$, the value normalized to the model output value is $\sum_{i=1}^K e^{\theta_j^T X^{(i)}}$, and the sum of the output values of all classes is 1. The cost function of the Softmax classifier is shown in equation (14).

$$C(\theta) = -\frac{1}{N} \left(\sum_{i=1}^N \sum_{j=1}^K I\{y^{(i)} = j\} \log \frac{e^{\theta_j^T X^{(i)}}}{\sum_{s=1}^K e^{\theta_s^T X^{(i)}}} \right) \quad (14)$$

In equation (14) I is the indicator function, when the expression is false, $I = 0$; otherwise, $I = 1$. The cost function of the partial derivative processing Softmax classifier yields the gradient expression of the parameters, which is calculated as shown in equation (15).

$$\nabla_{\theta_j} C(\theta) = -\frac{1}{N} \sum_{i=1}^N \left[X^{(i)} \left(I\{y^{(i)} = j\} - p(y^{(i)} = j|X^{(i)}; \theta) \right) \right] \quad (15)$$

B. Sustainability Performance Evaluation Model for Accounting Firms

After obtaining the enterprise performance evaluation data, the modular deep learning model combined with RBMs constructed by the institute is shown in Fig. 3. $S I_1 I_2$ The RBM training algorithm is used to obtain the output values of the first layer of RBMs u^2 and \bar{u}^{-2} connection weights, and the input data of the second RBM are the output values of RBMs u^2 and \bar{u}^{-2} . The output values and connection weights of each layer are obtained through continuous iteration using the RBM training algorithm and a greedy layer-by-layer unsupervised pre-training strategy, and are used as the initial parameters of the network. After reconstructing the last output values u^{L1} and \bar{u}^{-L2} , they are fed directly into the top layer Softmax classifier as input data, and the desired output data is used to obtain the initial parameters θ . A deep learning network model with classification function is formed by connecting the pre-trained RBMs(1), RBMs(2) and Softmax classifiers, and the parameters of the network are adjusted using the BP algorithm, and if the number of iterations meets the maximum number of iterations or the classification accuracy does not meet the requirements, the learning is terminated, otherwise the iteration step is repeated.

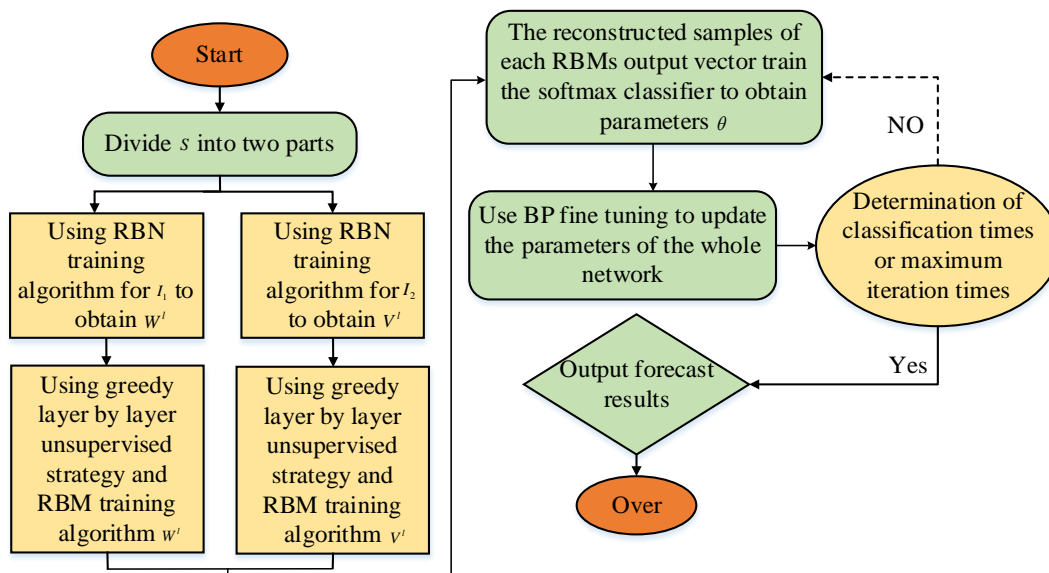

Fig. 3. Flow chart of modular deep learning algorithm based on two RBMs

The sustainable development of accounting enterprises depends on the optimal allocation of resources. Based on the experience of previous studies, the principles to be followed in the evaluation system for sustainable development of accounting enterprises are multiple evaluation subjects, multiple evaluation objectives, multiple evaluation contents and multiple evaluation methods, and the performance evaluation index system includes three aspects: social, resource and economic. According to the basic characteristics, completeness and reliability of the economic performance evaluation system, the study sets five secondary indicators, including cash flow, development capacity, profitability and quality, asset operation capacity and debt servicing capacity. Moreover, there are 15 tertiary indicators, including net asset cash return rate, net asset additional economic value rate, unit asset cash flow from operating activities, capital preservation growth rate, operating income growth rate, net asset additional economic value rate and net operating profit index. The 15 level 3 indicators are cash return on net assets, economic value added to net assets, cash flow from operating activities per unit of asset, capital preservation growth rate, operating income growth rate, economic value added to net assets, operating net profit index, return on total assets, return on net assets, total assets turnover, inventory turnover, accounts receivable turnover, quick ratio, interest earned multiple and gearing ratio.

According to the characteristics of human resources of the resource performance evaluation system, four secondary indicators are constructed including human resources output capacity, human resources utilization capacity, human resources input situation and basic human resources situation. 15 tertiary indicators include the adoption rate of rationalized suggestions, market share of new products, number of patents per capita, new technology development capacity, employees' profit generating capacity, staff turnover rate, employees' satisfaction rate, employees' career development level, staff training expenditure, human resources maintenance capacity, human resources investment level, professional work experience level of technical staff, proportion of technical staff, average age of staff, and education level of staff. Based on the definition of corporate social responsibility, the three secondary indicators of the social performance evaluation system selected for the study are the fulfillment of responsibility to the community, the fulfillment of responsibility to the government and the fulfillment of responsibility to consumers. After-sales service rate, return or repair rate, consumer complaint rate, and customer satisfaction. Table I refers to secondary and tertiary indicators at the social level.

TABLE I. SECONDARY AND TERTIARY INDICATORS OF SOCIETY, RESOURCES AND ECONOMY

Evaluation level	Evaluating indicator
Fulfillment of community responsibilities	Proportion of public service advertising expenditure
	Contribution rate of community activities
	Donation income ratio
Performance of government responsibilities	Employment rate of the disabled
	Employment ratio
	Social contribution rate
Performance of consumer responsibilities	Asset tax rate
	After sales service rate per unit income
	Return or repair rate
	Consumer complaint rate
	Customer satisfaction

The dataset selected for the study was data related to 83 accounting firms for the period 2017-2021, with a total sample data of 415 entries. Given the low relevance of the data sample data to the performance evaluation indicators, missing feature data and most of the data values being zero, the study cleared some of the indicator data. The raw values of the study performance were taken as 56-100, and the performance of the sample data was taken as the output variable, and the performance values were discretized into four category labels with values of 1, 2, 3 and 4 according to *K* mean clustering, with larger category labels indicating better performance, while the performance single output was discrete into a

multiple output form. Given the variation in input feature magnitudes and magnitude units, the study utilises minmax normalisation for sample data processing. Assuming that x_i is the input feature and x'_i is the normalised feature, the normalisation formula can be expressed as equation (16).

$$x'_i = \frac{x_i - \min(x_i)}{\max(x_i) - \min(x_i)}$$

In equation (16), the maximum and minimum values of the x_i feature are $\min(x_i)$ and $\max(x_i)$, respectively.

IV. ANALYSIS OF THE EFFECTIVENESS OF THE APPLICATION OF THE SUSTAINABLE DEVELOPMENT PERFORMANCE EVALUATION MODEL FOR ACCOUNTING FIRMS

The study used the 348 samples close to the centre of clustering as the training sample and the remaining samples as the test sample. Table II shows the results of the mean clustering referred to K . The four centres of performance clustering were 62.7, 68.5, 75.7 and 89.6.

The loss function values of the four different deep learning algorithms for both the training and test sets are shown in Fig. 4(a) and 4(b). From the figures, it can be seen that the RBM-Softmax deep learning algorithm has the lowest value of loss for both the training and test sets, and the reduced value of loss decreases gradually as the number of iterations

increases. The results for both the training and test sets show that the minimum loss value is achieved at 160 iterations, with corresponding values of 0.213 and 0.202, respectively.

TABLE II. RESULTS OF MEAN CLUSTERING K

Performance clustering centre	Category label	Multiple output form	Total samples	Number of training samples	Number of test samples
62.7	1	[1,0,0,0]	168	143	25
68.5	2	[0,1,0,0]	123	103	20
75.7	3	[0,0,1,0]	96	82	14
89.6	4	[0,0,0,1]	28	20	8

(a) Training set results of different depth learning algorithms

(b) Results of different depth learning algorithms

Fig. 4. Loss function values of four different depth learning algorithms in training set and test set

Setting the dimensionality of the input features and the dimensionality of the new features to 4 and 53, respectively, the changes of RBM fine-tuning, PCA (Principal Component Analysis) expression, and RBM expression on the performance of the Softmax classifier were analyzed, and the results are shown in Fig. 5. PCA expression and RBM expression refer to the method of classifying feature data through the Softmax classifier after the extraction of PCA and RBM features, respectively, while RBM fine-tuning refers to parameter tuning of the network based on the RBM expression (Ye F X et al. 2019) [22]. The study set each feature dimension to be run 10 times, and their average result was taken as the final result. Along with the gradual increase in the number of feature dimensions, the RBM expression Softmax

classifier performed better compared to the PCA expression, and the RBM expression Softmax classifier extracted features with a correct rate of up to 75%. This is due to the fact that PCA as a linear feature extraction method decreases significantly when the number of feature dimensions increases, while the performance of the RBM fine-tuned Softmax classifier is higher than that of both PCA and RBM expression. There is no significant fluctuation in the performance of the classifier at different dimensions, with accuracy varying within a certain range. This indicates that the data features extracted by RBM fine-tuning are highly effective and stable, which in turn improves the accuracy of the model with a high probability.

Fig. 5. Curve of accuracy with feature dimension

The study fed test samples into the already trained network and the corresponding classification results for each sample were obtained by classifying them with the top layer Softmax classifier. The input data of five randomly selected samples and the output values of the RBMs at each layer of the RBM were used as data for the performance analysis of the RBMs feature extractor, as shown in Fig. 6. For sample 1, sample 2, sample 3, sample 4 and sample 5 respectively, each dash in

Fig. 6 indicates the input data value or RBM output value of a sample. As can be seen from the figure, the samples have high input data complexity and low correlation, which results in poorly differentiated and distinguishable samples. Each dash in Fig. 6 represents a sample's input data value or RBM output value. The output values of the input data after the two-layer RBM action are shown in Fig. 7.

Fig. 6. Input value of sample

As can be seen in Fig. 7, after the extraction of data features by the two-layer RBM network, each sample presents an extremely clear data distribution, and the test samples are highly differentiable between different features. The feature results of the five samples show that the node output values of samples 3 and 4 are all greater than 0.7. The node output values of sample 2 are all relatively intermediate; and the number of nodes of samples 1 and 5 is close to 90% of the

Therefore, the study divided the test samples into three categories, namely sample 3 and sample 4, sample 2, sample 1 and sample 5. The longitudinal comparison shows that the relationship between the magnitude of the second layer RBM output values of the samples is, sample 4 > sample 3 > sample 2 > sample 1 > sample 5. The cross-sectional comparison of the samples illustrates the characteristic of differentiability of the sample features.

Fig. 7. Output value of the sample in the second layer RBM

The input samples indicate that the data distributions for sample 5 and sample 1 are indeed at a much lower position. The network outputs of the partial test sample data in the Softmax classifier are shown in Table III, where the sum of the probability values of each sample belonging to the four categories is 1. A higher probability value of a sample belonging to a category indicates that the sample belongs to

that type. The categories for samples 1 - sample 10 are 2, 2, 3, 1, 2, 1, 2, 4, 4, and 3 in that order. This further validates that the deep learning model, after obtaining abstract feature representations through a multi-layer RBM network structure, the higher the differentiability of the features, which in turn allows for more accurate classification.

TABLE III. PARTIAL TEST SAMPLE DATA OUTPUT VALUE

Sample	Category 1	Category 2	Category 3	Category 4
1	0.0426	0.9402	0.0086	0.0086
2	0.0303	0.9514	0.0151	0.0032
3	0.0016	0.0715	0.8948	0.0320
4	0.9403	0.0423	0.0088	0.0086
5	0.2406	0.7315	0.0188	0.0091
6	0.9388	0.0435	0.0090	0.0087
7	0.0952	0.8816	0.0172	0.0060
8	0.0005	0.0032	0.0460	0.9504
9	0.0030	0.0004	0.0442	0.9524
10	0.0214	0.0006	0.9602	0.0179

The model is evaluated by average precision (AP), average recall (AR) and prediction accuracy, as shown in Fig. 8. It can be seen from the table that the AP of the proposed method is 86.95%, AR is 89.74%, and the prediction accuracy is 88.29%. The three evaluation indicators of the proposed method are greater than Softmax classifier, BP neural network and DBN Softmax. BP neural network algorithm is likely to fall into

local extreme value, making training failure. The approximation and generalization ability of networks are closely related to the typicality of learning samples. For the Softmax classifier, the exponential Softmax function can be used to extend the numerical distance with large difference. Therefore, the proposed performance evaluation model for sustainable development of enterprises is more practical than other evaluation models.

Fig. 8. Comparison of evaluation indexes of each algorithm

V. CONCLUSION

On the basis of analyzing the sustainable development evaluation system of accounting enterprises, the research constructs a sustainable development performance evaluation model combining multiple RBMs and Softmax classifiers. The results of training set and test set show that the minimum loss value is obtained when the number of iterations is 160 and the corresponding values are 0.213 and 0.202, respectively. The model is evaluated by AP, AR and prediction accuracy. The AP, AR and prediction accuracy of the proposed method are 86.95%, 89.74% and 88.29% respectively, which are higher than the Softmax classifier, BP neural network and DBN based Softmax method. This method is superior to other algorithms in the application of accounting enterprise sustainable development performance evaluation model. Embed sustainable development into the theory of enterprise performance evaluation, realize the comprehensive combination of sustainable development and enterprise performance evaluation theory, theoretically solve the problem of disconnection between enterprise performance evaluation and sustainable development, and enhance the scientificity, integrity and systematicness of performance evaluation theory. In the context of sustainable development, the model has important reference value and significance in the application of accounting enterprise performance evaluation. Although the proposed model has effectively improved the accuracy, the network initialization parameter color setting of this model refers to the empirical value and previous research results, and the training algorithm needs to

be further studied in the future. The methods given need to be applied to empirical analysis in the future, and the follow-up research is expected to provide referential ideas and methods for the implementation of the concept of sustainable development at all social levels.

Abstract—Clustering Spatio-temporal data is challenging because of the complexity of processing the spatial and temporal aspects. Various enhanced clustering approaches, such as partition-based and hierarchical-based algorithms have been proposed. However, the ST-DBSCAN density-based algorithm is commonly used to process irregularly shaped clusters. Moreover, ST-DBSCAN considers neighborhood parameters as spatial and non-spatial. The preliminary results from our experiments indicate that the ST-DBSCAN algorithm addresses temporal elements less effectively. Therefore, an improvement to the ST-DBSCAN algorithm was proposed by considering three neighborhood boundaries in neighborhood function. This experiment used the El Niño dataset from the UCI repository. The experimental results show that the proposed algorithm increased the performance indices by 27% compared to existing approaches. Further improvement using the hierarchical Ward's method (with thresholds of 0.3 and 0.1) reduced the number of clusters from 240 to 6 and increased performance indices by up to 73%. It can be concluded that ST-HDBSCAN is a suitable clustering algorithm for Spatio-temporal data.

Keywords—Data mining; hierarchical clustering; density-based clustering; spatio-temporal clustering

I. INTRODUCTION

Clustering is a process for grouping data based on similarity distance. It is an effective data mining technique for data segmentation, feature selection, pattern recognition, and anomaly detection. Clustering is an unsupervised method that does not require a prior definition of the input data classes. Clustering techniques help uncover hidden patterns in the examined data [1]. Unlike conventional clustering algorithms that process nonspatial or non-temporal data, clustering spatio-temporal data is challenging. Spatio-temporal data is different from relational data, in which computational approaches are developed for both spatial and temporal attributes [2]. Because of spatio-temporal data structure features, which record the general variables and the corresponding location and time [3], it became challenging to cluster the spatial and temporal data together.

Spatio-temporal clustering is an emerging research area. It gains actual location and time information from the enormous amount of geographical data provided by GPS, satellite, wireless technology, sensor networks, and other devices that could transmit location and time-stamped data. For instance, an organization has invested more resources in obtaining hidden

knowledge and information from spatio-temporal data making research in this field more critical. The work by Bogorny and Shekar [4], Mazimpaka and Timpf [5], and Atluri *et al.* [6] have reviewed spatio-temporal data mining and its applications in surface ozone (O₃) variations [7], forest fire [8], groundwater potential zone [9], citizens security [10], traffic congestion [11], healthcare, and social media.

Kisilevich *et al.* [12] categorized spatio-temporal data based on temporal extension, spatial extension, and spatial location. Spatial extension expands the spatial shape from points into lines and then areas. The expansion starts from a single snapshot to an updated snapshot and the completed time series in temporal extension. The spatial location is divided into two categories depending on the data collection location (fixed or dynamic). Based on these extensions, Kisilevich *et al.* [12] defined the following five types of spatio-temporal data: ST-events, geo-referenced variable, geo-referenced time series, moving objects, and trajectories.

M. Y. Ansari *et al.* [13] presents six categories of spatiotemporal clustering algorithms: event clustering, geo-referenced data item clustering, geo-referenced time series clustering, moving clusters, trajectory clustering, and semantic based trajectory data mining. ST-events have a fixed location and only store one snapshot of variable values. The geo-referenced variable also has a fixed location but stores only the current updated values. Similarly, geo-referenced time series also have a fixed location, but it stores the entire history of variable values as time-series data for each location. Moving objects and trajectories have dynamic locations. The object changes its location over time; however, only current values are recorded. In contrast, trajectories record each object's movement as a completed time series. Similar to Madraky *et al.* [14], this research focuses on clustering geo-referenced time-series data and utilizes a nature-inspired approach.

Various clustering approaches have been proposed to enhance the traditional algorithm, such as density-based, partition-based, and hierarchical-based [15]. The density-based algorithm is widely used because it can process irregular-shaped clusters, e.g. ST-DBSCAN [16], ST-OPTICS [17], ST-Shared Nearest Neighbors (SNN) and ST-SEP-SNN [18], P-DBSCAN [19], ST-DCONTOUR [20], RT-DBSCAN [21], CorClust [22], and MDST-DBSCAN [23]. One of the commonly used spatio-temporal density-based clustering approaches is Spatio-temporal (ST)-Density-based Spatial

Clustering of Applications with Noise (DBSCAN) [16]. However, the algorithm does not address the temporal elements of data. The neighborhood parameters are defined as spatial and non-spatial objects only. Therefore, the maximum temporal distance was later introduced to improve the ST-DBSCAN algorithm.

Other techniques extended to other traditional density-based clustering algorithms. For example, Spatio-temporal Shared Nearest Neighbor (ST-SNN) and Spatio-temporal Separated Shared Nearest Neighbor (ST-SEP-SNN) extend SNN by Ertöz *et al.* [24] but introduce the polygon distance algorithm to search core polygon [18]. Their results have been compared with that of PDBSCAN [19]. 4D+SNN also added weighting for spatial and temporal attributes [25]. The ST-DCONTOUR algorithm by Zhang and Eick [20] emphasizes the batching process of SNN density-based clustering algorithms.

The ST-DBSCAN algorithm by Birant and Kut [16] is one of the standard benchmark algorithms for spatio-temporal clustering. In ST-DBSCAN, introducing a new distance limit for spatial data called *Eps 2* enhanced the DBSCAN algorithm. The sea surface temperature, sea surface height, and wave height in the Black, Marmara, Aegean, and Mediterranean seas were clustered. The result was presented as a map with labels of the cluster numbers for each group. Besides, utilizing a cluster map emphasizes the spatial aspect of the data rather than the temporal aspect. Therefore, this research aims to improve ST-DBSCAN by considering spatial and non-spatial.

The following Sections II discuss how the ST-DBSCAN algorithm is limited and how to improve it by proposing Three Neighborhood Boundary in neighborhood function and improving it again using the hierarchical ward's method. Section III discusses the dataset and parameter settings; Section IV discusses the results obtained from experiments, including comparison results with the benchmark algorithm, and the conclusion and future work.

II. RELATED WORK

Density-Based clustering is an unsupervised learning technique that locate distinct groups or clusters in the data. These techniques are based on the notion that a cluster in data space is a contiguous region of high point density, separated from other such clusters by contiguous regions of low point density. The fundamental density-based clustering algorithm is called Density-Based Spatial Clustering of Applications with Noise (DBSCAN). Outliers and noise-filled massive amounts of data can be used to find clusters of various sizes and shapes.

Three minor modifications to DBSCAN, known as ST-DBSCAN, are proposed by D. Birant *et al.* [16]. ST-DBSCAN deal with the detection of (i) core items, (ii) noise objects, and (iii) neighboring clusters. The ability to identify clusters on spatial-temporal data is the primary motivation behind this modification. When clusters of various densities occur, the second adjustment is required to locate noisy objects. D. Birant *et al.* [16] introduce the idea of density factor. Each cluster is given a density factor, which indicates how dense the cluster is. The third adjustment compares the cluster's average value with a new value that will soon be available.

In ST-DBSCAN, the DBSCAN algorithm was enhanced by introducing a new distance limit for spatial data called *Eps 2*. In terms of its research, sea surface temperature, sea surface height, and wave height in the Black Sea, the Marmara Sea, the Aegean Sea, and the Mediterranean Sea are clustered. The clustering result was presented on a map labeled with a cluster number for each area. Using a cluster map, the result focused more on the spatial part of data and lacked in showing the temporal part.

The problem with ST-DBSCAN is the lack of an algorithm on the temporal aspect of spatio-temporal data. This is because the temporal data were separated manually by filtering the data that occurred on a consecutive day or the same day in a different year [16]. Thus, the algorithm did not identify the cluster with a pattern that exists continuously in two different years. The cluster generated took into account the spatial and non-spatio-temporal part of the data; however, it lacks the usage of the temporal aspect of the data.

The clustering algorithm "Spatio-Temporal-Ordering Points to Identify Clustering Structure (ST-OPTICS)" was proposed by K.P. Agrawal *et al.* [17] and is a modified version of the previous density based technique "Ordering Points to Identify Clustering Structure (OPTICS)." The proposed algorithm can produce spatio-temporal clusters and address issues such as (i) handling spatio-temporal data, non-spatial values to take into account temporal dimensions, (ii) algorithm does not depend on dimensions of data, so it is ready to handle n-dimensions, and (iii) independence of ordering of observations in database can be observed by the working principle of the proposed technique like it first performs Orde, (iv) locating nested and nearby clusters, and (v) ultimately, it is also scalable.

The ST-OPTICS algorithm employs ST-DBSCAN to extract the clusters and then performs hierarchical clustering to aggregate the clusters. The result generated has better performance indices compared to ST-DBSCAN. However, comparing to a similar version of ST-DBSCAN, ST-OPTICS still performs clustering using spatial and non-spatio-temporal aspects of the data but lacks the temporal aspect of the data. Similarly, the results are also shown in the form of maps which limit the description of the temporal part of data. Therefore, there is still a need for a clustering algorithm that could cluster spatio-temporal data that will account not only the spatial and non-spatio-temporal parts of data but also the temporal part of data.

To cluster overlapping polygons that can change their positions, sizes, and shapes over time, Sujing Wang *et al.* [18] introduce two new spatiotemporal clustering algorithms, called Spatiotemporal Shared Nearest Neighbor clustering algorithm (ST-SNN) and Spatiotemporal Separated Shared Nearest Neighbor clustering algorithm (ST-SEP-SNN). The core polygon notion and the spatial closest neighborhood of a polygon are both redefined by Sujing Wang *et al.* [18]. Even with high-dimensional data with outliers, ST-SNN and ST-SEP-SNN may locate clusters of various sizes, shapes, and densities.

P-DBSCAN, a novel DBSCAN for analysis of locations and events utilizing a collection of geo-tagged photographs,

was proposed by Slava Kisilevich *et al.* [19]. Two new ideas were introduced by P-DBSCAN: (i) the density threshold, which is based on the population of the neighborhood, and (ii) adaptive density, which is utilized to quickly converge to high-density areas.

Yongli Zhang *et al.* [20] proposed the ST-DCONTOUR algorithm, a unique serial density-contour-based spatio-temporal clustering technique that uses location streams as input and a model-based clustering approach to produce spatio-temporal clusters. In our method, the incoming data is divided into batches, and we use a serial technique to construct spatial clusters for each batch individually first. The formation of spatio-temporal clusters is then accomplished by establishing ongoing connections between spatial clusters in successive batches. Our method makes use of contouring algorithms to recognize spatial clusters as closed contours of a region whose density exceeds a predetermined threshold and contour analysis methods to recognize persistent, transient, and freshly formed spatial clusters in batches.

Yikai Gong *et al.* [21] proposed a technique called RT-DBSCAN to enable continuous cluster checkpointing-based real-time data clustering. In order to provide scalability, the platform is developed using container-based technologies and Apache Spark running on massive Cloud resources. The real-time data streams were the exclusive focus of the DBSCAN algorithm. With the use of density-based clustering, the DBSCAN algorithm handles rapidly expanding high velocity data streams.

Based on empirical geographical correlations across time, M. Hüsich *et al.* [22] proposed a method called CorClustST. CorClustST compares and interprets clustering outcomes for various scenarios, such as those involving several underlying variables or various time scales. The clustering technique is extended in a way that enables massively parallel execution and works around memory constraints.

C. Choi *et al.* [23] proposed a clustering method, called MDST-DBSCAN for large-scale, multidimensional spatiotemporal data in a reliable and efficient manner. The MDST-DBSCAN is applied to idealized patterns and a real data set, and the results from both examples demonstrate that it

can identify clusters accurately within a reasonable amount of time. The MDST-DBSCAN has a limitation in that the method of defining the neighbors in the clustering process operates conservatively.

III. PROPOSED METHOD

The spatio-temporal dataset is different from the traditional dataset in many ways. Firstly, it contains implicit spatial or temporal data that initially need to be calculated. Secondly, spatio-temporal data has granularity, and making its selection differently will impact mining results. Thirdly, spatio-temporal data has an auto-correlation.

The ST-DBSCAN algorithm was proposed by Birant and Kut [16] and has been widely utilized in various studies, achieving impressive results on spatio-temporal data. The distance between two objects o and p denoted as $\text{dist}(o, p)$ is defined by measures such as the Manhattan, Euclidean and Haversine distance functions. The neighborhood of object o is defined as $\{p \in D \mid \text{dist}(o, p) \leq \text{Eps}\}$, where p is another object in database D and Eps is the predefined minimum distance between object o and p . Eq. 1 formally defines the neighborhood utilized in ST-DBSCAN as follows: $\text{Eps } 1$ for spatial data and $\text{Eps } 2$ for non-spatiotemporal data, whereas Eq. 2 defines the core objects. As per Eq. 2, objects that satisfy the minimum number of neighborhoods within the radius of Eps and are greater than or equal to the MinPts are defined as core objects. The ST-DBSCAN is also defined by its density-reachable, density-reachable, density-connected, density-based cluster and border objects [16].

The temporal data aspect was separated manually by filtering daily observations in different years. Thus, this method cannot identify clusters that contain patterns of two different years. The neighborhood in Eq. 1 only considers the spatial and non-spatial distances. It does not include the temporal features, as the algorithm uses two boundary neighborhood-clustering methods. Fig. 1 illustrates the limitation of ST-DBSCAN. Only the spatial dimension is considered in the clustering process; thus, only one cluster will be generated. However, the distance becomes apparent if the data is viewed from the right or topside. Hence, the blue and grey boxes will not be grouped into the same cluster.

Fig. 1. Two-dimensional view of spatio-temporal data with views from the front, right and top.

The proposed Hierarchical ST-DBSCAN (ST-HDBSCAN) algorithm was developed in two parts. The first part improves the neighborhood of the ST-DBSCAN by introducing Three Neighborhood Boundary. The second part introduces the hierarchical ward's method to improve the performance of DBSCAN.

$$spatial_dist(o,p) \leq Eps1 \wedge (var_dist(o,p) \leq Eps2) \rightarrow Neighbor(o,p) \quad (1)$$

$$NumNeighbor(o) \geq MinPts \rightarrow CoreObject(o) \quad (2)$$

A. ST-DBSCAN with Three Neighborhood Boundary

Fig. 2 illustrates the spatio-temporal data in three dimensions to incorporate the temporal aspect. The spatial dimension is represented along the z-axis and y-axis, whereas the temporal dimension is represented along the x-axis. In the three-dimensional view, it becomes clear that when the temporal aspect is taken into consideration, proper separation is achieved: the grey boxes are on the positive side of the x-axis, and the blue boxes are on the negative side of the x-axis. Therefore, ignoring the temporal aspect could lead to inconsistent clustering.

Fig. 2. A three-dimensional view of spatio-temporal data (the spatial dimension is represented along the z-axis and y-axis while the temporal dimension is represented along the x-axis).

Eq. 3 defines the spatio-temporal neighborhood utilized in the improved ST-DBSCAN algorithm. It is composed of Three Neighborhood Boundary: *Eps 1* for spatial data, *Eps 2* for non-spatio-temporal data, and *Eps 3* for temporal data.

In the improved ST-DBSCAN algorithm, temporal neighbors are defined by *Eps 3* to limit temporal distance. As a result, two objects are temporally close if the distance between them in terms of time is in the range of *Eps 3*. For example, the temporal distance could be defined over 1 year or 1 month. If values are collected daily, a temporal distance defined over 1 year will limit the data to the range of a year, that is, 182 days before and after the date for each value. Therefore, to spatially and temporally cluster the data, there is a need to develop a new algorithm that could incorporate the spatial and temporal aspects of data. Based on this information, in this research, the density-based algorithm ST-DBSCAN is enhanced by incorporating a temporal distance limit called maximum temporal distance (*Eps 3*). The maximum temporal distance is defined in Eq. 4.

The proposed approach can be illustrated as follows. Given objects O ($s1, s2, n1, n2, t1$) and P ($s3, s4, n3, n4, t2$), each comprising of five variables (latitude, longitude, wind speed, sea surface temperature, and date), Eq. 5 (haversine function) is utilized to compute the spatial distance (*spatial_dist*) between O and P and Eq. 6 (Euclidean distance) computes the non-spatiotemporal distance (*non_st_dist*). Also, Eq. 7 computes the absolute date difference between the two objects measured in days. The Euclidean distance was an unsuitable measure for the earth's curved surface due to the utilized spatial data (latitude and longitude coordinates). Therefore, the haversine distance was the preferred option for spatial distance computation.

$$(spatial_dist(o,p) \leq Eps1) \wedge (non_st_dist(o,p) \leq Eps2) \wedge (temp_dist(o,p) \leq Eps3) \rightarrow Neighbor(rs,p) \quad (3)$$

$$spatial_dist = 2r \arcsin \left(\sqrt{\sin^2 \left(\frac{s_3 - s_1}{2} \right) + \cos(s_1) \cos(s_3) \sin^2 \left(\frac{s_4 - s_2}{2} \right)} \right) \quad (4)$$

where:

h: is the haversine distance

r: is the radius of Earth with value 6371 km

φ_1 : is the latitude of point 1

φ_2 : is the latitude of point 2

λ_1 : is the longitude of point 1

λ_2 : is the longitude of point 2

$$spatial_dist = 2r \arcsin \left(\sqrt{\sin^2 \left(\frac{s_3 - s_1}{2} \right) + \cos(s_1) \cos(s_3) \sin^2 \left(\frac{s_4 - s_2}{2} \right)} \right) \quad (5)$$

$$non_st_dist = \sqrt{(n1 - n3)^2 + (n2 - n4)^2} \quad (6)$$

$$temp_dist = |t2 - t1| \quad (7)$$

Pseudocode 1 describes the pseudocode of ST-DBSCAN with maximum temporal distance (ST-DBSCAN *Eps 3*). The algorithm starts by initializing the cluster number as described in line 13. Afterward, it searches for the neighbors of unlabelled data utilizing the retrieve-neighbor function (lines 15–16). The expectation is that if the retrieve-neighbor function meets all the conditions, the objects are considered neighbors. Conversely, if the number of neighbors does not satisfy the *MinPts*, these objects will be labeled as noise (lines 19–20). Otherwise, its neighbors are labeled as the same cluster (lines 23–24). Therefore, the algorithm checks the neighbors of each discovered neighbor (lines 26–29). Similarly, the neighbor would be labeled the same cluster (lines 30–33). These processes are repeated until all objects have been observed. Lastly, the Clustered_Data set, which contains all data labeled with a Cluster ID, is returned as the result of the algorithm (line 42).

Line	Pseudocode 1: Pseudocode of ST-DBSCAN with Eps3 Algorithm
1.	Inputs:
2.	D = (d1, d2, ... , dn) Set of objects
3.	N = (d1, d2, ... , dn) Set of Retrieved Neighbors
4.	R = (r1, r2, ... , rn) Set of Retrieved Neighbors of N
5.	Eps1: Maximum spatial distance value
6.	Eps2: Maximum non-spatial distance value
7.	Eps3: Maximum temporal distance value
8.	Mint: Minimum number of points within Eps1, Eps2, and Eps3
9.	
10.	Output
11.	Clustered_Data : Data that has been labeled with ClusterID
12.	
13.	Initialize cluster label as 0
14.	
15.	For i in range of number of data rows in D
16.	If label of the current data with index i set as “unmarked”
17.	Retrieve neighbors of data with index i based on Eps1, Eps2, and Eps3 values
18.	Store the neighbors in N
19.	If number of neighbors are less than MinPts
20.	Set label of data with index i as “noise”
21.	Else
22.	Create new cluster label
23.	For all neighbors in N
24.	Set cluster label for each neighbor as new cluster label
25.	End For
26.	For all neighbors in N
27.	Get one neighbor data and store it as current object
28.	Retrieve neighbors of current object based on Eps1, Eps2, and Eps3
29.	Store the neighbors of current object in R
30.	If number of neighbors in R less than or equal to MinPts
31.	For all neighbors in R
32.	If the neighbor label’s is not “noise” or “unmarked”
33.	Set cluster label for the current object as new cluster label
34.	End If
35.	End For
36.	End If
37.	End For
38.	End Else
39.	End If
40.	End For
41.	
42.	Return data D with cluster label as Clustered_Data

Pseudocode 2 shows the pseudocode of the retrieve-neighbor function. This function returns the neighbors of an object by computing the spatial, temporal, and non-spatiotemporal distance between the object and other objects in the dataset. The algorithm starts by excluding the current object from the data (lines 12–13). It then computes the spatial distance between the two objects using the Haversine function (Eq. 5) and stores the distance in the spatial_dist variable (lines 15–16). Afterward, it computes the non-spatiotemporal distance utilizing the Euclidean distance function (Eq. 6) and stores the result in the non_st_dist variable (lines 17–18). Finally, it calculates the temporal distance by calculating the

date differences between the current object and other objects in the dataset (Eq. 7) and stores it in temporal_dist (lines 19–21).

The next step determines the neighbors of each object in the dataset in turn by comparing the spatial_dist, non_st_dist and temporal_dist with the values of *Eps 1*, *Eps 2* and *Eps 3*. For each evaluation, if each distance value is less than the corresponding *Eps* value, the current object (*p*) is considered a neighbor of the examined object (*o*) and will be added to the set of the object’s neighbors (Data_Neighbors) (lines 22–26). The Data_Neighbors is returned to the ST-DBSCAN *Eps 3* Algorithm (line 30).

Line	Pseudocode 2: Pseudocode of the Retrieve Neighbors for ST-DBSCAN with maximum temporal distance (Eps 3)
1.	Inputs:
2.	D : Data of all objects
3.	n : Index of current object
4.	Eps1: Maximum spatial distance value
5.	Eps2: Maximum non-spatial distance value
6.	Eps3: Maximum temporal distance value
7.	
8.	Output
9.	Data_neighbors : Data of current object's Neighbors
10.	
11.	For i in range of data row in D
12.	If i is equal to n
13.	Continue the program
14.	Else
15.	Calculate spatial distance of object index i with object index n using Harversine function
16.	Store the spatial distance as spatial_dist
17.	Calculate non-spatio-temporal distance of object i with object index n using Euclidean function
18.	Store the non-spatio-temporal distance as non_st_dist
19.	Calculate temporal distance of the object index i with object index n by
20.	subtracting time of object index i with object index n
21.	Store the temporal distance as temporal_dist
22.	If spatial_dist is less than Eps1 and
23.	non_st_dist is less than Eps2 and
24.	temporal_dist less than Eps3
25.	Set object index i as neighbor of object index n
26.	Add object index i to Data_neighbors
27.	End If
28.	End If
29.	End For
30.	Return Data_neighbors

B. An Improved ST-DBSCAN with Hierarchical Ward's Method

ST-HDBSCAN improves the ST-DBSCAN algorithm by utilizing the hierarchical ward's method. Pseudo code 3 shows the ST-HDBSCAN algorithm, which consists of the clustering and hierarchical phases. Lines 15–41 outline the clustering procedure with *Eps 3*. After clustering, the hierarchical ward's method is employed to aggregate the results (line 50). It combines close and similar clusters into new larger ones based

on the temporal distance value (computed by fast dynamic time warping) (lines 43–48). For the hierarchical phase, the Fast Dynamic Time Warping (FastDTW) algorithm warps the timeline of data points into compressed values (line 47) to simplify hierarchical cluster grouping. After computing the similarity pair of each cluster, the distance is condensed to minimize duplication (line 49). The minimum distance is selected as the cut point of the hierarchy to obtain the proper clusters (line 51).

Line	Pseudocode 3: Pseudocode of the ST-HDBSCAN Algorithm
1.	Inputs:
2.	D = (d1, d2, ... , dn) Set of objects
3.	N = (d1, d2, ... , dn) Set of Retrieved Neighbors
4.	R = (r1, r2, ... , rn) Set of Retrieved Neighbors of N
5.	Eps1: Maximum spatial distance value
6.	Eps2: Maximum non-spatial distance value
7.	Eps3: Maximum temporal distance value
8.	Mint: Minimum number of points within Eps1, Eps2, and Eps3
9.	
10.	Output
11.	Clustered_Data : Data that has been labeled with ClusterID
12.	
13.	Initialise cluster label as 0
14.	
15.	For i in range of number of data rows in D
16.	If label of the current data with index i set as "unmarked"
17.	Retrieve neighbors of data with index i based on Eps1, Eps2, and Eps3 values
18.	Store the neighbors in N
19.	If number of neighbors are less than MinPts
20.	Set label of data with index i as "noise"
21.	Else

```
22. Create new cluster label
23. For all neighbors in N
24.     Set cluster label for each neighbor as new cluster label
25. End For
26. For all neighbors in N
27.     Get one neighbor data and store it as current object
28.     Retrieve neighbor of current object based on Eps, Eps2, and Eps3
29.     Store the neighbor of current object in R
30.     If number neighbor in R less than or equal to MinPts
31.         For all neighbor in R
32.             If the neighbor label's is not "noise" or "unmarked"
33.                 Set cluster label for the current object as new cluster label
34.             End if
35.         End for
36.     End if
37. End for
38. End Else
39. End If
40. End For
41. Return data D with cluster label as Clustered_Data
42.
43. For i in range of number of cluster in Clustered_Data
44.     For j in range of number of cluster in Clustered_Data
45.         Get non spatial data with ClusterID i
46.         Get non Spatial data with ClusterID j
47.         Calculate FastDTW time series distance between cluster1 and cluster2
48.         Store the calculated value in variable 'dist'
49.     Convert pair distance 'dist' into condensed distance
50.     Generate hierarchy with ward method
51.     Get new cluster label from hierarchy with cutting level of threshold value
52.     For i in range of Clustered_Data
53.         Replace cluster label with the new cluster label from hierarchy
54.     Return Cluster_Data with new label
```

IV. EXPERIMENT RESULTS AND DISCUSSION

A. Equations

The El-Niño dataset from the UCI Repository was utilized for this research. This dataset was provided to study the El-Niño/Southern Oscillation cycle phenomena, which is well-known in climatology as the cause of the climate anomalies worldwide [26]. The data was collected from 1980 to 1998 and comprised different observations for each buoy. In total, there are 75 buoys and 178,080 observations in the dataset. The dataset was pre-processed using several techniques such as data cleaning, data transformation, and data reduction. The data cleaning technique employed the K-Nearest Neighbor Algorithm as the imputation technique. A new variable was added for data transformation, and Min-Max normalization

was implemented. Since the wind speed value is vital in determining El-Niño cycles, a new variable, 'Wind Speed,' is also estimated using the Zonal and Meridional wind values. On the other hand, air temperature and humidity were removed from the dataset because air temperature values are similar to sea surface temperature. It does not contribute much to determine El-Niño because 36% were missing the humidity values.

B. Parameter Setting

Table I shows the parameter settings used in the two experiments. The settings are as follows. Experiment 1 improves the ST-DBSCAN algorithm with the maximum temporal distance, whereas Experiment 2 improves it with the hierarchical ward's method.

TABLE I. PARAMETERS SETTINGS OF EXPERIMENT 1 AND 2

Parameters	Experiment 1		Experiment 2	
	ST-DBSCAN	ST-DBSCAN Eps 3	ST-HDBSCAN 0.3	ST-HDBSCAN 0.1
Eps 1 (spatial)	5000	5000	5000	5000
Eps 2 (non-spatio-temporal)	0.3	0.3	0.3	0.3
Minimum points	$\text{Log}(178080) = 12.0899$	$\text{Log}(178080) = 12.0899$	$\text{Log}(178080) = 12.0899$	$\text{Log}(178080) = 12.0899$
Eps 3 (temporal)	N/A	182	182	182
Threshold value	-	-	0.3	0.1

C. ST-DBSCAN with Three Neighbourhood Boundary Result

Table II and Table III show the clustering results for ST-DBSCAN compared with ST-DBSCAN Eps 3. The results indicate that the ST-DBSCAN algorithm does not consider the dataset's temporal aspect. Obs 87567–174633 was recognized as one cluster: Cluster 6. Its similarity term was based on the spatial distance (latitude, longitude) and non-spatio-temporal distance (wind speed and sea surface temperature) only. Similarly, in Table III, Obs 87799–151340 was grouped into Cluster 4 only. On the other hand, ST-DBSCAN Eps 3 grouped

Obs 87567–174633 into two clusters; 233 (Obs 174633–177614) and 166 (Obs 87230–87567), as shown in Table II. In Table III, Obs 87799–151340 was grouped into four clusters, which are 217, 220, 228, and 166. The results show that ST-DBSCAN Eps 3 clusters the data according to the temporal distance. It separated observation 177614, collected on November 5, 1998, from observation 87230, collected on April 5, 1994, which have about a four-year difference (Table II).

A heatmap can be utilized to visualize the performance of the algorithms. Fig. 3 shows the heatmap of the 14 clusters by ST-DBSCAN. Each color represents a different cluster, and each line represents the timeline of a buoy. Each buoy changes its cluster membership accordingly in its timeline, represented by the changing color in the buoy timeline. The heatmap shows that the clusters generated by ST-DBSCAN do not separate the data based on time. The small clusters indicate this problem with various colors spread across the timeline. This problem shows that clusters contain data with similar values but could occur at any time.

Fig. 4 shows the heatmap of the ST-DBSCAN *Eps* 3 algorithm. The Fig. 4 clearly shows the separation of data based on time, although 240 clusters were generated in the process. Though the cluster areas are enormous, the members in each cluster are small. However, the clusters are well-ordered based on time. However, since the number of clusters is enormous, it is difficult to interpret the data pattern, and each cluster has a tiny number of members. Therefore, to reduce the number of clusters and increase the understanding of the patterns generated, an improvement is conducted by aggregating the similar clusters based on the temporal similarity of the clusters. This technique was previously

employed in ST-OPTICS, where the algorithm combined the density-based and hierarchical-based methods to cluster spatio-temporal data [17].

D. ST-HDBSCAN Result

The ST-HDBSCAN algorithm was utilized to minimize the number of clusters generated by ST-DBSCAN with *Eps* 3. The clusters generated from the previous experiment were aggregated according to their similarity to form a hierarchy of clusters. FastDTW was employed as the cluster aggregation function. If the FastDTW value is small, the cluster is considered similar and is grouped into a larger cluster.

The cut point of the dendrogram decides the number of clusters generated by ST-HDBSCAN. The higher the cut point affect to the fewer clusters generated. The number of vertical lines at the different cut-point levels indicates the number of clusters. Fig. 5 shows the hierarchical clustering dendrogram for the ST-HDBSCAN algorithm using the hierarchy threshold (0.1). The cut point of the dendrogram is calculated by multiplying the threshold with the maximum hierarchy distance or maximum FastDTW distance of all clusters. For the data utilized in our experiment, the maximum distance was 249.95.

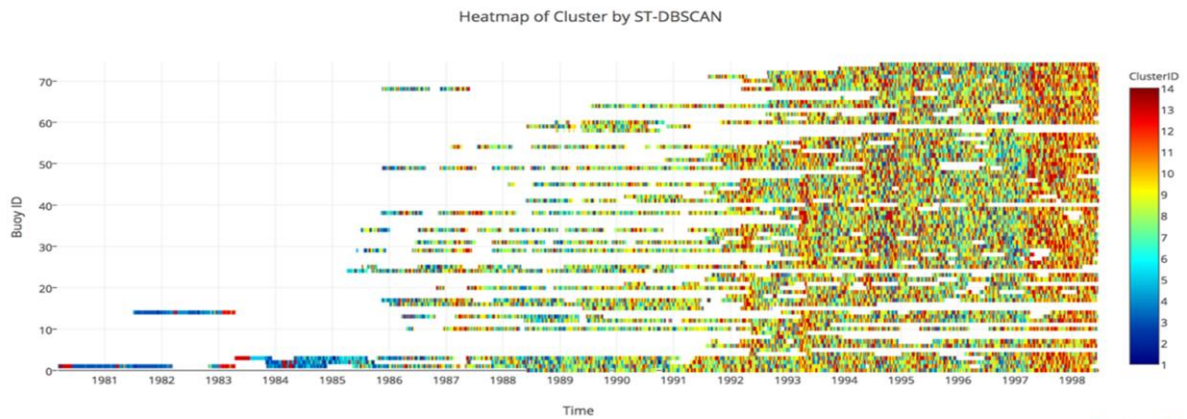

Fig. 3. The cluster heatmap of ST-DBSCAN.

Fig. 4. The cluster heatmap of ST-DBSCAN with *Eps* 3.

Fig. 5. Hierarchical Clustering Dendrogram ST-HDBSCAN 0.1.

Fig. 6. Hierarchical Clustering Dendrogram ST-HDBSCAN 0.3.

On the other hand, Fig. 6 shows the cut point hierarchy for the threshold (0.3). It achieved a maximum distance of 749.98 and generated six clusters.

It is evident from Fig. 5 and 6 that the cluster colors are similar because the groups are the same; only the level of detail is different. Also, the result of the ST-HDBSCAN algorithm with the threshold (0.1) is more detailed. It is observed when the smaller cluster size and more significant cluster number in Fig. 5 compared with Fig. 6. However, the result of ST-HDBSCAN with a threshold (0.3) has interesting cluster patterns.

Furthermore, Fig. 7 shows the heatmap of ST-HDBSCAN with a threshold (0.3). It indicates how each cluster is distinguished. This pattern appears at a particular timeline, identified by 'ClusterID 3' in cyan color. This distinctive cluster occurred between 1994 and 1995. According to the Earth System Research laboratory, one of the National Oceanic and Atmospheric Administration research centers, the El-Niño that occurred within the above specified years is considered one of the top 24 strongest between 1895 and 2015. It is also regarded as one of the new El-Niño events that warmed the central-equatorial area of the Pacific Ocean rather than the eastern part of the Pacific Ocean.

It is evident from the heatmaps of ST-HDBSCAN with a threshold (0.3) that the clusters are spread across the timeline, except for Cluster 3. Cluster 1 (dark blue) mostly appears between 1990 to 1995 and starts to disappear after a few years. On the other hand, cluster 2 (light blue) appears close to Cluster 1 and spreads through the entire timeline. Cluster 4 (yellow color) appears mostly early in the timeline but starts to disappear between 1990 to 1995. It is replaced by Cluster 6 (brown color), although Cluster 4 reappears in the following years. Cluster 5 only appeared in 1990, and its effect on the environment was significant in later years. Cluster 6 appears in the early years of the timeline but mostly has a strong presence between 1990 to 1995. It gradually diminishes, and it completely vanishes in early 1997.

Fig. 8 shows the heatmap of the ST-HDBSCAN of threshold (0.1). The heatmap indicates a similar pattern to that of Fig. 7. Furthermore, the clusters are not as clear compared with the ST-HDBSCAN threshold (0.3). A cluster 1 to 6 mostly appears from 1990 to 1995, whereas Cluster 7 to 9 appears after. Clusters 1 to 6 shows a resurgence in 1998. This pattern is similar to Cluster 1 and 2 in ST-HDBSCAN of threshold (0.3).

Fig. 7. Seven cluster 3 heatmaps of Cluster ST-HDBSCAN with Threshold (0.3).

Fig. 8. Cluster heatmap of ST-HDBSCAN with Threshold (0.1).

Similar to Clusters 4 and 6 in ST-HDBSCAN of threshold (0.3), Clusters 16 to 19 start appearing early (1981) and are dominant from 1994 to 1995. Likewise, Clusters 28 to 30 appear early (1988), but they appear primarily between 1990 and 1994. They are replaced by Clusters 24 to 26 but reappear in early 1997 and are replaced again by Clusters 24 to 26. However, other clusters generally spread across the timeline and are not noticeable in the heatmap.

E. Performance Indices of the Proposed Method

Table IV shows six performance indices for ST-HDBSCAN, ST-DBSCAN, and ST-DBSCAN with Eps 3. The high and low values differ according to the type of performance indices method, as indicated in column Best If Value. For example, in the performance index Ball-Hall, the higher value indicates the best performance, whereas Det Ratio is in direct contrast to it. The result specifies that ST-HDBSCAN with a threshold (0.3) has the best performance indices values for all performance indices except for KsqDetW. Table V specifies the comparison of the performance indices of ST-DBSCAN with ST-HDBSCAN 0.3. From Table V, it is evident that ST-HDBSCAN with 0.3 improves the performance indices of ST-DBSCAN by more than 40%.

Similarly, the GDI51 and Trace W performance indices of ST-HDBSCAN 0.3 improve ST-DBSCAN by more than 100%.

The negative percentage of Det Ratio and Log Det Ratio were converted to positive values to calculate the average percentage improvement. This conversion is because a negative percentage indicates that the index is getting lower. Note that lower indices imply better performance indices. The average percentage improvement in the Det Ratio index by ST-HDBSCAN 0.3 is 75%. Thus, adding the maximum temporal distance (*Eps 3*) and hierarchical aggregation using the ward's method improves all performance indices. However, this is not the case for the KsqDetW index.

The KsqDetW index value is lower because the number of clusters generated by ST-HDBSCAN (6 clusters) is smaller than that by ST-DBSCAN (14 clusters). Given that the function to evaluate the KsqDetW is highly dependent on the number of clusters, a smaller number of clusters results in lower KsqDetW values. Eq. 8 evaluates the value of KsqDetW, where K is the number of clusters and WG is the sum of the within-group scatter matrix.

$$KsqDetW = K^2 det(WG) \quad (8)$$

V. CONCLUSION AND FUTURE WORK

The proposed ST-HDBSCAN effectively incorporates the spatial and non-temporal data aspects in clustering. Likewise, it utilizes the temporal aspect of data in the clustering process, thus significantly improving the clustering performance indices. The algorithm introduces an additional temporal distance boundary (*Eps 3*), known as the Three Neighborhood boundary. ST-HDBSCAN further improves the clustering performance by employing the hierarchical ward's method and fast dynamic time warping. We made comparisons with the ST-DBSCAN algorithm utilizing heatmaps and some performance indices. ST-HDBSCAN outperformed by 185% and indicated interesting patterns with spatio-temporal data. Several directions in future work are possible such as adapting the algorithm to process streaming data, indexing spatial and temporal aspects of data, and implementing parallel computing to improve the efficiency of the ST-HDBSCAN algorithm. Also, implementing the experiments for other spatio-temporal datasets in other fields such as criminology, medical and social media will also be beneficial to discovering hidden knowledge in the data.

Abstract—Based on establishing the mathematical model of the system provided system parameters, using the discrete-time Markov chain and a function set by a non-negative integer random variable as Probabilistic methods, discrete time variable, two-queue different gated polling system has been fully analyzed, the low- and higher-order properties and cycle period of the system are deduced, and average queue pair length and average waiting delay for message packets are calculated accurately. The simulation experiments agree well with the theoretical calculations. The analysis further deepens the cognition of the asymmetric threshold polling system, lays a foundation for researches on the asymmetric threshold polling system, and has positive significance for a better and more flexible control periodic query polling work system.

Keywords—Discrete time query; asymmetric two-queue; threshold service; second-order characteristic quantity; information packets average delay

I. INTRODUCTION

Due to the difficulty of researches on asymmetric threshold service polling system [1], it generally begins by studying an asymmetric threshold service polling system with two queues. Therefore, the performance [2] of the two-queue asymmetric threshold service system is deeply analyzed and studied in this paper, whose purpose is to further explore the inherent laws [3] of the multi-queue threshold service polling system. As is known to all, the periodic [4] query queuing service system has been widely used in industrial process control [5], communication network technology [6], and computer network technology. However, for the periodic query queuing service system, parameters [7] such as the number of packets of information entering the network system at each moment, the time of packet service and the transfer time are all random variables, so the analysis of its related performance has considerable complexity [8]. Especially in the study of asymmetric systems [9], because there are still some problems in the analysis method [10], the results are local results obtained under certain limited conditions, and some precise parsing is given in the literature [11]. Based on the literature [12], This article uses the discrete-time Markov chain and a function [13] set by a non-negative integer random variable to parse the asymmetric threshold service system of discrete-time type and the double queue of periodic query type, deduces the low- and higher-order characteristic quantities [14] of the system, calculates the average length and cycle time of message grouping, and the mathematical reasoning of the average waiting delay [15]. The simulation experiments are in good agreement with the theoretical numerical calculations

[16]. This topic discusses a deeper understanding of the multi-queue asymmetric threshold service polling system, which has positive significance for a more flexible control polling system. The content and scope of this paper further expand the research space of polling system.

II. THEORETICAL MODEL OF THE ASYMMETRIC THRESHOLD SERVICE

A. Physical Model of the Asymmetric Threshold Service

The dual-queue asymmetric [17] threshold service receives service on a first-in, first-out basis in the same queue. Both Queue one and Queue two are running in threshold service policy mode [18]. In the first queue, until the current threshold information packet is serviced, the newly added information packets in the service process should be accumulated until the next polling cycle before service is performed, transition to queue two service after a transition time, and the service of queue two only serves the current threshold information packet until the service [19] is complete. And then, after a transition time, it is switched to another queue for the next round of service. The physical structure [20] of the asymmetric threshold service is shown in Fig. 1.

Buffer queue for any input, the numbers of information packets arriving in the buffer in each unit slot are independent of each other and have the same probability distribution [21]. The probabilities generating function, mean and variance of the distribution of the number of information groups in the queue are $A_i(z_i)$ 、 $\lambda_i = A_i'(1)$ 、 $\sigma_{\lambda_i}^2 = A_i''(1) + \lambda_i - \lambda_i^2$. The probabilities generating function, mean and variance of the transformation time distribution are $R_j(z_j)$ 、 $r_j = R_j'(1)$ 、 $\sigma_{\beta_k}^2 = R_k''(1) + r_k - r_k^2$. The probabilities generating function, mean and variance of service time distribution are $B_k(z_k)$ 、 $\beta_k = B_k'(1)$ 、 $\sigma_{\beta_k}^2 = B_k''(1) + \beta_k - \beta_k^2$. The above $i, j, k = 1, 2$. Large buffer storage capacity for each group of queues is enough not to cause packet loss. Services in each queue are done on a first-come, first-served basis.

*Corresponding Author.

Fig. 1. Physical model of the asymmetric dual-queue threshold service

In order to facilitate the analysis of the queuing system [22], it is necessary to define the following random variables. $u_i(n)$ is defined as the query conversion while for waiter from service site i to service site $i+1$ at t_n . $v_i(n)$ is defined as the waiter starts serving while for the service site i at t_n . The number of information packets[23] entered by the waiter in the 3rd column of the queue is within 3 times. $\mu_j(u_i)$ is defined as the number of information packets entered by the waiter in the j Queue at u_i . $\eta_j(v_i)$ is defined as the number of information packets entered by the waiter in the service site j within v_i . $\xi_i(n)$ is the number of information packets queued in the service object i at the t_n . For asymmetric two-queues $i, j = 1, 2$.

B. State Variable Expression [24]

For a two-queue asymmetric threshold service polling system, when querying the threshold service queue at the t_{n+1} , the relation [25] is as follows:

$$\xi_1(n+1) = 0 + \eta_1(v_1) + \mu_1(u_1) \quad (1)$$

$$\xi_2(n+1) = \xi_2(n) + \eta_2(v_1) + \mu_2(u_1) \quad (2)$$

C. A Function set by a Non-Negative Integer Random Variable of State Variable Distribution [26]

For a two-queue asymmetric threshold service polling system, systematic probability generating function expression is as follows:

$$G_{i+1}(z_1, z_2) = \lim_{n \rightarrow \infty} E \left[\prod_{j=1}^2 z_j^{\xi_j^{(n+1)}} \right] \quad (3)$$

Bring (1), (2) into (3), a function set by a non-negative integer random variable [27] is as follows

$$G_1(z_1, z_2) = R_2(A_1(z_1)A_2(z_2))G_2(z_1, B_2(A_1(z_1)A_2(z_2))) \quad (4)$$

$$G_2(z_1, z_2) = R_1(A_1(z_1)A_2(z_2))G_1(B_1(A_1(z_1)A_2(z_2)), z_2) \quad (5)$$

This $G_1(z_1, z_2)$ in (4) is a function set by a non-negative integer random variable of state variable probability distribution of information packet in threshold 1st Queue. This $G_2(z_1, z_2)$ in (5) is a function set by a non-negative integer random variable of state distribution of information packet in threshold 2nd Queue.

III. THEORETICAL ANALYSIS OF SYSTEM PERFORMANCE INDICATORS

A. Parse Low-Order Characteristic Quantities Expression [28]:

$$g_i(j) = \lim_{z_1, z_2 \rightarrow 1} \frac{\partial G_i(z_1, z_2)}{\partial z_j} \quad i=1,2; j=1,2 \quad (6)$$

The following expression [29] can be obtained by parsing (4), (5) and (6).

$$g_1(1) = r_2\lambda_1 + g_2(1) + g_2(2)\beta_2\lambda_1 \quad (7)$$

$$g_1(2) = r_2\lambda_2 + g_2(2)\beta_2\lambda_2 \quad (8)$$

$$g_2(1) = r_1\lambda_1 + g_1(1)\beta_1\lambda_1 \quad (9)$$

$$g_2(2) = r_1\lambda_2 + g_1(2) + g_1(1)\beta_1\lambda_2 \quad (10)$$

The following expression can be obtained by parsing (8) and (9).

$$g_1(2) = \frac{(r_2 - \rho_1 r_2 + \rho_2 r_1)\lambda_2}{1 - \rho_1 - \rho_2} \quad (11)$$

$$g_2(1) = \frac{(r_1 - \rho_2 r_1 + \rho_1 r_2)\lambda_1}{1 - \rho_1 - \rho_2} \quad (12)$$

The following expression is average length of queue by bringing (11) and (12) into (7) and (10).

$$g_1(1) = \frac{(r_1 + r_2)\lambda_1}{1 - \rho_1 - \rho_2} \quad (13)$$

$$g_2(2) = \frac{(r_1 + r_2)\lambda_2}{1 - \rho_1 - \rho_2} \quad (14)$$

B. Resolve Two-Order Characteristics [30] Define:

$$g_i(j, k) = \lim_{z_1, z_2 \rightarrow 1} \frac{\partial^2 G_i(z_1, z_2)}{\partial z_j \partial z_k} \quad i=1,2; j=1,2; k=1,2 \quad (15)$$

The equation can be obtained by reduction and resolving (4) and (5) according to (15).

$$g_1(1,1) = \lambda_1^2 R_1''(1) + (r_2 + \beta_2 g_2(2)) A_1''(1) + \lambda_1^2 g_2(2) B_2''(1) + 2r_2 \lambda_1 g_2(1) + 2\beta_2 r_2 \lambda_1^2 g_2(2) + g_2(1,1) + 2\beta_2 \lambda_1 g_2(1,2) + \beta_2^2 \lambda_1^2 g_2(2,2) \quad (16)$$

$$g_2(2,1) = g_2(1,2) = \lambda_1 \lambda_2 R_1''(1) + \lambda_1 \lambda_2 g_1(1) B_1''(1) + r_1 \lambda_1 \lambda_2 + r_1 \lambda_1 g_1(2) + (2r_1 + 1) \rho_1 \lambda_2 g_1(1) + \rho_1 g_1(2,1) + \rho_1 \beta_1 \lambda_2 g_1(1,1) \quad (19)$$

$$g_2(2,2) = \lambda_2^2 R_1''(1) + (r_1 + \beta_1 g_1(1)) A_2''(1) + \lambda_2^2 g_1(1) B_1''(1) + 2r_1 \lambda_2 g_1(2) + 2\beta_1 \lambda_2^2 g_1(1,1) + 2\beta_1 r_1 \lambda_2^2 g_1(1) + g_1(2,2) + 2\beta_1 \lambda_2 g_1(1,2) + \beta_1^2 \lambda_2^2 g_1(1,1) \quad (17)$$

$$g_2(1,1) = \lambda_1^2 R_1''(1) + (r_1 + \beta_1 g_1(1)) A_1''(1) + \lambda_1^2 B_1''(1) + 2\rho_1 r_1 \lambda_1 g_1(1) + \rho_1^2 g_1(1,1) \quad (20)$$

$$g_1(1,2) = g_1(2,1) = \lambda_1 \lambda_2 R_2''(1) + \lambda_1 \lambda_2 g_2(2) B_2''(1) + r_2 \lambda_1 \lambda_2 + r_2 \lambda_2 g_2(1) + (2r_2 + 1) \rho_2 \lambda_1 g_2(2) + \rho_2 g_2(1,2) + \rho_2 \beta_2 \lambda_1 g_2(2,2) \quad (18)$$

$$g_2(1,1) = \lambda_1^2 R_1''(1) + (r_1 + \beta_1 g_1(1)) A_1''(1) + \lambda_1^2 B_1''(1) + 2\rho_1 r_1 \lambda_1 g_1(1) + \rho_1^2 g_1(1,1) \quad (21)$$

The higher-order feature [31] can be obtained by solving (16), (17), (18), (19), (20) and (21).

$$g_1(1,1) = \left\{ \lambda_1^2 \left[(1 + 2\rho_2 - 2\rho_1 \rho_2 - 2\rho_2^3 - 4\rho_1 \rho_2^2 + \rho_1^2 \rho_2^2 + 2\rho_1 \rho_2^4 + 2\rho_1^2 \rho_2^3) R_1''(1) + (1 - \rho_1^2 \rho_2^2) R_2''(1) \right] + \frac{(1 - \rho_1 \rho_2)(r_1 + r_2)}{1 - \rho_1 - \rho_2} \left[(1 - \rho_2^2 - \rho_1 \rho_2 - 2\rho_1 \rho_2^2 + \rho_1 \rho_2^3) A_1''(1) + (1 + \rho_1 \rho_2) \beta_2^2 \lambda_1^2 A_2''(1) \right] + \frac{(r_1 + r_2) \lambda_1^2}{1 - \rho_1 - \rho_2} \left[(1 + 2\rho_2 - 2\rho_1 \rho_2 - 2\rho_2^3 - 4\rho_1 \rho_2^2 + \rho_1^2 \rho_2^2 + 2\rho_1 \rho_2^4 + 2\rho_1^2 \rho_2^3) \lambda_1 B_1''(1) + (1 - \rho_1^2 \rho_2^2) \lambda_2 B_2''(1) \right] + \frac{2\lambda_1^2}{1 - \rho_1 - \rho_2} \left\{ (1 - \rho_2^2 - \rho_1 \rho_2 - 2\rho_1 \rho_2^2 + \rho_1 \rho_2^3) \right\} \times \left[\rho_1 (1 + 2\rho_2 - \rho_1 \rho_2) r_1 (r_1 + r_2) + \rho_2 r_1 (r_2 - \rho_1 r_2 + \rho_2 r_1) + r_2 (r_1 - \rho_2 r_1 + \rho_1 r_2) + \rho_2 (1 + \rho_1 \rho_2) r_2 (r_1 + r_2) \right] + \rho_2^2 (1 + \rho_1 \rho_2) \left[\rho_1 (1 + \rho_1 \rho_2) \times r_1 (r_1 + r_2) + r_1 (r_2 - \rho_1 r_2 + \rho_2 r_1) + \rho_1 r_2 (r_1 - \rho_2 r_1 + \rho_1 r_2) + \rho_2 (1 + 2\rho_1 - \rho_1 \rho_2) \times r_2 (r_1 + r_2) \right] \right\} + \frac{2\rho_2 \lambda_1^2}{1 - \rho_1 - \rho_2} \left\{ (1 - \rho_2^2 - \rho_1 \rho_2 - 2\rho_1 \rho_2^2 + \rho_1 \rho_2^3) \right\} \times \left[(1 - \rho_1 - \rho_2) \times (r_1 + \rho_1 r_2) + \rho_1 (1 + \rho_2)(r_1 + r_2) \right] + \rho_1 \rho_2 (1 + \rho_1 \rho_2) \left[(1 - \rho_1 - \rho_2)(r_2 + \rho_2 r_1) + \rho_2 (1 + \rho_1)(r_1 + r_2) \right] \right\} / \left[(1 - \rho_1^2 - \rho_1 \rho_2 - 2\rho_1^2 \rho_2 + \rho_1^3 \rho_2)(1 - \rho_2^2 - \rho_1 \rho_2 - 2\rho_1 \rho_2^2 + \rho_1 \rho_2^3) - \rho_1^2 \rho_2^2 (1 + \rho_1 \rho_2)^2 \right] \quad (22)$$

$$\begin{aligned}

 \end{aligned}$$

C. The Average Waiting Time of the System

In the periodic query threshold service, the average waiting time of the service object is the average waiting time [32], of the information packet from entering the queue to the start of the service. From [33], the average waiting delay of the two queues of the gate service [34] can be obtained.

$$\overline{W}_{G1} = \frac{(1 + \rho_1) g_1(1,1)}{2\lambda_1 g_1(1)} - \frac{A_1''(1)}{2\lambda_1^2} \quad (24)$$

$$\overline{W}_{G2} = \frac{(1 + \rho_2) g_2(2,2)}{2\lambda_1 g_2(2)} - \frac{A_2''(1)}{2\lambda_2^2} \quad (25)$$

IV. NUMERICAL CALCULATION AND EXPERIMENTAL SIMULATION

Numerical calculations from theoretical analysis, it is time to carry out programming and simulation experiments according to the operating mechanism of the system. Let the arrival process of each queue in any time slot obey the Poisson distribution. The channel rate is 54Mbit/s; the message packet length is 2700 bit; the query conversion time is 10μs; the slot

width is 10μs. And the numerical calculation is consistent with the simulation experimental parameters. Set polling number $M = 10^6$. When $r_1 = r_2 = 1$, $\lambda_1 = 0.01$, $\lambda_2 = 0.04$ the average-length and average waiting time of the first and second queue changes with service rate is in Tables I and II. If you set the number of cycles $M = 3 \times 10^6$. Under $r_1 = r_2 = 1$, $\beta_1 = 1$, $\beta_2 = 3$ conditions, the average-length and average waiting time of the first and second queue will change with arrival rate in Tables III and IV. If you set the number of cycles $M = 5 \times 10^7$ under $\beta_1 = \beta_2 = 10$, $\lambda_1 = 0.01$, $\lambda_2 = 0.04$ conditions, the average waiting time will change with shifting-time, which is shown in Tables V and VI. If the first and second queue is exactly the same, running the number of polling cycles $M = 5 \times 10^7$ the average-length and average waiting time of the first and second queue changes will change with the variation-load, which is shown in Fig. 2 and Fig. 3.

V. DISCUSSION ON SIMULATION EXPERIMENT AND NUMERICAL CALCULATION RESULTS

Referring to Tables I and II, it can be seen that the average queuing length and average waiting delay changes with the variety of β_i when λ_i and γ_i remains constant. Looking at the two types of plots in Fig. 2 and 3, it can be seen that the system delay changes faster with the changing of λ_i . System delay is bigger when λ_i is bigger and when β_i remains constant. Experiment results and theoretical analysis expression (24) and (25) are consistent. In practice, the experimental results are approximately equal to the theoretical numerical calculations, there is a certain deviation. The main factor is that the number of polling statistics loops is too small, which is only $M = 10^6$. If the number of polling cycle statistics is further increased, the error between the experimental value and the theoretical value will be further reduced.

By viewing Tables III and IV, it can be seen that the average queuing length and system delay changes with the variety of λ_i when β_i and γ_i remains constant. It can be seen that the average waiting delay changes faster as β_i is variety. System delay is bigger as β_i is bigger and λ_i remains constant. Experiment results and theoretical analysis expression (24) and (25) are consistent. Experimental data are subject to minor deviations, which is because the polling statistics loop count reaches $M = 3 \times 10^6$. If the number of polling cycle statistics is further increased, the error between the experimental value and the theoretical value will be smaller.

Referring to Tables V and VI, It can be seen that the average queuing length and average waiting delay changes with the variety of γ_i when λ_i and β_i remains constant. It can be seen that the system delay changes faster as ρ_i is changing. System delay of the ones if lighter loads are smaller and shifting time remains constant. Experiment simulations and theoretical calculation expression (24), (25) are consistent. Experimental data are subject to minor deviations, which is because the polling statistics loop count reaches $M = 3 \times 10^6$. If the number of polling cycle statistics is further increased, the error between the experimental value and the theoretical value will be smaller.

By viewing Fig. 2 and 3, it can be seen that the system queuing length and system waiting delay changes when the variety of ρ_i if the same γ_i under the two queues are set to be symmetrical. Experiment results and theoretical analysis expression (24) and (25) are consistent. There may be minimal deviation of experimental data because the polling statistics loop count reaches $M = 5 \times 10^7$. If the number of polling cycle statistics is further increased, it can also improve the quality of experimental data analysis and can further reduce the uncertainty of the system.

Comparing Tables I and II, the load on the 10th service terminal is $\rho_{\max 1,10} = 0.1$, $\rho_{\max 2,10} = 0.4$, Comparison Table III and IV, the maximum load on the 10th service terminal is $\rho_{\max 1,10} = 0.145$, $\rho_{\max 2,10} = 0.435$, Comparison Table V and VI, the maximum load on the 10th service terminal is $\rho_{\max 1,10} = 0.1$, $\rho_{\max 2,10} = 0.4$. In a word, the value of the maximum load on the service terminal is $\rho_{\max} < 0.5$, System service terminals are running under light load. In the following research work, it is also necessary to analyze and discuss the system under heavy load, so as to strive for the integrity of the analysis.

By comparing Tables I, II, III, IV, V and VI as well as Fig. 2 and Fig. 3, it can be seen that the deviation between the simulated experimental value and the numerical calculation value is further reduced with the increase of the threshold polling times. Proven by experiment, if you take the statistical polling times $M \geq 10^8$, it can prove that the error can be controlled within 1% under heavy load.

When the network system operates with symmetric parameters, Formula (24) and (25) of theoretical analysis is simplified to formula (20) in [26] under the $N = 2$ condition is exactly the same.

VI. SUMMARY

The article, using the discrete-time Markov chain and a function set by a non-negative integer random variable, Accurate Analysis of Two-Queue Asymmetric Threshold Service System, is based on the establishment of a theoretical model and the definition of system-related parameters, in which the low-order characteristic quantity, higher-order characteristic quantity and query period of the system are deduced, and the system queuing length and system waiting delay are accurately calculated. The simulation experiment comes from the operating mechanism of the system and the theoretical analysis and sample calculation are in good agreement. The article lays a foundation for the researches on the related problems of multi-queue asymmetric threshold service polling system, further deepens the cognition of the asymmetric threshold polling system, and further expands the research space of polling system.

ACKNOWLEDGMENT

The authors extend their appreciation to the Funded Project that Modeling and Performance Analysis of Asymmetric Polling System of Scientific Research Fund Project of Department Education of Yunnan Province (2019J0401), Modeling Performance Analysis and Application Research of Asymmetric Polling System of Joint Special Projects of Local Colleges and Universities of Department of Science and Technology of Yunnan Province (202001BA070001-200).

Abstract—Cross-lingual summarization (CLS) is a process of generating a summary in the target language from a source document in another language. CLS is a challenging task because it involves two different languages. Traditionally, CLS is carried out in a pipeline scheme that involves two steps: summarization and translation. This approach has a problem, it introduces error propagation. To address this problem, we present a novel end-to-end abstractive CLS without the explicit use of machine translation. The CLS architecture is based on Transformer which is proven to be able to perform text generation well. The CLS model is a jointly trained CLS task and monolingual summarization (MS) task. This is accomplished by adding a second decoder to handle the MS task, while the first decoder handles the CLS task. We also incorporated multilingual word embeddings (MWE) components into the architecture to further improve the performance of the CLS models. Both English and Bahasa Indonesia are represented by MWE whose embeddings have already been mapped into the same vector space. MWE helps to better map the relation between input and output that use different languages. Experiments show that the proposed model achieves improvement up to +0.2981 ROUGE-1, +0.2084 ROUGE-2, and +0.2771 ROUGE-L when compared to the pipeline baselines and up to +0.1288 ROUGE-1, +0.1185 ROUGE-2, and +0.1413 ROUGE-L when compared to the end-to-end baselines.

Keywords—Cross-lingual summarization; multilingual word embeddings; transformer; automatic summarization

I. INTRODUCTION

Automatic summarization is a process of automatically producing a shorter version of an original while retaining contents and meanings that are considered essential. This shorter version is called a summary. The purpose of summarizing is to produce a summary that contains the main content of a document in less space [1]. Automatic summarization helps users get the main idea of a document without having to read the whole document thus saving time and effort compared to doing it manually [2]. In general, automatic summarization can be categorized into two based on the approach in summarizing: extractive summarization and abstractive summarization. The extractive approach produces a summary by copying words or sentences from source documents that are considered important. The abstractive approach produces a summary using its own words or sentences. In addition to text, summaries of images and videos can also be produced [3] [4] [5]. In the context of this work,

automatic summarization is an activity that uses a machine (computer) to automatically summarize a document using a certain algorithm or method.

The study on automatic summarization was first reported by Luhn [6]. The system is based on bag-of-words. The frequency and relative position of a word in a sentence are the main features in determining how important the sentence is. Gradually, linguistic information such as word type and structure are utilized using natural language processing (NLP). The extractive approach is then widely used because of its simple approach without the need for extensive NLP [7] [8]. The success of the sequence-to-sequence (Seq2Seq) recurrent neural network (RNN) model has made the rapid development of abstractive approaches [9] [10]. Inspired by the attention-based neural machine translation (MT) model [11] [12], the RNN is used by adding the attention mechanism so that the model can focus on some parts of text while diminishing other parts at a certain time/context.

Cross-lingual summarization (CLS) is a task to produce a summary in the target language, from source documents in another language [13] [14]. Traditionally, CLS can be done by involving two processes: translation and monolingual summarization (MS). However, there is a problem when doing it with two processes in a pipeline scheme. The pipeline process introduces error propagation which adversely affects the final quality of the summary. This problem can be solved by conducting end-to-end model training [15] [16]. Another challenge in CLS research is the limited data or corpus that can be used to train the model. Research on end-to-end CLS is still relatively new, so resources related to it are still quite scarce. There is no dataset that is considered a standard that can be used as a benchmark. The researchers still tend to create their own dataset for the language pair domain that is of interest to them.

In this paper, we present a novel end-to-end abstractive CLS that solves the error propagation problem found in the pipeline scheme. We adapt transformer-based architecture and extended it by including multilingual word embeddings (MWE) [17] components. These components allow the model to be able to represent words in two different languages. This paper is an extended study of our previous work on the end-to-end abstractive CLS model [18]. The model is trained in the English domain for source documents and the Bahasa Indonesia domain for its summary using the dataset that we

have constructed. Inspired by [19] and [20], we use a round-trip translation technique to generate CLS dataset from MS dataset. This technique is similar to that used by [15], but we apply it to the document and its summary, not just the summary. The resulting dataset is then evaluated using bilingual evaluation understudy (BLEU) [21]. BLEU is a method for evaluating the quality of text that has been machine translated from one language to another automatically. The CLS model can produce a Bahasa Indonesia summary from an English source document end-to-end without explicitly using a machine translator.

The main contributions of this work are:

- A novel framework for generating end-to-end abstractive cross-lingual summary by incorporating MWE components in the architecture. These components are used to represent words in both languages used in the source document and its summary.
- This work produces a new cross-lingual dataset. This dataset can be used for CLS research with the English domain as the source document and the Bahasa Indonesia domain as the summary.

The rest of this paper is organized as follows. In Section II, we review the related work in CLS. In Section III, we explain the proposed method. In Section IV, the details of the experimental setup and the evaluation metrics are presented. The experimental results are given in Section V. Finally, the conclusions of this research are found in Section VI.

II. RELATED WORKS

CLS is the process of generating a summary in the target language from source documents in another language. Unlike MS, CLS involves at least two different languages. Traditional approaches treat CLS as a pipeline scheme. The newer approach does it end-to-end to avoid error propagation that occurs in the pipeline process.

A. Traditional Cross-Lingual Summarization

CLS research has been conducted [22] [23] [24]. The approaches are generally divided into extraction-based and compression-based. Summarization is done in a pipeline manner which is divided into two steps: summarizing and translating. There are two patterns of utilization or use of machine translation. The first pattern is to first translate the source document using a machine translator and then the results of the translation are used to summarize. The second pattern summarizes the source document first and then translates the results using a machine translator into the target language. Another approach utilizes existing source documents in two languages to generate summaries in the target language [25] [26]. This target language is one of the two languages. In addition to the extraction process, a compression process is also carried out in the compression-based approach. Summarization begins with a selection process to obtain relevant content in the form of sentences or phrases (bilingual). The compression is carried out by removing parts of sentences or phrases that do not meet some criteria, such as information content, legibility, and grammar/structure [27] [28] [29].

In contrast to the CLS previously described which uses an extractive approach, Zhang, Zhou, and Zong [30] developed an abstractive CLS system. The system works by first translating the source document from English to Chinese using Google Translate. The next step is to extract bilingual concepts and fact pairs. Then the score of translation and salience is calculated from this set of pairs. Based on the scores, a set of pairs is selected to be used in the summary. This selection considers several criteria, including compatibility between concepts and facts, number of sentences, summary length, etc. Post-processing begins with determining which pairs of concepts and facts are included in a particular sentence. Then the last step is to put them in order. Abstractive summarization has the ability to paraphrase. In the system developed by [30], the abstractive process is carried out by combining pairs of concepts and facts into one sentence. This process is indeed a form of paraphrasing, but these pairs of concepts and facts are taken extractively and used as they are.

Similar to [30], our work also falls under the abstractive CLS category. The difference is that our approach is based on neural networks and summarization is done directly, rather than in two steps in a pipeline scheme. This straightforward CLS can avoid error propagation that occurs in the pipeline process.

B. Neural Network-based Cross-Lingual Summarization

In 2019, neural network-based CLS began to emerge. Ouyang, Song, and McKeown [31] use neural networks for CLS in pipeline schemes, on the translation side using Marian [32] and on the summarization side using pointer-generators [33]. The system summarizes Somali, Swahili, or Tagalog source documents into an English summary. Zhu et al. [15] are the first to report on end-to-end CLS. A CLS from English to Chinese was built using transformer architecture that has been proven to have good performance in text generation. The network is trained using a multi-task learning approach. Specifically, they combine CLS loss with MS loss. The CLS dataset used was built by modifying the CNN/Dailymail dataset. The dataset is translated into Chinese using a machine translation service. Duan et al. [16] see CLS as a zero-shot problem. They do not have a CLS dataset to train the model directly. The network is trained by adapting a paradigm on neural machine translation (NMT) called triangular NMT systems. A network called a student network is a CLS network that is trained to imitate the behavior of a teacher network which is an MS network. Ladhak et al. [34] proposed a benchmark dataset for abstractive CLS named WikiLingua. The data is taken from WikiHow in the form of document and summary pairs in 18 languages. Not all data is available in 18 languages, availability in each language varies. The dataset is tested for CLS with pipeline and end-to-end approach. The end-to-end approach uses mBART [35] which is fine-tuned using the source language document and the target language summary.

Our approach is inspired by [15]. However, we propose to add MWE components which we believe will improve the performance of the model. MWE represents the two languages in the CLS task in the same vector space. This facilitates the mapping of the relation between inputs and outputs during model training.

C. Multilingual Word Embeddings

Multilingual word embeddings (MWE) are word embeddings that represent words in various languages in one vector space [17]. Conneau et al. [36] developed MWE using an unsupervised approach. Supervised approaches generally require bilingual resources such as dictionaries or parallel corpus. They proposed an unsupervised way to map monolingual word embeddings without the need for bilingual data. Word embeddings for each language are initially trained independently. Then, each word in the two languages is mapped into the same vector space using deep adversarial networks [37]. Heinzerling & Strube [38] developed MWE for word segmentation (subword embeddings). Word segmentation is done by using the byte pair encoding (BPE) approach. BPE performs segmentation to words that rarely appear into several tokens. Embeddings are trained in a simple way. All articles from Wikipedia in various languages are combined, then used to train subword embeddings. Artetxe & Schwenk [39] also developed multilingual embeddings but specifically developed embeddings for sentences. These sentence embeddings were trained using a single bidirectional LSTM (BiLSTM) encoder.

In this work, we use MUSE from Conneau et al. [36]. MUSE is used because the embedding is word-based so it is expected to be able to cover most of the vocab. MWE based on word segmentation such as BPEmb from Heinzerling & Strube [38] may be better than MUSE because it can recognize tokens that rarely or never appear in the training data. However, it is not suitable for the case in this work because the embedding is trained using various language versions of the articles available on Wikipedia. The amount of data which is an aggregate of all articles in various language versions can also result in many words being segmented due to their small frequency, thus causing the size of vocab to be very large. In general, a vocab size that is too large can adversely affect the performance of NLP system.

III. METHODS

CLS can be expressed as an input sentence in the source language $x = (x_1, x_2, x_3, \dots, x_m)$ and $x_i \in V_s$, where m is the input sentence length and V_s is the source vocab in the source language, with an output summary in the target language

$y = (y_1, y_2, y_3, \dots, y_n)$ and $y_i \in V_t$, where n is the output summary length, $n \leq m$, and V_t is the target vocab in the target language.

A. Transformer-based Cross-Lingual Summarization

NLP systems that are built specifically for a particular language are generally trained using datasets in that language. This approach has a problem when applied to other languages. The system needs to be retrained with separate datasets in the other specific language. This is equivalent to building the system from scratch. Another way is to use machine translation. The system is combined with machine translation in a pipeline so that it can produce output in the desired language. MWE can be used to tackle this problem. Both languages are represented by embeddings that are mapped into the same vector space. This mapping makes the two languages seem to be the same language, at least at the word level. The CLS architecture proposed in this work is based on transformer architecture [40] by adding MWE components to handle cross-lingual problem. Transformer was chosen because it is state-of-the-art in many NLP topics including CLS and has proven to be able to perform text generation well [41] [42].

Inspired by Zhu et al. [15], the architecture also added a second decoder with a single shared encoder. During training, the input of CLS decoder (decoder1) is a summary in Bahasa Indonesia, while the input of MS decoder (decoder2) is a summary in English. MS decoder is only used during training. So, in the training process, encoder-decoder1 is trained for CLS problems, while encoder-decoder2 is trained for MS problems. The losses from the two are combined and can be calculated as follows:

$$J(w) = -\frac{1}{N} \sum_{i=1}^N [y_i^a \log(\hat{y}_i^a) + (1 - y_i^a) \log(1 - \hat{y}_i^a)] + \\ -\frac{1}{N} \sum_{i=1}^N [y_i^b \log(\hat{y}_i^b) + (1 - y_i^b) \log(1 - \hat{y}_i^b)] \quad (1)$$

where w are parameters in the model, y_i^a and y_i^b are the correct labels for both tasks, and \hat{y}_i^a and \hat{y}_i^b are predictive labels for both tasks. The combined loss was used to update the weight. During test, the MS decoder was ignored. The architectural diagram can be seen in Fig. 1.

Fig. 1. CLS architecture

B. Cross-Lingual Summarization Architecture Components

1) *Input and output*: The input of the encoder is an English document $x = (x_1, x_2, x_3, \dots, x_m)$. This document is tokenized using a subword tokenizer. Words that occur infrequently will be segmented into several tokens, while words that occur frequently (high frequency) are left as is. This sequence of tokens is then converted into a sequence of indexes according to the vocab. The output of CLS decoder is a Bahasa Indonesia summary and the output of MS decoder is an English summary. At the time of training, the tokens here are also an input that will be converted into a sequence of indexes according to the vocab. Vocab for Bahasa Indonesia is different from vocab for English. At the time of test, the CLS decoder generates a Bahasa Indonesia summary $y = (y_1, y_2, y_3, \dots, y_n)$ while the MS decoder is ignored.

2) *Multilingual word embeddings*: The proposed CLS architecture incorporated pre-trained MWE from MUSE [36]. We use MUSE because it can cover most of the words in vocab while maintaining vocab cohesiveness. MWE Component maps the input English document $x = (x_1, x_2, x_3, \dots, x_m)$ into a sequence of embeddings $Z = (Z_1, Z_2, Z_3, \dots, Z_m)$ whose size varies with respect to the source sequence length.

3) *Positional Encoding*: This component provides position information to the tokens in the sequence by adding the "positional encodings" to the embeddings. The positional encodings are obtained using the following formula:

$$PE_{(pos,2i)} = \sin(pos/10000^{2i/d})$$

$$PE_{(pos,2i+1)} = \cos(pos/10000^{2i/d}) \quad (2)$$

where pos is the position ($0 \leq pos < \frac{L}{2}$, where L is the length of the sequence), d is the embedding dimension, and i is used for mapping to indices of elements in positional encoding vector ($0 \leq i < \frac{d}{2}$). Positional encoding is necessary because the proposed transformer-based architecture does not consider positional information or word order. Without positional encoding, this architecture is essentially a bag-of-words model.

4) *Multi-head self-attention*: Multi-head self-attention consists of several heads which correspond to scaled dot-product attention (self-attention). Called self-attention because it can generate its own value of query (Q), key (K), and value (V). These three values are abstractions that represent the input needed to calculate the attention weight. It is obtained using the following formula:

$$\begin{aligned} Q &= ZW_Q \\ K &= ZW_K \\ V &= ZW_V \end{aligned} \quad (3)$$

where Z is the input embeddings and $W_Q, W_K,$ and W_V are learnable matrices. The scaled dot-product attention is then calculated using the scaling factor of $\frac{1}{\sqrt{d_k}}$.

$$Attention(Q, K, V) = softmax\left(\frac{QK^T}{\sqrt{d_k}}\right)V \quad (4)$$

where d_k is dimension of K . The output of each head is then concatenated to get the final values.

$$\begin{aligned} \text{MultiHead}(Q, K, V) &= \text{Concat}(\text{head}_1, \text{head}_2, \dots, \text{head}_h)W^O \\ \text{where } \text{head}_i &= \text{Attention}(QW_i^Q, KW_i^K, VW_i^V) \end{aligned} \quad (5)$$

where h is the number of heads and W^O , W_i^Q , W_i^K , and W_i^V are learnable matrices. Multi-head self-attention on the decoder is also called encoder-decoder attention because it receives input from the encoder and decoder. There is a mapping of the relation between input and output here. This component can be calculated in parallel because the attention weight here is independent of one another.

5) *Masked multi-head self-attention*: This component has a similar function to the multi-head self-attention component. However, unlike multi-head self-attention, masked multi-head self-attention has a function to mask output that has not been seen/predicted. The model must predict the output based on the results of the previous output and must not look at the output that appears later. When the matrix operation is performed, the output that has not been seen/predicted will be masked/changed to zero so that it cannot be seen by the model.

6) *Positionwise FNN*: Positionwise FNN is a simple feedforward neural network that runs for all attention weights. Its main task is to convert the attention weight into an acceptable form for the next step, such as encoder layer, decoder layer, or linear layer. This component consists of two linear layers. The first layer uses ReLU activation.

$$FFN(x) = \max(0, xW_1 + b_1)W_2 + b_2 \quad (6)$$

7) *Linear Layer and Softmax*: Linear layer is a component in the form of a feedforward layer that acts as a classifier. This component is used to adjust the dimensions as needed. For example, to accommodate the number of words (classes) in the vocab. Finally, there is the softmax layer which converts the vector into a probability distribution.

IV. EXPERIMENTS

This section describes the experiments. First, we describe the dataset which includes English documents and their summary, Bahasa Indonesia documents and their summary, and English-Bahasa Indonesia parallel corpus. Then, we explain the implementation and model variations including the baseline model. Finally, we discuss the evaluation metrics used to measure the performance of CLS models.

A. Dataset

Developing a CLS system is a challenging task because it involves two different languages, especially if the language is a low-resource language. The experiments conducted in this work require a cross-lingual dataset from English documents to Bahasa Indonesia summaries which is not readily available. Therefore, the dataset needs to be created first. Creating a dataset from scratch for deep learning-based models can take a lot of time and effort. The alternative is to create a new dataset by utilizing existing data. The closest problem to CLS is the MS problem. The best dataset as a basis to work with is a dataset of MS for Bahasa Indonesia because the output target of our CLS model is a summary in Bahasa Indonesia. We use

IndoSum [43] as the basis for creating a new CLS dataset. IndoSum is an attempt to create a benchmark dataset for Bahasa Indonesia summarization. This dataset contains nearly 20000 news articles taken from online websites. This number is still relatively small when compared to the available English summarization dataset. Each article has an abstract summary that was created manually by 2 native Bahasa Indonesia speakers. The dataset has 6 categories: entertainment, inspiration, sports, show world, headlines, and technology. The dataset has been divided into 5-fold cross-validation and has been divided into training sets, development sets, and test sets. In this work, only the first fold was used. This dataset is written in JSON format.

Based on the need to train the CLS models, IndoSum's articles and summaries need to be translated into English. English articles are used as input for the CLS model. In addition, these English articles and their English summary are used to train the English MS model used in the pipeline approach. The strategy for creating the CLS dataset can be seen in Fig. 2. At first the original dataset of Bahasa Indonesia documents and summaries are translated into English using Google Translate (forward translation). The result of this English translation is then translated back into Bahasa Indonesia (back translation). This is done to ensure the quality of the CLS dataset. The back translation results were evaluated against the original dataset using BLEU [21]. The evaluation of the back translation can be seen in Table I. The evaluation is the cumulative BLEU score calculated using the NLTK. The results show that the quality of the cross-lingual dataset is quite good. As a comparison to get the intuition of the BLEU score, specific machine translators from English to Bahasa Indonesia have been reported to have BLEU scores of 25.3 [44] and 24.5 [45]. In the end, we obtained the Sum (Ina) dataset to train Bahasa Indonesia summarization, the Sum (Eng) dataset to train English summarization, and the CLS (Eng-Ina) dataset to train CLS as can be seen in Fig. 3. The total of data is 18774 document-summary pairs. The statistics of the CLS dataset are presented in Table II. To train machine translators from English to Bahasa Indonesia, the Pan Asia Networking Localization (PANL) parallel corpus dataset was used [45]. This data is divided into 15373 train data, 3845 validation data, and 4806 test data.

B. Implementation

In this work, we train 10 CLS models. Two models are pipeline and eight models are end-to-end. All models use transformer as their basis. The model is implemented using Python programming language and TensorFlow library. TensorFlow is an open-source library for machine learning and artificial intelligence. TensorFlow is developed by Google Brain Team. TensorFlow can run on CPUs and GPUs and is available for Linux, macOS, Windows, Android, and iOS operating systems. TensorFlow is widely used for NLP and computer vision applications. Each model is accompanied by a subword tokenizer which is used to prepare the input to be submitted to the model. The vocab size for English is 26331 and the vocab size for Bahasa Indonesia is 27373. All models have the same hyperparameters as can be seen in Table III. Each model uses Adam's optimization [46] with a custom learning rate scheduler. Regarding randomness, all models are trained on the same seed value of 777, whether it is a seed for Python, NumPy, or TensorFlow. The same seed is applied to global conditions as well as to any operations involving

randomness. The pre-processing carried out are: 1) converting all text to lowercase; 2) removing symbols, special characters, HTML tags, and emoticons; 3) performing Unicode normalization; and 4) brackets: (), [], {} and all characters in between are discarded. The 26 characters of the alphabet are preserved, digits/numbers are preserved, and some punctuation marks are preserved, such as period, comma, exclamation mark, and question mark.

POSITIONAL_INPUT	202
POSITIONAL_OUTPUT	122

C. Model Variations

In this work we build ten variations of the model which are grouped into three main groups: 1) pipeline CLS; 2) end-to-end CLS; and 3) end-to-end CLS with MWE components. We also conducted experiments by implementing two strategies of truncating the input, namely using only the head of the document and using the head and tail of the document. This input truncation strategy is inspired by Sun et al. [47] and Mutasodirin & Prasojo [48] who use this strategy for text classification problems. Both use the BERT model [42] but get different conclusions about this input truncation strategy, so this strategy cannot be generalized yet. In this work, the head strategy means using the first 200 tokens from the document, while the head-tail strategy means using the first 100 tokens from the document and concatenating them with the last 100 tokens from the document. So, the models in groups 2 and 3 are further divided into two groups: models that use the head of the document as input and models that use the head and tail of the document as input. Four out of 10 are baseline models: two pipeline models, PipeTS and PipeST, an end-to-end model that uses a vanilla transformer, VCLS, and an end-to-end model based on Zhu et al. [15], MCLS. The following is an explanation of each model variation:

1) *PipeTS*: Translation \rightarrow Summarization. The model is built in a pipeline scheme, starting with the English translation process first and then continuing with the Bahasa Indonesia summarization process. The machine translation model is trained using the PANL dataset. The Bahasa Indonesia summarization model is trained using the Sum (Ina) dataset. Both the translation and the summarization models use a vanilla transformer.

2) *PipeST*: Summarization \rightarrow Translation. The model is built in a pipeline scheme, starting with the English summarization process first and then continuing with the English translation process. The English summarization model is trained using the Sum (Eng) dataset. The machine translation model is the same as that used in PipeTS. Both the summarization and the translation models use a vanilla transformer.

3) *VCLS*: Head + CLS. The model is built end-to-end with head truncation strategy for the input. The model uses a vanilla transformer architecture but is trained using the CLS (Eng-Ina) dataset.

4) *MCLS*: Head + CLS-MS. The model is built end-to-end with head truncation strategy for the input. The model is based on Zhu et al. [15] CLS architecture. The model is trained with 2-task learning, which is jointly training CLS and MS using CLS (Eng-Ina) dataset and Sum (Eng) dataset.

5) *VCLS_T*: Head-Tail + CLS. The model is built end-to-end with head-tail truncation strategy for the input. The model uses a vanilla transformer architecture but is trained using the CLS (Eng-Ina) dataset.

6) *MCLS_T*: Head-Tail + CLS-MS. The model is built end-to-end with head-tail truncation strategy for the input. The model is based on Zhu et al. [15] CLS architecture. The model is trained with 2-task learning, which is jointly training CLS and MS using CLS (Eng-Ina) dataset and Sum (Eng) dataset.

7) *MWE_VCLS*: Head + CLS + MWE. The model is built end-to-end with head truncation strategy for the input. The model uses a vanilla transformer architecture but is trained using the CLS (Eng-Ina) dataset. This model is equipped with MWE components.

8) *MWE_MCLS*: Head + CLS-MS + MWE. The model is built end-to-end with head truncation strategy for the input. The model uses the proposed CLS architecture explained in section 3. The model is trained with 2-task learning, which is jointly training CLS and MS using CLS (Eng-Ina) dataset and Sum (Eng) dataset.

9) *MWE_VCLS_T*: Head-Tail + CLS + MWE. The model is built end-to-end with head-tail truncation strategy for the input. The model uses a vanilla transformer architecture but is trained using the CLS (Eng-Ina) dataset. This model is equipped with MWE components.

10) *MWE_MCLS_T*: Head-Tail + CLS-MS + MWE. The model is built end-to-end with head-tail truncation strategy for the input. The model uses the proposed CLS architecture explained in Section III. The model is trained with 2-task learning, which is jointly training CLS and MS using CLS (Eng-Ina) dataset and Sum (Eng) dataset.

D. Evaluation Metrics

This work uses a quantitative research method with the independent variable being the transformer-based CLS model and the dependent variable being the evaluation of the model's performance measured quantitatively. Recall-oriented understudy for gisting evaluation (ROUGE) is a suite of measurement metrics and a software package used to evaluate

automatic summarization and machine translation [49] [50] [51]. ROUGE is a popular metric widely used to evaluate automatic summarization. The advantages of using ROUGE:

- ROUGE is easy and fast compared to evaluation by humans,
- ROUGE is used by “everyone” so it is easy to compare one research result with another.

ROUGE compares the summary generated by the system with a reference summary or a set of reference summaries. Here are some of the available comparison methods:

- ROUGE-N: Compares n-grams between system summary and reference summary.
- ROUGE-L: Compares the longest matching sequence (LCS) between system summary and reference summary.
- ROUGE-S: Compare skip-bigrams, whether there are any word pairs in a consecutive sentence, gaps are possible. For example, skip-bigram measures the overlap of word pairs that can have a maximum of two gaps between words. The sentence “I eat fried rice” then the skip-bigram is “I eat, I fried, I rice, eat fried, eat rice, fried rice.”

There are still other measurement metrics, for more information refer to Lin [49].

Bilingual evaluation understudy (BLEU) is a method for automatic evaluation of machine translation. The BLEU score is a measurement metric that assesses the degree of similarity between sentences produced by machine translation and reference sentences made by human translators. The more similar, the higher is the value. This method works by counting the number of n-grams in the produced sentence that matches the n-grams in the reference sentence. BLEU was proposed by papineni et al. [21].

V. RESULTS AND DISCUSSION

We evaluated the models trained using the ROUGE metric described in the previous section. Specifically, we used ROUGE-1, ROUGE-2, and ROUGE-L. The discussion regarding the experimental results is divided into three parts. First, we discuss the comparison of the pipeline model and the end-to-end model. Second, we discuss the comparison of the end-to-end model with the MWE components and the end-to-end model without the MWE components. In the end, we discuss the strategy of input truncation.

A. Comparison between Pipeline CLS Model and End-to-End CLS Model

Traditionally, CLS is done in a pipeline which involves two steps: summarization and translation. There are two patterns of using a machine translator in a pipeline scheme. The first pattern does the translation on the source document first and then the results of the translation are used to generate the summary. The second pattern performs summarization on the source document first and then the summary is translated into the target language. To construct CLS for these two patterns, three constituent models are needed: English summarization

model, Bahasa Indonesia summarization model, and English translation model. We trained a transformer-based English summarization model on Sum (Eng) dataset and a transformer-based Bahasa Indonesia summarization model on Sum (Ina) dataset. Then, we trained a transformer-based English translation model on PANL parallel corpus. The performance of these three models individually can be seen in Table IV and Table V.

We use the two patterns of the pipeline scheme as baseline models (PipeTS and PipeST). These two pipeline models were constructed using MS model and MT model which had previously been trained independently. Both are then tested using the CLS (Eng-Ina) dataset. The results are shown in Table VI. The pipeline approach introduces error propagation. To solve this, we trained several end-to-end CLS models (4 variations of VCLS models and 4 variations of MCLS models) on CLS (Eng-Ina) dataset. The performance of these end-to-end models can also be seen in Table VI. All the end-to-end models outperform the model that uses the pipeline scheme.

The end-to-end model can achieve improvement from +0.1298 ROUGE-1, +0.0763 ROUGE-2, +0.1083 ROUGE-L up to +0.2981 ROUGE-1, +0.2084 ROUGE-2, +0.2771 ROUGE-L compared to the pipeline baselines. This verifies the purpose of performing end-to-end summarization. Unlike the pipeline method, the end-to-end model performs CLS in one direct step. This approach avoids the error propagation that occurs when doing it in two steps, namely in the pipeline scheme.

TABLE IV. PERFORMANCE OF OUR MONOLINGUAL SUMMARIZATION

Model	ROUGE-1	ROUGE-2	ROUGE-L
SumINA	0.6456	0.5580	0.6355
SumENG	0.6434	0.5123	0.6088

TABLE V. PERFORMANCE OF OUR MACHINE TRANSLATION

Model	BLEU-1	BLEU-2	BLEU-3	BLEU-4
Tran	0.3683	0.2078	0.1191	0.0628

TABLE VI. ROUGE F1 SCORE

Type	Model	Variations	ROUGE-1	ROUGE-2	ROUGE-L
Pipeline	PipeTS	Translation → Summarization	0.1266	0.0142	0.1038
	PipeST	Summarization → Translation	0.1661	0.0278	0.1313
End-to-End	VCLS	Head + CLS	0.2959	0.1041	0.2396
	MCLS	Head + CLS-MS	0.4087	0.2112	0.3652
	VCLS_T	Head-Tail + CLS	0.2981	0.1093	0.2448
	MCLS_T	Head-Tail + CLS-MS	0.3809	0.1893	0.3385
End-to-End MWE	MWE_VCLS	Head + CLS + MWE	0.3617	0.1519	0.3038
	MWE_MCLS	Head + CLS-MS + MWE	0.4247	0.2226	0.3809
	MWE_VCLS_T	Head-Tail + CLS + MWE	0.3347	0.1311	0.2767
	MWE_MCLS_T	Head-Tail + CLS-MS + MWE	0.3886	0.1919	0.3438

B. Comparison between End-to-End CLS Model with MWE and End-to-End CLS Model without MWE

We also use two end-to-end models as baseline besides the two pipeline baselines which were discussed in the previous section. The first end-to-end baseline is an end-to-end CLS model built using a vanilla transformer (VCLS). The second end-to-end baseline is an end-to-end CLS model based on Zhu et al. [15] (MCLS). The model is trained with 2-task learning, which is jointly training CLS and MS using CLS (Eng-Ina) dataset and Sum (Eng) dataset.

CLS is a Seq2Seq problem, when given a text sequence in the source language it produces a shorter version of an original text sequence in the target language. In Seq2Seq problem, it is important to learn the relation (alignment) between the input sequence and the output sequence. The CLS model that cannot do a proper alignment mapping is unable to produce a correct and meaningful summary. We propose using MWE to help with this alignment. MWE can represent words in various languages in one vector space. Words that have similar meanings are in proximity. This pre-mapping of words is expected to facilitate the model in aligning word sequences

between input and output. The VCLS and MCLS are then modified by adding MWE components (MWE_VCLS and MWE_MCLS).

The experimental results can be seen in Table VI. We can find that the model that utilized MWE components beats the underlying baseline model that does not use it. This shows that the MWE helps to better map the relation (alignment) between source document input in English and its summary output in Bahasa Indonesia. This can happen because every word in both languages is already in the same vector space. The MWE_MCLS model can achieve maximum improvement up to +0.1288 ROUGE-1, +0.1185 ROUGE-2, and +0.1413 ROUGE-L when compared to the end-to-end baselines. This is the best-performing model in our experiments.

C. Input Truncation Strategy

Sun et al. [47] and Mutasodirin & Prasojo [48] use an input truncation strategy on text classification problems. The strategy is not only to take the head of the data as input but also to combine it with the tail of the data. Generally, only the head of the data is used because it is assumed that the core information is here. However, their experimental results did not reach the

same conclusion, so this strategy cannot be generalized yet. We adapt this strategy to our CLS models which previously only took the head part of the document into a combination of the head and the tail. This adaptation produces models VCLS_T, MCLS_T, MWE_VCLS_T, and MWE_MCLS_T. The experimental results of these four models can be seen in Table VI. However, in general, the results have not been able to exceed the score obtained by the model that only uses the head of the document. The best score is obtained by MWE_MCLS_T. A decrease in performance of -0.0361 ROUGE-1, -0.0307 ROUGE-2, and -0.0371 ROUGE-L when compared to the best model uses the head truncation strategy (MWE_MCLS).

The IndoSum dataset that we use is constructed from online news articles. Upon further examination of this dataset, we found that most of the important information is at the beginning of the document. This information appears in the summary, while the end of the news article generally contains additional information or explanatory information that does not appear in the summary. Strategies that use a combination of head and tail from the document are proven to be unable to improve the performance of the models that originally uses head truncation strategy, it even can decrease the model performance due to including insignificant information in the summary.

VI. CONCLUSION

In this work, we present the end-to-end abstractive CLS for English documents to Bahasa Indonesia summary. The CLS architecture is based on transformers, modified by adding MWE components to address cross-lingual problems. The architecture also has a second decoder with a shared encoder. This second decoder is used only during training to carry out joint learning between CLS and MS. During the test, the second decoder is ignored. The model is also trained using two input truncation strategies: head and head-tail. The head truncation strategy cuts off and takes the head part of the document as input while the head-tail truncation strategy combines the head and the tail of the document as input. To train the model, we create a new CLS dataset from MS dataset by adapting the round-trip translation technique. The resulting CLS dataset is evaluated using BLEU to ensure its quality.

Based on the experimental results, it can be concluded that the use of MWE improves the performance of the CLS model, specifically for summarizing an English source document into a Bahasa Indonesia summary. The proposed model successfully outperformed the baseline model and improved its performance. The strategy of utilizing information at the end of the data failed in improving the performance of the model. Using only the head part of the data is still better. Furthermore, it can be concluded that the end-to-end model is better than the pipeline model. The use of machine translation is a weak point of the pipeline model because it introduces error propagation.

Abstract—Image retrieval using a textual query becomes a major challenge mainly due to human perception subjectivity and the impreciseness of image annotations. These drawbacks can be overcome by focusing on the content of images rather than on the textual descriptions of images. Traditional feature extraction techniques demand for expert knowledge to select the limited feature types and are also sensitive to changing imaging conditions. Deep feature extraction using Convolutional Neural Network (CNN) are a solution to these drawbacks as they can learn the feature representations automatically. This work carries out a detailed performance comparison of various pre-trained models of CNN in feature extraction. Features are extracted from men footwear and women clothing datasets using the VGG16, VGG19, InceptionV3, Xception and ResNet50 models. Further, these extracted features are used for classification using SVM, Random Forest and K-Nearest Neighbors classifiers. Results of feature extraction and image retrieval show that VGG19, Inception and Xception features perform well with feature extraction, achieving a good image classification accuracy of 97.5%. These results are further justified by performing a comparison of image retrieval efficiency, with the extracted features and similarity metrics. This work also compares the accuracy obtained by features extracted by the selected pre-trained CNN models with the results obtained using conventional classification techniques on CIFAR 10 dataset. The features extracted using CNN can be used in image-based systems like recommender systems, where images have to be analyzed to generate item profiles.

Keywords—Convolutional neural network; deep learning; feature extraction; accuracy; similarity

I. INTRODUCTION

Image retrieval systems browse, search and retrieve visually similar images from large image databases. Traditional image retrieval methods utilize the image annotations for obtaining the metadata that help in finding the similar images, but this is a laborious process and is subjective to human perceptions. Efficient image retrieval is the backbone of most of the search engines and recommender systems. Search engines may not be able to retrieve relevant information according to user's preferences due to imperfect textual query, less knowledge about the search query or due to wrong tagging of the database images. This gap between real intention of a user's search and his understanding of the object is called as semantic gap [1]. With the large amount of image data encountered in social networks, online e-commerce website, medical imaging, etc., it is a challenging problem to search the

humongous databases for similar images, especially when it comes to real time image retrieval. Feature extraction techniques help in getting a representation of the attributes of an image, which gives information about the image contents and hence helps in efficient retrieval of visually similar images. Feature extraction transforms data into more informative forms with efficient representation for analysis and classification [2]. Advantages of feature extraction include:

- Reduction of redundancy.
- Reduction in the number of processing resources.
- Helps in avoiding overfitting problem in machine learning models.
- Increase in accuracy.

Motivation: Any image recognition or image retrieval task requires a good feature representation in order to achieve high performance. However, since it is not feasible to define a good feature set manually, feature extraction plays a major role in image retrieval tasks. Features obtained using traditional methods of feature extraction are not capable of expressing the semantic information of the image. Deep Learning techniques make the task of feature extraction automatic and more efficient. Since deep learning techniques require a large amount of labelled training data, transfer learning can be used to reduce this overhead [3]. Fine tuning a CNN allows pretrained models to be used in a new task with a new dataset.

CNN models have two stages, of which, the first is feature extraction and the second is classification. This paper focusses on feature extraction using pretrained CNN and comparing their performance.

The open research questions which are addressed in this work include:

- i) How effective are deep learning methods for learning good feature representations from images for Content Based Image Retrieval?
- ii) How do the feature extraction and image retrieval time vary with the different models?

A. Contributions:

- This work contributes to the existing knowledge of feature learning by exploring feature extraction and transfer learning techniques using the five selected pre-trained CNN architectures.

- Comparison of the goodness of the features extracted by the selected CNN models by comparing the image retrieval performance using similar image search technique and also by using the extracted features for image classification.

The following sections of this paper are organized as follows. Related work in the domain of feature extraction and image retrieval is discussed in Section II. The fundamental concepts in image retrieval and the methodology adopted are given in Section III. Section IV gives the framework and the algorithm used in Reverse Image Search. Section V discusses the implementation details and results in Feature Visualization and Feature Extraction. Section VI concludes the paper by discussing the open research issues in the field of image retrieval and deriving an outlook for further research.

II. RELATED WORK

The goodness of an effective image retrieval system is attributed to the effectiveness of image feature extraction techniques used by the system. Various techniques have been proposed for feature extraction, starting from extraction of handcrafted features using traditional feature extraction techniques like SIFT, SURF, HOG to recent techniques utilizing Deep Learning. Work proposed in [4] investigated the use of various color, texture and shape features for image retrieval in CBIR (Content Based Image Retrieval) and biometrics systems, by mapping the image content onto low-level features.

An integrated image representation model has been proposed by complementary fusion of SIFT and CNN, to describe contents at multiple levels in images, followed by a series of operations of L2 normalization, PCA and whitening, on the integrated representation for a more compact representation [5].

The various techniques for extraction of texture and color features include color correlogram, color histogram, color co-occurrence matrix, wavelet transform and Tamura feature [6]. Several recent works have focused on the use of machine learning and Deep Learning for feature extraction [7-9]. The convolution layers in CNN can change the shape of the output, thereby enabling the learning of basic object shapes in the primary layers and more complex objects in the deeper layers, with a drastic reduction in the error rate [10].

Studies reveal that high level features are of different behavior from low and middle level features under certain conditions, and hence, CNN features in each of the layers can be utilized for representation of knowledge. The level of noise included in these features have been studied and a thresholding approach is proposed to remove as much noise as possible, thereby generating efficient CNN embedding spaces [11].

Some of the models with combination of CNN features and handcrafted images have also shown good results. The work in [12] automates the extraction of electroencephalogram (EEG) signals the feature extraction methods of Wavelet Packet decomposition and Genetic Algorithm-Based Frequency-Domain Feature Search. A combination of handcrafted and

CNN features has been used for liver MR image adequacy assessment yielding a model performance of $AUC = 0.94$, wherein, HC features of intensity values, topological structure, texture information (GMM, ECC, and GLCM features) are extracted from the images and used for classification using Random Forest classifier.

Many algorithms use Hashing based methods for image retrieval. While some of the algorithms identified approximate regions of the objects in an image using attention sub-network, focusing mainly on the foreground objects [13], image features extracted using deep hashing methods with deep neural networks (DNN) gave better image retrieval performance [14].

Histogram features have also given good results in CBIR. Work proposed in [15] used color spectral histogram for computing the similarity between images, whereas the method proposed in [16] used correlated primary visual texture histogram features.

The use of color and texture features have been proposed in several works. The work proposed in [17], calculates the image similarity by giving equal priority to dominant color Hu moments for CBIR, wherein, the texture template detects and extracts the consistent zone of an image and uses the seed point's selection approach for initiating the clustering process. Study [18] uses both Hu moments and dominant color descriptor on the pixels. Research [19] uses LBP-DBN training algorithm with adaptive momentum learning rate to overcome the issues of longer training time and reduction in classification accuracy. The author in [20] uses Directional Magnitude Local Hexadecimal Patterns, for image retrieval, by reducing the semantic gap problem using a learning-based approach. Quadruplet loss function and feature fusion are also used for clothing retrieval [21]. The features extracted using Resnet-50 are merged with middle-level features to get a combined feature representation. Work proposed in [22] uses a visual re-ranking approach, by using a correlation matrix of an image retrieval list and a CNN model learns the relevance of each of the image pairs simultaneously. The model is further optimized using a weighted MSE loss, which also considers the sparsity of labels. Feature reduction using an improved CNN and PCA quadratic dimensionality reduction has been proposed [23]. Deep Learning techniques for feature extraction are more promising due to their capability to extract and learn features of an image automatically.

Recent advances in image retrieval have started focusing on graph neural networks for CBIR. The work done in [24] proposes graph neural networks to reframe the re-ranking process for CBIR by using a 2-layer GNN to aggregate neighbor information of the entire data. Several new approaches have been proposed for deep feature embedding. In [25] a GNN characterizes and predicts the local correlation structure of images in the feature space, using which, neighboring images collaborate and refine their feature embeddings based on local linear combination. The representation capability of graphs has led to various graph-based image recommendation systems also [26]. Table I gives a performance comparison of some of the results obtained in CBIR.

TABLE I. PERFORMANCE COMPARISON OF REVIEWED CBIR SYSTEMS

Author	Method	Dataset	Performance
Salamh et al. [7]	Multi-descriptor-local binary patterns	Extended Yale B & Grimace database	Accuracy=99.4%
Alsawaike t et al.[9]	Wavelet Packet decomposition (WPD), Genetic Algorithm-Based Frequency-Domain Feature Search (GAFDS)	Children’s Hospital Boston: EEG recordings of 23 cases	CNN: 97.93% accuracy SVM: 94.49% accuracy RF : 88.03% accuracy

Y. Zhang et al. [13]	Supervised hashing method which fusions simplex feature similarity & location similarity among multiple objects	VOC 2007 VOC 2012 NUS-WIDE	6% increase on Weighted MAP -3.0% increase on NDCG@1000 -2.9% on ACG@1000
X. Zhang [19]	Classification: Image local feature multi-level clustering and image-class nearest	RPC: Defiance Technology Nanjing Research Institute	Average Classification accuracy=84% as compared to ISDH(Instance Similarity Deep Hashing)

III. FUNDAMENTAL CONCEPTS AND METHODOLOGY

The basic steps involved in image retrieval include extraction of features and computation of image similarity. The features of the collection of database images are extracted and stored. The query image undergoes the feature extraction process and subsequently the similarity matching algorithm computes the similarity between the features of query image and the features of the database images. Distance metrics like Cosine distance and Euclidean distance are used for similarity computation. Finally, top-n similar images are retrieved.

A. CNN Models

Convolutional Neural Networks use supervised learning and train the network by backpropagation. CNNs have the advantage of reduced amount of preprocessing when compared to other deep learning networks. A CNN consists of two basic parts of feature extraction and classification.

The feature extraction part has several convolution layers followed by max pooling layers and an activation function. The classifier part consists of fully connected layers. Normalization layers in CNN help in keeping signals from each layer at suitable levels.

The output size at each of the convolution layer is given by the following formula:

$$\text{Output size} = [(W-F+2P)/S] + 1$$

where, W is the size of the input image, F is the size of the receptive field, S is the stride, and P indicates the zero-padding used on the border.

1) *ResNet50*: The ResNet model was developed by He et al. in the year 2015 with the concept of residual connections

[27]. ResNet50 consisting of 50 weighted layers, has five times lesser memory requirement as compared to VGG model because of the usage of Global Average Pooling layer, converting the 2D feature maps of the last layer to an n-classes vector calculating the probability of belonging to each class.

Fig. 1 shows the Residual block which is the basic building block of ResNet model. In a plain CNN network, the input X gets transformed into H(X) by passing through the different layers. In the residual model, the identity connection transforms the input X into F(X)+X, i.e., the original H(x) gets modified into F(X)+X. The ResNet model can learn from much deeper network, as the identity mapping from the input acts as a shortcut for the gradient to pass through, thereby avoiding the vanishing gradient problem.

2) *VGG16*: VGG 16 architecture proposed by Simonyan and Zisserman in 2014 [28], consists of blocks with increasing number of convolutional layers with 3x3 filters as shown in Fig. 2.

The size of the activation maps reduces by half due to the max-pooling blocks between the convolutional blocks. The classification blocks consist of two layers, each with 4096 neurons, followed by the final output layer of 1000 neurons.

3) *VGG19*: VGG19 model consists of 16 convolution layers, three Fully connected layers, five Max Pool layers and one SoftMax layer. RGB image of dimension (224 * 224) is given as input and the kernels used are of (3 * 3) size with a stride of 1. Max pooling over a (2 * 2) window with stride 2, followed by Rectified linear unit introduces non-linearity for better classification and improved computation time as compared to the models using sigmoid or tanh functions. Two fully connected layers of size 4096 is followed by a layer with 1000 channels and final layer is softmax function.

4) *InceptionV3*: Szegedy et al. proposed the Inception V3 architecture [29]. This model uses varying sizes filters and a concatenation of these filters is used to extract features at different scales as shown in Fig. 3. In Inception, the input is compressed using 1x1 convolutions after which, filters of different sizes are used on each of these spaces.

5) *Xception*: The Xception model is an “extreme” version of the Inception module that involves “Depthwise Separable Convolutions” [30]. The number of computations is high in the case of a basic convolution operation because the operation of applying filters on every input channel and the combining of these values is done in one step.

Fig. 1. Residual block in ResNet model.

Fig. 2. VGG16 and VGG19 models.

Fig. 3. The inception module.

Depthwise separable convolutions separates these steps into two, the first being the depthwise separation which is the filtering stage, followed by combining stage of pointwise convolution. Depthwise convolution applies convolution to the input image ($D_f * D_f * M$) with filters of depth 1 ($D_k * D_k * 1$), to a single input channel at a time as shown in equation (1) and then pointwise convolution compresses the input by applying N filters of dimension $1 * 1 * M$ across the depth as shown in equation (2).

$$D_f * D_f * M \rightarrow D_g * D_g \quad (1)$$

$$D_g * D_g * M \rightarrow D_g * D_g * N \quad (2)$$

where D_f is dimension of input image, D_g is dimension of feature map and M is number of channels in input image

Table II gives a summary of the five pre-trained CNN models used in feature extraction.

B. Fine Tuning CNN

Fine tuning is the technique for speeding up the training process by overcoming the problems posed by small size dataset, by taking the weights of a pre-trained neural network and using it to initialize a new model which is being trained on similar domain data. This can be broadly categorized into Transfer Learning and Feature Extraction.

TABLE II. SUMMARY OF CNN MODELS USED IN FEATURE EXTRACTION

Model	Input Size	Length of Feature Vector	Parameters
Inception V3 (2015)	299*299*3	2048	Total parameters: 23,851,784 Trainable parameters: 23,817,352 Non-trainable parameters: 34,432
ResNet50 (2015)	224*224*3	2048	Total parameters: 25,636,712 Trainable parameters 25,583,592 Non-trainable parameters: 53,120 SGD - mini-batch size = 256 Learning rate starts from 0.1 and is divided by 10 when the error plateaus Weight decay = 0.0001 Momentum = 0.9 No Dropout
VGG16 (2014)	224*224*3	4096	Total parameters: 138,357,544 Trainable parameters: 138,357,544 Non-trainable parameters: 0 SGD(lr=0.1,decay=1e-6, momentum=0.9)
VGG19 (2015)	224*224*3	4096	Total parameters: 143,667,240 Trainable parameters 143,667,240 Non-trainable parameters 0
Xception (2015)	299*299*3	2048	Total parameters: 22,910,480 Trainable parameters: 22,855,952 Non-trainable parameters: 54,528

Most of the popular CNN architectures including VGG16, VGG19, ResNet50, AlexNet, InceptionV3, Xception have been pre-trained on ImageNet dataset. ImageNet consists of around 1.2 million training images, 50,000 validation images and 100,000 testing images, belonging to 1000 categories.

1) *Transfer learning*: Transfer learning works by loading pre-trained weights into a base CNN model, followed by freezing all the base model layers, making them non-trainable. This is followed by creating a new model on top of the output of any of the base model layers and training this newly created model on the new dataset.

2) *Feature extraction*: Feature Extraction is a lighter approach, wherein, after loading pre-trained weights into a base CNN model, the new dataset is run through the base model to extract the output of the layers of this model, and use this output as the input data for a new model.

C. Classification Algorithms

Classification is a “Supervised Learning” technique for identification of the category of new observations based on the training data. In classification, a program learns from the given observations and then classifies new observations into categories. In this work, classifiers are used for classification of images by utilizing the features extracted by the CNN models on the fashion dataset having men footwear and women clothing.

1) *Random forest*: Random Forest classifiers use a combination of many classifiers to solve complex problems. The advantages of Random Forest include its capability to maintain high accuracy through cross validation with higher dimensionality dataset, prevention of overfitting and the capability to handle missing data.

2) *Support Vector Machine*: Support Vector Machine (SVM) is a “supervised” machine learning algorithm that finds a hyperplane in an N-dimensional space that distinctly classifies the data points. SVM is very effective in high dimensional cases with the number of features deciding the dimension of the hyperplane. SVM maximizes the margin between the data points and the hyperplane.

3) *K Nearest Neighbors*: KNN is a “supervised learning” algorithm for regression and classification. KNN takes into consideration K nearest data points to predict the category or continuous value of the newly observed data. KNN uses all of the training instances for output prediction for new data. Model learning process is performed only at the time when prediction is requested on the new instance.

D. Similarity Metrics

The similarity metrics used for similarity matching are:

- **Minkowski Distance**: This distance metric takes two vectors and computes the distance between these vectors. The parameter “p” is called the “order”, which allows calculation of different distance measures.

$$d(x, y) = (\sum_{i=1}^n |x_i - y_i|^p)^{1/p} \quad (3)$$

For Manhattan distance, $p = 1$.

For Euclidean distance $p = 2$.

- **Manhattan Distance**: This distance is computed as the sum of the absolute differences between two vectors.

$$d(x, y) = \sum_{i=1}^n |x_i - y_i| \quad (4)$$

- **Euclidean Distance**:

$$d(x, y) = \sqrt{\sum_{i=1}^n (x_i - y_i)^2} \quad (5)$$

- **Cosine Similarity**:

$$sim(a, b) = \frac{a \cdot b}{||a|| \cdot ||b||} \quad (6)$$

- **Jaccard Similarity**:

$$J(A, B) = \frac{|A \cap B|}{|A \cup B|} \quad (7)$$

IV. REVERSE IMAGE SEARCH FRAMEWORK AND ALGORITHM

Problem Definition: For a given image query, retrieve the top-n similar images.

The features extracted using the different CNN models are utilized for reverse image search, using the framework shown in Fig. 4. For dimensionality reduction, Principal Component Analysis is used. Manhattan, Euclidean, Cosine distances and Jaccard similarity are used as the similarity measures.

A. Framework

The Reverse Image Search framework for retrieving visually similar images, shown in Fig. 4, consists of the following modules:

1) *Data collection and preprocessing module*: The Crawler utility fetches the retailer-specific webpages and extracts images. The preprocessing module prepares the images for the feature extraction process according to the input specifications of the selected pre-trained model. The image preprocessing utilities transform the raw image data to dataset objects, that can be further used as inputs to the model.

2) *Feature extraction module*: Text-based image retrieval methods may fail to retrieve visually similar relevant images because of the absence of query terms in the description of image. The feature extraction module overcomes this disadvantage by incorporating CNN layers for extraction of features. This module consists of the specific CNN model with the last fully connected layers removed, to extract the various levels of features. The extracted feature vectors are of high dimensionality and are therefore computationally expensive, with high memory requirement. Principal component analysis transforms the data into fewer number of dimensions, thereby giving summarized feature vectors. This helps to reduce the complexity in data and at the same time retains the patterns in the images.

3) *Similarity Calculation module*: This module computes the similarity between the feature vector of the input query image and the feature vectors of the database images extracted using the CNN models and the ranking of images is done according to their similarity. Finally, the top-n ranked images will be retrieved using the similarity metrics as in Equation (3) – Equation (7).

B. Algorithm: Top-n similar Images Retrieval

The algorithm for Top-n similar images retrieval is as follows:

Input : User query Image q, Image database I_{db} with image I.

Output: Top-n similar images

begin

Offline:

Pre-process the images in the image database I_{db} based on the input size of the CNN models

Extract Visual features F using the pre-trained CNN models for each image I in I_{db}

Reduce dimensionality using Principal Component Analysis

Online:

Extract Visual features F_q of the input query image q using the CNN models

for each feature vector F_j in F **do**

 Compute the feature similarity $Sim(F_q, F_j)$ using Equation (6)

Retrieve the Top-n similar images based on similarity calculation.

Fig. 4. Reverse image search framework.

V. IMPLEMENTATION AND RESULTS

A. Dataset and Experiment Setup

This work is carried out on 11th Gen Intel Core i7 processor with NVIDIA GeForce RTX 3050 Ti GPU. The men footwear dataset consists of a total of 2167 images belonging to three different classes of casual sandals, formal shoes and flip flops. The women clothes dataset consists of 4339 images belonging to five different classes of jeans, salwars, shirts, shorts and tops. The data is split into train and test sets with 80:20 ratio. The work concentrates on feature extraction using the pre-trained models VGG16, VGG19, InceptionV3, Xception and ResNet50 models, followed by evaluating the feature extraction efficiency by giving the extracted features as input to classifiers. Feature Visualization is done to know the depth and granularity of different features extracted at different layers.

B. Feature Extraction and Classification

This work utilizes the Keras Implementation of the pre trained CNN models. After initializing the input image size and applying the corresponding preprocessing functions, the pretrained weights are loaded into the model. The preprocessing function of the ImageDataGenerator module is used for data augmentation to improve generalization. Next, for feature extraction, the training images are loaded after expanding their dimensions according to the input size of the respective CNN models. Random Forest Classifier from Scikit learn library with n estimators' value of 50 is used in this work. SVC from the Scikit learn library is used here with a Linear kernel for SVM classification. KNN classifier with K=20 is used for the nearest neighbour classification.

For the men footwear dataset, as shown in Fig. 5, Random Forest gave an image classification accuracy of 97.5% with VGG19 features, SVM gave an accuracy of 97.5% with Xception features and KNN gave an accuracy of 95.8% with Xception features.

Fig. 5. Classification accuracy with features extracted by the different CNN models on the men footwear dataset.

For the women clothes dataset, as shown in Fig. 6, RF and SVM gave image classification accuracy of 89.1% and 96.8% respectively with InceptionV3 features and KNN gave an accuracy of 85.9% with Xception features.

The accuracy results show the efficiency of our selected pre-trained CNN models in feature extraction as compared to the work proposed in [10], where the authors achieved classification accuracy of 28.2% and 37.4% with KNN and SVM respectively on CIFAR 10 dataset, which consists of objects belonging to 10 classes. The results obtained with pretrained CNN model feature extraction and classification, outperform these with a classification accuracy of 72.4% and 86% with KNN and SVM classifiers respectively, using the features extracted by the Xception model on CIFAR 10 dataset.

Fig. 7 gives the classification accuracy obtained with the features extracted by the pretrained models on the CIFAR 10 dataset, along with the results obtained in [10] given as M1.

Fig. 6. Classification accuracy with features extracted by the different CNN models on the women clothes dataset.

Fig. 7. Classification accuracy on the CIFAR 10 dataset.

C. Feature Visualization

The application of different convolutional filters to the input image, results in different feature maps, wherein, each pixel of each feature map is an output of the convolutional layer. Visualization of feature map for an image helps in understanding the detected features. The feature maps closer to the input layer of the neural network detect details of features like edges. The feature maps closer to the output layer of the model capture much more abstract features like texture.

Fig. 8 shows the feature map visualization of the different blocks of convolution layers of InceptionV3 model on a men footwear input image.

D. Reverse Image Search

The image retrieval results with features extracted by the five CNN models on Men footwear and women clothes dataset using Manhattan, Euclidean, Cosine and Jaccard similarity as the similarity measures, is compared in this section, in terms of the time taken for feature extraction and also the visual similarity of the retrieved images. The utilities for image

preprocessing is imported from `tf.keras.preprocessing`. This transforms the raw image data to a `tf.data.Dataset` object, that can be further used to train the model. The extracted feature vectors are of high dimensionality and have high memory requirement. For dimensionality reduction, Principal Component Analysis with 300 components is used.

1) *Time taken for feature extraction and image retrieval:* The Men Footwear train dataset consists of 1732 training images belonging to three classes and the Women Clothes dataset consists of 3469 training images belonging to five classes. On an average, VGG19 takes more time for extracting the features of the training set images followed by VGG16, ResNet50, Inception V3, and Xception.

Fig. 8. Feature visualization using Inceptionv3 on men footwear image.

Fig. 9 shows the time taken for extraction of Men Footwear database image features by the different CNN models. Fig. 10 shows the time taken for query image feature extraction by the different CNN models and retrieval of top five similar images.

Fig. 9. Time taken in seconds for extraction of men footwear database image features by the different CNN models.

Fig. 10. Time taken in seconds for query image feature extraction by the different CNN models and retrieval of top 5 similar images.

Fig. 11 and Fig. 13 show the image retrieval results with features extracted by the five CNN models on Men footwear and women clothes dataset using Manhattan, Euclidean and Cosine similarity as the similarity measures.

Fig. 11. Men footwear reverse image search with Cosine, Euclidean and Manhattan similarity metrics using the different CNN models for feature extraction (query image on top and top 5 result images below for each CNN model).

Image retrieval results with Jaccard similarity show poor results as compared to Manhattan, Euclidean and Cosine as can be seen from Fig. 12.

Fig. 12. Men footwear reverse image search with Jaccard similarity metrics using VGG19 and InceptionV3 CNN models for feature extraction (query image on top and top 5 result images below).

Fig. 13. Women clothes reverse image search with Cosine, Euclidean and Manhattan similarity metrics using the different CNN models for feature extraction (query image on top and top 5 result images below for each CNN model).

VI. CONCLUSION

The work carried out focuses on feature extraction using VGG19, VGG16, ResNet50, InceptionV3 and Xception models, followed by evaluating the feature extraction efficiency by feeding the extracted features as input to classifiers. Results of feature extraction and image retrieval show that VGG19 features show best results with both men footwear and women clothes dataset. The classification accuracy results show that VGG19 features give more accuracy with men footwear, whereas InceptionV3 and Xception features are better with women clothes. This work also compares the time taken for feature extraction and image retrieval with each of the five CNN models. The features extracted using the deep learning models can be used to analyze images in various image-based systems. One practical application of this would be in image-based recommender systems. The features extracted from images can be used to build item profiles in content-based recommendations. Recent advances in the field of recommender systems use graph-based methods like Graph Convolutional Network, as they are capable of representing the complex embeddings.

Future research directions include:

- Utilization of Deep Learning models for transfer learning with optimization techniques.
- Using a fusion of different handcrafted local features and CNN features is also one of the challenging future directions for research.

Emotion Recognition on Multimodal with Deep Learning and Ensemble

David Adi Dharma, Amalia Zahra

Computer Science Department-BINUS Graduate Program-Master of Computer Science
Bina Nusantara University, Jakarta, Indonesia 11480

Abstract—Emotion Recognition on multimodal dataset is a difficult task, which is one of the most important tasks in topics like Human Computer Interaction (HCI). This paper presents a multimodal approach for emotion recognition on dataset MELD. The dataset contains three modalities, audio, text, and facial features. In this research, only audio and text features will be experimented on. For audio data, the raw audio is converted into MFCC as an input to a bidirectional LSTM, which will be built to perform emotion classification. On the other hand, BERT will be used to tokenize the text data as an input to the text model. To classify the emotion in text data, a Bidirectional LSTM will be built. And finally, the voting ensemble method will be implemented to combine the result from two modalities. The model will be evaluated using F1-score and confusion matrix. The unimodal audio model achieved 41.69% of F1-score, while the unimodal text model achieved 47.29% of F1-score, and the voting ensemble model achieved 47.47% of F1-score. To conclude this research, this paper also discussed future works, which involved how to build and improve deep learning models and combine them with ensemble model for better performance in emotion recognition tasks in multimodal dataset.

Keywords—Emotion recognition; deep learning; ensemble method; transformer; natural language processing

I. INTRODUCTION

Humans, along with technological developments pour their emotions or feelings either through some media such as text, photos, audio, or video recordings. Human emotions are complex, which make it difficult to be studied or predicted, and it takes a high level of intelligence to be able to recognize the emotions expressed by people in the current media [1]. Due to the complexity of human emotions, the variety of human's feelings, and the media where they convey their emotions, the AI model's learning has evolved to multimodal datasets, where existing media, audio, video, text, biological information, can improve the model's ability to classify emotions more accurately [2]. This emotion recognition task is involved in some study subjects, which are Natural Language Processing (NLP) and Machine Learning (ML).

The algorithms used to classify emotions are also being actively researched and developed. The same algorithm used for classification can have different results, depending on the dataset used. The datasets used for classification are media such as text, or images, or EEG (Electroencephalogram) signals, as well as sound. Examples of Machine Learning (ML) method that was used for classifying emotions are SVM (Support Vector Machine), KNN (K-Nearest Neighbor), and

Bayesian Network in the research [3]. Then the emotion classification method developed to neural networks-based model which are Deep Learning (DL) such as Recurrent Neural Network (RNN) in [4] research, Deep Neural Network (DNN) in [5], DialogueRNN which is RNN-based model in the research by [6], LSTM (Long Short-Term Memory) and CNN (Convolutional Neural Network) conducted in the [7] experiment. Lastly, a Bidirectional LSTM-CNN model was used to learn context and classify emotions in the [8] and [9] works.

Transformer which is proposed in 2017 [10] is the neural network architecture. This model outperformed any RNN and LSTM model that were popular in NLP. Thus, Transformer develops into BERT in 2019 [11]. BERT stands for Bidirectional Encoder Representation of Transformer, and until today BERT has been widely used to extract contextual information from texts. BERT also used in emotion recognition task on the text dataset, in [11] research published in 2022.

An ensemble learning [12] is a technique that combines base predictors model and improves it to become more outstanding predictor. There are few kinds of ensemble learnings which are called bagging, boosting, and stacking [13]. In the [14], there is ensemble learning called voting, which choose the highest probability value as the final classification result. In this experiment, the voting ensemble learning will be performed.

There are some datasets that are widely used in multimodal emotion classification research, such as IEMOCAP (The Interactive Emotional Dyadic Motion Capture) and MELD (Multimodal EmotionLines Dataset). MELD was made and published in 2018 by [15]. These works have used IEMOCAP dan MELD for building and developing models that are used to classify emotion in multimodal. This paper built a model using MELD dataset, which contains 7 labels of emotions, such as anger, disgust, sadness, joy, neutral, surprise and fear. All data in the MELD dataset are in English. There are three modalities that are provided the dataset, video which are audio and facial data, and textual data.

The purposes of the experiment are to extract emotion features in multimodal dataset and build a model that could recognize the emotion that is learned from the features. This experiment also intends to evaluate the model built and compare the evaluation result with the existing models.

There are two tasks that will be conducted in this research, Speech Emotion Recognition (SER) and Text Emotion Recognition (TER). Based on the state-of-the-art mentioned above, BERT will be built to tokenize the textual dataset, then a Bidirectional LSTM model is built to classify the emotion for the text dataset. On the other hand, a Bidirectional LSTM model will be used for SER task. Finally, a voting ensemble learning model will be applied as the ensemble learning. This paper will utilize the advantages of models that were mentioned above for improving emotion recognition model's performance.

The remainder of the paper is structured as follows: Section II will review related research for emotion recognition for both unimodal and multimodal dataset, Section III will provide proposed method in this research, Section IV on experiment scenario, discussion on Section V, and finally, conclusion and future works are provided on Section VI.

II. RELATED WORKS

Research related to emotion classification has been developed using various combinations of algorithms with various datasets. Datasets can be in the form of text, sound, images, to multimodal such as a combination of text with sound and video recordings (image and sound). Research conducted in [4] uses the IEMOCAP dataset as the multimodal dataset, where the researcher takes audio and text data. In the audio dataset, the features are extracted using the tools openSMILE for audio and NLTK for text. In the classification of emotions, the results of the extraction of these features are processed by an RNN model. Another study by [16] used the OMG (One-Minute Gradual-Emotion Recognition) dataset and divided the dataset into 2 classes, namely arousal and valence. To extract video data features, researchers used OpenFace and VGG Face, to extract audio data features using OpenSMILE, and for text using Lexicon.

Then another study using the AFEW (Acted Facial Expression in the Wild) dataset conducted in [2] and compared several feature extraction methods, such as TF-IDF (Term Frequency-Inverse Document Frequency) and WV (Word Vectors) for text data, C3D and VGG for visual datasets, then MFCC, SoundNet, and VGG for audio data. Then each data type, namely audio, text, and visual is classified using 3 methods, namely RF (Random Forest), SVM (Support Vector Machine), and LSTM (Long Short-Term Memory).

Subsequent research conducted in [6] proposed a model called DialogueRNN, which was used to classify emotions from the IEMOCAP and AVEC datasets. In this study, audio data features were extracted using OpenSMILE tools, 3D-CNN to extract visual features, and CNN to extract text features. Further research by [17] used the IEMOCAP dataset by taking audio and text data. Text data is extracted using Word2Vec, while audio dataset is extracted to new low-level features and then processed into high-level features or contextual features using CNN-LSTM. The method used for emotion classification is Deep Neural Network (DNN) which consists of four layers, namely input layer, hidden layer 1, hidden layer 2, and softmax layer.

Research by [18] uses the IEMOCAP dataset and retrieves audio and text data. The method used to classify is divided into two, namely, several Machine Learning (ML) models and several Deep Learning (DL) models. The ML methods used are Random Forest (RF), Gradient Boosting (XGB), Support Vector Machine (SVM), Multinomial Naïve Bayes (MNB), and Logistic Regression (LR). Meanwhile, the DL method used is Multi-Layer Perceptron (MLP) and Long Short-Term Memory (LSTM).

Another study conducted by [5] used the IEMOCAP dataset, taking audio and text data from IEMOCAP. Text data feature extraction using GloVe, while audio data is handcrafted. Researchers combined CNN (Convolutional Neural Network) with LSTM (Long Short-Term Memory) to classify emotions from audio data, and Bi-LSTM (Bidirectional Long Short-Term Memory) to classify text data. Then in the classification of multimodal data, the method used is DNN (Deep Neural Network) by combining high-level features from 2 data, namely audio and text, then using a softmax layer to perform the classification.

Furthermore, research conducted by [19] used the MELD dataset where the data taken were audio and text data. Audio data is converted to MFCC first, while text data is processed using BERT. Then the audio and text data are entered into the GRU and then forwarded to the proposed model, namely MMFA (Multi-Level Multi-Head Fusion Attention).

The next study conducted in [17] used the MELD dataset and took the audio and text data as multimodal data, where the proposed model is GNN (Graph Neural Network). Research by [20] uses the MELD dataset and uses all data modalities, namely audio, text, and visual. The proposed model is HFGCN (Hierarchical Fusion Graph Convolutional Network). HFGCN provides output in the form of utterance-level features which are then entered into a fully connected layer for emotional classification.

In the [21] research in 2018, Bi-LSTM and LSTM are combined with Attention Layer to classify emotions, while the datasets are crawled from the internet. After bi-LSTM and LSTM layers are being utilized, a soft voting model is deployed as the ensemble strategy to get the final emotion. In [11] used ResNet for emotion recognition in audio modality and used BERT based model to emotion recognition in text modality. Then final score is being calculated using weighted score formula mention in [11].

In the [15] along with MELD dataset, a Bidirectional LSTM model was built to classify the emotions. This bidirectional LSTM will be included as a baseline model for the unimodal emotion model in this experiment. Also, in the [22], there are some bidirectional architectures that were experimented on. The best architecture will be included as the baseline model in this experiment. The unimodal model that will be built is the modified version from these two baseline models. Then, for the multimodal classification, voting will be performed from the predictions which are generated by these baseline models as the benchmarks.

III. RESEARCH FRAMEWORK

The topic of this research is to recognize emotion through classification from the model that will be built with multimodal dataset. Many Machine Learning and Deep Learning models have been researched to do emotion recognition tasks in the multimodal dataset. Common multimodal datasets such as IEMOCAP, AFEW, OMG, and MELD are being widely used to train the emotion recognition model. Most research uses bimodal such as audio and text dataset, there are also few research that use audio, facial, and text features. There are many combinations of methods in multimodal dataset, but to find the most effective one for emotion classification, it will need a lot of experiments.

This research proposed deep learning models to recognize emotions in the two dataset modalities in the MELD dataset. This research will be done in supervised learning as MELD has already been labeled to train deep learning models. For audio features, bidirectional LSTM (Long-Short Term Memory) will be used to classify emotions. Then, as for text modality, BERT will be deployed to extract contextual features and classify the emotions. Lastly, voting ensemble learning is also being experimented in research.

As shown in Fig. 1, this research starts from choosing the topic of the research, and then studies all the literature related to the topic. After that the method and deep learning model is chosen. The next part will be preparing the dataset, preprocessing the data, and extracting the features from the dataset. Then, in the next part of the research, the model will be tuned, then train the model for each modality, which are audio and text. After that, voting ensemble learning is applied. At last, after all models are trained, the models will be evaluated using evaluation metrics such as F1-score and confusion matrix, then analyze the experiment result, and conclude the experiment result in the paper.

Fig. 1. Experiment scenario.

A. Preparing Dataset

In this research, MELD dataset will be used to train and build the model. MELD [15] contains 13,000 utterances from 1,433 dialogs in the TV series called “Friends”. The dataset is divided into three parts, train, test, and dev. Every utterance from 1,433 dialogs already has emotion label and sentiment label. The dataset contains three modalities, which are audio, facial, and text modality. There are seven emotion labels annotated in the dataset, Joy, Sadness, Fear, Anger, Surprise, Disgust, and lastly Neutral. There are also three annotations for sentiment analysis, such as neutral, positive, and negative. But in this research, only emotion labels will be used as the label to train the model.

The distribution of the emotion in the dataset is shown the Fig. 2. The train part contains the most data, while test and dev parts contain less data respectively. Fig. 3 below will show how the emotion labels are divided in percentage using pie chart. Neutral label is dominant with 47% label from all emotion label that exist in the MELD dataset. Then followed by Joy with 17%, Anger and Surprise with 12% each, Sadness is 7%, Disgust is 3% and Fear with only 2% from the dataset.

As the dataset is greatly imbalance, which will affect the model’s performance, the emotion labels in this experiment will be converted to only five emotion labels, which are neutral, anger, joy, sadness, and surprise. Fear and disgust are excluded because of the lack of data. As for the train data, the labels distribution will be divided into 683 data for neutral, anger, joy, and surprise, and sadness label. The total training data for the model will be 3415. The data distribution bar chart is represented in Fig. 4.

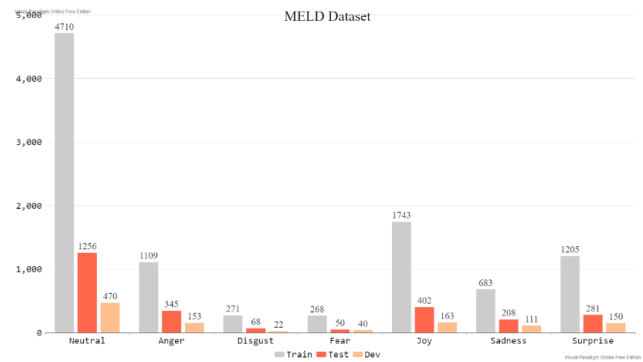

Fig. 2. MELD label distribution.

Fig. 3. Labels percentage.

Fig. 4. Training data distribution.

B. Feature Extraction

There are two feature extraction methods in this research. For text data, raw texts are tokenized with Distil-BERT model. As for the audio modality, the audio file will be extracted into MFCC [23]. Feature extractor methods are being used to convert the raw data so that the data can be learned by the model. After features are extracted from the dataset, there will be unimodal emotion recognition to classify emotion from given features. As for text data, an embedding layer will be applied before Bidirectional LSTM to understand the context of the text.

IV. THEORY AND METHODS

A. Emotion Recognition

Emotion recognition is one of the topics that has been widely researched along with the development of AI (Artificial Intelligence), the main reason being that the application of emotion classification is carried out on many difficult AI tasks, such as creating dialogues, understanding user behavior, and multimodal interactions [15]. The classification of emotions in a conversation can be used to make a suitable response by analyzing the emotions of the user.

Human emotions become the most important aspect to perform and develop natural human-machine interaction (HMI). While AI is one of the most developed topics in recent years, it'll need data from several modalities. Also, there are many methods to be explored to make AI learn effectively.

B. MFCC

The mel-frequency cepstral coefficient (MFCC) is an interpretation of an audio file in the form of a sequence of numbers [23]. The sequence of numbers is obtained from dividing raw audio files into frames, then performed some steps that are shown in Fig. 5. Lastly, the MFCC array is transposed using arithmetic formula. These MFCC numbers represented human voices amplitude.

C. LSTM

LSTM (Long Short-Term Memory) is one of the Deep Learning models derived from the RNN (Recurrent Neural Network) model which has special properties [24]. LSTM is the proposed solution model after finding the shortcomings of

the traditional RNN model, where the RNN has a vanishing gradient and an exploding gradient, causing the RNN to fail to capture long-term dependencies, and as a result, the prediction accuracy of the RNN model decreases.

Fig. 5. MFCC process.

The LSTM network architecture treats the hidden layers contained in the neural network as memory units, where the memory units collected in one recurrent hidden layer are called memory blocks. These memory blocks can be used to memorize temporal state from the neural network so that LSTM can remember the correlation between features in a sequence of time.

D. BERT

BERT (Bidirectional Encoder Representations from Transformers) is a new Transformer model for language representation designed to understand the contextual relationship between words from unlabeled text [25]. BERT also penetrated the start-of-the-art because it can see the context of a sentence from two directions, from left to right and from right to left. The BERT model architecture consists of a multi-layer bidirectional Transformers encoder.

BERT can be used to process not only embedding in text data, but also perform classification. The total Transformers blocks contained in the BERT baseline model are 12 blocks, with 768 hidden units, and 12 self-attention heads. The corpus used for pre-training in BERT is Books Corpus (800 million words) and English Wikipedia (2,500 million words).

V. PROPOSED METHOD

The proposed method for this research is shown in Fig. 6, Fig. 7, and Fig. 8. There are two models that are used to classify emotion from each modality. For the audio data, Bidirectional LSTM is used to recognize emotion in audio dataset, where the model learns audio features that were already extracted into MFCC.

This SER model's architecture is based on Bidirectional LSTM that was experimented on [15] and [22]. The baseline models have two layers of Bidirectional LSTM. These two layers can learn the MFCC features very well, better than 1 layer or 3 or more layers, based on the first experiment by the authors. Bidirectional LSTM that are too complex couldn't perform well with the MFCC features, so the Bidirectional LSTM adjusted into two layers. The LSTM unit in the layers are 256 and 128 units, respectively. Then, Dense Layer and Dropout is applied to reduce the complexity of the output from Bidirectional LSTM layers. The SER model architecture is shown in Fig. 6.

On the other hand, Distil-BERT pretrained model is utilized to tokenize the raw words from the text dataset. Then, the tokenized words are fed into an embedding layer. This embedding layer is trained with training dataset to understand

the context from the text data. The output from the embedding layer is inputted to 3-layered Bidirectional LSTM and classifies the emotion.

Fig. 6. Proposed SER deep learning model.

This TER model’s architecture is based on Bidirectional LSTM that was built in [15] and [22]. There are two layered Bidirectional LSTM that were applied on both experiments. Also, in the [22] there are six layers of BiLSTM and two Dense Layers. But the performance of the 6-layered BiLSTM is worse than the 2-layered BiLSTM. So, the 2-layered BiLSTM can be the baseline model of this experiment. Then, 2-layered BiLSTM is adjusted into 3-layered BiLSTM which can perform better than the 2-layered. Then, a flatten layer and three layers of Dense layers are added to reduce the complexity of the output from the Bidirectional LSTM layers. The TER model architecture is shown in the following Fig. 7.

Fig. 7. Proposed TER deep learning model.

Lastly, a voting ensemble method is deployed to classify the final emotion. The voting ensemble model is shown in the following Fig. 8. First, the unimodal models, SER model and TER model are trained. After that, each model, both SER and TER model predict using the features of the test data. The output would be on one-hot encoded format, because of the softmax activation function in the last layer in both models. This softmax function produces numbers that could be interpreted as probability. For example, the prediction generated from the first model is ([0.654 0.346]). The second model generates ([0.781 0.219]). Because the probability from the second model which is 0.781 is higher than 0.654, the voting will choose prediction from the second model.

So, every prediction that is generated from the unimodal models will be compared, which model produces higher probability. If the SER model generates output with higher probability, then the final emotion label will be selected from the SER model’s prediction. On the contrary, if TER model generates output with higher probability, then the emotion label will be selected from TER model.

Fig. 8. Proposed voting ensemble learning.

The experiment is implemented using Keras library with the help of librosa library as the audio feature extractor and BERT tokenizer from transformers library built by the Hugging Face. The librosa library is utilized to extract raw audio files into MFCC while the BERT model was used as the word tokenizer in the experiment.

The details of the bidirectional LSTM and deep learning layers which is the proposed method for classifying emotions from audio data, text data, and the voting result from the two modalities are written in the following tables. The details of the SER model are shown in Table I.

On the other side, the construction bidirectional LSTM and deep learning layers for the textual emotion recognition (TER) are written in the following Table II.

TABLE I. BIDIRECTIONAL LSTM LAYERS FOR SER

Bidirectional LSTM				
Layers	Units	Dropout	Output Size	Activation
Input layer	1	-	(None, 128, 1)	-
Masking	1	-	(None, 128, 1)	-
Bidirectional LSTM	256	0.4	(None, 128, 512)	tanh
Bidirectional LSTM	128	0.3	(None, 256)	tanh
Dense	64	-	(None, 64)	ReLU
Dropout	0	0.2	(None, 64)	-
Dense	32	-	(None, 32)	ReLU
Dense	5	-	(None, 5)	Softmax

TABLE II. BIDIRECTIONAL LSTM LAYERS FOR TER

Bidirectional LSTM				
Layers	Units	Dropout	Output Size	Activation

Dense	32	-	(None, 32)	ReLU
Dense	5	-	(None, 5)	Softmax

VI. RESULT AND DISCUSSION

Results from the experiment provided in Table III presented model's performance on the single modality and multimodality. Since the MELD has already been divided into train and test datasets, the model is being built using train data. The validation dataset takes 15% randomly from the train dataset to show the learning progress of each epoch.

The Bidirectional LSTM for the SER task trained with 30 epochs with batch size 32. While the TER task trained with only 20 epochs using the same batch size, which is 32. Both proposed SER and TER model used the l2 kernel regularizer where the kernel regularizer is set to 1×10^{-4} . This regularizer is added to reduce or prevent the models that were built in the experiment from overfitting. The optimizer used to train both SER and TER model is Adam. For the TER model, the learning rate was set to 1×10^{-5} . On the SER model, the learning rate was set to 1×10^{-4} because the number of epochs to train SER model is higher compared to TER model. These hyperparameters are manually tuned until receive the best result.

The experiment results are compared to some research papers shown in the following Table III. The benchmark models are trained using the same amount data as the proposed model with the same hyperparameters. The proposed method could surpass the baseline models with small gaps in decimals. If the f1-score is converted from decimal into percent, the proposed model does not surpass more than 1%. The gap between voting performed on model built by [15] and the proposed model approximately 1.5%.

From the evaluation result that is shown in Table III, proposed SER model, TER model, and the vote result based on SER and TER models could surpass the F1-score benchmarks. The emotion labels are strongly related with the context spoken by the speaker. This shows that the embedding layer that has been trained could understand contextual features better compared to MFCC, so that the TER model could perform better in recognizing the emotions given in the dataset.

As for the baseline TER model that was built in [15], an embedding layer is added, so the baseline model could learn the contextual features from tokenized word like model that was built in [22]. Both embedding layers are trained with the same parameter from the proposed model, so that the architecture of Bidirectional LSTM can be evaluated and compared fairly.

The details of the evaluation metrics such as precision, recall, and f1-score for each emotion label are provided in the following Tables IV, V, and VI. Table IV contains the details from SER model, while Table V contains the details from TER model and voting result, respectively.

The metrics that are shown in Table IV above interpret the details of how the proposed SER model predicted each label from the test dataset. As the test data mainly contain neutral emotion, the precision, recall, and f1-score for neutral emotion are good. But, for other emotions such as joy and surprised, the model performed poorly on predicting both emotions.

TABLE III. EXPERIMENT RESULT ON MELD DATASET BASED ON F1-SCORE

Modality	Approach	F1-score
Audio	BiLSTM [15]	0.408
	BiLSTM [22]	0.402
	BiLSTM (Proposed)	0.417
Text	BiLSTM [15]	0.443
	BiLSTM [22]	0.464
	BiLSTM (Proposed)	0.473
Multimodal	Voting from 2 modalities [15]	0.459
	Voting from 2 modalities [22]	0.468
	Voting from 2 modalities (proposed)	0.475

TABLE IV. EVALUATION METRICS SCORE FOR PROPOSED SER MODEL

Emotion	Precision	Recall	F1-score	Support
Anger	0.297	0.183	0.226	345
Joy	0.196	0.067	0.1	402
Neutral	0.521	0.705	0.599	1256
Sadness	0.145	0.255	0.185	208
Surprised	0.145	0.039	0.062	280

TABLE V. EVALUATION METRICS SCORE FOR PROPOSED TER MODEL

Emotion	Precision	Recall	F1-score	Support
Anger	0.310	0.446	0.366	345
Joy	0.344	0.236	0.280	402
Neutral	0.746	0.584	0.655	1256
Sadness	0.132	0.284	0.179	208
Surprised	0.476	0.489	0.482	280

The metrics that are shown in Table V interpret the details of how the proposed TER model predicted each label from the test dataset. Just like SER model, the TER model could predict neutral emotion well enough. The difference between the SER and the TER model is how well the TER model predicted surprised emotion, compared to the SER model. Overall, the TER model performed better except in predicting sadness emotion label, but only by inches.

TABLE VI. EVALUATION METRICS SCORE FOR PROPOSED VOTING ENSEMBLE

Emotion	Precision	Recall	F1-score	Support
Anger	0.313	0.452	0.370	345
Joy	0.363	0.246	0.293	402
Neutral	0.745	0.582	0.654	1256
Sadness	0.132	0.288	0.181	208
Surprised	0.477	0.488	0.482	280

The metrics that are shown in Table VI above interpret the details of the performance from two modalities TER and SER combined. Overall, the F1-score in the models is not as good as F1-score on the other dataset, for example research by [14] on WASSA2018 dataset. The main reason of the overall scores only in range 40% of F1-score is because the dataset is greatly imbalanced. To cope the imbalanced label from the train dataset, undersampling was performed so that the training data is much fewer compared to all training data, which is 3415 compared to 9989. So, the models only trained with one third of the full dataset.

Secondly, some of the data also does not contain keywords that are related to the emotion, for example, in the dataset, there is 1 word that is used in different emotions, which is "Hey." This word is used in joy, anger, and neutral expression in the dataset. It creates confusion so the model can't recognize the emotion in each sentence or utterance.

VII. CONCLUSION

This study experimented with a deep learning architecture which is bidirectional LSTM for doing unimodal emotion classification. This study also includes voting ensemble learning to combine two different modalities of the input information.

Experimental results on the MELD dataset demonstrated the good result of the proposed method. The performance of the proposed method could improve the performance from the previous state-of-the-art strategies both [15] and [22] around 1% performance improvement in F1-score on both SER and TER model. However, both unimodal models and the multimodal model performed poor in predicting some emotions such as sadness and joy.

For future studies, other input modalities such as different physiological measurements, or sentiment, or maybe context of the dialogue should also be added and included to the dataset, so that the input for the deep learning model become more complex and richer. Also, the facial features from the video dataset could be utilized as a feature to predict the human's emotions.

The imbalanced dataset also could be tackled by undersampling the dataset, especially on some emotion labels that only have a little data, which leaves some spaces to work in the future. Therefore, more multimodal datasets should be evaluated in future work.

ACKNOWLEDGMENT

The present paper was supported by the University of Bina Nusantara as thesis research to complete the graduate program. The writers are genuinely thankful and honored to those who help with the work on this paper and hopefully can produce many other great research or projects in the future.

Fault Diagnosis Technology of Railway Signal Equipment based on Improved FP-Growth Algorithm

Yueqin Yang

Urban Rail Transit College, Jilin Railway Technology College, Jilin, 132299, China

Abstract—The rapid development of computer information technology has made various fault diagnosis and detection technologies emerge in an endless stream. As one of the main transportation vehicles, the detection efficiency of fault diagnosis of railway signal equipment has important practical significance for maintaining the overall safe operation of railways. On the basis of the traditional FP-Growth algorithm, improve the TF-IDF algorithm to realize the weight discretization of text features, and realize the improvement of the FP-Growth algorithm by adjusting the adaptive confidence and support. The FP-Growth algorithm will be improved. FP-Growth algorithm is used for performance tests and applications. The results show that the minimum running time-saving of the proposed algorithm is 1500ms, and the average accuracy of P@N exceeds 85%, which is higher than that of the FP-Growth algorithm (81.4%) and VSM algorithm (82.1%). The PR curve of the improved algorithm is closer to the upper right, which effectively ensures the processing of correlated data, and the overall average precision performance under the influence of positive and negative signal-to-noise ratio values exceeds 95%. And the signal curve generated by the algorithm. The error range of the data under the four fault types of track circuit, turnout, signal, and connecting line floats between 1% and 5%. The improved FP-Growth algorithm can effectively analyze railway fault types and data. Perform analysis and data processing to minimize diagnostic errors.

Keywords—FP-growth algorithm; railway; signal equipment; fault diagnosis; relevance; frequent itemsets; vector space model

I. INTRODUCTION

The railway has always been in the backbone position in the modern comprehensive transportation system. It is an important infrastructure and the main means of transportation for the public in China, and also an important industrial sector to promote the national economy and social development. With the rapid development of China's railways in recent years, the safety requirements for railway transportation are becoming increasingly strict. With the in-depth development and application of information technology, the era of big data has come [1]. In the aspect of railway, the important premise to ensure traffic safety is to ensure the normal operation of railway signal equipment. Under the railway big data application platform, using data mining technology to process fault text data is one of the current research hotspots. The fault text data is extracted and mined, and the final results can guide maintenance personnel to process the fault equipment. As important technical equipment, railway signal equipment plays a key role in organizing and directing train operations, ensuring running safety and transportation efficiency. However, the

types and causes of railway signal faults are complex, and traditional detection methods are difficult to detect railway signals. Once the signal equipment fails, it is easy to cause a major safety accident, which will seriously affect the maintenance efficiency and endanger the life safety of the staff. The rapid development of information technology provides a variety of diagnostic methods for the detection of railway signals. Different methods are used to diagnose railway faults, such as the application of neural networks, fuzzy logic fault diagnosis, expert diagnosis systems, etc. Data analysis of fault signals is one of the key contents of detection. Common text data association analysis algorithms include Apriori Algorithms and Frequent Pattern Growth (FP-Growth) algorithms. The correlation algorithm can provide a practical basis for fault diagnosis based on ensuring the correlation analysis of signal detection data. The FP Growth algorithm is often used in data mining processing because of its fewer traversal times and the ability to compress the data, but its application effect will be affected by the data type [2]. Therefore, it is studied to improve the traditional FP Growth algorithm and discretize the weight value of the text feature based on considering the type and characteristics of the railway fault causes, to ensure the objectivity and standardization of data processing, and adaptively set the confidence and support to reduce the non-objectivity of manually set parameters, to detect and analyze the railway signal fault problems with the improved FP Growth algorithm. The research ensures that the improved FP Growth algorithm can better analyze and process the fault information by discussing the status quo of relevant research methods and designing experimental methods, and verifies the effectiveness of the proposed algorithm with the help of simulation experiments and algorithm comparison, in order to provide new data diagnosis and treatment means for future railway fault maintenance and operation maintenance, so as to ensure the normal operation of railway construction.

II. RELATED WORKS

The construction and operation of the railway system and the information transmission of the command and dispatch of the trains are all centered on the signal equipment. With the increase of traffic volume, it is very important to strengthen the fault detection of the signal equipment to ensure the normal development of railway safety operation and maintenance. Different scholars have put forward different views on the detection and processing of railway signals. For example, Fang et al. used FP growth algorithm to carry out secondary equipment defect monitoring, and used frame algorithm to establish an exception model [3]. Jiang et al. used FP growth algorithm for association analysis and data mining, but found

that this algorithm still has problems of low query efficiency and frequent item set traversal [4]. Yang and other scholars used the text mining intelligent fault classification model of signal equipment to realize the feature extraction and transformation of text information, and combined the characteristics of different classifiers. The ensemble study of learning classification was carried out under the experimental results. The experimental results showed that the model has high accuracy and recall [5]. Yuan and his team used the biased classification algorithm to divide the data flow of railway fault signals, and divided the data into line segments. The data block matrix is constructed to realize the integrated calculation of data consumption, and the experiments have verified that the algorithm can effectively reduce the memory consumption and greatly improve the data operation efficiency [6]. Han combines the hash table technology with the original FP growth algorithm, and conducts database experiments on it. It is found that the improved algorithm effectively shortens the running time, and its advantages gradually become prominent with the decrease of support [7]. Scholars such as Jiyang QI fully consider other external and objective factors when carrying out fault diagnosis, not only using a single indicator such as fault symptoms as the judgment standard, but also using the Weibull distribution model to calculate the failure rate based on, and carry out example analysis, the experimental results prove that the proposed algorithm can greatly improve the accuracy of fault diagnosis, and effectively reduce the interference of multi-information fusion on fault diagnosis [8]. Due to the diversity and complexity of information storage and application, word segmentation algorithms and topic models are used to extract features from information data, and then use support vector machines to diagnose equipment faults. It is found that the algorithm can provide algorithm guidance value for railway operation and maintenance [9]. Zhang scholars use association rules to achieve fault diagnosis of railway signals, and use TF-IDF algorithm to achieve fault feature extraction. The average diagnostic rate of this algorithm is 11.44% higher than that of Bayesian network [10]. Scholars such as Cheng integrate particle swarm optimization and minimum entropy to improve back - rolling the product method is used to detect the faults of rolling bearings, and the auxiliary coordinate transformation is used to optimize the algorithm. In the experimental simulation, it is found that the algorithm has good deconvolution performance, which effectively improves the diagnosis accuracy [11]. Zheng et al. designed constraints and screened data features to diagnose UAV flight faults. The experimental results show that the rule base of the improved algorithm has good scale growth and good application effect [12]. Ding scholars added the tail attribute to the traditional FP Growth algorithm to achieve tire data analysis. The experimental results show that the improved algorithm can effectively find the quality influencing factors and data feature mining [13]. Li et al. The fault feature vector acquisition and neural network improvement are carried out with the particle swarm optimization algorithm. The improved algorithm can show a short training time under the fault signal data of different states and its diagnosis accuracy rate is above 95%, which has a good application potential [14]. Jin and his team of scholars the power grid fault diagnosis based on layer data fusion is used to construct the model to process the data of

different information sources, and the restoration path algorithm based on the fault rules is used to make the optimal judgment of the power supply restoration path. The results show that the method has strong practicability and effective the accuracy of power grid fault diagnosis has been improved [15]. At the same time, Cho and other scholars have achieved a safe and efficient train by reviewing and analyzing the control unit and current relay interface of the automatic train protection system, and detecting the fault type after analyzing the cause of the fault [16].

Fuzzy logic method, artificial neural network method and other methods will be interfered by artificial thinking to a certain extent when detecting railway signals and the application of FP-growth algorithm to railway fault detection has attracted the attention of many scholars. Fang et al. used FP growth algorithm to conduct secondary equipment defect monitoring, and used Hadoop framework and Mapreduce algorithm to establish an exception model. The results show that the algorithm can effectively find equipment abnormal defects and provide a data basis for diagnosis [17]. In order to reduce the disadvantage that feature extraction of fault data mostly depends on manual work, Jiangquan scholars use convolutional neural network to perform two-dimensional transformation and feature extraction of signals, and the algorithm proposed has good application timeliness under different cost and load conditions [18]. Scholars such as Syakur MA use the FP-Growth algorithm to understand the clustering results and classification of sales data and customer data, and use it can better explore the correlation between the subject and object of commodity consumption, and combine it with the frequent pattern tree to determine the item set. The test results show that the algorithm can effectively mine the data relationship, improve the average processing time of the data, and achieve better smooth operation efficiency. Guarantee [19]. Scholars such as Ariestya WW use frequent patterns and a priori algorithms to process selection, transformation and evaluation of data, and then conduct marketing strategy analysis to analyze the degree of consumer demand. The experimental results show that this method is used in data processing. It has good application performance and effectively provides a supporting basis for the formulation of consumer marketing strategies [20].

The railway fault signal detection can analyze its fault signal according to the classification idea. Some scholars use text data mining, biased classification algorithms and frequent patterns to identify and analyze the fault signal. Considering the complexity of the fault signal and the multi-source of the data, some scholars use wavelet decomposition, particle swarm optimization algorithm and convolution neural network to transform the features, and they have achieved certain results. Some research results of FP growth algorithm application, defect detection and data classification also show that it can be used in better classification and recognition. Based on this research idea, the text feature data with discrete weight is proposed as the input value of FP Growth algorithm, and the algorithm is improved through adaptive setting, effectively taking into account the characteristics and changes of railway signal fault data.

III. FAULT DIAGNOSIS ANALYSIS OF RAILWAY SIGNAL EQUIPMENT BASED ON IMPROVED FP-GROWTH ALGORITHM

A. Application of Improved FP-Growth Algorithm in Signal Fault Diagnosis

The continuous increase of railway lines and the continuous updating of signal equipment make the fault diagnosis records in the operation and maintenance of the current railway system mostly exist in the form of text, and the traditional railway text data are mostly analyzed from the aspects of safety management, and are not based on the type of fault diagnosis. It is difficult to improve the efficiency and accuracy of fault diagnosis by analyzing the characteristics and causes of faults. It is difficult to improve the efficiency and accuracy of fault diagnosis. The phenomenon of multiple meanings, the difference of signal fault text records and the existence of redundant information make the diagnosis of railway signal faults difficult. There are problems such as untimely and inaccurate problems, which further increase the difficulty of railway signal equipment diagnosis. Therefore, on this basis, the research is based on text data to carry out feature extraction and data mining to improve the accuracy of fault diagnosis, that is, to establish an association rule based the fault detection of the fault signal can realize the diagnosis and real-time analysis of the fault type and cause from different aspects. First, the fault signal text is segmented and feature extracted to ensure the vectorization of its data. The Vector Space Model (VSM) will the feature item is used as the smallest unit of the text, and the corresponding feature weight is given to it, and the mathematical expression of the model is shown in the formula [21].

$$V(d_i) = (t_1, w_{i1}; t_2, w_{i2}; t_3, w_{i3}; \dots; t_n, w_{in}) \quad (1)$$

In formula (1), is t_n the first n feature item w_{in} of the text, and is the feature weight corresponding to the d_i feature item t_n . The weighted algorithm TF-IDF (Term Frequency - Inverse Document Frequency) algorithm is often used in data mining, and its core idea is to evaluate the importance of a word to a certain document in the corpus, its calculation formula is shown in the formula.

$$W_{t,d} = tf_{t,d} * idf_{t,d} \quad (2)$$

formula (2), is $W_{t,d}$ the weight value of the $tf_{t,d}$ feature value in the text, t and $idf_{t,d}$ is the word frequency and the inverse document frequency, respectively. The calculation formulas of the word frequency and the inverse document frequency are shown in formula (3) and formula (4).

$$tf_{t,d} = n_{t,d} / \sum_{kw,d} \quad (3)$$

$$idf_{t,d} = \log(N / N_{t,d} + 1) \quad (4)$$

equations (3) and (4), $n_{t,d}$ is the number of times the feature value appears in the $\sum_{kw,d}$ text, is the sum of the number of feature values in the text, is the total number N of texts, and is the number $N_{t,d}$ of texts with feature values in the text. The individual differences of text data and the appearance

of synonyms will increase the difficulty and accuracy of fault diagnosis. The research adjusts the traditional Term Frequency-Inverse Document Frequency (TF-IDF) algorithm to obtain the formula (5).

$$W_{t,d}' = tf_{t,d} * idf_{t,d} = tf_{t,d} * \log(N / N_{t,d} + 1) \quad (5)$$

In the formula, is $W_{t,d}'$ the final weight of the feature item, $tf_{t,d}$ and t_n is $idf_{t,d}$ the word frequency and inverse document frequency of the feature item, $N_{t,d} = N_{m,d} + N_{l,m,d}$, respectively, and is the sum of the number of texts t_n containing the feature item t_n, t_m . At the same time, the fault feature weight is discretized and divided into three categories according to its importance., and the value of 0-2 indicates the low, general and high importance. Fig. 1 is a schematic diagram of the level division under the weight discretization.

When marking the keywords extracted by the algorithm, it is evaluated by means of the hit rate (Recall), the accuracy rate (Precision) and the comprehensive evaluation (F measure).

$$Recall = \frac{|Y_{real} \cap X_{re}|}{Y_{real}} * 100\% \quad (6)$$

$$Precision = \frac{|Y_{real} \cap X_{re}|}{X_{re}} * 100\% \quad (7)$$

$$F - measure = \frac{2 * Recall * Precision}{Recall + Precision} * 100\% \quad (8)$$

In formulas (6)-(8), it Y_{real} represents the keyword set obtained by the measurement algorithm, which is Y_{real} the keyword set under manual marking. To diagnose and detect railway signal faults, it is possible to determine the fault feature layer, fault type layer and the fault cause layer realizes the subdivision and classification of fault information, and then provides a reference for subsequent countermeasures and improvements. For a variety of railway fault signal information, the text information data is often analyzed by means of association analysis. The value correlation or association pattern between itemsets is found in a large number of databases, emphasizing the interdependence between data, and then helping decision making and judging the feasibility of data. The key lies in the decomposition of association tasks and the formulation of association rules. The running framework of association rules is shown in Fig. 2.

Fig. 1. Schematic diagram of grade division under weight discretization.

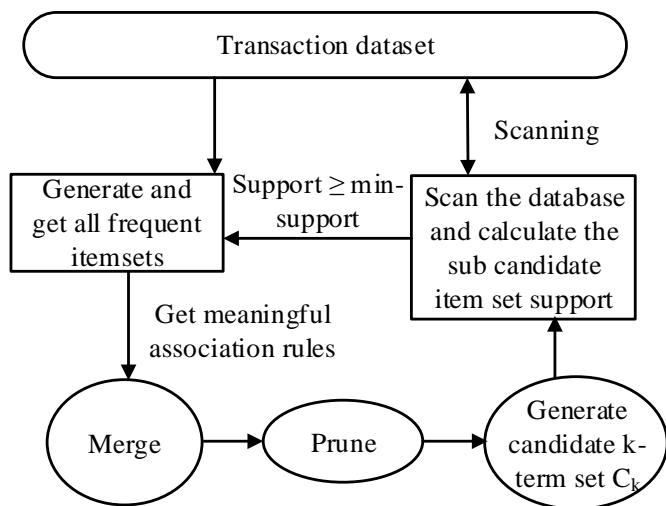

Fig. 2. Schematic diagram of association rule operation framework.

Association rules mainly realize the processing of itemsets by scanning the data set and determining the support degree, which is $A \rightarrow B$ an implication of the form, which A, B is an itemset containing one or more items, $A \cap B = \Phi$, which is the antecedent A, B of the association rule. and consequent. The constraints of association rules are the minimum values of support and confidence, and their mathematical expressions are shown in equations (9) and (10).

$$\text{sup}(A) = \text{count}(A \subseteq T) / |D| \quad (9)$$

Equation (9) is the calculation formula of the support degree, which is expressed as the ratio of the frequency of a certain item set appearing in the transaction to the corresponding transaction number, where D, A is the corresponding transaction database and item set, and sup-count is the corresponding support degree count. Confidence is expressed as the ratio of the probability that two related rules appear at the same time to the probability that a single rule appears $\text{confidence}(A \Rightarrow B)$, and its mathematical expression is Equation (10).

$$\text{confidence}(A \Rightarrow B) = \text{sup-count}(A \cup B) / \text{sup-count}(A) \quad (10)$$

Frequent Pattern-Growth (FP-Growth), as a typical algorithm for solving association problems, is different from the Apriori algorithm that scans each potential frequent itemset, which only scans the database twice and does not generate candidate sets. In the case of compressing the database containing frequent itemsets into a frequent pattern tree (Frequent Pattern-Tree, FP-tree), the frequent itemsets are obtained. The FP-Growth algorithm reduces the processing of itemsets to a certain extent. In the transaction database processing, the sorted frequent itemsets are used to reconstruct the database, then the root node of the tree is created, and the transactions are compressed into the FP-Tree branch in the form of merge prefix to realize the frequent itemsets. Fig. 3 shows the construction process of the algorithm pattern number.

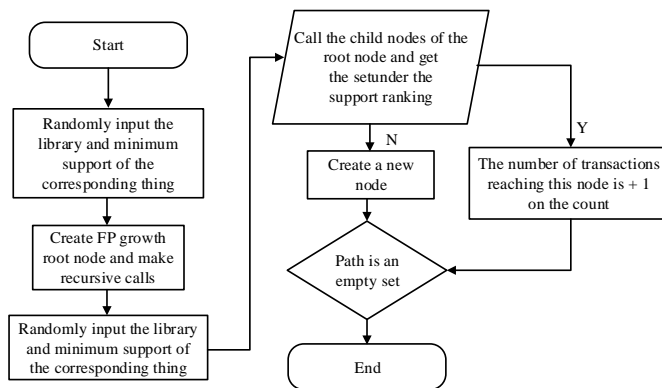

Fig. 3. Construction process of algorithm pattern number.

However, the traditional FP-Growth algorithm will artificially set the minimum support degree and the minimum confidence set when dealing with related transactions, which makes the selection of algorithm parameters to a large extent subjective and arbitrary, and it is difficult to ensure the authenticity of the algorithm and the operation. Feasibility. Also, the ambiguity of determining the size of frequent itemsets will also cause the pattern tree to consume more memory during the traversal process, thereby reducing the efficiency of data mining. Therefore, the research is based on this to eliminate the defects of artificially setting parameters., based on the characteristics of the data itself, the minimum support and confidence are set. The improved FP-Growth algorithm first sorts the support number of the transaction set in descending order, and builds a sequence table corresponding to “order-value”, in which There is a monotonically decreasing relationship trend between the sequence value and the ordinal value. The polynomial curve fitting function is set by the numbers corresponding to the ordinal-value table, and its mathematical expression is shown in formula (11).

$$y = f(x) = \sum_{i=0}^t m_i * x^i \quad (11)$$

In formula (11), y, x is the serial number value and the sequence value, t is the support number, i is the item set, and m is the upper limit of the interval satisfied by the function. Perform the quadratic derivative of the obtained function to obtain the second-order derivative function, as shown in formula (12). Show:

$$y' = f''(x) = \sum_{i=2}^t i(i-1) * m_i * x^{i-2} \quad (12)$$

When the sequence value of the second derivative function of the fitting curve appears for the first time in the interval, $y' = f''(x) = 0$ the sequence number value under the point is rounded down, and the rounded result is used as the algorithm parameter. Then set according to the adaptive support degree Threshold, get deleted items less than support degree, merge them to get sub-database, build its TP-Tree with sub-database, at this time, the data sub-database realizes the association of frequent itemsets under the recursive call tree structure Mining, but also to ensure that the obtained results are strong association rules.

B. Design of Railway Fault Signal Diagnosis System

The detection and diagnosis of railway signals based on the improved FP-Growth algorithm is to mine the rules in the fault storage knowledge base, and the reasoning flow chart is shown in Fig. 4.

By judging the fault characteristics of railway signals and saving them in a comprehensive database, and judging whether there are countermeasures for the type of problem, if so, the fault diagnosis results will be output directly, if not, the information characteristics will be screened in the historical fault database. Extraction, reasoning and correlation judgment, and consider a variety of factual basis in the process of fault type and cause analysis, and directly seek manual diagnosis when it is difficult to obtain a clear diagnosis result. This fault diagnosis process can effectively realize the processing of information data, detection, judgment, etc. effectively ensure the efficiency and accuracy of detection. The diagnosis of railway fault signals is the basis for staff to carry out equipment maintenance. The design of railway signal equipment fault maintenance system can make the diagnosis results intuitive, so as to carry out corresponding diagnosis countermeasures Research. On the basis of improving the FP-Growth algorithm, the research proposes a multi-level signal diagnosis structure including fault diagnosis, fault data management, post-maintenance management and user management. The picture shows the architecture diagram of the railway signal equipment fault repair prototype system.

As shown in Fig. 5, the architecture diagram of the fault repair prototype system includes the presentation layer, the business logic layer and the data access layer to realize the input and storage of the fault data, the logical interaction of the data business information and the human-computer interaction of the personnel related to the fault information., and then realize the cause and effect of fault data and interactive processing. The most important one is the business logic layer. The fault word database is established through the fault signal record, and then the knowledge base and data reasoning are used to diagnose the strong correlation. The fault causes of the rules are identified, and this is used as a reference for the maintenance plan to judge whether it needs manual modification. Continuously improve the fault case database of railway signal equipment and improve the overall fault diagnosis efficiency.

At the same time, when combining association rule mining and manual identification and diagnosis results, in order to avoid the omission of important fault causes, $P@N$ is used as the evaluation index, and its meaning is expressed as the accuracy rate of the retrieved fault cause as the real cause, and its calculation formula as shown in formula (13).

$$P@N = \sum_{j=1}^n I(j) / n \tag{13}$$

In formula (13), n is the set number of output fault causes, $I(j)$ and is the ratio between the input value of the test set conforming to the fault cause under the diagnosis algorithm and the actual cause of the fault, if the diagnosed cause is consistent with the actual cause, then $P@N$ The value of 1.

Fig. 4. Schematic diagram of fault diagnosis process.

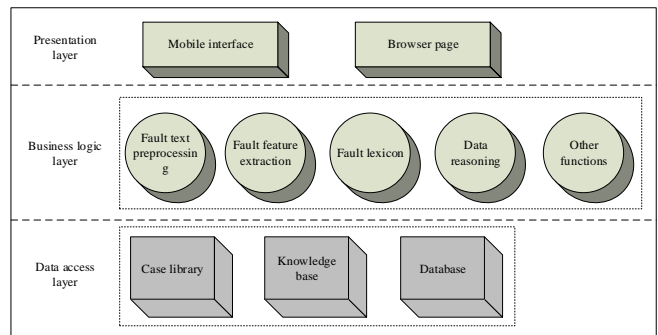

Fig. 5. Architecture diagram of railway signal equipment fault maintenance prototype system.

IV. APPLICATION ANALYSIS OF RAILWAY SIGNAL EQUIPMENT FAULT DIAGNOSIS UNDER THE IMPROVED FP-GROWTH ALGORITHM

The development momentum of railway construction projects has shown a good trend with the enhancement of China's economic strength. As one of the main means of transportation in China, the safety monitoring awareness of railways increases with the development of safety accidents. Research is improving FP- With the support of the Growth algorithm, the fault signal system is designed and analyzed experimentally. First, the experimental development environment is set up. The fault detection application environment includes two parts: browser and mobile terminal. The main parameter setting conditions are shown in Table I.

TABLE I. DEVELOPMENT ENVIRONMENT OF THE SYSTEM

Software type	Development environment		Version
Browser	Operating environment		Windows7 64bit
	Hardware environment	Hardware environment	i7-4790 CPU @ 3.60GHz 8G R
		Development tool	MyEclipse8.5
	Software environment	Database	MySQL (5.5.2)
		JDK	JDK1.8
		The server	Tomcat7.0
Mobile end	Operating system		Android4.0.4 or above
	Hardware environment		RAM 512M ROM 1G or above
	Development tool		Android Studio

The key to the detection of railway faults is to accurately judge the causes of the fault types. However, the levels and contents involved in railway operation and maintenance are relatively complex, and the original fault storage data has a certain amount of meaningless content. Research Using the VSM algorithm as the comparison algorithm, randomly select transaction data in the fault database for analysis, and ensure the consistency of the corresponding algorithm parameter settings when comparing the algorithms. The VSM algorithm uses the space vector of the feature items to represent the text information. The text similarity problem is transformed into a dimensional space vector problem. The data is counted and sorted on the algorithm running time and correlation accuracy, and the results are shown in Fig. 6.

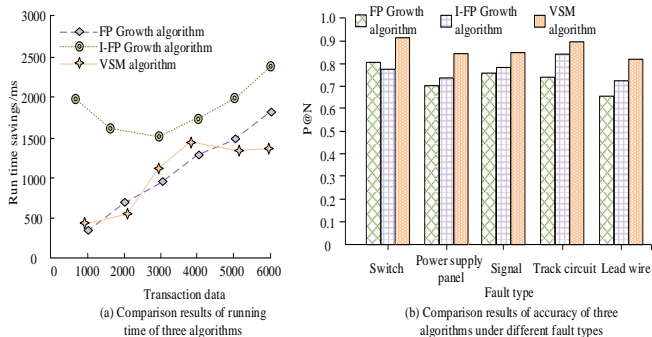

Fig. 6. Comparison results of running time and fault correlation accuracy of three algorithms.

In Fig. 6, “I - FP Growth algorithm” represents the improved FP-Growth algorithm proposed by the study. It can be seen from Fig. 6(a) that with the increase of transaction data volume, the performance of the three algorithms. The running time is quite different. The specific performance is that the overall running time of the traditional FP-Growth algorithm shows an upward trend. The minimum and maximum values are 350ms and 1700ms respectively, while the improved FP-Growth algorithm is It shows a downward trend first and then upward trend, and takes 3000 data sets as the dividing point, the minimum and maximum values are 1500ms and 2400ms, respectively. The VSM algorithm shows a relatively obvious numerical fluctuation. The reason is that the improvement of FP-Growth The algorithm can reduce the frequent itemsets occupying memory by dividing the database into subsets, and avoid the redundant database under the condition tree generation of the original algorithm. The results in Fig. 6(b) show that the P@ N is higher than the other two

algorithms, and its average accuracy exceeds 85%, which is about 5 times and 9 times that of the other two algorithms. The average accuracy of the traditional FP-Growth algorithm and the VSM algorithm are 81.4% and 82.1, respectively. %. The reason is that the improved FP-Growth algorithm can mine the correlation between the fault information by discretizing the weight feature words, which greatly improves the diagnostic accuracy of the algorithm. However, the traditional FP Growth algorithm and VSM algorithm lack of consideration of the potential information in the fault text data, and when encountering texts with similar contents but with synonyms, the calculated similarity will be far from the actual. Because the number of topics is artificially determined, there is a certain degree of experience, which ultimately leads to less fault features, and it is difficult to deeply mine the associated meaning of fault information, so it is difficult to maintain the accuracy of inferred information. The accuracy of the three algorithms is calculated, the result is shown in Fig. 7.

Fig. 7. PR curves of three algorithms.

The research uses the Precision-Recall (PR) curve as a judging tool. The more the PR curve is convex to the upper right, the better the data classification effect is. The PR curves on A and dataset B are closer to the upper right, and their average accuracy reaches 87.15%, which is much higher than the 83.12% and 81.06% of the FP-Growth algorithm and the VSM algorithm. The reason is that the VSM algorithm and the FP-Growth algorithm. It is difficult to reduce the negative impact of objective factors and algorithm parameters on the results of data processing only with vector features and correlations. The improved FP-Growth algorithm can effectively take into account the characteristics of railway signal faults for correlation analysis, reducing redundant and redundant data. Then, the statistical results of the algorithm are organized, and the results are shown in Fig. 8.

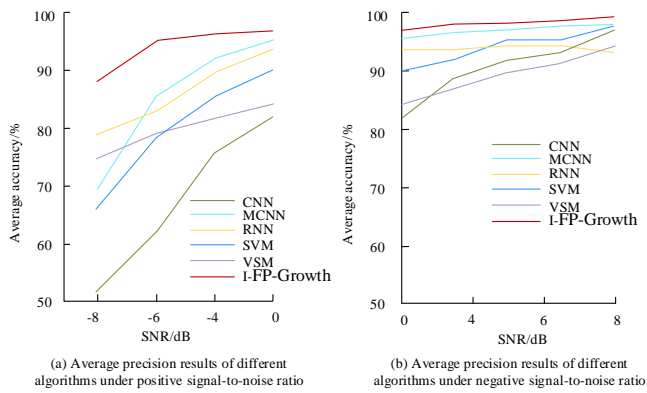

Fig. 8. Average precision results of different algorithms under signal-to-noise ratio.

Fig. 8 shows the average precision results of SNR under different algorithms. Fig. 8(a) shows that when the SNR is negative, the average precision results shown by various algorithms are quite different. When the ratio is -8 to -6, the average precision is from large to small as I- FP-Growth > RNN > VSM > MCNN > SVM > CNN, and when the signal-to-noise ratio is -6 to -0, the average precision is from large to the smaller is I- FP-Growth > MCNN > RNN > SVM > CNN. The average precision of the I- FP-Growth algorithm and the CNN algorithm shows a good upward trend, and the I- FP-Growth algorithm is better than the CNN algorithm. In Fig. 8(b), when the signal-to-noise ratio is positive, the overall average accuracy performance of the algorithms from good to poor is I -FP-Growth > MCNN > SVM > CNN > RNN > VSM, where I -FP-Growth algorithm The average precision shown is more than 95%, and the maximum value is 98.2%. The accuracy performance is second only to the I -FP-Growth algorithm for the MCNN algorithm, and the maximum value of the MCNN algorithm is 96.3%. As the ratio of signal power and noise power, the signal-to-noise ratio is one of the important indicators to characterize the signal quality. It may be difficult to express a good communication effect if signal power or noise power is used to represent the quality of signal processing. However, the reduction of signal-to-noise ratio will increase the bit error rate, which will greatly reduce the visual presentation effect of signal quality. When the SNR value is very low, it indicates that the working environment suffers from great noise interference, and the method in this paper still obtains satisfactory diagnostic accuracy in the task of adding very low SNR value noise signal. Although the noise causes a great difference in the data distribution of the training and test data sets in the target task, the method in this paper can still achieve effective fault diagnosis, which shows that the method in this paper has excellent robustness, can complete high-precision and stable fault diagnosis when the noise is seriously disturbed, and has good feature stability. The FP-Growth algorithm is less affected by the value of the signal-to-noise ratio, and is in an upward trend as a whole, and its average precision performance is better than other algorithms. The proposed algorithm is tested for signal generation and selected under different fault types. The signal data of the real curve is compared with it, and the results are shown in Fig. 9.

Fig. 9. Signal generation results under four fault types.

Fig. 9 represents the traditional FP-Growth algorithm, “Test signal 2” represents the improved FP-Growth algorithm, Fig. 9(a)-(d) are the track circuit fault, switch fault, signal fault and the connecting line is faulty. The results in Fig. 9(a) show that the test data 2 has a large difference between the real signal and the data before the time point of 300s, but with the increase of time, the magnitude of the power difference between the two is not More than 5%. However, the error between the signal curve graph of test data 1 and the real signal curve is large, and the fluctuation between the time point range (0-750) s is large. In Fig. 9(b), the test data the generated signal curve of 2 is continuous, and the time point at which the peak appears is basically the same as that of the real signal, and the trend is roughly the same. The signal curve of the improved algorithm in Fig. 9(c) is in the range of time points (0-380)s. The error range amplitude The value is less than 3%. The traditional FP-Growth algorithm curve has short and small fluctuations in a large range, and the error value compared with the real signal curve exceeds 6.8%. In Fig. 9(d), the curve of the improved FP-Growth algorithm is compared with the real signal. The fluctuation of the curve is basically the same, and the error margin value is less than 1%. However, the signal trend curve of the traditional FP-Growth algorithm has begun to deviate from the real signal curve after the time point is 100s, and the signal missing phenomenon occurs at the time point of 400s. The above results show that the improved FP-Growth algorithm can effectively detect and analyze signals of different fault types, and its accuracy and algorithm performance are better, which can effectively provide data support for fault diagnosis and maintenance countermeasures.

V. CONCLUSION

At present, the detection and diagnosis of railway faults mostly rely on manual operation. The complexity and redundancy of data types increase the difficulty and accuracy of fault analysis, and it is difficult to provide a guarantee for railway safety operation and maintenance. Based on the analysis and extraction, the improved FP-Growth algorithm is used to detect the fault signal data, and its performance test and application analysis are carried out. The results show that the improved FP-Growth algorithm takes 3000 data sets as the

dividing point. The maximum and minimum time are 2400ms and 1500ms, respectively, which are significantly higher than the 350ms and 1700ms of the traditional FP-Growth algorithm, and its P@N accuracy is 5 times and 9 times that of the other two algorithms. The classification performance of data mining is better, and its average accuracy reaches 87.15%, which is much higher than 83.12% and 81.06% of the FP-Growth algorithm and VSM algorithm. The average accuracy of the Growth algorithm is better than other algorithms, with a maximum value of 98.2%. The error values between the signal generation results and the real signals under the four fault types are small, all lower than 5%. The above results show that the improved FP-Growth algorithm proposed by the study is less affected by the value of the signal-to-noise ratio, and its performance is better than other algorithms in terms of running time saving and accuracy, and can effectively diagnose fault data. The research only selects text data as the data source for analysis, which makes the fault problems it solves more limited and less comprehensive. For example, the data generated by microcomputer monitoring may also be an important source of fault problems. Strengthening the diagnosis and analysis of multiple data is one of the important contents to be studied in the future. At the same time, the research only uses the feature weight number as the source of fault analysis, without taking into account the post fault risk. Therefore, it is necessary to carry out combined weighting in the later stage to ensure the accuracy of fault information features.

VI. FINDINGS

The research is supported by Provincial Project: Research and Practice of "223" Talent Training Model for Railway locomotive operation and maintenance professional (No. JGJX2022D721).

Abstract—The Increasing food needs and climate instability require researchers to innovate agriculture using smart greenhouses that are integrated with the Internet of Things (IoT). The Systematic Literature Review (SLR) begins with determining the topic keywords followed by searching the publisher link. It obtains 301 publications to be reviewed, 58 of which address the research questions posed. This study aims to collect and analyze in depth various knowledge about the Internet of Things Smart Greenhouse regarding sensors, methods used and publishers who publish the most related topics and the possibility of a research gap. The findings are as many as 12 publications that use temperature and humidity sensors and use the research and development methods integrated with Artificial intelligence methods, of which 62.1% do not use the datasets and 37.9% use the datasets. It obtains two possibilities of a research gap, namely improvising the algorithm and the dataset used and placing full control on the microcontroller development board and making IoT a supporting tool.

Keywords—IoT; SLR; Smart greenhouse; agriculture; research gap

I. INTRODUCTION

As the world's population grows and the need for food continues to increase and the decrease in agricultural land that is used as land for residence requires us to continue to innovate to meet these needs. Not only that climate change, which is increasingly erratic, make the planting period of food crops unstable. One of the innovations that can be done is to use a greenhouse in the agricultural process, by using a greenhouse the planting process can be carried out continuously regardless of the current climatic conditions. The placement of a greenhouse can also be done in places with a limited area such as the rooftop of a building. However, the greenhouse is just a place to grow crops, there needs to be innovation which will later be known as the Internet of Things Smart Greenhouse (IoTSG). These technological innovations include automation, artificial intelligence and the internet of things. The integration of these innovations is proven to have a good impact on agricultural processes and results in greenhouses as described below. This study dissected and dug deeper into various IoTSG literature regarding the sensors used, the methods applied, publisher statistics and the possibility of research gaps that were obtained so that improvisation of the IoTSG could be done.

More specifically about smart green houses, by using smart greenhouses, pest control of food crops can be done easily. As has been done by [1], the robot sprays pesticides around the plants for pest control. Preventive measures by predicting plant diseases in greenhouses can also be carried out as done by [2], [3] on cucumber and vegetable crops.

Preventive measures not only in controlling plant pest diseases, the harvesting process of mushroom plants can also be carried out by robots in a greenhouse environment [4], [5]. Irrigation management in greenhouses and large-scale planting areas can be done easily with the integration of IoT technology and remote sensing [6], [7]. Using the water more effectively and efficiently is an important aspect and needs to be taken seriously. Adequacy of water sources can be monitored and controlled properly by farmers, maintainers and administrators using mobile apps.

Various mobile apps based on the IoT platform can be used as part of an agriculture information system, such as in the FIWARE case [8], [9], this system allows every mobile app holder to convey information models sent to the cloud such as planting, harvesting, product packing, transportation and distribution of agricultural products. All the information is stored properly in the cloud database.

The development of smart greenhouses equipped with sensors, actuators and cloud connections as well as artificial intelligence algorithms has also been carried out, but the IoT platform system is still suspended [10]. The system that is built is called an automated hybrid, some systems work automatically and some are controlled manually.

In sensor data acquisition, the measurement accuracy of the measuring instrument is very important so that the resulting decision will be very accurate. What needs to be done is the calibration of measuring instruments made by comparison with standard measuring instruments. Not only on measuring instruments or IoT sensor systems, calibration is also carried out on measuring instruments or geomagnetic sensor systems and soil temperature sensors that produce the MAG3119 standard deviation sensor for x coordinates of 8.5, y coordinates of 2.66 and z coordinates of 1.9 and standard deviation of the DHT11 sensor of 0.1161 [11].

II. RESEARCH METHODOLOGY

This SLR was carried out with the ultimate goal of knowing the main information about the IoTSG that was documented. The SLR that was carried out was different from Traditional Literature Review (TLR), the SLR was carried out methodically and systematically. A good review is a review that can be imitated by other researchers and produces a better scientific value. In addition, it can also evaluate all existing evidence on a validated research topic. The SLR process that has been carried out can be seen in Fig. 1.

Fig. 1. SLR process [12].

The first thing to do in this SLR is planning a literature review by considering the needs of future research and defining a literature search protocol. Next, the supervisor analyzes and assesses its adequacy. Literature searches were carried out on various sources such as Scencedirect and IEEE. This search was conducted using only English keywords. Next, conduct an initial review of the search results that have been obtained to optimize publications that are very useful. To

delete duplicate publications and the rest of the results of this initial review, an in-depth analysis is carried out. The planning and realization stages of the SLR are described next, while the analysis of the results is presented in Section 4.

A. SLR Planning

To achieve the objectives as described above, Research Questions (RQ) are prepared to define research needs in more detail.

RQ1: What are the sensors used

RQ2: What are the methods used

RQ3: What publishers most related topics

RQ4: What are the research gap possibility

Literature search links include: Science Direct (<https://www.sciencedirect.com/>), IEEE (<https://ieeexplore.ieee.org/Xplore/home.jsp>) and MDPI publisher (<https://www.mdpi.com/>).

B. Search String

The search string uses keywords from the pre-planned research topic. There are four keywords used in this search, namely: IoT, farming, agriculture and greenhouse. The combination of four keywords above for literature searches on each search link is as follows:

C. IoT and Farming and Agriculture and Greenhouse

The search year is limited to 2017 to 2022. Search results are entered into the Zotero reference manager (<https://www.zotero.org/>) by forming a folder with the name of each folder, including: Scencedirect and IEEE.

III. RESULT AND DISCUSSION

A. Search String Review

At this stage, a partial review of literature obtained was carried out to obtain the most potential literature in this study. This partial review was carried out on the title and abstract, but in certain specifications a review was carried out on the introduction and conclusion. Definitions related to RQ were included and potentially useful literature was obtained. The realization of this SLR was only done with one search string. The total articles obtained were 301 articles as shown in Fig. 2.

The results were generally displayed at the beginning and the answer for each RQ was placed after it. From each reviewed paper, on average, each paper uses more than one sensor. The general number of sensors used were 26 sensors as shown in Fig. 3. The most widely used sensors in IoTSG were temperature and humidity sensors as many as 12 and the second most sensors are soil moisture sensors with 10.

The method used in each paper was a research and development method integrated with various other methods such as the addition of artificial intelligence as decision support such as recurrent neural networks, artificial neural networks, fuzzy logic, decision trees and so on.

Fig. 2. SLR Step.

Fig. 3. Sensors used

Development of a meteorological information system using the KOSEN Weather Station (KWS) [13], the Google web toolkit implementing the inter-browser communication method of remote method calls [14], sharing and linking data using partnerships for data innovation that provide the information needs of farmers [15]. The system can help farmers with weather forecasts that are stored in the cloud and information can be viewed via a web that is easy for farmers to understand. To compare the level of accuracy of KWS, the

same data was also built using the WXT520 sensor and it was proven that KWS was more accurate.

In greenhouses, there is a way to maximize plant growth by adding lighting using LEDs [16]. The method used was research and development to build an automatic control system for adding lighting using three LEDs among others: red LED, blue LED and a combination of both. Plant growth was observed using IoT, the results obtained from the addition of lighting were better seen from the leaf area index, leaf area

rate index and leaf weight rate, besides that the photosynthetic activity of plants was the highest if green light was added in terms of redistribution of quanta absorbed by the plant the entire leaf thickness [17].

By utilizing the application of IoT technology in agriculture, it is proven to increase productivity and production, harvest quality and resource efficiency. This research and development has been carried out using case studies and models as a service approach [18]–[21] real time and historical data and predictive models can be accessed via the web [22]. Firebase servers [23], one of the protocols used is LoRa which is considered sufficient to transmit small data from sensors to the cloud [24]–[26]. The system helps farmers because it produces a Decision Support System (DSS).

To improve the sustainability of agricultural cultivation, research and development methods are used integrated with deep learning, maps of planting sustainability forecasts can be obtained in real time using IoT networks [27].

Energy use in agricultural IoT systems is very important, it is necessary to pay attention and take into account the peak times and prediction models of energy use in IoT-based greenhouses have been made. Various algorithms have been used with research and development integrated with machine learning algorithms such as artificial neural networks, support vector machines, extreme gradient boost and random forest, in research [28] it was found that random forest produces predictions with the highest accuracy compared to other algorithms of 92 %. Integrate the Multi agent System to build greenhouse energy management to optimize energy use for two seasons in one year [29]. The original genetic algorithm was also used for predictive lighting for lighting control in the greenhouse, from the result of measurements that was carried out on growth there was no difference between greenhouses with lighting control and those without lighting control, but there was an efficient use of electrical energy from greenhouses that used lighting control [30].

Various algorithms have been developed for smart agriculture in greenhouses for various estimates that produce contributions, one of which is the algorithm that has been developed is a Repetitive Neural Network (RNN) which can estimate plant growth rates in greenhouses from 0.75 to 0.81 in all growth periods [31].

To obtain data from physical dynamics, a greenhouse requires sensors that are integrated in a wide range. A sensor network was built in a wireless sensor network (WSN) using a wireless Zigbee module with a mesh topology to sense air temperature, CO₂ levels [32]. In addition to the Zigbee module, you can also use the SL900A module in the UHF band [33]. The measurement of wave attenuation for the 2.4 GHz frequency band that penetrated the greenhouse was also measured to determine the effect of the waves on plants [34]. The data loss rate between data acquisition units in WSN was also measured, where data loss at the gateway was 1.52%, between gateways and server was 0.4% [35].

Not only in terms of sensor networks in greenhouses, the development of robot agriculture with a three-device system (3DS) for growth plant monitoring and pest management used

the main features of spectroscopy in Automated Guided Vehicles (AGV) [36]. In addition, by utilizing image analysis, image processing technology based on IoT cameras on tomato cultivation in greenhouses was able to estimate the number of blooming flowers, ripe fruit and harvest date with an error of approximately 2.03 days which can support plant growth management [37]. Sending the water level measurement value from the HC-SR04 sensor using a short message service shows good results and efficient [38], in maximum water level is 3.182m have resolution about 19.2 mm [39] and using MW22B multi turn Potentiometer have obtained vertical resolution about 0.03 m and error is 1.11% [40]. Detection of whole tomatoes used research and development methods by integrating Convolutional Neural Network (R-CNN) with an accuracy of 87.83% [41]. While using deep learning based classification and detection, the accuracy rate reached 99% [42], this method showed that the method used had great potential for predicting tomato ripeness and yield. A genetic algorithm was used to predict tomato growth using data on air temperature, PAR radiation and CO₂ concentration [43].

The algorithms used to estimate plant growth in greenhouses can also be used to estimate temperatures in cold greenhouses which cause the greenhouse to freeze, the method used is research and development by integrating Artificial Neural Network (ANN) algorithms and Fuzzy Associative Memory (FAM) with the effectiveness of the results reaching 90% accurate [44]. The root mean square error for temperature prediction with a value of 0.2, CO₂ 1.29 and humidity 0.14 [45], using a network of long short term memory and Recurrent NN with a root value mean square error of 0.289 [46]. The estimation of soil moisture content or soil moisture as a planting medium in a greenhouse can also use the ARX, ARMX, BJ and State algorithms with values of 91.31%, 91.09%, 91.08% and 90.75% [47]. The development model of Soil Moisture Forecasting (SMF) to activate Constant Moisture Automatic Irrigation (CAIS) using soil moisture data using sensors on planting media soil with different depths with the estimated error values of 0.011 [48], 0.962 [49], 0.014 [50]. The use of capacitive soil moisture sensors in measuring soil moisture is more resistant to rust than resistive soil moisture [51]. While using a model based on long short term memory, the error value is 0.72% [52] and if using a synthesis algorithm and combining it with a triangular affiliation function 0.99% [53]. By controlling soil moisture in the planting medium in the greenhouse automatically the estimation results of the algorithm used can save both, water irrigation and plant nutrients [54]. To overcome the problems of irrigation control due to the weakness of the internet network, an edge of the network was created. All sensor data is stored in the cloud database if there is a network problem it will affect the resulting decision [55].

The application of fuzzy inference engine determines for control and monitoring of hydroponic plants in greenhouses, the defuzzification obtained from sensor network data was used to control irrigation. Plant growth was monitored as input fuzzy parameters [56]. The application of fuzzy logic [57] and Neural Network [58] in this irrigation control can improve water use efficiency. Sensor networks have also been created in several zoning to facilitate obtaining fuzzy parameter input

data based on crop area [59]. The water needs of the plants are properly fulfilled and the efficiency of water use is obtained.

Generally, the roofing material for greenhouses is Ultra violet (UV) plastic, but the presence of a transparent photovoltaic solar module that is used as a roof as well as a source of energy for the greenhouse is a distinct advantage [60]. Sunlight as a light source for the photosynthesis process of plants in the greenhouse can enter through transparent photovoltaic which is also a source of electrical energy for the greenhouse.

In addition to the sensor network in the greenhouse which is used as data input in controlling the application of intelligent robots based on the Intelligent Mechatronic System, research has also been carried out. This intelligent robot was tasked with monitoring plant growth conditions in the greenhouse, this robot was used as a substitute for officers in the greenhouse and had an operating efficiency of 95.86% [61]. The use of drones in greenhouses can also help manage greenhouses. Simultaneous visual localization and mapping algorithms and ORB-SLAM utilize the camera as a sensor [62].

The publishers who published the most papers with related topics are MDPI as much as 56.9%, IFAC-Paper Online as much and Information Processing Agriculture as much as 10.3% and the remaining less than 5% as shown in Fig. 4, from this information we can obtain information highest probability of publishers publishing related topics. So that the technical paper that will be produced from this SLR is most likely to be published by the publishers who publish the most related topics.

To find out the quality of publishers at the Quartile level, each paper was analyzed through <https://www.scimagojr.com/> by using the ISSN number in each paper as a search keyword. The results of the journal rank analysis can be seen in Fig. 5.

Paper in quartile 1 is 72.4%, quartile 2 is 17.2% and quartile 3 is 10.3%. This shows that the papers on this SLR, which will later become references to technical papers, occupy journal quality in quartiles 1 to 3.

Fig. 4. Publisher statistics.

Fig. 5. Rank journal.

Fig. 6. Publication year.

To find out the research position of related topics, an analysis of the year of publication of each paper, the results are as shown in Fig. 6 above with the number of papers published in 2022 of 28.6% (until August 2022), 23.8% in 2021, 19.0% in 2020, 14.3% in 2019, 9.5% in 2018 and 4.8% in 2017. Judging from the increase in the number of related topics from year to year, it shows that related topics are still good topics for research.

Answering RQ4 to obtain a research gap, one of the analysis carried out was to group paper papers into two groups, namely groups of papers that use datasets and those that do not. The result obtained was 62.1% not using a dataset and 37.9% using a dataset as shown in Fig. 7 using a dataset.

Fig. 7. Dataset.

B. The Possibility of a Research Gap 1

To obtain the possibility of a research gap, a more in-depth analysis was carried out, both on papers that used datasets or not. Papers that used datasets were papers whose research used artificial intelligence such as machine learning using artificial neural network algorithms, decision trees, and so on. The dataset used was a private dataset built by collecting data for some time, then the dataset obtained was used to train the algorithm created. Prediction accuracy and speed as well as memory usage was recorded as a result of the study. To improve the algorithms and datasets that were created, we corresponded to researchers using the correspondence email contained in each paper. We asked for the source code and dataset, then compiled and tested it on another microprocessor, after obtaining the accuracy and predictive speed and using the same memory, we tried to improve and produced a research gap or novelty, and the results were presented in another technical paper. For example, an algorithm used to create a greenhouse temperature model using the Light Gradient Boosting Machine algorithm (LGBM) [63] median error /°C -0.027, mean error/°C -0.058 and Root Mean Square Error /°C 0.645, it is hoped that after improvement the algorithm (call the x algorithm) a smaller predictive error value is obtained as shown in Fig. 8.

Fig. 8. x algorithm.

Not only did the predictive error value improve, the time training x algorithm also improved as shown in Fig. 9.

Fig. 9. Time training algorithm.

For papers that did not use datasets in their research, they only built systems for control and monitoring in greenhouses.

In general, the system built in each paper can be seen in Fig. 10 as follows.

Fig. 10. General IoT system.

The IoTSG system that was created for both control and monitoring was completely on the server or on smart phone mobile apps. The developed board or nodeMCU is only a transmitter and receiver of the sensors and actuators in the greenhouse. The system is very dependent on internet connection, if the internet connection is good then monitoring greenhouse conditions such as temperature, humidity, soil moisture and soil nutrient levels were monitored properly as well as controlling actuators for the process of watering plants and fertilizing can be done properly too. If the internet connection is not good or disconnected, the system will die, monitoring and controlling cannot be done, which can be fatal to plants.

C. The Possibility of a Research Gap 2

To overcome the weaknesses of the IoT system, as stated above, it is necessary to add a developed board that is connected to sensors and actuators in the greenhouse to carry out real time control and monitoring and to compose the IoT system as supporting tools instead of full monitoring and control. In addition, artificial intelligence algorithms can be written on this developed board, for the results of this second novelty will be presented in the next technical paper.

IV. CONCLUSION AND FUTURE WORK

The results of the SLR confirmed that The Internet of Things research on Smart greenhouses was still a trend, as seen from the increasing number of related topics from year to year in quartile 1 to 3 journals. The most widely used sensors were temperature and humidity sensors with research and development methods that were integrated with other algorithms as a decision support system. The decision obtained was used to control the actuators in controlling conditions in the greenhouse such as temperature conditions, air humidity, soil moisture, robot control, nutrient levels of both soil and water planting media.

From the publisher statistics, information was obtained that published the most related topics so that we can choose where to publish the next technical paper; this increased the probability of an accepted paper.

For future work, we will conduct research with topics obtained from two possibilities of a research gap, the first future work: the improving algorithm to obtain better prediction and error values than before. The second future work: the addition of a developed board like developed board

which is connected to sensors and actuators in the greenhouse to carry out real time control and monitoring. The developed board communicates serially with the cloud-connected Nodemcu.

V. DECLARATION AND COMPETING INTEREST

The researchers declare that they have no known competing financial interests or personal relationships that could have appeared to influence the work reported in this paper.

An Adaptive Texture Enhancement Algorithm for AR Live Screen Based on Approximate Matching

Panpan Yang, Lingfei Ma, Chao Yin*, Yang Ping

Institute of Data Science and Agricultural Economy
Beijing Academy of Agricultural and Forestry Sciences, Beijing, 100097, China

Abstract—In order to improve the visual effect of AR live video detail texture, an adaptive enhancement algorithm based on approximate matching is proposed. According to the local self-similarity of the original image, the best matching block of the initial super-resolution image block is obtained. After extracting its high-frequency information, the improved singular value decomposition (SVD) is used to embed the watermark into the original super-resolution gray image; And through the watermark extraction and reconstruction matrix, the effective high-frequency detail texture information is obtained, then the final super-resolution image is obtained, and the AR live video detail texture enhancement is completed. The experimental results show that the peak signal-to-noise ratio, structure similarity and feature similarity of the algorithm are high, and the reconstruction effect is good; After detail texture enhancement, the detail texture clarity and edge sharpness of AR live picture are better, and the best visual effect is achieved.

Keywords—Approximate matching; AR live; picture details; adaptive; texture enhancement; matrix reconstruction

I. INTRODUCTION

AR, also known as augmented reality, is a fusion technology used between the real and virtual worlds. It can realize the real environment and virtual objects overlap, so that both appear in the same screen. It has 5 core technologies, namely, tracking registration, display, virtual object generation, interaction and merging [1]. AR live broadcast is the product of this technology, which uses cameras and sensors to collect information and data in real environment. After the input processor is analyzed and reconstructed, it is returned to the display terminal such as the camera, And AR live terminal screens can have multiple special effects [2]. AR live images usually contain three categories, such as flower, car screen type images, human-dominated portrait images and scene images that can sense the environment. When these pictures are presented through a display terminal such as a camera, the details and texture of the live pictures will be affected by the network, device itself and other problems [3]. The visual homogeneity in the picture is the detailed texture of the picture, and it also represents a feature of the picture. Texture can give the picture a depth or can be understood as an object of visual presentation. Approximate matching refers to the image which has the highest similarity degree and can be matched with the original image by obtaining the most similar image, and can retain the original image features.

In order to ensure the visual effect of the detailed texture of AR live images, the algorithms based on guiding coefficient weighting, NSST multi-scale and deep learning are proposed

respectively in [4], [5] and [6] to improve the visual effect of images. Guide coefficient weighting algorithm in the enhancement process. Mainly through the brightness of the image and non-brightness region to complete the division of the screen processing. NSST multi-scale algorithm is the implementation of low-light picture conversion to complete the screen processing. Deep learning algorithm adopts the strategy of mixing deep learning and image fusion to improve the image quality. In the process of processing, the three algorithms do not extract and reconstruct the detailed texture features, so the clarity of the enhanced texture is poor. Based on this, this paper uses approximate matching algorithm to enhance the detail texture and improve the clarity of detail texture.

II. APPROXIMATE MATCHING TEXTURE ADAPTIVE ENHANCEMENT ALGORITHM

A. Approximate Matching of AR Live Broadcast Screen Detail Texture High Frequency Component Extraction

The pictures in the local neighborhood have similar picture image blocks, which is an obvious feature of the local self-similarity of AR live broadcast pictures. And there are the same scale or different scales in the same picture. Correlation analysis and research are carried out on this feature, and the high frequency detail of similar blocks are extracted and analyzed. The detailed texture of the picture is processed by synthetic method. High frequency detail is obtained from high resolution images, and super-resolution reconstruction is based on local self-similarity. The original live picture I , its corresponding high frequency live picture HF and its corresponding interpolation magnified live picture LR are used as the training set to generate the super-resolution AR live picture HR .

The initial high-resolution image LR is obtained by the contour template interpolation algorithm, and I is amplified after the implementation of processing, and the magnification is α . In order to avoid the missing of the image detail texture, it is necessary to determine the window in LR , which is represented by small window image block e . And formed in the case of pixel (i, j) as the center; If a similar block is retrieved at the same time, belongs to a large window of q , and is in I 's position for (x, y) , then:

*Corresponding Author.

$$x = i/\alpha, y = j/\alpha \quad (1)$$

In formula: The scaling factor is expressed as α . Through matching window e in the search window f near the scope of similar block search, access to similar blocks n , is e_1, e_2, \dots, e_n . Screen e block can be solved by weighted average of similar blocks. The solution formula is as follows:

$$\hat{e} = \sum_k w(d)e(d) \quad (2)$$

Expression: the d similar block and weight are described by $e(d)$ and $w(d)$. And the weights meet the following conditions:

$$\sum_d w(d) = 1, 0 \leq w(d) \leq 1 \quad (3)$$

$w(d)$ can be described by equation (4):

$$w(d) = \frac{1}{Z} \exp\left(-\frac{l(d)}{h^2}\right) \quad (4)$$

In the formula: the pixel intensity of the picture block is represented by h^2 . The Euclidean distance and normalization constant of picture blocks e and e_k are $l(d)$ and Z respectively.

$$l(d) = \|e - e_k\|_G^2 \quad (5)$$

In the formula: the controllable coefficient of the picture block is represented by k . The grayscale of the high-frequency picture block is denoted by G . On this basis, Z is solved by formula (6):

$$Z = \sum_k \exp\left(-\frac{l(d)}{h^2}\right) \quad (6)$$

After the self-similarity super-resolution reconstruction of the AR live broadcast screen is completed by the above method, it will ensure the integrity of the detailed texture features and implement the self-similarity reconstruction.

In order to obtain the most similar matching block R in the vicinity of the retrieval window f . After the matching search is completed through e , the high-frequency picture block R_{mn} corresponding to R is obtained, and belongs to

HF . The similarity indicator is described by the mean of the sum of absolute values of the difference between two picture blocks. Therefore, the total absolute value of the difference between the two picture blocks is the matching block with the highest degree of similarity [7], then:

$$R = \arg \min |e - f| \quad (7)$$

The calculation formula to obtain the high-frequency picture block of R_{mn} is:

$$R_{mn} = R - R * C_0 \quad (8)$$

Where the guided filter and convolution are described by C_0 and $*$, respectively. To obtain the sum of \hat{e} and R_{mn} , it is done by formulas (2) and (8). Its calculation formula is:

$$e = \hat{e} \sqcup R_{mn} \quad (9)$$

B. Improved Singular Value Decomposition Detail Texture Enhancement

The high-frequency picture block R_{mn} obtained above is processed as follows with the improved singular value decomposition:

1) *Watermark embedding*: Let W_{pq} ($p = q$) denote the matrix with embedded watermark, and P denote the dimension of the matrix.

a) After the high-frequency picture block R_{mn} is decomposed by the first-order wavelet transform, a new matrix B can be obtained, and it is composed of low-frequency coefficients [8].

b) Use 16×16 blocks to perform processing on B , then $B_{ij} = f_{ij}(x, y)$ represents each block after processing, and $i = 1, 2, \dots, m$, $j = 1, 2, \dots, n$, $x \geq 1$, $16 \geq y$. The decomposition formula of each block matrix after processing is:

$$B_{ij} = U_{ij} S_{ij} V_{ij}^T \quad (10)$$

Where: U and V are orthogonal matrices.

c) Suppose the largest singular value of S_{ij} is denoted by ϕ_{ij} . According to the properties of singular value decomposition, ϕ_{ij} is adjusted, and the adjustment formula is:

$$\left. \begin{aligned} & \text{if } (W_{ij} = 1) \left\{ \begin{aligned} & \text{if } (\text{mod}(\varphi_{ij}, a) < a/4) \varphi_{ij} = \\ & \varphi_{ij} - (\text{mod}(\varphi_{ij}, a) - a/4); \\ & \text{else } \varphi_{ij} = \varphi_{ij} - (\text{mod}(\varphi_{ij}, a) + 3 * a/4) \end{aligned} \right. \\ & \text{else } \left\{ \begin{aligned} & \text{if } (\text{mod}(\varphi_{ij}, a) > 3 * a/4) \varphi_{ij} = \\ & \varphi_{ij} - (\text{mod}(\varphi_{ij}, a) + 5 * a/4); \\ & \text{else } \varphi_{ij} = \varphi_{ij} - (\text{mod}(\varphi_{ij}, a) + a/4) \end{aligned} \right. \end{aligned} \right\} \quad (11)$$

In the formula: $\text{mod}(x, y)$ is used to represent $x \bmod y$. The watermark signal values corresponding to the embedded strength factor and S_{ij} are a and W_{ij} , respectively. The adjusted S_{ij} is represented by \hat{S}_{ij} , and singular value decomposition is performed on all \hat{S}_{ij} , so that each block contains watermark information [9].

d) According to the ordinal position, all the blocks containing the watermark are recombined to form a new matrix R' of low frequency coefficients. Reconstruction method is used to process the changed wavelet coefficients [10] to obtain the super-resolution grayscale image I' with the initial watermark embedded.

2) Watermark extraction

a) I' is processed by first-order wavelet decomposition to obtain a matrix M , which consists of decomposed low-frequency coefficients.

b) Use 16×16 blocks to process M , then $M_{ij} = q_{ij}(x, y)$ represents each block after processing, and $i = 1, 2, \dots, m, j = 1, 2, \dots, n, x \geq 1, 16 \geq y$.

$$M_{ij} = U'_{ij} S'_{ij} V'^T_{ij} \quad (12)$$

c) If the largest singular value of S'_{ij} is represented by σ'_{ij} , and adjust it, its formula is:

$$iq(\text{mod}(\varphi'_{ij}, s) > s/2) \{W_{ij} = 1\} \text{ else } \{W_{ij} = 0\} \quad (13)$$

The above steps are taken, and each block is processed to obtain the restored watermark binary picture B_i .

Referring to the overlapping characteristics of the blocks, it is impossible to directly add the B_i obtained by reconstruction to M_{ij} , and a control strategy should be adopted for the overlap to avoid the interference caused by it

[11]. Therefore, the window processing is performed on the picture block, which is completed by the Gaussian function.

And it is centrally symmetric, and \bar{R}_{mns} is obtained after processing, and its formula is:

$$\bar{R}_{mns} = \bar{R}_{mn} G_{\varphi}(\|x - x_c\|) \quad (14)$$

$$G_{\varphi}(\|x - x_c\|) = \frac{1}{2\pi\varphi^2} u^{-\frac{\|x-x_c\|^2}{2\varphi^2}}$$

Where $G_{\varphi}(\|x - x_c\|)$ is the Gaussian window function.

The acquired \bar{R}_{mns} and M_{ij} are combined to form a super-resolution picture M^i_{mn} , which contains all the detailed texture features of the high-resolution picture [12], which is:

$$M^i_{mn} = M_{ij} + \bar{R}_{mns} \quad (15)$$

C. Algorithm Flow

The implementation of adaptive enhancement algorithm based on approximate matching for AR live-broadcast image details texture is divided into two parts. One is to get the high frequency information of the best matching block based on approximate matching. Secondly, the improved singular value decomposition is used to reconstruct the matrix to obtain the effective high frequency texture information. The detailed texture is synthesized to obtain the enhanced ultra-detailed texture [13-15]. Its enhanced overall flow is shown in Fig. 1.

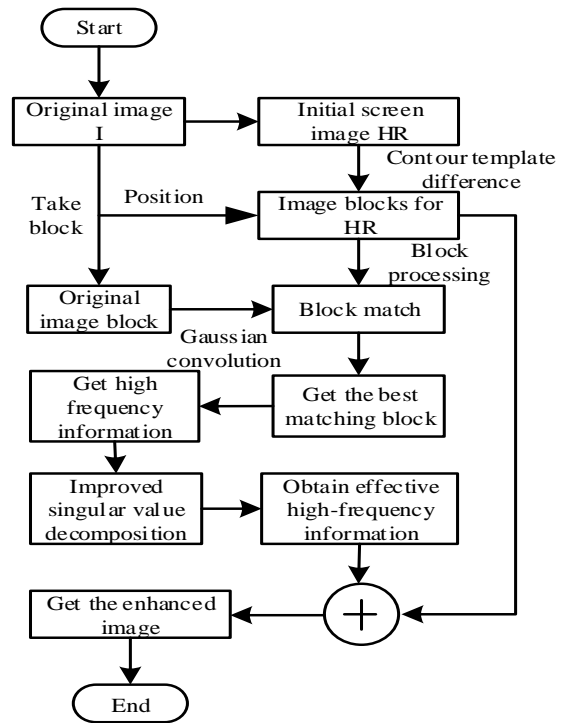

Fig. 1. Algorithmic flow.

III. TEST ANALYSIS

In order to test this algorithm for AR live picture details texture enhancement effect. Five live images are randomly selected from the image database of an AR live company in order to verify the effectiveness of the algorithm. The test environment operating system was Windows 10 x 64 8 GB of memory with CPU 3.4 GHz. The application development environment is Matlab 2018a.

In order to test the influence of scaling factor values on approximate matching, the sizes of matching blocks and retrieval windows are set to 2×2 and 4×4 respectively, and the gray space values (0 ~ 255) are used as features to obtain the normalized mean of the total absolute values of the difference between the two blocks. The smaller the value, the higher the similarity of the matching block. Test the results of the different zoom factor values, as shown in Fig. 2.

Fig. 2. Normalized mean change results.

According to the test results in Fig. 2, it can be seen that with the increase of the scaling factor value, the normalized mean value first decreases and then increases. When the scaling factor is 1.2, the normalized mean is the smallest. So in this article, determine that the zoom factor has a value of 1.2. In order to more intuitively reflect the impact of the algorithm with the scaling factor changes in image quality. We plotted the changes in the FSIM (feature similarity) metrics to show the picture quality, as shown in Fig. 3.

Fig. 3. Influence of Zoom Factor Parameter Value on Screen.

As shown in Fig. 3, the FSIM value is highest when the scale factor parameter is set to a value of 1.2. When the scaling factor parameter value reaches 0.97, the picture quality is the best. Therefore, the best scaling factor for this article is 1.2.

The quality of reconstructed image has some influence on the effect of texture enhancement. In order to measure the quality of the reconstructed images, peak signal-to-noise ratio (PSNR), structural similarity (MSSIM) and feature similarity (FSIM) are used as measurement criteria. The higher the value is, the better the quality is. The calculation formulas are as follows:

$$PSNR = 10 \lg \left(\frac{255^2}{\frac{1}{MN} \sum_{i=1}^M \sum_{j=1}^N (X_1(i, j) - X_2(i, j))^2} \right) \quad (16)$$

$$MSSIM = \frac{1}{W} \sum_{i=1}^W (b_i)^\alpha (c_i)^\rho (h_i)^\gamma \quad (17)$$

$$FSIM = \frac{\sum S_L(X_1, X_2) G(X_1, X_2)}{\sum G(X_1, X_2)} \quad (18)$$

Type: original picture and reconstruction picture for X_1 and X_2 . The brightness, contrast and structure comparison functions of L block are b_i , c_i and h_i . The corresponding adjustment weights are α , ρ and γ . The number of blocks is W . The phase congruence is described by $S_L(X_1, X_2)$. The similarity measure of gradient features is described by $G(X_1, X_2)$.

In the process of decomposition, the value of the threshold has a great influence on the effect of image details texture enhancement. We choose PSNR and MSSIM as the metrics to get the effect of enhancing the image detail texture under different threshold values. The results are shown in Fig. 4 and Fig. 5.

Fig. 4. Picture enhancement PSNR results with different thresholds

Fig. 5. Picture enhancement MSSIM results with different thresholds

According to Figs. 4 and 5, the PSNR and MSSIM results of the five live images are changed under different thresholds. When the threshold value is 3.0, the PSNR and MSSIM values of all live images after enhancement are the highest, indicating that the effect is best when the threshold value is 3.0. So the threshold value is 3.0 in the following experiment.

The enhanced algorithm based on the weight of the guide coefficient (Document [4] algorithm), the enhanced algorithm based on the multi-scale of NSST (Document [5] algorithm) and the enhanced algorithm based on the deep learning algorithm (Document [6] algorithm) are selected as the comparison algorithm. Through the above formula to obtain the effect of three kinds of algorithm picture reconstruction, as shown in Table I.

According to the test results in Table I, the results of PSNR, MSSIM and FSIM show that the three values of this algorithm are the best, significantly better than the three contrast algorithms. Therefore, it is shown that the reconstruction features of the proposed algorithm are closer to those of the original image and the reconstruction effect is better.

In order to test the subjective effect of the enhanced method, the detailed texture visual effect image of the enhanced image is obtained by three methods. Due to space constraints, only Screen 3 was selected for the test, as shown in Fig. 6.

According to the test results in Fig. 6, it can be seen that after the enhancement, the clarity and edge sharpness of the texture details are better than those of the three contrast algorithms. Experimental results show that the proposed algorithm is better than three contrast methods.

TABLE I. RECONSTRUCTION RESULTS OF THREE ALGORITHMS

Test content	Image number	Algorithm of this paper	Bootstrap weighted enhancement algorithm	Multiscale enhancement algorithm based on NSST	Enhancement algorithm based on deep learning
PSNR/dB	1	28	23	24	23
	2	29	25	26	24
	3	34	30	31	29
	4	32	29	27	28
	5	26	22	23	23

(b) Enhancement algorithm based on guide coefficient weighting

(c) NSST based multi-scale enhancement algorithm

(d) Enhancement algorithm based on deep Learning

Fig. 6. The visual comparison effect of the three methods.

Fig. 7. Changes in MSSIM and FSIM indicators.

The algorithm designed in this paper is to improve the quality of AR live images, but the live images change with time. Therefore, it is necessary to verify the quality of the algorithm. With time as a variable, PSNR, MSSIM, and FSIM as metrics, the test results are shown in Fig. 7 and Fig. 8.

According to the changes of the three indexes in Fig. 7 and Fig. 8, the indexes of MSSIM and FSIM are more than 0.93 and PSNR is more than 26dB, and the indexes are higher. Therefore, the algorithm presented in this paper has good continuity effect and meets the requirements of AR live broadcast.

Fig. 8. Changes in PSNR indicators.

IV. CONCLUSION

AR live broadcast is the product of the rapid development of the Internet. It has been used in many fields, such as education, e-commerce and so on. This paper uses approximate matching algorithm to enhance the image texture details in order to improve the visual effect of AR live images. Self-similarity high frequency matching block is used to obtain and improve the singular value decomposition algorithm to reconstruct the image details and enhance the image texture. Experimental results show that the algorithm has good enhancement effect, and the sharpness and clarity of texture details are improved.

ACKNOWLEDGMENT

The study was supported by Scientific research project of the first-class Municipal Science and Technology Commission: Youth Fund of Beijing Academy of agricultural and Forestry Sciences, "recognition and production state determination of greenhouse vegetables based on image recognition" (qnjj202213).

State Grid Jibei Electric Power Company Limited, Smart Distribution Network Center, Beijing, China⁴

Abstract—As one of the core equipment of power system, power transformer has great fault influence and complex fault causes. In order to ensure the safe and stable operation of power system, its operation state must be monitored and judged. With the increasing maturity of the Internet industry and the continuous development of sensor technology, the emergence of smart grid has contributed to the realization of intelligent transformer on-line monitoring, condition evaluation and fault diagnosis. This paper studies the deep primary and secondary fusion transformer based on the Internet of Things technology, summarizes the development status of intelligent transformer and its existing problems on the basis of relevant literature, and proposes the optimization technology of deep primary and secondary fusion transformer based on the Internet of Things technology to solve its existing problems, and conducts related experiments and fault detection research on the proposed technology. The experimental results show that this optimization technology has good feasibility, good self-state evaluation and fault diagnosis functions. The deep primary and secondary fusion based on the Internet of Things technology proposed in this study can increase the reliability monitoring of intelligent transformer operation, provide a strong technical guarantee for the normal operation of distribution network, and also provide important technical support for the next research of distribution network technology.

Keywords—Internet of things technology; primary and secondary integration; smart transformer; fault detection

I. INTRODUCTION

In recent years, the rapid growth of China's national economy has driven the rapid growth of energy industry, the main industry of economic growth [1, 2]. In order to meet the needs of national economic development, China Power Grid Corporation has successively put forward the construction objectives of "building a strong intelligent network" and "developing UHV technology", and strive to build a "3 / 5" structure with international scale and a network system to realize efficient power supply [3, 4]. In such a "large power grid", the power transformer as the power supply infrastructure of node substation is more important, which directly affects the safety and reliability of network power supply system [5, 6]. In addition to a large number of more functional relay protection and operation control equipment, modern power transformers also require that they can operate continuously in the power grid for a longer and longer time. Therefore, the accidents caused by the failure of transformer parts are completely unavoidable [7, 8]. In case of failure or major accident, even if there is an emergency plan in place in

advance, it will not ensure that the power failure does not affect residents' daily life and commercial operation. Therefore, due to the particularity and complexity of transformer operation, it is of great practical significance to effectively monitor the transformer from multiple directions and angles, diagnose whether it is in an abnormal state, whether there is the possibility of error, and how to analyze, judge and use it [9, 10].

Regarding the research on intelligent evaluation and early warning of substation equipment status, some researchers have proposed that the comprehensive evaluation method in China is mainly based on the equipment status evaluation guidelines issued by the State Grid Corporation comprehensive evaluation method. The state quantities used in the method are relatively comprehensive, including family defects, maintenance records, inspection information, online monitoring, live detection and preventive test data, etc., which basically cover all relevant information of the equipment, including a large number of non-stop power supplies. The detection status quantity and the power failure detection status quantity, therefore, the workload of data acquisition in actual operation is relatively large. In addition, the introduction of various artificial intelligence methods into equipment condition evaluation has become a hot topic at home and abroad. The most widely used intelligent evaluation method is the fuzzy comprehensive evaluation method. The core of the fuzzy comprehensive evaluation method is the determination of the membership function and the determination of the weight. In addition, the gray theory, matter element analysis, evidence theory, Bayesian network, support vector machine and other intelligence analytical methods are also widely used in equipment condition evaluation [11]. Some researchers have proposed that the basic condition for power transformer maintenance is accurate, reasonable and efficient power transformer maintenance, and the reliability of evaluation directly affects the reliability of maintenance decision-making. At this stage, the latest research results are mainly focused on the use of intelligent algorithms to analyze DGA data and part of the electric quantity. These are the lack of overall representation of the transformer status. How to simplify system evaluation, maximize the collection of collectible information, and fully reflect the condition of the transformer is a very important step in the process of transformer maintenance. Nowadays, users have higher and higher requirements for reliability, and it is developing dynamically [12]. In summary, there are many research results on power transformers, but there are few research results on deep

primary and secondary fusion transformers based on the Internet of Things technology.

This article studies the deep primary and secondary fusion transformer based on the Internet of Things technology. After a general understanding of the relevant theories on the basis of relevant literature data, the realization of deep primary and secondary fusion is analyzed, and then conduct experiments on the transformer with deep primary and secondary fusion. This experiment uses the DGA data and electrical test data of the selected transformer as the input feature vector of the diagnosis model, according to the existing research literature, the five characteristic gases are used as the input vector of the multi-parameter information fusion transformer fault diagnosis model. The transformer automatic fault diagnosis model is modeled based on Adaboost_rbf and dsmt, the sample data set is preprocessed by normalization method. Taking the relative volume fractions of the five characteristic gases in the DGA as the input feature vector, the three models of BP neural network, M-RVM, AdaBoost_RBF1 and PSO-IGWO optimized hybrid KELM are used to diagnose transformer faults. It is concluded that the diagnostic accuracy of transformers based on deep primary and secondary fusion is higher than that of transformers based on DGA.

II. DEEP PRIMARY AND SECONDARY FUSION TRANSFORMER RESEARCH

A. Problems with Smart Transformers

1) *Integrated design of overall structure:* The integrated design of sensors and transformers needs to fully consider issues such as insulation, energy acquisition, communication, interference, heat dissipation, and maintenance. It also needs to meet the conditions of outdoor operation, and complete the research and design of high protection level structures according to actual use scenarios. In addition, it is more difficult to combine control methods such as capacity adjustment, voltage adjustment, three-phase power adjustment, and automatic load switching with the transformer itself.

2) *Self-diagnosis and control system mechanism research and development:* The intelligent fusion terminal needs to collect information for self-evaluation and self-diagnosis of the transformer, accurately reflect the operating status of the equipment, the appearance of the equipment, and the environmental operation and maintenance status to the platform, and can realize the corresponding automatic adjustment after being approved by the equipment owner or superior management unit as well as autonomous system

actions with other equipment (such as distribution transformer clusters, low-voltage switches, etc), reasonable and accurate judgment algorithms and control mechanisms are essential for this project.

3) *Wireless communication:* In the data transmission part, the collected information includes analog signals and digital signals, and the types of information sources are different. This requires better compatibility of the communication module, and in this project, the data collected by the sensor is mainly collected through wireless communication. Transmitted to the remote monitoring terminal, this poses a challenge to data transmission. First, the transmission distance must be large enough, and secondly, the transmission delay must be small enough. Foreign countries usually use a combination of multiple communication technology methods, and integrate the best communication methods according to the actual needs of condition monitoring.

B. The Realization of Deep One-two Fusion Optimize the Layout of Transformer Structure

1) *Transformer monitoring unit:* The transformer online monitoring unit has a variety of communication interfaces, which can communicate with the transformer's environmental sensors, noise sensors, power quality management modules, oil chromatographic analysis modules, etc. It also has the ability to interact with the intelligent terminal of the station and the master station. The online monitoring device can also directly control the voltage and capacity adjustment switches of the transformer through the built-in APP capacity and voltage adjustment strategy, and through the built-in algorithm, cut off some unimportant branches when the transformer is overloaded to ensure the safe operation of the transformer.

2) *Communication structure:* The online monitoring platform communicates with the master station through wireless, optical fiber and other methods, interacts with data through 104 or MQTT, accepts the APP download of the master station, parameter settings, container management, cluster control; and can be integrated with the station area through the terminal 104 or MQTT interactive data; the environment and noise of the transformer are mainly collected through 485, wireless and other methods for data analysis; the component collection of the oil chromatogram is mainly carried out through 485; the communication with the power quality management module is mainly through the 485 method, Fig. 1.

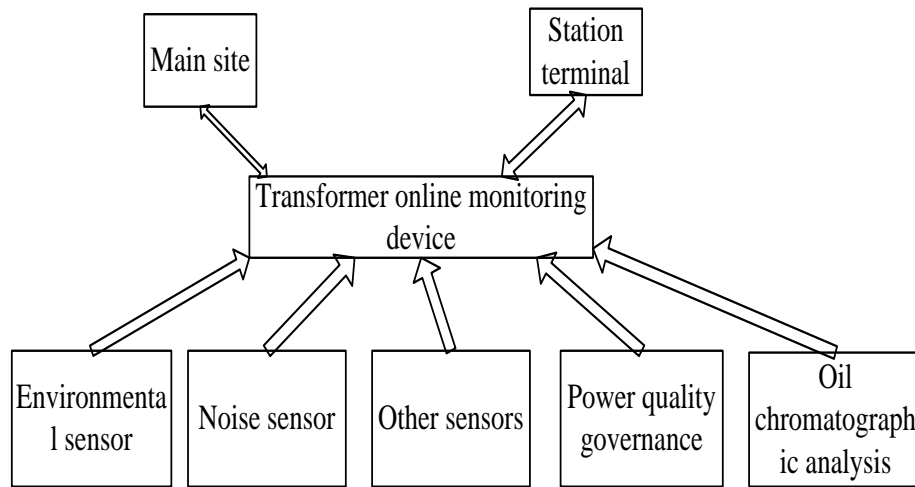

Fig. 1. Communication architecture.

C. Fault Diagnosis

1) Comprehensive application of artificial neural network (ANN) and evidence theory and other methods to construct a multi-information fusion comprehensive state assessment model for transformers. First, the data preprocessing module processes the operating data, constructs the parameter subspace and the fault subspace, selects training samples from the actual operating data, and constructs and trains the sub-network. Based on the evidence theory, construct the identification framework of the diagnosis system, determine the basic probability distribution function of each evidence, and seek to effectively fuse multiple preliminary diagnosis results, including models and methods that can quickly fuse feature-level diagnosis results based on multiple methods. Finally, the evidence is synthesized and diagnosed, so that it can identify the fault correctly and efficiently.

2) Through the creation of state test scenarios, a comprehensive simulation of the various states of the transformer, and the creation of a test data information database. Find the mutual influence relationship between the amount of information sensed by the distribution transformer, establish the transformer condition monitoring system and fault diagnosis model, complete the interactive algorithm between the computing unit and the ontology perception, environmental perception, historical state extraction, interconnection of similar equipment, etc, and realize the status communication and exchange between the equipment owner and the superior management unit, establish the transformer load capacity evaluation parameter system, and evaluate and predict the transformer load capacity. Incorporating systematic data such as transformer body structure, internal faults, technical parameters, cooling methods, power grid operating environment, geographical and meteorological environment, and using principal component analysis algorithm to establish a transformer state evaluation model to obtain a transformer health status score.

D. Panorama Detection

1) Distribution line image monitoring system is suitable for visual monitoring and patrolling of distribution lines. It is a lightweight and convenient installation image monitoring device designed for the visualization of distribution lines. This device can pass 3G/4G/OPGW, optical fiber network, etc, will transmit pictures to the monitoring center regularly, and line maintenance personnel can realize remote picture browsing through computer clients and WeChat clients. The realized functions mainly include: picture capture; timed picture upload; when there is no network or poor signal, the current picture is temporarily stored, and the picture will be resumed after the network is normal; remote manual wake-up capture/small video recording; supporting mobile client, anytime grasp the line status anywhere, and effectively solve the problem of high cost of line channel visualization.

2) Configure high/low voltage current and voltage transformer (built-in), pressure sensor, low oil level / pressure release sensor, temperature sensor, vibration sensor, configure oil chromatography online monitoring device, partial discharge detection device, camera (support picture with 4G / 5G way to upload to the station area).

E. Application of Iot Technology in Deep Primary and Secondary Integration Transformers

1) *Global positioning system:* Applying the timing characteristics of the GPS to the power system is more important and more extensive than the general positioning characteristics [13]. The power system includes monitoring and protection systems, such as automated microcomputers and safety systems, dispatch automation systems, monitoring systems, fault recorders and accident recorders. All of the above require an accurate time standard to achieve accurate synchronization. In addition, with the development and expansion of the power system, especially the expansion of the power grid, higher requirements are put forward for the convenience and accuracy of the time standard.

2) *Radio frequency technology*: Radio frequency technology mainly identifies tags. The label usually represents the data information on the device, which is set when the device leaves the factory. The information contained in the label usually refers to data parameters that may have a significant impact [14]. The label and the measured object have a binding relationship. The device information reflected on the label usually includes parameters that have a significant impact on the device, rated voltage, and operating current.

F. Fusion Algorithm

1) The RBF neural network is based on how to manipulate multiple variables and is a three-level network suitable for solving classification problems. A general RBF neural network structure composed of input layer, hidden layer and output layer [15].

The node output returned by the hidden layer of the RBF network can be expressed as:

$$r = \exp\left(-\frac{1}{2\sigma^2}\|R-T\|^2\right) \quad (1)$$

Among them, n is the output of the final hidden layer node normalized in the hidden layer, r is the return input vector n , t is the normalized center vector of the return function of the final hidden layer node, and σ is the normalization of the final hidden layer node the output, the normalized linear combination formula of the final hidden layer node is as follows:

$$y = \sum_{k=1}^h \omega r - \theta_j \quad (2)$$

Where r is the output returned by the hidden layer from the node, y is the output of the hidden layer from node j , a is the threshold for returning from the hidden layer to the output plane, and θ is the input threshold for outputting node j from the hidden layer.

2) The structure of DBN is to iterate multiple restricted Boltzmann machines (RBMs), each layer is composed of multiple RBMs, and form a multi-layer deep learning structure by stacking multiple RBMs. These restricted Boltzmann machines can complete bottom-up unsupervised learning. According to the sensing data characteristics of substation equipment, a BP network is set at the top layer as the top-down supervised learning in deep learning [16]. This structure can better obtain the excellent feature expression of data, that is, more abstract and effective high-level features are extracted on the basis of multiple fusion features. In order to realize the evaluation of equipment status, on the basis of feature extraction, a supervised classifier needs to be added at the top of the network to predict and classify the equipment status, so as to determine the early warning and diagnosis information according to the classification results [17]. The basic structure of equipment condition assessment network is shown in Fig. 2.

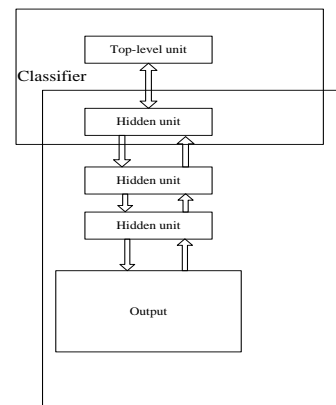

Fig. 2. Basic structure of equipment condition assessment network.

III. DEEP PRIMARY AND SECONDARY FUSION TRANSFORMER EXPERIMENT BASED ON INTERNET OF THINGS TECHNOLOGY

A. The Purpose of the Experiment

This article conducts experiments on the deep primary and secondary fusion transformers based on the Internet of Things technology, mainly to test the fault detection of the proposed deep primary and secondary fusion transformers.

B. Experimental Data

The transformer is a complex system, and its fault factors are so complicated that selecting a single DGA data cannot completely and accurately reflect the operating status of the transformer. Different characteristic signals of different levels must be used to synthesize for diagnostic purposes. In order to improve the accuracy of transformer fault diagnosis and more accurately determine the operating status of the transformer, this paper uses the DGA data and electrical test data of the selected transformer as the input feature vector of the diagnosis model [18]. At the same time, according to the existing research literature, the five characteristic gases (CH₄, C₂H₂, C₂H₄, C₂H₆, H₂), EC 3 ratio (C₂H₂/CH₄, CH₄/H₂, C₂H₄/C₂H₆), Rogers ratio (C₂H₂/C₂H₄, CH₄/H₂, C₂H₄/C₂H₆), Donenberg ratio (C₂H₂/C₂H₄, CH₄/H₂, C₂H₂/C₂H₆), CH₄/H₂, C₂H₂/C₂H₄, CH₄/H₂, C₂H₂/C₂H₆) are used as the input vector of the multi-parameter information fusion transformer fault diagnosis model.

C. Failure Model Construction

In the fault diagnosis of power transformer, various state parameters and test characteristic parameters can reflect the fault type and fault location of transformer. It is important to select reliable and effective characteristic parameters to improve the accuracy of transformer fault diagnosis. The selection of characteristic parameters for fault diagnosis should not only meet the practicability of information, but also meet the independence of detection and collection, that is, the characteristic parameters should be independent of each other and reflect the fault characteristics of the transformer as a whole. According to the selection principle of the above characteristic parameters, the transformer fault characteristic parameters are classified into three parts: dissolved gas content in oil (unit: $\mu\text{L}/\text{L}$), electrical test and insulating oil test information, and gas production rate.

Fig. 3. Transformer fault diagnosis model.

The automatic fault diagnosis model of the transformer is based on Adaboost_rbf and dsmt, and the resulting block diagram after modeling is shown in Fig. 3. In this model, the reference unit of the average volume and fraction of each gas contained in the gas that can be dissolved in the oil is i_1 . As the core internal current, the oil breakdown trend and the data of the insulating oil test are the diagnostic information unit i_2 , which contains c_2h_2 , h_2 and their total hydrocarbons. The information unit of the absolute value of the gas production rate is the information unit of i_3 to diagnose the gas production rate [19]. Combine a classified diagnostic module, use h_1 , h_2 , h_3 as the input of Adaboost_rbf, and connect each AdaBoost_RBF module in parallel as a first-level diagnostic model system.

The output nodes are diagnostic information modules AdaBoost-RBF1, AdaBoost-RBF2 and AdaBoost-RBF3 corresponding to the basic reliability assignment of the identification framework. In the DSmT fusion module, each reliability assignment is fused to obtain the fused reliability assignment. The final transformer fault diagnosis results are obtained based on the decision rules of maximum reliability allocation.

D. Sample Preprocessing

Due to the large data differences and measurement errors between the transformer oil chromatographic data, the number of samples used only for fault state estimation will affect the final classification performance. In addition, due to different transformer models and peripherals, there are some differences in data [20]. Therefore, in order to effectively eliminate the impact of data differences on fault determination, this article introduces the following normalization methods for preprocessing sample data sets.

$$x_{mew} = \frac{x - x_{\min}}{x_{\max} - x_{\min}} \quad (3)$$

Where x is the value after normalization of the sample; x is the initial sample value.

IV. ANALYSIS OF EXPERIMENTAL RESULTS

A. Accuracy of Diagnosis Results

This paper conducts algorithm training on the 110kV transformer operation test data collected from the official website of the Power Grid Research Institute. Among the collected samples, there are 50 groups of positive samples and

300 groups of negative samples [21]. Negative samples are classified according to the location where the fault occurs, and are also called winding faults, core performance faults, and petroleum paper electrode performance faults. Finally, the data information of the case sample and the label of the error type of the case sample together constitute a data set of three information modules [22]. Including 320 sets of dga test data, 156 sets of inspection result data and 187 sets of gas rate test data; among them, 320 sets of training sets and 100 sets of dga data tests; 100 sets of training sets and 20 sets of test data. In the air data, there are 100 training sets and 20 total tests.

Set the number of iterations $T = 16$, the neural network spread factor RBF spread = 0.06, and set the decision limit to $\epsilon = 0.3$. Table 1 shows the AdaBoost RBF1 training results of the DGA information module. Here, the correct sample rate is the correct test rate of the correct 320 data set diagnostic index and the model's DGA training set.

It can be seen from Fig. 4 that the diagnostic accuracy of AdaBoost_RBF1 is better than that of BF neural network. The diagnostic accuracy of AdaBoost_RBF1 has been increasing and is infinitely close to 100%, while BF neural network has increased at the beginning, but then began to decline.

The electrical test/oil test information module AdaBoost_RBF2 and the gas production rate information module AdaBoost_RBF3 were trained respectively. The iteration parameter $T=16$ was set, and the spread was 1 and 0.1, respectively. The test sample accuracy of the three AdaBoost_RBF modules, RBF test sample accuracy and SVM test sample accuracy are compared in Table II. It can be seen that the performance of AdaBoost_RBF algorithm is obviously better than RBF and SVM.

TABLE I. ACCURACY OF DIAGNOSIS RESULTS

	RBF neural network	AdaBoost_RBF1
1	80%	80%
2	81%	81%
4	78%	90%
6	71%	91%
8	70%	93%
10	68%	95%
12	67%	96%
14	60%	98%
16	71%	99%

Fig. 4. Accuracy of diagnosis results.

TABLE II. TEST SAMPLE RECOGNITION ACCURACY

The accuracy of test samples under different algorithms	Module class		
	DGA	Electrical test and oil test	Gas production rate
AdaBoost_RBF	78.33%	93.33%	76.59%
RBF	66.67%	76.67%	51.06%
SVM	63.33%	83.33%	53.19%

B. Comprehensive Diagnosis

Taking the relative volume fractions of the five characteristic gases in the DGA as the input feature vector, the three models of BP neural network, M-RVM, AdaBoost_RBF1 and PSO-IGWO optimized hybrid KELM are used to diagnose transformer faults. The diagnosis results are shown in Table III.

It can be seen from Fig. 5 that the diagnostic accuracy of transformers based on deep primary and secondary fusion is higher than that of transformers based on DGA, which increases the accuracy by about 3%.

According to the above experimental results, the diagnostic accuracy of AdaBoost_RBF1 is better than that of BF neural network. The diagnostic accuracy of transformer based on depth primary and secondary fusion is higher than that of transformer based on DGA. It can be concluded that the diagnostic accuracy of the depth-based primary and secondary fusion transformer is high, the performance of fault detection is good, the accuracy of information detection is improved, the range of data observation is expanded, and the working test performance of the primary and secondary fusion transformer is improved.

TABLE III. COMPREHENSIVE DIAGNOSIS RESULT

	Deep primary and secondary fusion transformer	DGA transformer
BP neural network	76.1%	72.1%
M-RVM	83.5%	81.4%
AdaBoost_RBF1	89.8%	87.3%
PSO-IGWO optimized hybrid KELM	87.8%	86.3%

Fig. 5. Comprehensive diagnosis result.

The structure of the model has a direct impact on the effect of diagnosis: (1) Deep learning should fully consider the depth of the model, model parameters and other information. (2) Ensemble learning should not only select homogeneous base classifiers, but also combine different base classifiers to fully synthesize the advantages of each model. (3) Combine the advantages of various intelligent algorithms. Expert system, fuzzy theory, neural network, intelligent optimization computing and other intelligent methods should complement each other, enhance strengths and avoid weaknesses, so as to develop models with superior performance. (4) Model selection and training methods should consider the characteristics of data. To solve the problems of data imbalance and data redundancy with appropriate models and training methods will be more conducive to improving the accuracy of transformer fault diagnosis and guiding the production operation.

V. CONCLUSION

This paper focuses on the research of the deep primary and secondary fusion transformer based on the Internet of Things technology, through optimizing the transformer structure layout and neural network intelligent algorithm realizes the physical fusion and information fusion of primary and secondary equipment. So that it has the ability of panoramic perception of self-state, and realizes the holographic transparent operation of transformers, intelligent research and judgment of situation, active decision-making of hidden dangers, and dynamic autonomous adjustment. This paper verifies the feasibility and effectiveness of fault detection and fusion technology of deep primary and secondary fusion transformer based on Internet of Things technology through theory and experiment, which provides a reference for the subsequent development of intelligent transformers with higher fusion degree. The development of primary and secondary fusion equipment solves a series of complex management problems of the original primary and secondary equipment, but there are also shortcomings in some aspects. Future technology needs to further solve the safety, reliability and efficient fusion problems of primary and secondary fusion equipment. It needs to be further studied in the later period.

Abstract—The development and progress of modern society cannot be achieved without the support of electric power resources, and at present, electric power is the most important energy source to promote social development and maintain human life. As a key unit under the power distribution and transmission system, the high-voltage cable of the power grid will undertake the task of supplying power resources to the whole power grid. Therefore, based on the transmission line fault diagnosis framework of Wireless Sensor Networks (WSN), a high-voltage cable path condition monitoring scheme using LoRa technology is proposed. Three high-voltage cable condition monitoring periods are proposed according to the difference of high-voltage cable fault rate, and the delay and energy consumption of the high-voltage cable monitoring system are optimized by multi-objective particle swarm algorithm reality. The experimental results show that the proposed high-voltage cable detection technology can switch the working mode according to different environments, and the data communication packet loss rate is less than 5%, while the detection platform has excellent delay performance and energy saving effect. The high-voltage cable status detection solution can effectively solve the problem of blind high-voltage cable channels in high mountain areas of China. The research content has important reference value for the detection of China's power grid circuit system.

Keywords—Wireless sensor; high-voltage cable; fault diagnosis; particle swarm algorithm

I. INTRODUCTION

Wireless sensor network is a kind of communication and acquisition network composed of nodes, which can realize the detection and acquisition of external physical energy. With the development of information and communication technology in recent years, wireless sensor networks have a wide range of applications in modern medical, industrial manufacturing, smart grid, etc. [1]. Wireless sensor network has the characteristics of bottom power consumption, simple application and easy expandability; therefore, wireless sensor network also has a very wide application in the field of smart grid power data acquisition, cable status monitoring, grid fault diagnosis, etc. [2-3]. With the advent of the information era, smart grid construction has become the new goal of China's power grid development. The United States as the representative of the developed countries on the future development of smart grid development strategy, which will be the wireless sensor network ZigBee protocol as an important communication standard for the construction of smart grid [4].

This shows that wireless sensor networks play an important role in the construction of smart grid. However, the construction of smart grid needs to meet the requirements of delay, bandwidth, reliability, and coverage, etc. The high-voltage grid is in a complex working environment, subject to harsh environment, complex weather, and interference from various electrical equipment signals, which will affect the application of wireless sensor networks [5]. Therefore, in view of the high difficulty in maintenance and repair of transmission lines in remote mountainous areas, a detection scheme for high-voltage cables in mountainous areas is proposed based on WSN technology. Different detection schemes are adopted for cables in different periods, and multi-objective particle swarm optimization algorithm is used to solve the problem, so as to solve the problem of high-voltage cable line fault detection in remote areas. The research content has important research value for the construction and development of smart grid in China.

Wireless sensor networks are widely used in modern medical, industrial manufacturing, smart grid, etc. A lot of work has been done by domestic and foreign researchers to study wireless sensor networks. Tabella et al. investigated the effect of wireless sensor networks (WSN) on oil spill detection and localization in subsea production systems. Four localization algorithms were studied and the detection and localization performance were compared with the (location) perspective chair Varshney's rule (CVR) and Cramér-Rao lower limit (CRLB), respectively. The results show that the components that would lead to leakage in case of failure and their corresponding failure rates [6]. Xf et al. found that the routing survivability in harsh environments is questionable. To address this issue, an environmental fusion multipath routing protocol (EFMRP) was proposed. The results show that EFMRP can significantly improve packet delivery rate and network lifetime in harsh environments [7]. Hu et al. found that a fully distributed time synchronization method based on Gaussian belief propagation would lead to degradation of synchronization accuracy. Thus, a Sequential Belief Propagation-based Distributed Time Synchronization algorithm (SBP-DTS) was proposed to reduce the number of Gaussian mixture components in messages using a weighted expectation maximization (EM) algorithm. Finally, the performance of SBP-DTS was evaluated under asymmetric Gaussian and exponential delay models [8]. Houssein et al. found it a challenging task to determine the location of convergence nodes in LSWSNs, and Harris' hawk's optimization (HHO)

algorithm was used to solve this problem. The results show that the adopted approach has advantages in terms of energy consumption and localization errors [9]. Lin et al. proposed a priority-aware packet transmission scheduling (PPTS) framework in a cluster-based IWSN, in which the PPTS policy, optimization theory, and implementation design are systematically considered. The results show that the proposed PPTS policy not only minimizes the transmission delay of high-priority packets but also improves the transmission delay of low-priority packets [10]. Zhan et al. propose an optimization problem that minimizes the weighted sum of the above two costs by optimizing the UAV trajectory and wake-up time allocation as well as the transmit power of all SNs. In addition, a new approach to design the initial UAV trajectory using the multi-traveler problem (MTSP) technique is proposed. The results show that the proposed design achieves a flexible trade-off in cost balance between UAVs and SNs [11]. Wang et al. propose a LEACH-EA protocol based on the LEACH algorithm for the low-power requirements of wireless sensor networks. Experiments show that the LEACH-EA protocol provides significant improvements in network life cycle, total network data transmission and number of cluster heads [12]. Verma et al. found limitations when using the battery power of sensor nodes. A fuzzy logic based effective clustering (FLEC) for homogeneous wireless sensor networks for mobile receivers is proposed. The probability of average energy is used to select the appropriate cluster head and the results show that the proposed FLEC scheme outperforms LEACH, DEEC and LEACH fuzzy protocols [13]. Jaber et al. proposed an “adaptive fully distributed duty cycle for content-centric wireless sensor networks (ADDC-CCWSN)” mechanism. The ADDC-CCWSN aims to reduce the activity of nodes with a high percentage of unsatisfied interest in the PIT. The results show that the proposed approach achieves significant energy efficiency gains while ensuring a high interest satisfaction rate and maintaining almost the same latency [14].

Neural network algorithms have a wide range of applications in the field of smart grid, providing important data support for data collection and grid diagnosis, and researchers at home and abroad have done a lot of work to study them. Yu et al. proposed a deep reinforcement learning algorithm for safe shutdown strategy in order to deal with incomplete distribution grid models to solve the voltage reactive power control problem in a model-free manner. The results show that the proposed algorithm outperforms existing reinforcement learning algorithms [15]. Pan E et al. used hierarchical cluster analysis to analyze grid influencing factors, and the results show that the prediction model is important to achieve accurate calculation of provincial enterprise investment [16]. Ying et al. proposed a coordinated scheduling method for plug-in electric vehicle PV generation microgrid based on extended power prediction, using a clustering algorithm to build the power prediction model was established and the results showed the good performance of the proposed extended coordinated scheduling algorithm [17]. Bhamidipati et al. developed Wide Area Monitoring Systems (WAMSs) in order to monitor the grid in a wide area. And a new wide-area monitoring algorithm was developed to verify each substation

in an artificial intelligence framework. The results show that the Kullback-Leibler scatter-based method has fast detection time and the timing error estimation accuracy exceeds the limits provided by the IEEE C37.118.1-2011 standard [18]. Iliadis et al. developed a new algorithm for managing the currents of an islanded power system that enables more stable conventional unit operation and peak demand reduction. The results demonstrate that the proposed algorithm can achieve smoother diesel generator operation [19]. Jyotheeswara et al. proposed a neural network-based maximum power point tracking (MPPT) controller for PEMFC grid-connected systems to extract maximum power from proton exchange membrane fuel cells. The results show that the proposed RBFN-MPPT controller has excellent performance [20].

It can be seen from related domestic research that neural network algorithms have a wide range of applications in the field of smart grid. Optimization of wireless sensor network parameters by neural network algorithm is important to improve the monitoring effect of power grid cables.

II. CONSTRUCTION OF HIGH-VOLTAGE CABLE CONDITION DETECTION MODEL BASED ON WIRELESS SENSOR NETWORK

A. Mountain High Voltage Cable Path Loss Model Construction

Wireless sensor network is a wireless communication technology, and its low cost and maintenance-free characteristics make WSN technology gradually replace the backward wired monitoring scheme. Therefore, WSN technology will have a very broad application prospect in the field of smart grid. High-voltage cables in mountainous areas are susceptible to seasonal climate and harsh environment, and high-voltage cable faults are mainly concentrated in summer and winter time. To meet the requirements of monitoring high voltage cables in mountainous areas, transmission cable monitoring solutions need to meet the challenges of signal transmission, harsh environmental issues, and service life in mountainous areas. Therefore, based on wireless sensor network technology, an in-line monitoring system for high voltage cables in mountainous areas using LoRa is proposed. The high-voltage line transmission architecture is constructed by setting LoRa and cellular modules in the mountainous environment, and dynamic LoRa packet networking modules are set to guarantee the stable transmission of data signals as well as to improve the efficiency of system resources utilization and reduce system energy consumption. As shown in Fig. 1, the application principle of WSN in the field of smart grid.

Fig. 1. Application principle of WSN in Smart Grid

According to the analysis of mountain high-voltage cable monitoring data, the probability of cable failure is different at different times, and mountain high-voltage cable monitoring is divided into three monitoring time periods. In the mountain storm season, snowstorm and frost season, when the relevant values are higher than the meteorological safety indicators, the occurrence of natural disasters around the mountain area of high-voltage cables is high, and the monitoring of mountain high-voltage cables is at the high-risk monitoring stage; natural disasters or abnormal communication signal transmission occur in the mountainous grid area, and the monitoring of mountain high-voltage cables is at the fault monitoring stage; cable monitoring data return to normal, and meteorological disasters gradually decrease, and mountain high-voltage cable monitoring is in the low-risk monitoring stage. According to the characteristics of the monitoring period, the fault stage gives priority to feedback data to the monitoring and issue fault maintenance orders; secondly, the high-risk stage feeds data to the monitoring and monitors the grid route fault problem; the low-risk stage only needs to meet the requirements of stable data transmission and cable detection. The signal strength of the transceiver module LoRa at a point in the mountainous area is expressed as the difference between the field strength of the system base station antenna and the field strength loss of the signal reaching that point, as seen in equation (1).

$$E_R = E_T - L_{PS} \quad (1)$$

In equation (1), L_{PS} represents the signal loss in the median path, and E_T represents the field generated by the LoRa antenna position of the transceiver module. During the transmission of the signal in the non-direct path, the bypassing phenomenon will occur, as shown in Fig. 2, then the bypassing path expression is seen in equation (2).

$$d_D = \sqrt{d_1^2 + (h_m - h_T)^2} + \sqrt{d_2^2 + (h_m - h_R)^2} \quad (2)$$

In equation (2), d_1 indicates the distance between the mountain and the transceiver module, d_D indicates the signal bypass distance, d_2 indicates the distance between the mountain and the antenna, h_R indicates the antenna altitude, h_T indicates the transceiver module altitude, and h_m indicates the mountain altitude.

Fig. 2. Radio diffraction principle

The colored building areas in Fig. 2 represent signal blocking areas such as mountains and forests. The signal tower transmitting signal is blocked by the mountain and signal bypassing phenomenon occurs. The transceiver module LoRa signal band is 433-915Mhz, to meet the bypass signal loss requirements, the model applicable to the loss monitoring in this band is Egli model, which can be more accurate to evaluate the terrain field strength in mountainous and hilly

areas, etc. The Egli signal loss expression is seen in equation (3).

$$L_{ps} = 88 + 201gf + 401gd - 201g(h_i h_r) - K_n \quad (3)$$

In equation (3), h_r indicates the antenna height, h_i indicates the transceiver module height, f radio frequency,

K_h environmental correction factor, and d indicates the distance between the transceiver and signal antennas.

B. Construction of Time Delay and Energy Consumption Model of High Voltage Cable in Mountainous Areas

The high-voltage cable monitoring model uses LoRa to achieve optimization of dynamic grouping with multiple objectives, and algorithms are used to find the number of cellular wireless modules installed as well as the number, so as

to achieve the type of network under different system delay and energy consumption conditions, and to meet the switching of multiple working states of the high-voltage cable monitoring system of smart grid. Network modeling is used in the study as a data directed graph, and transmission towers are located at substation locations, which can directly use LoRa modules to achieve end-to-end data transmission. Therefore, the directed graph then mainly considers the number of transmission towers required by the wireless transmission module. The directional diagram of network data transmission is shown in Fig. 3.

Fig. 3. Directed graph of network data transmission

The cable detection model mainly needs to find the available communication path and the communication link delay is kept minimum and can save the network construction cost, then the communication link delay should be less than or equal to the maximum communication delay, as seen in equation (4).

$$\sum_{(i,j)} D_{i,j,k} M_{i,j,k} \leq D_{\max} \quad \forall k \in N \quad (4)$$

In equation (4), $M_{i,j,k}$ denotes the binary decision variable, $D_{i,j,k}$ denotes the node k communication delay, and D_{\max} denotes the system maximum delay requirement. To ensure that the communication link is reused at a reduced cost, then $O_{i,j}$ denotes the binary variable, if the data link (i, j) is used, there is $O_{i,j} = 1$, otherwise $O_{i,j} = 0$, expressed as seen in equation (5).

$$M_{i,j,k}, L_i, G_i, O_{i,j} \in \{0,1\} \quad \forall (i, j) \in p, \forall k \in N \quad (5)$$

In equation (5), L_i and G_i are binary variables, where i towers use cellular network, then there is $G_i = 1$, otherwise 0, and if i towers use LoRa, then $L_i = 1$, otherwise 0. The variables $M_{i,j,k}$ and $O_{i,j}$ can be determined by equation (5). Also combine equation (4) with equation (5) to get all network delay functions as seen in equation (6).

$$D(M_{i,j,k}, L_i, G_i, O_{i,j}) \quad \forall (i, j) \in p, \forall k \in N \quad (6)$$

The expression of the network loss function can be found by equation (6) as seen in equation (7).

$$E(G_i, L_i) = \sum_{i=1}^N (dG_i + bL_i) + \sum_{(i,j) \in p} C_{i,j} O_{i,j} + L_{ps} \quad (7)$$

In equation (7), d denotes the energy consumption of the cellular radio module, b denotes the energy consumption of the LoRa module, and $C_{i,j}$ denotes the energy consumption at the data link (i, j) . The expression of the dynamic model of mountain cable LoRa obtained by Eq. (4) to Eq. (7) is seen in Eq. (8).

$$F[D(i, j, k), E(i, j)] \quad \forall (i, j) \in p, \forall k \in N \quad (8)$$

In the LoRa module, SF is the spreading factor, BW is the signal bandwidth, and CR is the encoding rate. Using the sem tech formula, the transmission time of a LoRa individual node packet over the air can be calculated, and by using the user key control parameters, the LoRa symbol rate is expressed as seen in equation (9).

$$R_s = \frac{BW}{2^{SF}} \quad (9)$$

With the user control parameters and the symbol rate definition information, the LoRa symbol period representation is obtained as seen in equation (10).

$$T_s = 1/R \quad (10)$$

The number of propagation times of LoRa data in the air is the sum of the packet transmission time and the leading code time, while the leading code is calculated as seen in equation (11).

$$T_p = (n_p + 4.25)T_s \quad (11)$$

In equation (11), n_p is the leading code setting length, which is stored in the register location, then the payload transmission time is equation (12).

$$T_l = \varepsilon * T_s \quad (12)$$

In equation (12), ε denotes the payload symbol, then the LoRa data transmission time can be obtained as the sum of the leading code transmission time and the payload time, as seen in equation (13).

$$T = T_p + T_l \quad (13)$$

In equation (13), T_p is the lead code transmission time, T_l is the payload time. LoRa data transmission process energy generation as seen in Figure 4.

Fig. 4. Lora energy generation in lora data transmission process

Then, in LoRa data transmission, E_{RX} denotes the data transmitting energy consumption, E_{TX} denotes the data receiving energy consumption, d denotes the distance of data transmission process, and n denotes the data size. The total energy consumption of LoRa data transmission is shown in equation (14).

$$\begin{cases} T_{TX}(n, d) = E_{Telec} \times n + \varepsilon_{amp} \times n \times d^k \\ E_{RX(n)} = E_{RX-elec(n)} = E_{Relec} \times n \\ E_{LoRa} = E_{TX}(n, d) + E_{RX}(n) \\ E = L_{LoRa} + E_{CC}(n) \end{cases} \quad (14)$$

In equation (14), E_{Telec} is the energy consumption of the device sending data, E_{Relec} is the energy consumption of the device receiving data, ε_{amp} is the energy consumption of the device power amplifier unit, $E_{CC}(n)$ is the energy consumption of the cellular module sending data, and k is the signal attenuation index with a value of 4 in the mountain area.

C. Lora Transmission Model Construction based on MOPSO Algorithm

The analysis of the LoRa transmission model reveals that the delay model is influenced by the LoRa transmission data and device transmission parameters, while the energy consumption model is influenced by the data transmission distance, data transmission volume, and transceiver module power. Meanwhile delay and energy consumption are two contradictory target data. To ensure both low latency and good energy consumption for high voltage cable monitoring system, a compromise approach is needed. A neural network algorithm is used to optimize the delay and energy consumption objectives so that the delay and energy consumption targets meet the requirements of the online high-voltage cable detection system. Therefore, the multi-objective particle optimization algorithm (MOPSO) is used to optimize the energy consumption E and T two important parameter objectives, then the mathematical expression of MOPSO for M objectives is seen in equation (15).

$$\begin{cases} \min y = f(x) = |f_1(X), f_2(X), \dots, f_m(X)| \\ S.t. \quad x = (x_1, x_2, \dots, x_D) \in X \\ \quad \quad y = (y_1, y_2, \dots, y_M) \end{cases} \quad (15)$$

In Eq. (15), y denotes the target space, X denotes the decision space, y denotes the target vector, and x denotes the decision vector. In the multi-objective particle swarm algorithm calculation, each particle has a unique solution in the solution space and adjusts its target flight according to the

spatial flight experience of its peers and its own experience. The particle trajectory in space has the best flight position, which is the optimal solution for the particle swarm. And the flight position that the whole particle swarm experiences is the optimal solution that the swarm finally searches for.

Define $H_a = (h_{a1}, h_{a2}, \dots, h_{aD})$ as the D dimensional position of the a particle of the particle swarm and the particle $a = 1, 2, \dots, s$. The flight speed of particle a is $aV_a = (v_{a1}, v_{a2}, v_{a3}, \dots, v_{aD})$. The optimal solution of the particle swarm a is $p_a = (p_{a1}, p_{a2}, p_{a3}, \dots, p_{aD})$, and the global optimal solution of the whole particle population is $p_o = (p_{o1}, p_{o2}, p_{o3}, \dots, p_{oD})$. The particle population counts the velocity expression of the particles in each iterative update as seen in equation (16).

$$v_{ab}(k+1) = \theta v_{ab}(k) + c_1 r_1 (p_{ab} - h_{ab}(k)) + c_2 r_2 (p_{gb} - h_{ab}(k)) \quad (16)$$

In Eq. (16), denotes the number of particle swarm, $a = 1, 2, \dots, s$ and b are the parameter values, $b = 1, 2, 3, \dots, D$ and L_b denote the lower limit of the search space, U_b denotes the upper limit of the search space, v_{ab} denotes the swarm flight speed, c_1 and c_2 denote the swarm learning factor, θ denotes the inertia weight, and r_1 and r_2 denote the random number. For each iteration, the position of the particles is expressed as shown in equation (17).

$$h_{ab}(k+1) = h_{ab}(k) + v_{ab}(k+1) \quad (17)$$

In equation (17), h_{ab} is the particle swarm dimensional position, $Dh_{ab} \in [L_b, U_b]$. The flow of multi-objective particle swarm to achieve the objective optimization is shown in Fig. 5.

Fig. 5. Multi-objective particle swarm optimization process

III. HIGH VOLTAGE CABLE CONDITION DETECTION MODEL SIMULATION TEST

In order to verify the performance of the proposed online high-voltage cable detection model, the online high-voltage cable monitoring network will be simulated and tested using MATLAB with Pocket Tracer simulation platform. The LoRa module used in the experimental test transmits from 1km to 5km range, and the transmission rate ranges from 5kb to 30kb range, and the distance is inversely proportional to the data transmission rate; while the cellular wireless module is used without considering the distance, and the rate is 125m/s. The cellular network has been affected by data access delay, routing conversion, and the delay is taken as the average value of 55ms. 100 transmission poles with a spacing of 1 km, and each inductive pole tower are placed a group of sensors, each group of sensors each time to collect data capacity of a total of 2.78kb.

In the test of the relationship between path loss and the influence of LoRa signal receiving and transmitting segment distance, the experiments are based on the Egli path loss model, and the relationship between path loss and LoRa signal segment is obtained through simulation tests, as shown in Fig. 6.

Fig. 6 shows the results of the relationship between the actual field strength of the path and the theoretical field strength. The real field strength test shows that the LoRa signal becomes weaker with the increasing distance of the field strength, which corresponds to the decreasing trend of field strength with increasing distance of Egli model. However, the actual comparison shows that the decreasing trend of field strength in the experimental test is significantly smaller than the trend of Egli's theoretical calculation. In the case of mountain peaks, the difference between the actual field strength and the theoretical field strength will be monotonically reduced by the increasing distance, but the error value will increase in the case of mountain peaks. Although the Egli model can describe the relationship between field strength and distance for transmission signals in mountainous areas, the model has a large error and needs to be optimized to effectively predict the path loss in mountainous areas. Meanwhile, in online high-voltage cable detection system, delay model and

energy consumption model are the key to system optimization. To discuss the performance of LoRa wireless networking, it is necessary to analyze the LoRa bottleneck energy in cellular wireless modules as well as the number of groups in LoRa modules and multi-hop transmission distance between modules. Therefore, the relationship between different wireless transmissions and the maximum system delay during networking is tested in the Pocket Tracer simulation platform, as shown in Fig. 7.

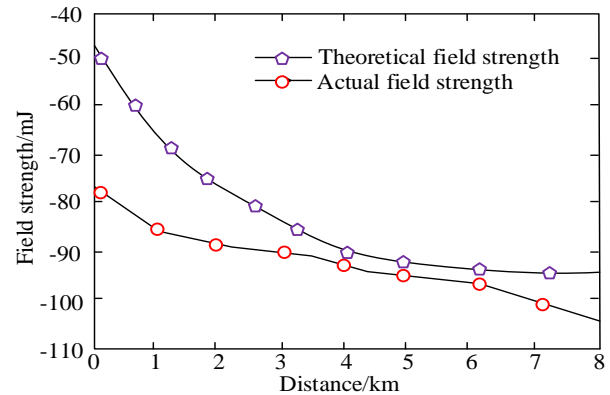

Fig. 6. It is the result of the relationship between the actual field strength and the theoretical field strength of the path

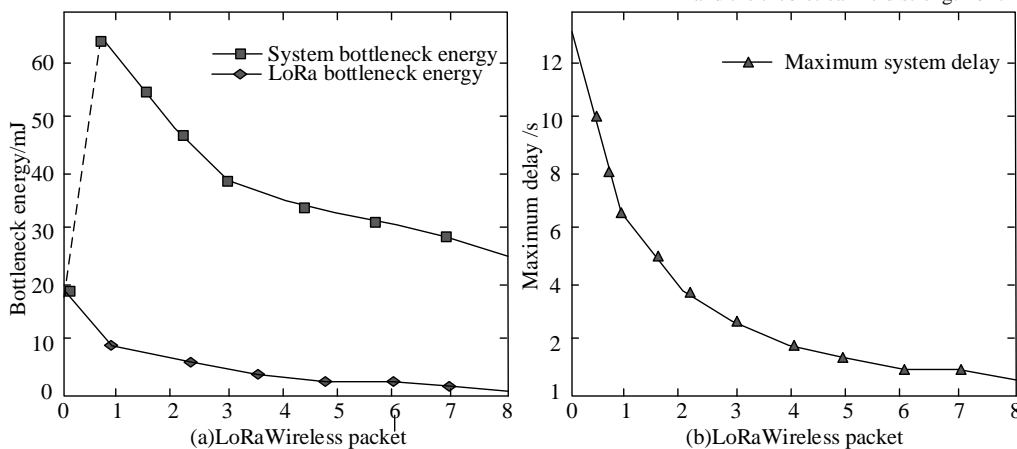

Fig. 7. Results of the relationship between system delay and bottleneck energy consumption

Fig. 7 shows the results of the relationship between the system delay and the bottleneck energy consumption. In Fig. 7(a) the results of the relationship between the number of LoRa wireless groups and the bottleneck energy are shown. When the cable monitoring network belongs to LoRa step-by-step hopping network, the system bottleneck energy is the same as LoRa bottleneck energy, and the terminal node closest to the gateway node transmission network will forward all node data at this moment, and the system bottleneck energy is consumed as the energy of this node; meanwhile, LoRa transmission group expands with the number, this network system takes cellular module for data transmission, and the cellular module energy consumption is much higher than the LoRa module, and the system bottleneck energy at this moment also increases with it. However, along with the expansion of the number of cellular modules, the transmission of data information of individual modules decreases, so the system bottleneck energy under the network will decrease as the number of module

groups increases. Also, when the system uses a heterogeneous network, LoRa modules will also consume less bottleneck energy as the number of LoRa groups increases. The bottleneck energy consumed by the LoRa and cellular networks is relatively fixed at this moment, with the LoRa bottleneck energy consumption being 2mJ and the cellular 27mJ. The results of the relationship between the number of wireless groups and the maximum delay are shown in Fig. 7(b).

Due to the increasing number of LoRa wireless packets, the data transmission between individual LoRa modules is reduced, and not only the energy consumption is reduced, but also the maximum delay of data transmission is gradually reduced.

The MATLAB platform is used to implement the simulation test for the multi-objective optimization of the system, and the multi-objective particle swarm algorithm is

used to optimize the two objectives of the delay module and the energy consumption module. The simulation test continues to reflect the results of the relationship between energy consumption and delay by bottleneck energy and maximum delay, as seen in Fig. 8.

Fig. 8. Results of the relationship between time delay and energy consumption under particle swarm optimization algorithm

The results of the relationship between time delay and energy consumption under the particle swarm algorithm are shown in Fig. 8. The time delay and energy consumption are two conflicting objectives that show an inverse proportional relationship. Optimization of the two models of time delay and energy consumption by the multi-objective particle swarm algorithm does not search for the optimal solution set that matches the objective function. However, in the simulation test, the blue area of the image ellipse is the optimal solution range of the objective. In order to find the best working conditions parameters that meet the system work, it is necessary to further analyze the optimal solution set obtained by the particle swarm algorithm, and through the weighting process, the weights achieve the switching effect of working mode, and the normalization process is carried out to get the results corresponding to the parameters of time delay and energy consumption under different weights ω , as shown in Table I.

TABLE I. SHOWS THE RESULTS OF TIME DELAY, ENERGY CONSUMPTION AND THE RELATIONSHIP BETWEEN PARAMETERS

Weight	Transmission distance/km	Signal bandwidth/KHz	System energy consumption/mJ	System delay/s
0.1	1	125	12	9.13
0.2	1.5	125	14	5.01
0.3	2	125	25	2.72
0.4	2.6	125	32	0.91
0.5	3	125	48	0.53
0.6	3.5	250	53	0.47
0.7	4	125	59	0.36
0.8	4.5	250	71	0.26
0.9	5	250	74	0.16

Table I shows the results of time delay, energy consumption and the relationship between each parameter. At the weight of $\omega=0.2$, the system has the best balance of energy consumption and time delay, which can be used as the monitoring mode of cable detection system at this moment, and at $\omega=0.5$, the system has low delay and good signal transmission distance, which can be used as the warning mode of the system. At $\omega=0.9$, the system has the best delay performance and transmission distance, 0.16s and 5km, respectively, as maintenance mode. The proposed wireless inspection system can effectively meet the work content requirements of cable repair and maintenance, and the energy consumption is reduced by 81% compared with the traditional wired inspection system.

Packet loss rate is an important parameter to evaluate the quality of communication transmission, mainly refers to the ratio of the amount of data lost during the transmission and exchange process of communication data to the actual sent communication data. A higher packet loss rate means a worse quality of communication data transmission. Therefore, in order to ensure that the system communication has a high quality, it is necessary to consider the communication packet loss rate. The packet loss rate is related to the communication distance, packet length and the transmitting frequency of the signal base station. Therefore, the packet loss rate was tested under three detection models, and 2000 16-bit byte packets were sent simultaneously in the three operating modes of the system, as shown in Table II.

TABLE II. SHOWS THE RESULTS OF PACKET LOSS RATE OF THE SYSTEM UNDER VARIOUS WORKING MODES

System working mode	Total transmitted packets	Communication distance /kg	Packet loss rate	Time delay/s
Early warning mode	1950	3	<3%	0.51
	1956	3	<3%	0.52
	1972	3	<3%	0.53
Monitoring mode	1901	1.5	<5%	5.12
	1908	1.5	<5%	5.16
	1910	1.5	<5%	5.19
Maintenance mode	1980	5	<1%	0.16
	1982	5	<1%	1.17
	1986	5	<1%	1.17

Table II shows the results of the packet loss rate situation of the system under each operating mode. The packet loss rate of the system under all three modes tested is controlled within 5%, which meets the relevant requirements of packet loss rate for China's power grid communication construction. In the early warning mode and maintenance mode, the packet loss rate is significantly lower than that in the monitoring mode, mainly because the communication system needs to maintain high frequency signal bandwidth to meet the requirements of low delay in communication in both working environments, and therefore the energy consumption in both working modes

is relatively high. It can be concluded that the three working modes will be freely switched according to the environmental conditions where the high-voltage cable is located, maintaining the basic communication and low energy consumption detection requirements in the detection mode, and switching to the warning or maintenance mode under the harsh environmental conditions to guarantee the detection of the system and the exchange of communication data. Finally, compare the wireless cable detection technology studied with the traditional wired cable detection technology, as shown in Table III.

TABLE III. COMPARISON BETWEEN THE PROPOSED CABLE DETECTION TECHNOLOGY AND TRADITIONAL CABLE DETECTION TECHNOLOGY

Comparison type	Traditional cable detection technology	The proposed wireless cable detection technology
Scope of application	Only applicable to places where wired equipment can be built	It can adapt to most places, including high mountains, cold and hot areas
Unit energy consumption	higher	moderate
Self energy level system	Manual automatic control	Intelligent/manual control
Construction requirements	High construction difficulty, not suitable for all places	It can be built in most places and mobile communication coverage areas
Maintain	High maintenance difficulty and cost	Lower overall maintenance and cost
Check the accuracy	No time interval monitoring, and manual monitoring is required for special environment	Adapt to full time and assist manual monitoring, with higher detection accuracy

Table III is a comparison table between the proposed scheme and the traditional cable detection technology. It can be seen from the information in the table that compared with the traditional cable detection technology, the proposed wireless cable detection technology has obvious advantages in the scope of application, construction cost and detectability. At the same time, the cable detection technology based on wireless technology has more advantages than the traditional cable detection technology in terms of system updating and technology upgrading, and is more in line with the construction requirements of the existing smart grid.

IV. CONCLUSION

High-voltage transmission circuit is an important part of the grid system, and the reliability of high-voltage cables directly affects the safe operation of the grid system. Along with the development of interest communication technology, advanced wireless communication technology will provide important technical support for the development of smart grid. To address the problem of insufficient maintenance of traditional wired high-voltage cable detection system in remote mountainous areas, a high-voltage cable path state monitoring scheme using LoRa technology is proposed based on wireless sensor network. And three monitoring modes are proposed according to the fault types of high-voltage cables; the balance of energy consumption and delay of cable communication is achieved by

multi-objective particle swarm algorithm. The experimental results show that the system delay, energy consumption and signal bandwidth are different under different weight parameters, and the overall effect of the cable detection system can be improved by selecting the appropriate cable detection model according to the different weight of the cable detection area. When the weight is $\omega=0.5$, the system has low delay and good signal transmission distance. At this moment, the system adopts warning mode. At the weight $\omega=0.9$, the system signal and transmission distance are in the best state. At this moment, the system uses maintenance fuzziness for routine cable maintenance. Compared with the traditional cable detection system, the overall energy consumption of the proposed system is reduced by 81%. Finally, in the communication data transmission test, the packet loss rate of data transmission under the three working modes is less than 5%. The system reasonably selects the working model according to the environment and ensures that the system has excellent data signal transmission performance, and meets the cable fault detection requirements. Compared with the traditional wired cable detection technology, the wireless cable detection technology consumes less energy and can adapt to a more demanding detection environment. At the same time, the system uses neural algorithms to balance the system parameters, which makes the overall detection performance more stable and better. Therefore, the high voltage cable detection technology based on wireless sensor network meets the requirements of smart grid construction and ensures the timely and effective detection of high voltage cables. However, there are also shortcomings in this research. The wireless cable detection technology only considers the impact of mountain environment on technology. In the actual technology construction, more demanding environment needs to be considered. At the same time, the wireless technology needs to consider the regional communication coverage during the construction process, and the combination of wired and wireless technology is the most effective method at present.

Research on the Application of Improved Decision Tree Algorithm based on Information Entropy in the Financial Management of Colleges and Universities

Huirong Zhao

School of Economics and Management, Jiangsu College of Engineering and Technology, Nantong, 226000, China

Abstract—In the era of information technology, the work relies on information technology to generate a huge amount of data and information. Among them, the financial data information of universities is growing exponentially, and the manual method of organizing data and extracting key information can no longer meet the requirements of financial data management of universities. Taking the financial management of higher education institutions as an example, it is difficult to grasp the progress of financial budget execution with frequent and complicated daily expenditure and income problems, and then it is difficult to execute correct decisions in the management. The study uses information entropy as the decision basis of decision tree in the financial management of higher education institutions. The higher the value of information entropy generated in financial management, the higher the prediction accuracy of the decision tree. The metric calculation method is introduced to obtain the information entropy as well as the information gain rate to predict the likelihood of problematic events. The study validates the performance of the improved decision tree with a dataset that achieves a maximum accuracy of 95% in the experiment. With the higher prediction accuracy, for the university financial management system, a decision tree for financial warning is established and the link between the current month's financial expenditure and the warning mechanism is analyzed, and finally the two common decision tree algorithms, (Iterative Dichotomiser3, ID3) ID3 and (Classification and regression tree, CART) CART, are compared with the algorithm proposed in the study. The mean square error and the sum of squared error metrics are used to conclude that the algorithm proposed in the study has better performance. By improving the existing decision tree algorithm, the study proposes a decision tree model based on information entropy, which aims to help decision makers to quickly and accurately distill relevant data and make correct decisions in a large amount of information data for more rational financial management.

Keywords—*Information entropy; financial management; decision tree; information gain rate; C4.5 algorithm; early warning structure*

I. INTRODUCTION

Financial management in colleges and universities is one of the core management works of higher education institutions, and also an important guarantee for normal daily work of institutions. As the enrollment scale of colleges and universities is expanding, the financial data of colleges and universities also usher in an explosive growth. How to mine these data information and fully apply the useful information

in the data for effective college financial management and financial decision making is the focus of current intelligent algorithms in the field of college management research [1]. Since the society has entered the information age, computer technology and information technology have been developed rapidly. The development of computer information technology has brought a large amount of data information. The large amount of data can provide more reliable basis in extracting key information, but at the same time the redundant information mixed with it also brings redundant workload.

In the present time when the intelligent technology is popular, the information extraction technology is more in the form of automation, so the construction and improvement of financial information system has become the key research content in the management of universities. With the continuous development and improvement of financial management information systems in universities, the managers' use of traditional financial statements and manual decision-making solutions can no longer meet the needs of university financial management informatization, not to mention the development goals of data and information in the intelligent information era [2]. With the increasing requirements of university management for management effectiveness, reasonable decision quality and decision speed become crucial. The use of advanced technology and intelligent decision-making tools can make more effective management decisions and solve various problems in the financial management of colleges and universities. The financial information system of colleges and universities has a large amount of financial information. The financial information contains many important data, and the relevant information extracted from the data can be used as the judgment basis for the financial management decision of colleges and universities. The current information management of university finance is far from meeting the development requirements at this stage, and the management of finance only stays on the surface basis, focusing only on the accounting situation of financial data and the supervision of data. With the speed of digital campus construction, the needs of university development and financial data are accumulated in large quantities, and the managers need not only to achieve the most basic financial management, but also to control the risks of university development to the minimum through financial management. Therefore, using intelligent algorithms for management decisions can not only provide new management directions for university financial management,

but also predict other types of financial problems.

At present, many data processing techniques and intelligent algorithms have been applied to financial management and risk decision making in universities. For example, data warehouse technology, data mining technology, data analysis technology, etc. The study introduces digital and information technology into the financial management of universities to get the improved algorithm of decision tree about information entropy. The improved algorithm can reasonably use a large amount of data generated in the financial system of universities, extract key information for the sustainable development of universities, provide a scientific theoretical basis for the construction of universities, and then control the risks in the financial management of universities for the purpose of financial budget progress management as well as financial early warning management^[3]. The research content firstly uses information entropy as the decision basis of decision tree in financial management of universities, and proposes the decision tree algorithm based on information entropy and analyzes it. The higher the value of information entropy generated in financial management indicates the higher the prediction accuracy of the decision tree. Then, the metric is introduced, and the information entropy and the information gain rate are calculated, and a model based on the improved decision tree algorithm is proposed for the application of college financial management, and the likelihood of problematic events is predicted using the model. Finally, the performance of the constructed improved decision tree model is verified by the data set.

II. RELATED WORK

The construction of higher education institutions is the basis of social progress and development. In order to ensure the normal operation and development of colleges and universities, many scholars have conducted relevant research on the management of colleges and universities. Priya E (Priya E 20210 [4] proposed a breast cancer diagnosis model based on deep segmentation of residual network, and applied it in the initial detection stage of breast cancer. In order to detect and classify breast images, the model adopts decision tree classifier for operation. It is proved by relevant experiments that the model has excellent classification performance, and the accuracy reaches 98.86%. Al C (Al C 2021) [5] classifies the students' tendency to choose TVET after completing their studies through multiple decision tree models, and constructs different decision tree algorithm types. The experimental results show that the decision tree has a low misclassification rate in TVET classification. Researchers such as Mao L (Mao L et al. 2021) [6] conducted an evaluation and analysis of entrepreneurship education in higher education institutions, improved and optimized the algorithm on the basis of decision tree and fuzzy algorithm, and constructed an efficient entrepreneurship education evaluation system. Through empirical research, the evaluation system established in the study has a certain degree of effect in practical application. S Ziweritin team (S Ziweritin et al. 2021) [7] through the simulation experiment, the decision tree is trained and tested,

and the accuracy of the model reaches 99.86%. Mabuni D and Babu S A (Mabuni D and Babu S A 2021) [8] found that the classification effects obtained in smaller datasets were arranged to be reliable, and therefore performed cross-validation with multiple random folds on the same dataset. The verification method is also tested experimentally, and the experimental results show that the classification accuracy of the decision tree with prime number folding is higher than that of the existing decision tree classification.

Ahmad N (Ahmad N et al. 2019) [9] collected public university leaders' views on the overall financial management and sustainability of institutions through questionnaires. According to the survey results, the leaders interviewed believe that the key to the sustainability of financial management is to make use of university resources. The financial management of the school takes the basic activities of the school as the management, which is of great significance to the financial management of public universities. Researchers such as Asandimitra N (Asandimitra N et al. 2020) [10] designed a conclusive causal relationship study, conducted multiple regression analysis on the research results through relevant statistical software, and found that teachers' financial management behavior has an important relationship with teachers' own financial knowledge and financial literacy. Cultivating teachers' financial self-efficacy is of great help to school financial management. The Mohammad M team (Mohammad M et al. 2021) [11] used the mean and standard deviation of the collected data as a measure of the importance of the research question in their research on the quality and impact of AI on classified hotel financial statements. Through the survey results, it is found that the hotel application AI performs linear regression analysis on financial information, analyzes the important factors affecting financial management, and plays an important role in the sustainability of financial management. Malikov VV scholars (Malikov V V 2020) [12] constructed the algorithm of financial management system in enterprise management. The system first determines the overall financial goals of the enterprise, allocates the corresponding financial management subsystems, and formulates corresponding financial management rules. In practical application, the algorithm of the system successfully avoids the problem of cash gap and optimizes the relationship between creditors. Researchers such as UJ A (UJ A et al. 2020) [13] have developed some data classification models for financial management decision-making, which include the feature selection stage and data classification stage of ant colony feature optimization. Through the validation of multiple algorithms in the same dataset, the proposed model has better performance than other algorithms.

In summary, decision trees are widely used in classification, forecasting and other fields. Financial management needs to make predictive behaviors for the future. However, there are few and immature studies on the combination of the two. Therefore, the research combines the two. A relatively complete research is conducted to help colleges and universities become more scientific in financial management.

III. APPLICATION AND IMPROVEMENT OF DECISION TREE ALGORITHM IN FINANCIAL MANAGEMENT

A. Improvement Analysis of Decision Tree Algorithm based on Information Entropy

Decision tree algorithm can classify data purposefully, and find and extract valuable information from the data, thus helping decision makers to provide a choice path [14]. Based on the above advantages, decision tree algorithm is widely used in prediction models. In data mining technology, the good tree structure formed by the decision tree can highly summarize the sample data and correctly identify the old samples or different types of samples. Compared with other classification algorithms, decision tree has a classification rule that is easier to understand. In the classification task, the algorithm runs faster and has higher classification accuracy.

Common decision tree algorithms include ID3 algorithm, C4.5 algorithm and CART algorithm. In the late 1970s, J Ross Quinlan proposed the ID3 algorithm, which aims to reduce the depth of the decision tree and simplify the operation steps of the model. However, ID3 algorithm ignores the study of the number of leaves while reducing the depth of the tree. Therefore, C4.5 algorithm is proposed to improve ID3 algorithm. As a decision tree algorithm based on information entropy, C4.5 algorithm has the advantage that it can use the information gain rate to replace the information entropy as the selection standard, avoiding the defects of ID3 algorithm. As an improved decision tree algorithm, the basic process of the algorithm is: first, select the training set as the root node, and select the appropriate criteria to select the splitting attributes. Secondly, according to the difference of split attribute values, the training set is divided into several subsets and used as the first sub node of the root node. Then, treat these sub nodes as root nodes and repeat the above steps until the final classification conditions are met.

In practical application, when there are many data items, more complex decision trees will be generated, which will lead to uneven data and even loss of attributes, affecting the operation efficiency and classification accuracy of the algorithm [15]. In view of the shortcomings of decision tree algorithm, C4.5 algorithm is proposed to be used in the decision tree. C4.5 algorithm is an improved decision tree algorithm, which mainly operates on the basis of information entropy. When dealing with continuous lost data, tree pruning technology is introduced. This technology not only simplifies decision-making, but also improves classification accuracy. In addition, the research attempts to introduce a measurement method into information entropy. This method can be used for data reference at the same time when classifying, and finally an improved decision tree algorithm based on measurement is obtained. The flow chart of the improved algorithm's decision tree is shown in Fig. 1.

Fig. 1. Decision tree flow chart of improved algorithm

The decision tree model established by introducing the measurement method is essentially a recursive algorithm, which forms the branch conditions of the decision tree and adopts the threshold method. Assuming that $T = \{t_i\}$ the set of $A = \{a_i\}$ samples is taken as the feature space of the samples, the total number of samples is expressed by C , and the attributes of the feature space are expressed by m . The power space of the feature space is represented by $B = \{b | b \in A\}$, the misclassification threshold in the model is represented by β_e , and the cross misclassification threshold is represented by β_c . For the superset, it includes samples of multiple categories. If the sample attribute set threshold value in the superset x is the smallest, and the distance from the other category values in the typical Mahalanobis distance is the smallest, the sample will be classified into this category. Assuming that the sample is misclassified to other samples, and the proportion is greater than the cross misclassification, the two samples will be considered to be the same class and continue to be classified in the lower layer. The classification strategy adopted when the above attribute set is not found is the best classification situation of the model. When all samples are classified or can no longer be classified, the model classification process ends. In the model, the randomness of information entropy is used as a standard to select model samples to test attributes [16]. In the process of building a decision tree, an attribute is required to divide the data, so that the data class values in the child nodes are basically the same. When the data class values in the node are unevenly distributed, it means that the entropy of the node is small. The definition of entropy is shown in formula (1).

$$Entropy(p_1, p_2, \dots, p_n) = p_1 \log_{2,p_1} - p_2 \log_{2,p_2} - \dots - p_n \log_{2,p_n} \quad (1)$$

In formula (1), "-" indicates that the logarithm of the score is negative; P represents the fraction in the definition of entropy. In fact, the entropy is positive, as shown in formula (2) in general.

$$Info\{[C_1, C_2, \dots, C_n]\} = entropy[E_s] \quad (2)$$

In formula (2), it is the expression of the training set E_s ; it is used to represent the samples in the training set C . All training sets are grouped, and the spatial features are used to $entropy[E_s]$ reduce the value. Assume that the training set is set with a new expected amount of information, and its expression is shown in formula (3).

$$new_entropy(E_s, A) = \sum_{i \notin value_{(A)}} [E_s / |E_s|] entropy[E_s] \quad (3)$$

The reduced expectation value of the training set is the information gain of the feature space relative to the training set. If it is beneficial to the training set, the larger attribute of the information gain needs to be removed. The specific expression is shown in formula (4).

$$Gain[E_s, A] = entropy[E_s] - new_entropy(E_s, A) \quad (4)$$

Equation (4) $Gain[E_s, A]$ is the expression of information gain. Information entropy is the average amount of information obtained after excluding redundant information, which is used to represent the degree of confusion of information. The calculation formula of information entropy is shown in Equation (5).

$$I(S_1, S_2, \dots, S_m) = -\sum_{i=1}^m P_i \log_2(P_i) \quad (5)$$

In formula (5), it is used to represent the sample set S , which is used to represent P_i the probability of any sample in $P_i = S_i / S$, and C_i . The measure of the amount of information is the size of the information gain. When all attributes are classified, the value of the information gain is first calculated, and then the node selected for the construction of the decision tree is determined. big. Therefore, the feature space branching obtains the information gain as shown in Equation (6).

$$Gain(A) = I(s_1, s_2, \dots, s_m) - E(A) \quad (6)$$

In formula (6), it $I(s_1, s_2, \dots, s_m)$ represents the expected information entropy of a given sample, and the calculation method of sample expectation is shown in formula (7).

$$E(A) = -\sum_{j=1}^v \frac{s_{1j} + \dots + s_{mj}}{s} I(s_{1j}, s_{2j}, \dots, s_{mj}) \quad (7)$$

When calculating the information gain, it mainly depends on the attribute value, but in special cases, such calculation is also meaningless. Therefore, the division of nodes plays an important role in the construction of decision trees. The C4.5

algorithm optimizes the node division by means of the information gain rate, that is, the ratio between the information gain and the information entropy. When comparing, the amount of information of sample attributes is not the total amount. When the information gain is divided into subsets, there will be a certain degree of deviation in the value of its variables, which can be reduced by formula (8).

$$SplitInfo(S, v) = \sum_{i=1}^m \frac{|s_i|}{|s|} \times \log_2 \frac{|s_i|}{|s|} \quad (8)$$

Therefore, the gain rate expression is specifically as shown in Equation (9).

$$GrainRatio = -\frac{Grain(S, v)}{SplitInfo(S, v)} \quad (9)$$

By introducing information entropy and measurement methods, the C4.5 algorithm assumes a data set T in which different categories are represented by sets C , selects an attribute to divide the data set into multiple subsets, and the values of the attributes are all equal. If they are not the same, the dataset is divided into the same number of subsets. The probability of category selection occurring is shown in formula (10).

$$P(C_i) = |C_j| / |T| \quad (10)$$

Because the instances of the subset all take the value of the attribute, the probability of the occurrence of the attribute value and the probability of having the category condition are shown in formula (11).

$$\begin{cases} P(v_i) = T_i / T \\ P(C_j | V_j) = c_{jv} / |T_i| \end{cases} \quad (11)$$

In formula (11), the probability of occurrence $P(C_j | V_j)$ with C_j category conditions is expressed, and the probability calculation formula can be obtained to further obtain the calculation of category information entropy and category condition information entropy, as shown in formula (12).

$$\begin{cases} Info(C) = -\sum_j p(C_j) \log p(C_j) = -\sum_{j=1}^k \frac{P(C_j)}{|T|} \log \frac{P(C_j)}{|T|} = Info(T) \\ Info(\frac{C}{v}) = -\sum_j p(v_j) \sum_i p(\frac{C_j}{v_j}) \log p(\frac{C_j}{v_j}) = -\sum_{i=1}^n \frac{|T_i|}{|V_i|} Info(T_i) = Info(T) \end{cases} \quad (12)$$

Finally, the information entropy of the attribute is obtained according to formula (8), as shown in formula (13).

$$Info(V) = -\sum_i p(v_i) \log p(v_i) = -\sum_{i=1}^n \frac{|T_i|}{|T|} \log \frac{|T_i|}{|T|} = split_Info(v) \quad (13)$$

The attribute information gain rate is obtained according to formula (9), and the specific expression is shown in formula (14).

$$gai_ration(V) = n \frac{gain(v)}{split_Info(v)} \quad (14)$$

B. The Application of the Improved Decision Tree Algorithm in the Financial Management Model of Colleges and Universities

The above research method introduces the decision tree algorithm based on information entropy, and obtains the specific calculation method of information gain rate. This calculation method is very important in practical application. The size of the decision tree can be judged through the calculation of information entropy. Part 2.2 will give an overall description of the financial management of colleges and universities, and apply the decision tree to it. In college financial management, college budget management and budget performance management play an important role. The budget management of colleges and universities can make detailed use plans for financial income and use according to financial and teaching contents [17]. The flow chart of budget performance management is shown in Fig. 2.

Fig. 2. Flow chart of budget performance management

The data in the process of decision tree calculation needs to be processed, so it is necessary to select a more appropriate algorithm to build the decision tree model. After the decision tree is built, it is pruned, that is, the decision tree is optimized. The main purpose is to eliminate isolated nodes and noise, cut meaningless branches, and make the decision tree have the ability to correctly classify [18-20]. The pruning idea in the algorithm firstly sets the node of the tree as the number t of $n(t)$ samples that reach the node; to $e(t)$ represent the number of samples that can reach the node but does not belong to the node; the ratio of error samples at the node is expressed as $r(t)$. The probability of repeating the experiment multiple times is the probability of occurrence $e(t)$, and the confidence interval of the wrong sample ratio can also be obtained. The confidence interval is expressed in CF, and the value of the confidence interval can control the degree of pruning. The higher the

value of the confidence interval, the lower the degree of pruning. In C4.5 algorithm, the default value of confidence interval is 0.25, and the samples obey binomial distribution. The calculation process of the decision tree algorithm is integrated and calculated in the Clementine platform. The decision tree 4.5 algorithm is used to extract, process and mine the database data, and then establish a decision tree of financial budget to achieve early warning analysis of financial budget. The overall framework of early warning analysis is shown in Fig. 3.

Fig. 3. Overall framework of early warning analysis

The data warehouse in Fig. 3 includes a lot of information, such as information of various departments of the university, opening balance, income and expenditure data, balance data, and so on. There are many problems in many data, such as clutter, duplication and incompleteness, so cleaning the data is a necessary step of the system. For data processing, there are methods of filling and deleting. When multiple attributes are missing in the sample, and the number of missing attribute values is more than one-tenth of the total number of attributes, the sample data will be deleted; when the mean values of the sample attributes are the same, then fill it. In the financial management early warning analysis sub-structure system, it also includes a maximum tree growth module, an incremental learning module, a pruning optimization module, and a weight generation module. Its early warning program first selects the said information from the database for preprocessing, and saves the data of the financial budget report to the data warehouse; the data warehouse is an organization method for storing data. Then, the data is classified by the C4.5 algorithms to obtain new knowledge; the new knowledge generated includes the weight generation module, which uses the weight distribution method to assign corresponding weights to each node on the decision tree value, and an incremental learning module. The incremental learning module combines incremental learning with the C4.5 algorithms, and uses incremental data and learning methods to modify the generated decision tree; output to help decision makers make corresponding countermeasures. The details are shown in Fig. 4.

Fig. 4. Data flow chart of early warning analysis system

The construction of financial budget data warehouse is established from the three-level model of determining data source, data preprocessing and data warehouse. The data sources are all from the financial budget database of universities, and the data warehouse is studied according to the theme of decision tree; data preprocessing cleans the data, eliminates noise and irrelevant attributes, and converts the data; the three-level model of the data warehouse is established. The three-level model of the data warehouse, the first is the conceptual model, which determines the boundary

of the financial budget model, extracts the data information required by the financial budget, determines the main performance indicators of the model, and defines the relevant data dimensions. The second is the logical model. The logical model is designed according to the data table division, granularity, financial budget execution progress and relational model. The third is the establishment of the physical model, the process of designing the physical database with the data organization form stored in the data warehouse as the main body.

IV. FINANCIAL MANAGEMENT APPLICATION ANALYSIS OF IMPROVED DECISION TREE ALGORITHM BASED ON INFORMATION ENTROPY

A. Analysis of the Application Effect of Financial Management based on Improved Algorithm

The research selects representative universities as the experimental object, and analyzes the data according to the accumulated data of the financial department of universities. In order to make the data mining information have the characteristics of high quality and high informatization, the selected samples should be small and representative. Table I shows the experimental data of mining 2022 college financial data after preprocessing.

TABLE I. COLLEGE 2021 FINANCIAL DATA PREPROCESSING RESULTS

Project	Contrast ratio	Uniformity	Relevance	Entropy
T1	379.0191	19.3456	-0.0001	199.2554

The research uses the information entropy reduction of the C4.5 algorithms to determine the optimal branch variable and segmentation threshold of the decision tree. In the world of information data, the size of the entropy value can represent how much information is transmitted. If the entropy value is higher, it means that the transmission information is more; on the contrary, the transmission information is less, the information entropy value is smaller. In financial management, it can be divided by payment method to indicate the entropy value of the event. In ordinary budget indicators, the payment methods are divided into two types: direct payment and

authorized payment, and the two payment methods are guaranteed to have equal probability of opportunity, which makes it difficult to predict the result of the next financial payment method, and the two results are mutually exclusive. Independently, the entropy in this form is one bit. When the budget index amount is relatively large and the university only allows direct payment, the entropy value of the event division method is 0. Algorithm C4.5 takes the decreasing speed of information entropy as the basis for judging the progress of budget execution, and the decision tree for getting early warning of budget execution progress is shown in Fig. 4.

Fig. 5. Decision tree for budget implementation progress alert

In Fig. 5, 23.8% is the cut-off point for the payment method of the decision tree. A Situation: if the budget implementation progress of the project in July is not more than 23.8%, and the direct payment amount in January is not less than 150000 yuan, no budget is required; B Situation: For the same project, if the budget implementation progress is no more than 23.8%, the direct payment amount in January is less than 150000 yuan, and the authorized payment amount in September is no less than 522000 yuan. The decision tree needs to give an alert; In case b, when the authorized payment amount in September is less than 522000 yuan, it is necessary to judge according to the authorized payment amount in January. If it is not less than 8800 yuan, there is no need for early warning. On the contrary, if it is less than 8800 yuan, there is a need for early warning. By analogy, we can pay

more attention to the financial budget of the current month according to the results and budget implementation progress. The study obtains an early warning decision tree about the execution progress of the budget, and puts the data in the three test sets into the decision tree. The purpose is to compare the prediction result with the real value to verify the prediction accuracy of the decision tree in financial management. A decision tree was built on some data in test set 2, and the budgets of 100 projects were predicted and analyzed. In the judgment of the decision tree, the predicted results of 95 projects were the same as the actual results, and the predicted results of only five projects were the same as the actual results. Therefore, the decision tree built on the basis of information entropy has a higher prediction effect. Different test sets are used to verify the prediction accuracy of decision tree, as

shown in Fig. 6.

Fig. 6. Verification of prediction accuracy of decision tree with different test sets

Through the verification of the prediction accuracy of the decision tree from three data sets, it is found that the decision tree based on information entropy has a higher prediction accuracy, which verifies that the decision tree based on information entropy is applicable to a variety of data. Therefore, the analysis results of the decision tree constructed in Fig. 5, which is used in colleges and universities, are reliable.

B. Performance Comparison of Improved Decision Tree Algorithm based on Information Entropy

The experiment uses the ID3 algorithm, the CART algorithm and the improved C4.5 algorithms to compare to verify the superiority of the algorithm performance. The performance experiment of the algorithm uses the relevant error indicators as the judgment basis. The mean square error results of the three algorithms in the model are shown in Fig. 6.

Fig. 7. Mean square error results of three algorithms in the model

From Fig. 7 it is seen that the mean square error of the C4.5 algorithms is lower among the three models, and when the number of branch nodes is small, the mean square error of the algorithm is still higher, and the mean square error gradually decreases with the increase of the number of nodes, after a certain number of nodes, the mean square error value begins to converge, and the change range is small.

Fig. 8. Mean square error result of C4.5 algorithm

Fig. 8 shows the mean square error result of C4.5 algorithms. From Fig. 8 it is seen that when the number of nodes in the decision tree is small, its mean square error is large, and the increase in the number of nodes makes the mean square error of the decision tree change significantly. When the number of nodes is about three, the mean square error begins to converge gradually, and the variation range is small; but when the number of nodes is about 12, the mean square error increases gradually. It shows that the increasing number of nodes will lead to the increase of algorithm operation, and the decrease of its efficiency and prediction accuracy. The algorithm is further compared. The error square of the algorithm is further compared. The sum of the error squares of the two algorithms is further compared.

Fig. 9 shows the sum of error squares of ID3 algorithm and CART algorithm, and the sum of error squares of CART algorithm and C4.5 algorithms. It can be seen from Fig. 9(a) that the sum of error squares of CART algorithm is smaller than that of ID3 algorithm as a whole. When the number of branch nodes is 1-3, the error square changes greatly, and the sum of error squares changes from eight to about one. Since the number of nodes is four, the convergence speed of the average error square and the minimum error square of the algorithm decreases significantly, and the convergence tends to be smooth. The sum of squares of the CART algorithm converges to about 0.9. From Fig. 9 (b), it can be concluded that the sum of squares of errors of C4.5 algorithms is smaller than CART algorithm as a whole. When the number of branch nodes is no more than three, the error square of C4.5 algorithm changes greatly, and the convergence speed is fast. The sum of error squares changes from 7.5 to about 0.5. When the number of self-nodes is no less than four, the convergence speed of the average error square and the minimum error square of the algorithm decreases significantly, and the convergence tends to be smooth. The sum of squares of C4.5 algorithm converges to about 0.17.

Fig. 9. The result of the sum of squares of errors of ID3 algorithm and CART algorithm, and the result of the sum of squares of errors of CART algorithm and C4.5 algorithm

Fig. 10. Prediction results of CART algorithm on test samples and C4.5 algorithm on test samples

Fig. 10 shows the prediction results of CART algorithm on test samples and C4.5 algorithm on test samples. It can be seen from Fig. 10(a) that there is a certain degree of difference between the predicted results of CART algorithm and the actual results. The actual data results fluctuate between 0.70 and 0.80, while the predicted results of CART algorithm vary between 0.70 and 0.85. It can be seen from Fig. 10(b) that the improved prediction results have a high coincidence with the actual results. Therefore, the improved C4.5 algorithm has a high accuracy, and there is no significant error between the prediction results and the actual results.

Fig. 11 is a comparison chart of prediction model accuracy under three different algorithms. In Fig. 11, the predicted average value of CART model is 89.96%. The predicted average value of ID3 model is 92.56%. Decision tree algorithm C4.5 based on information entropy has a prediction accuracy of 95.1% in the model. By comparing the accuracy values of the prediction models under three different algorithms, it can be seen that the model proposed in this study has better prediction accuracy, so it can be used in actual prediction.

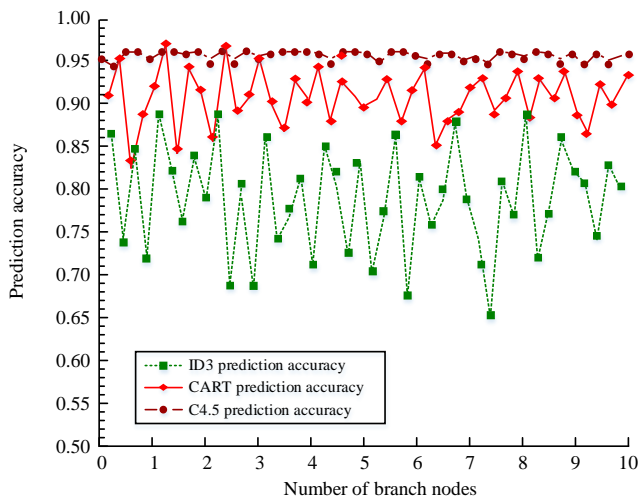

Fig. 11. Comparison chart of prediction model accuracy under three different algorithms

In conclusion, the improved decision tree algorithm model built by this research can have better prediction accuracy. Applying this model to the analysis of financial data in colleges and universities can obtain the financial implementation progress. The improved decision tree algorithm model can give an early warning according to the monthly financial income and expenditure of colleges and universities, so as to remind managers of the financial situation of colleges and universities in the current month.

V. CONCLUSION

The development of information industry has brought great impact to society, making information everywhere. The financial management in higher education institutions, due to the tedious work, generates a lot of information and is difficult to sort out, which affects the leaders' decision on the follow-up work. Therefore, in order to extract relevant data from redundant information data and facilitate making correct decisions, a decision tree algorithm based on information entropy is proposed. The algorithm uses entropy value and information gain rate to predict the probability of event occurrence, which can achieve different early warning effects for different events. The research verifies the prediction performance of the decision tree through the test set. In the three test sets, the precision measurement of the algorithm prediction under the support of information entropy reaches 95%. Then, the current financial data of colleges and universities are analyzed, and the financial implementation progress is obtained. Colleges and universities should be cautious about their financial expenditure in the month, otherwise the decision tree will issue a financial warning. Finally, to verify the performance of the algorithm, compared with ID3 algorithm and CART algorithm, the decision tree algorithm based on information entropy performs best by comparing the mean square error, the sum of squares of errors and the accuracy.

VI. FUTURE WORK

Although the C4.5 algorithm in the traditional decision tree algorithm has been improved in this research, the decision tree algorithm based on information entropy is proposed and analyzed with information entropy as the decision basis of the decision tree. At the same time, the measurement method is introduced to calculate the information entropy and information gain rate, and then an application model of university financial management based on the improved decision tree algorithm is proposed. However, there are still shortcomings in this research. The calculation of the information gain rate of the decision tree established on the basis of information entropy is more complex, which increases the difficulty of the algorithm. In the experiment, there are few sample data, resulting in some errors in accuracy. In the subsequent research, we can find a more simple calculation method and add more data samples from more colleges to improve the algorithm efficiency and prediction accuracy.

Abstract—Complexity, heterogeneity, schemaless-ness, data visualization, and extraction of consistent knowledge from Big Data are the biggest challenges in NoSQL databases. This paper presents a general semantic NoSQL Application Program Interface that integrates and converts NoSQL databases to semantic representation. The generated knowledge base is suitable for visualization and knowledge extraction from different Big Data sources. The authors use a case study of the COVID-19 pandemic prediction and other weather occurrences in various parts of the world to illustrate the suggested API. The Authors find a correlation between COVID-19 spread and deteriorating weather. According to the experimental findings, the API's performance is enough for heterogeneous Big Data.

Keywords—NoSQL database; formatting; semantic technology; data integration; pandemic prediction

I. INTRODUCTION

Large data sets have their roots in the 1960s and 1970s when the world of data was just getting started with the creation of the first data centers and the development of the relational database. Nowadays, the data grows at sky-high rates. The world has multiple Big Data sources with different structures like sensors, scientific experiments, and social networks. We produce and collect more data every minute, and we need to be able to process them as soon as possible. Everything depends on timing, including stock trading, tracking the growth of epidemics, and traffic monitoring. A minor misunderstanding could lead to both financial loss and fatalities. The high level of adoption of Big Data technology is influenced by the quick and continual growth in data volumes.

A. Research Problem

Researchers face many problems when dealing with data from multiple sources. Because the structure of the data is different it makes it difficult to process the data and extract knowledge. Most researchers are now trying to store the data in a semantic form to make it easier to process. To do this they need to collect data from different data stores and preprocess these data to present them in semantic form. The preprocessing phase takes much time and effort which we need to solve the real problems we face and take better decisions based on the knowledge extracted from the data.

This research is funded by the Academy of Scientific Research and Technology (ASRT), Cairo, Egypt, project titled "Coronavirus Prevalence Prediction Model" (Project ID: 6641).

B. Research Objectives

This article studies many semantic Big Data frameworks and their limitations. Then it proposes a semantic NoSQL application program interface (API). The proposed API can read data from multiple NoSQL databases and convert them to Ontology. By using the proposed API, it will be possible to apply semantic queries on different data stores. The proposed API can also be used to integrate different data stores into a defined format.

C. Organization

This paper is organized in the following way to fulfill the research goals: Section 2 reviews a background about Big Data, Ontology, and NoSQL databases. Section 3 examines the history of earlier similar works. Section 4 Shows the proposed API architecture. The implementation of our proposed API is described in Section 5. Section 6 provides a case study of the API to analyze COVID-19 spread and weather behavior. The impact of utilizing the suggested API is described in Section 7. The paper's conclusion is covered in Section 8, which also analyses the research's significant contribution and limitations.

II. BACKGROUND

A. Big Data

The term Big Data refers to a concept mostly used to classify large amounts of data. Despite the wide agreement on the promises and prospects of Big Data, there is no standard definition for it at this time.

The Institute of McKinsey Global defined the term Big Data as a "very Big Data set that can't be stored or managed with database software tools" [1].

Gartner [2] defined Big Data as "a high-volume, high-variety, and/or high-velocity information asset that necessitates cost-effective, novel types of data processing that provide better insight, decision-making, and process automation."

The term "Big Data" was defined by Deepak Gupta and Rinkle Rani [3] as 'Big data refers to large datasets which require non-traditional scalable solutions for data gathering, storage, management, analysis, and visualization, to extract actionable insights that could have an impact on every area of human life'. Big data characteristics are portrayed as extensions of 'V's [3][4]. Fig. 1 presents the Big Data characteristics.

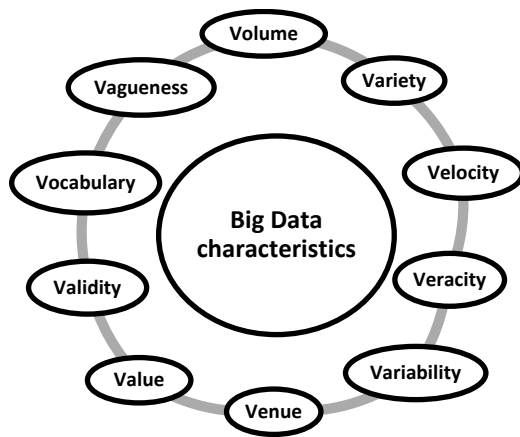

Fig. 1. Big Data characteristics

B. Ontology

An Ontology consists of $O = A, C, I, P, R, T$. Where A is the set of axioms; C is the set of concepts or classes; I is the set of instances; P is the set of properties of the concepts describing various features; R is the set of relationships between concepts and T is the set of hierarchical relationships among concepts that are called taxonomies [5].

The components of Ontology are as follows:[6]

- **Individuals:** “The ontology population is represented by individuals, which are objects. They are instances of classes.”
- **Classes:** “Classes are particular categories of objects or things that represent a collection of instances or specify a particular category of entities. They are frequently referred to as concepts or entity types. Classes can be used to classify individuals, other classes, or a combination of both.”
- **Attributes:** “Properties associated with objects or classes are called attributes. They include statements about Datatypes and their DataValues, characteristics, features, or parameters of individuals and classes.”
- **Relations:**” The numerous links that indicate how two individuals or classes are related. Additionally called associations, roles, relationship types, and object properties”.
- **Axioms:**” Logical rules and assertions that together create the general theory that describes the relationship between the ontology elements. They represent formal definitions of the ontology knowledge.”

C. NoSQL Databases

NoSQL (Not Only SQL) is a database that is a non-relational distributed database system. It facilitates the rapid structuring of data analysis with large volumes of data and a variety of data types. NoSQL is also referred to as a cloud database, a non-relational database. NoSQL databases are not based on tables and do not often employ structured query language to manipulate data. Receive and append operations are frequently highly optimized in NoSQL database systems.

When working with large amounts of data and this data structure does not require a relational model, NoSQL databases come in handy [4].

When compared to relational databases, NoSQL databases are more scalable, diverse, simple to use, flexible, and give better performance. MongoDB is now the most popular NoSQL database, with Apache Cassandra, Redis, and HBase following closely behind. Neo4j is the most popular NoSQL graph database and the most common cloud database is Amazon DynamoDB [7]. NoSQL data models allow related data to be stored in a nested data structure [8].

Based on their data model, NoSQL databases are classified into a variety of types[5]. The main types of NoSQL databases are wide-column databases, document databases, key-value databases, and graph databases. They provide flexible schemas and they are very scalable to large amounts of data and high user loads. Table I provides a comparative study of the four types of NoSQL databases.

TABLE I. A COMPARATIVE STUDY OF THE FOUR TYPES OF NOSQL DATABASES

NoSQL database types	Document database	Key-value store	Wide-column store	Graph store
Data Storage	It stores data in JSON, BSON, or XML documents	It stores data as an attribute name (or "key") combined with its value	It stores data in tables, rows, and dynamic columns	It stores data in nodes and edges
Use Cases	It is great for a wide variety of use cases and can be used as a general-purpose database	It is the best to use when you need to store large amounts of data but you don't need to perform complex queries to retrieve it such as storing user preferences or caching	Common use cases for wide-column stores include storing Internet of Things data and user profile data	It is the best to use when you need to traverse relationships to look for patterns such as fraud detection, social networks, and recommendation engines
Performance and scalability	High	High	High	Very high
Flexibility	High	High	Moderate	High
Complexity	Low	Very Low	Low	High
Examples	MongoDB, CouchDB	Redis, DynamoDB, Voldemort	Hbase, Big Table, Cassandra	Neo4j, HyperGraph, InfiniteGraph

III. RELATED WORK

Many researchers studied the relationship between semantic technology and Big Data technology. They tried to connect knowledge management systems with NoSQL database management systems to apply semantic queries on Big Data.

Bansal S and Kagemann S proposed Semantic Extract-Transform-Load (ETL) framework that uses semantic technologies to integrate and publish data from multiple sources. The Extract-Transform-Load (ETL) process refers to a process in data warehousing that extracts data from outside sources, transforms it to fit operational needs, which can include quality checks, and loads it into the end target database. The authors extracted data from different sources in flat file formats such as CSV. The proposed semantic ETL framework first creates a semantic model of the datasets being integrated, and then it creates semantically linked data that adheres to the data model. A semantic data model and semantically linked data (RDF triples) are produced using semantic technologies and stored in a data warehouse during the transform phase of an ETL process. The transformation phase will involve a manual process of analyzing the datasets, the schema, and their purpose. Based on the findings, the schema will have to be mapped to an existing domain-specific Ontology or Ontology will have to be created from scratch [9].

Hanan Abbes and Faiez Gargouri implemented a tool to generate Ontology from MongoDB databases. It proposed transformation rules from MongoDB to OWL Ontology. This work is done in five main steps. First is the creation of the Ontology skeleton by defining Ontology classes and detecting the relationships between them. Second, learn object properties and datatype properties. Third, identify Individuals. Forth, deduce class axioms, property axioms, and constraints. Finally, enrich the Ontology with class definition operators [10].

Mahmudul Hassan and Srividya K. Bansal proposed a solution to execute SPARQL query as SQL query using Apache Spark on large-scale RDF data stored in NoSQL databases such as HBase and Cassandra. It translated the SPARQL query to SPARK SQL for both HBase and Cassandra storage schemas. It first converted RDF data to store it in HBase and Cassandra and then proposed an algorithm to convert SPARQL query to SPARK SQL using the in-memory data processing engine Spark. The main purpose of this paper is to execute a query on RDF data (semantic data) with a large volume. To achieve that, it stored the RDF data in a NoSQL database. However, the algorithm can be used to perform SPARQL queries on data already stored in HBase or Cassandra [11].

K. EIDahshan, E. K. Elsayed, and H. Mancy developed a semantic dashboard using java JDK to connect to HBase and built a universal knowledge base using Protégé. It converted the SPARQL query to spark SQL using Sempala. The conversion is done using the algebra tree [12].

S. Mhammedi, H. El Massari, and N. Gherabi proposed an approach to automatically learn OWL Ontology from data in the Couchbase database by applying six mapping rules. The mapping rules are learning classes, learning object properties

from the embedded document, learning datatype properties, transforming all data values of fields in each document to individuals, learning property restrictions, and learning class hierarchies [13].

All of them except [11,12] do not handle Big Data. All of them allow the conversion of only one NoSQL database type. The proposed API handles Big Data, accepts any type of NoSQL database, allows schema conversion, and the proposed API is platform-independent. Table II shows the comparison among related works through data sources, NoSQL type, tools used, and limitations.

TABLE II. A COMPARATIVE STUDY OF THE RELATED WORKS

Research	Data Source	NoSQL Type	Tools	Limitations
[9]	Data from multiple sources in flat file formats such as CSV	--	Semantic Extract-Transform-Load (ETL) framework which generates a semantic model of the datasets under integration and then generates semantically linked data	The framework can not deal with NoSQL database stores
[10]	MongoDB	Document database	A tool to generate Ontology from MongoDB implemented by the JAVA programming language	The tool can deal with only one type of NoSQL database store
[11]	HBase and Cassandra	Wide-column	A query compiler that is written in Flex and Bison that translates SPARQL to Spark SQL to execute a query on RDF data stored in HBase and Cassandra	The tool can deal with semantic data in RDF format stored in a wide-column database
[12]	HBase	Wide-column	A semantic dashboard using java JDK to connect to HBase and built a universal knowledge base using Protégé	The tool can deal with only one type of NoSQL database stores
[13]	Couchbase	Document database	An approach to learning Ontology from the Couchbase database using mapping rules. This work is done by the JAVA programming language and OWL API	The tool can deal with only one type of NoSQL database stores

IV. THE PROPOSED SEMANTIC INTEGRATION APPLICATION PROGRAM INTERFACE ARCHITECTURE

Researchers and academics regard data access to be unattainable in many situations for a variety of reasons. These include the following: a profusion of data, non-computerization of processes, heterogeneity, data duplication, and the presence of a lot of isolated data in databases that can only be accessed in a specific context. These traits typically lead to low-quality information, which makes it challenging for researchers to organize and evaluate them during the decision-making process [14]. Data integration is the process of making it possible for people to access, deliver, and utilize data from several sources and huge businesses while preserving its integrity and quality. Real-time updates to data saved in one source can also be mirrored in other sources thanks to this [15].

Although Ontology development is not a new field of study, Big Data faces new difficulties due to its features (velocity, variety, and volume). Therefore, our API takes into account the properties of Big Data for Big Data Ontology creation. The main idea is to create Ontology from a large number of diverse sources. The authors' goal is to make the process of automatically generating Ontology and importing Big Data as simple as possible for the user by providing an

independent application program interface. The research's additional significant contributions include (1) the ability to integrate different sources of NoSQL, (2) the ability to support the Ontology creation-based Big Data access layer, (3) the ability to re-engineer and combine different Ontologies, and (4) the capability to easily build a semantic query over Big Data. Fig. 2 shows the proposed API overview.

The structure of the proposed API is as follows:

- *Connection Phase:* In this phase, the authors build a Big Data access layer that allows users to connect to any NoSQL database.
- *Integration and Extraction Phase:* In this phase, the API reads and extracts every record in the database and puts them in a Python dictionary.
- *Conversion phase:* In this phase, the API converts the dictionary to an XML file.
- *OWL Creation phase:* In this phase, the API creates OWL from the XML file.
- *Semantic and visualization phase:* In this phase, the API builds semantic rules and visualizes the data in a graph.

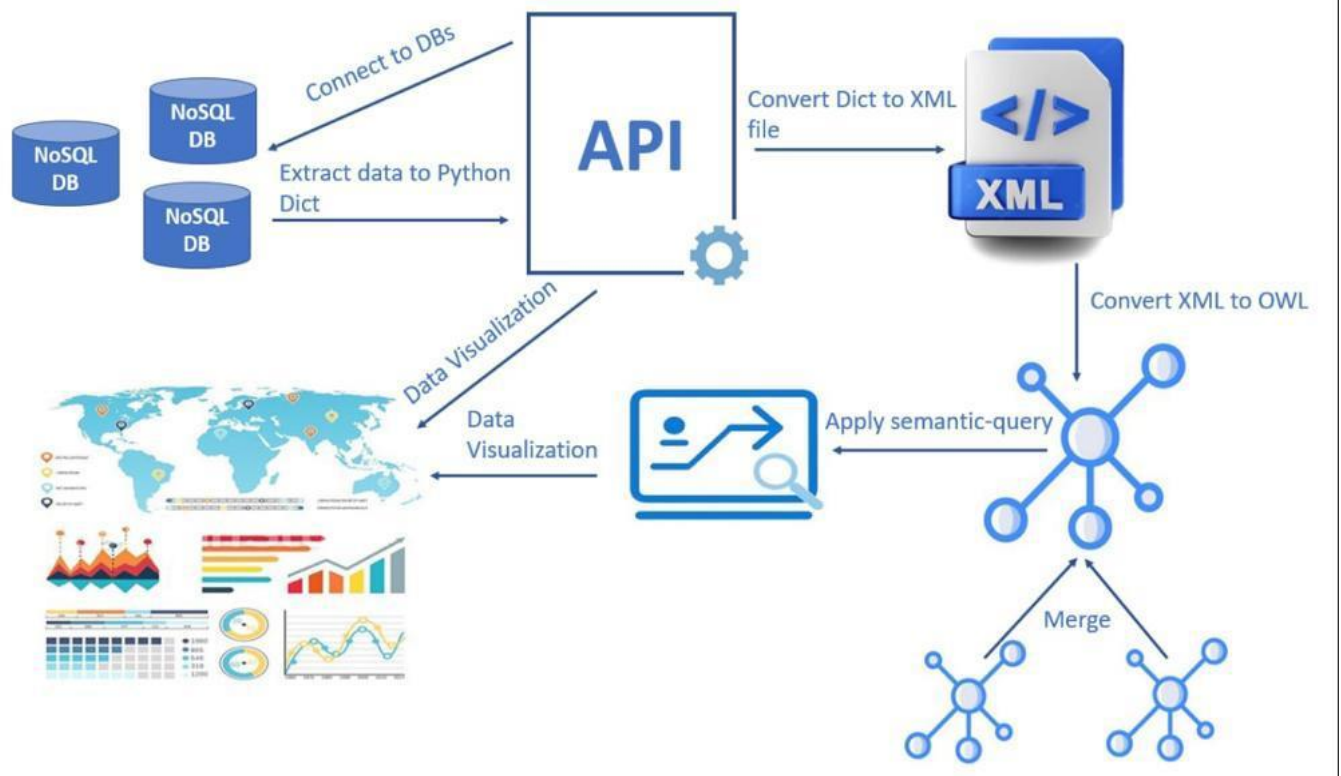

Fig. 2. The proposed API Overview

VI. PROPOSED SEMANTIC INTEGRATION APPLICATION PROGRAM INTERFACE IMPLEMENTATION

The API is created with Python 3.8.5 on Windows 10

operating system with Intel(R) Core(TM) i7-6500U CPU and 8GB RAM. The proposed API asks the user to enter the databases' names to be converted. The API scans the databases and retrieves every record in them with the same structure as it was in the database. After getting every record, it will be converted to XML. The API can handle data with any structure. Every record will be retrieved as a dictionary data type in Python. Then it will be converted to a JSON array. The JSON array will be converted to XML using the 'dicttoxml' package. The API can handle documents with complex structures and large sizes. For every collection in MongoDB and every table in HBase, a root class will be created. A subclass will be created to represent each attribute in the records. If the document in the MongoDB collection has embedded objects, other subclasses will be created to represent the attributes of the embedded object. After the conversion is completed, the XML is converted to OWL Ontology using DTD2OWL. Fig. 3 explains the proposed API workflow. Algorithm 1 demonstrates the Semantic NoSQL API execution steps.

Algorithm 1: Semantic NoSQL API

```
Initialize
Connect to the database
Scan every record in the database
For (every record) do
    Put the record in Python dictionary
    Convert the dictionary to XML
    Save the output to a file
End
Convert XML to OWL
Build semantic Query
Visualize the result
```

Fig. 3. The proposed API workflow

The phases of the proposed Onto-NoSQL API are implemented as follows:

A. Connection Phase

To access a NoSQL database, the author used the pymongo package to connect to MongoDB as a document database type, the happybase package to connect to HBase as a Wide-Column database type, the Redis-py package to connect to Redis as a Key-value database, and the Neo4j Python Driver to connect to Neo4j as a Graph database type. Algorithm 2 represents the connection code to MongoDB. Algorithm 3 represents the connection code to Hbase.

This paper focuses on both document database stores and column-oriented database stores as they are the most used NoSQL database stores. The most popular document store is MongoDB [6]. MongoDB is very popular because it allows multiple data types to be used. The database consists of collections. The collection stores the data as JSON documents. Schema is not needed to store the data in MongoDB. The data stored can be a string, number, date, array, or object. MongoDB can store data from multiple sources in different formats.

Algorithm 2: Connect to MongoDB

```
from pymongo import MongoClient
client = MongoClient()
#enter database name
database= input('Enter DB name:')
db = client[database]
```

One of the most popular column-oriented database stores is HBase. HBase is an open-source management system that is a versioned and distributed database based on Google's BigTable.

This system is column-oriented and built on top of HDFS, which speeds up read and write operations across Big Data sets. Application programming interfaces (APIs) such as Thrift and Java provide access to HBase. There are no query or scripting languages specific to these APIs. HBase is reliant on a ZooKeeper instance by default [16].

Algorithm 3: Connect to HBase

```
import happybase as hb  
conn= hb.Connection(HostName,PortNumber)  
conn.open()
```

B. Integration and Extraction Phase

The proposed API integrates MongoDB and HBase databases. It extracts every record in the database and puts them in a Python dictionary. Algorithm 4 reads records from MongoDB. Algorithm 5 reads records from HBase.

Algorithm 4: Read records from MongoDB

```
collection_names = db.collection_names()  
For (every collection ) do  
    #retrieve documents in each collection  
    docs = db[collection_name].find()  
End
```

Algorithm 5: Read records from HBase

```
table = conn.table('table_name')  
For (every key, row) do  
    # retrieve records  
    row = str(row)  
    row =json.loads(row)  
End
```

C. Conversion Phase

The proposed API converts the dictionary to an XML file. Algorithm 6 converts the dictionary generated from MongoDB records to an XML file. Algorithm 7 converts the dictionary generated from HBase records to an XML file.

Algorithm 6: Convert dictionary generated from MongoDB to XML file

```
#create XML file  
f = open(database+'/' +collection_name+'.xml', 'wb')  
For (every doc) do  
    #convert object id to string  
    doc_sanitized = json.loads(json_util.dumps(doc))  
    #convert to XML  
    xml = dicttoxml.dicttoxml(doc_sanitized)  
    f.write(xml)  
End  
f.close()
```

Algorithm 7: Convert dictionary generated from HBase to XML file

```
#create XML file  
f = open('table_name.xml', 'wb')  
For (every key, row) do  
    | xml = dicttoxml(row)  
    | f.write(xml)  
    | End  
f.close()
```

The interface of the API was created using PHP (Laravel Framework). First, we need to install the Process component that executes commands in sub-processes. This can be done using the composer to install the package. Second, use the Process class that enables Laravel to run a script. Third, create a new instance of the Process class, which takes three parameters the name of the script, the script itself, and the arguments passed to the script. An HTML form was created to read the data from the user. The user chooses the NoSQL database engine (MongoDB or HBase) and writes the name of the database (in the case of choosing MongoDB) or the table (in the case of choosing HBase) to be converted to XML. After the script is executed, the user gets a message that the database (in the case of using MongoDB) or the table (in the case of using HBase) is converted successfully. The XML files are located in the public folder in the Laravel project. Fig. 4, 5, and 6 represent the screens of the proposed API. Fig. 7 is a snapshot from the generated XML file.

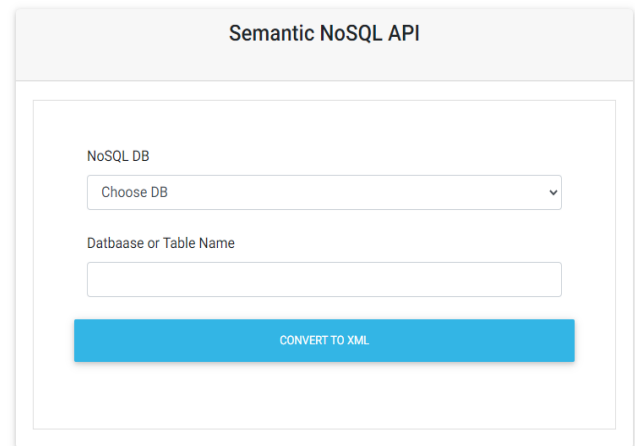

Fig. 4. The API screens- the input form

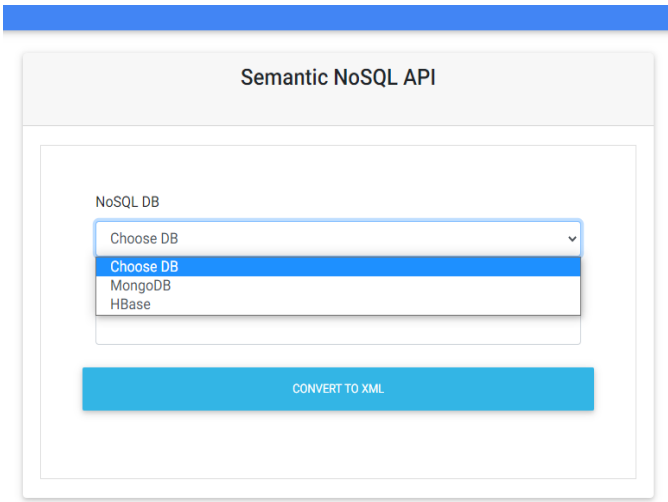

Fig. 5. The API screens- choose NoSQL data store

Fig. 6. The API screens- the success message after the database is converted

Fig. 7. A snapshot of the generated XML file

D. OWL Creation Phase

The proposed API converts XML format to OWL. The Authors implement the DTD2OWL2 Method in python [17].

E. Semantic and Visualization Phase

The proposed API builds a semantic query using rdflib [18] and visualization using the Plotly package in Python.

VII. CASE STUDY

The authors apply API to COVID-19 and weather data. Data was collected from various sources regarding the spread of Covid19. The number of cases was collected from the WHO. The weather data was collected from National Centers for Environmental Information website [19]. The authors used the number of confirmed cases, population, and weather data to predict a new pattern of confirmed cases and to find a relation between it and the other factors. The data was preprocessed and converted to JSON format. MongoDB was used to store the confirmed case data. HBase was used to store the weather data. By converting the database to OWL, it is possible to apply semantic queries and extract more knowledge from the data. It was possible to visualize the data and find a relation between them despite being stored in different databases with different structures. Fig. 8, 9, and 10 visualize the data on the world map.

Fig. 8. The population of world countries

Yearly Average

Fig. 9. The yearly average temperature of the world

The Covid-19 data was used to implement the proposed API. These data are various, change rapidly, and have large sizes. The data type can be text describing the case or symptoms, numbers describing the number of infected cases, images of the X-ray performed on the patients, or geographical data describing the spread of the virus. All these data can be stored in NoSQL databases. The user can work with one type of stored data to predict the behavior of the virus or even diagnose a patient based on the X-ray performed on his chest. The user needs to integrate these data from multiple sources to achieve his goal. The data can be integrated to extract more knowledge from them and help countries to prepare and deal with the spread of the virus. NoSQL databases can help to improve dealing with such important and various data to make better decisions. By converting the NoSQL database to Ontology, the user can discover new rules and relationships.

VIII. ANALYSIS OF RESULTS

The used data were in the form of text and integers that represent the number of confirmed cases of Covid19 around the world. They also represent other factors like each country's temperature and population. The interval of the collected data was over 500 days from 22nd Jan 2020 to 31st Aug 2021. The confirmed case data and the population of every country in the world were stored in MongoDB, whereas the weather data were stored in HBase. By studying Fig. 10, it may be possible to see the spread of the virus around the world. By studying other factors, it could be possible to find a pattern or even a factor that deeply affects the infection rate, which will help us find a way to decrease the infection rate.

In Fig. 11 you could see the relation between the temperature represented by the blue curve and the number of confirmed cases represented by the red curve. The data were scaled in the range of 0 to 1 using the min-max scaler

As stated before, these data were stored in different NoSQL databases with different types. By using the proposed API, it was possible to connect to these databases and retrieve data from them. Four countries from around the globe were chosen to study the effect of temperature on the spread rate of the virus. The X-axis represents the number of days while the Y-axis represents the number of confirmed cases and temperature degrees every day.

By choosing a small interval of time such as in Fig. 12, it could be concluded that the infection rate is inversely proportional to the temperature degree. Of course, other factors affect the infection rate such as the population of the country under study (Fig. 8 demonstrates the population of world countries), the educational level of most of the population that affects their behavior, or the economy of the country that affects the medical care system.

Confirmed Cases of 01-02-2020

Confirmed Cases of 01-06-2020

Confirmed Cases of 01-12-2020

Confirmed Cases of 01-06-2021

Fig. 11. The relation between temperature (blue) and number of confirmed cases (red) (The X-axis represents the number of days)

Fig. 12. The confirmed cases in Egypt during June, July, and August 2020 are in red, and the temperature is in blue (The X-axis represents the number of days)

IX. CONCLUSION

This paper presented Big Data concepts, technologies, and challenges. It studied NoSQL databases, their types, and the relationship between NoSQL Databases and Ontology. A proposed API was developed to integrate multiple NoSQL databases and generate OWL Ontology from them. By using the proposed API, it is possible to apply semantic queries, find new rules, and extract more knowledge. Also, it can be used to integrate data from different data stores into a unified defined format. Semantic data visualization has shown the relation between different data and discovered new patterns. One can say that the temperature is a factor in the virus's spread. It spreads faster in lower temperatures like in the USA, Russia, and some European countries (Fig. 9 demonstrates the yearly average temperature of the world). It also spreads faster in countries with a high population like India.

Big Data Application in Forecasting Financial Investment of e-Commerce Industry for Sustainability

Yanfeng Zhang

Business School, Sias University, Xinzheng, 451150, China

Abstract—With the rapid development of e-commerce, financial investment forecasting in the e-commerce industry has gradually become a concern of relevant personnel. Based on DBN, the study proposes a PVD prediction model. For training and test sample sets, the PLR_VIP algorithm is calculated and min-max normalization is applied to the original financial time series. To determine appropriate network parameters, the DBN network is trained and tested, and then Elliott wave patterns are predicted based on financial time series. The experimental results show that the MSE of the PVD model is 0.4015 and the prediction accuracy is 70.21%, indicating that it can efficiently and accurately identify the Elliott wave pattern of financial time series. Comparing the prediction results of the PVD model with the other five models, the values of the four evaluation indicators of PVD are the lowest among all models, which are 0.6336, 0.4015, 0.9052, and 29.79%, respectively. Compared with the training error changes of other models, it can be seen that the error curve of the DBN network is smoother and the training error is smaller. It shows that it has higher stability, faster convergence speed, higher reliability and accuracy, and shows excellent prediction performance, which is significantly better than other models. Experiments show that under the background of sustainable development, the PVD forecasting model proposed in the study performs well in financial investment forecasting, which provides a reference for the development of financial investment forecasting in the e-commerce industry.

Keywords—Stainable development; big data; e-commerce industry; financial investment forecast; deep belief network

I. INTRODUCTION

The financial investment market plays an important role in today's social and economic field, and the direction of the financial market will directly affect the core competitiveness of enterprises [1]. The academic community continues to study the changing laws of the financial market, and find reliable means that can describe and predict the changing laws and future trends of the financial market [2]. Neural networks have been developing continuously in recent years, and a large number of related technologies have been applied to various fields, including forecasting the financial investment market [3]. e-Commerce is a new type of networked economic activity. In recent years, it has become an important means for many countries to enhance their economic strength and gain the advantages of global resource allocation. However, the e-commerce industry in China currently has problems such as waste of resources and inconsistent supply and demand, so it is necessary to use effective forecasting methods to forecast the financial investment market in the e-commerce industry [4]. To improve the development ability of financial investment in China's e-commerce industry, the research

proposes a PVD (Piecewise Linear Representation VIP DBN) prediction model based on Deep Belief Network (DBN), which uses a deep learning model to model financial time series, and innovatively combines DBN and piecewise linear representation based on very important points (PLR_VIP). It can discriminate the Elliott wave pattern of financial time series and then predict the trend of the financial investment market in the e-commerce industry.

There are two innovation points in the research. First, the financial investment forecast dataset is built against the background of big data; secondly, intelligent algorithm is introduced into financial forecasting to realize automatic forecasting of financial investment. Compared with previous studies, the use of intelligent algorithms and big data technology can more effectively achieve its change prediction, and can more easily update data with the help of Internet technology.

II. RELATED WORK

With the related research and development of big data, deep learning related technologies have been applied to the field of financial forecasting, and many scholars at home and abroad have conducted research on it. Kare et al. used Singular Spectrum Analysis (SSA) and Multi-channel Singular Spectrum Analysis (MSSA) to identify important deterministic cycles in residential property prices, private non-financial sector credit shares. Prediction test results show that the inclusion of financial big data significantly improves the prediction accuracy of financial cycle components [5]. Scholars such as Kelotra proposed a stock market forecasting system that effectively predicts the state of the stock market. First, the calculation of technical indicators is performed on the data from the real-time stock market, indicating that the necessary features are obtained by clustering using Sparse Fuzzy C-means (Sparse-FCM), and then feature selection is performed. The selected features are given to the Deep-ConvLSTM model to perform accurate predictions. Evaluation Based on evaluation metrics such as Mean Squared Error (MSE) and Root Mean Squared Error (RMSE), the proposed stock market forecasting model obtained the minimum MSE and RMSE of 7.2487 and 2.6923, which showed the effectiveness of the method in stock market forecasting [6]. Chen et al. proposed a new stock price prediction model that combines a Convolutional Neural Network (CNN), a Bidirectional Long Short-Term Memory (BiLSTM) network, and an Efficient Channel Attention (ECA). CNNs are used to extract deep features from stock data to reduce the effects of high noise and nonlinearity. BiLSTM network is used to predict stock prices based on the extracted

deep features. At the same time, a novel ECA module is introduced into the network model, which further improves the sensitivity of the network to important features and key information. The results demonstrate the effectiveness and feasibility of the proposed CNN-BILSTM-ECA network model [7]. Lei et al. constructed investor attention factors through Baidu search antecedent index, and then combined other transaction information such as transaction volume, trend indicators, and quotation rate of change as input indicators, and finally used a deep temporal convolutional network (TCN) learning model to predict Volatility under high frequency financial data. Compared with the traditional econometric model, the multi-step forecast results of the TCN model have higher stability, provide a more accurate and reliable method for volatility forecasting of big data, and enrich the index system of volatility forecasting [8]. Scholars such as Yh proposed a new financial data prediction model based on Variational Mode Decomposition (VMD). In this model, the parameters of VMD are optimized by genetic algorithm. VMD then decomposes the data series into long-term and short-term trends. Finally, a long short-term memory (LSTM) network is used to predict future data, and the data input generated by the VMD is used. Experimental results show that the model has high accuracy in the advance forecasting of financial time series and outperforms the baseline model [9].

Researchers such as Bukhari AH proposed a novel hybrid model with fractional derivative strength and its dynamic characteristics of deep learning, long short-term memory (LSTM) networks to predict changes in financial markets; where the ARFIMA model-based filter has a linear trend in the data that outperforms the Autoregressive Integrated Moving Average model (ARIMA) model, and passes the residuals to the LSTM model, which has the help of an external dependent variable. The residual value that captures the nonlinearity below. This model not only alleviates the volatility problem, but also overcomes the overfitting problem of neural networks [10]. Luo et al. propose a hybrid model that combines ensemble empirical mode decomposition (EEMD), autoregressive integral moving average (ARIMA), and Taylor expansion using tracking differentiators to forecast financial time series. Specifically, financial time series are decomposed into subsequences by EEMD. Then, the linear part of each subsequence is predicted by the linear ARIMA model, while the nonlinear part is predicted by the nonlinear Taylor expansion model. Combine predictions from linear and nonlinear models into predictions for each subseries. The final prediction result is obtained by combining the predicted values of all subsequences [11]. Scholars such as Darley Olufunke use the ARIMA model to analyze and model the price trend, and propose a model suitable for prediction. The results show that the ARIMA (6, 1, 12) model is the most suitable, based on a combination of the number of significant coefficients and volatility values, the Akaike Information Criterion (AIC) and the Bayesian Information Criterion (BIC). After two months of experiments, the results show that the prediction accuracy gradually decreases as the number of days in the test period increases [12].

The study proposes a PVD prediction model based on

DBN, which performs PLR_VIP algorithm calculation and min-max normalization on the original financial time series to obtain training sample sets and test sample sets, trains and tests the DBN network to obtain appropriate network parameters, and then predicts Elliott wave patterns for financial time series.

III. PVD FINANCIAL INVESTMENT PREDICTION MODEL BASED ON DEEP BELIEF NETWORK

A. Fusion of Deep Belief Network and Elliott Wave Model

DBN is a model of deep learning technology, which is composed of stacking units. The training process of DBN includes two stages: pre-training and fine-tuning. The pre-training adopts an unsupervised greedy layer-by-layer learning strategy to train each Restricted Boltzmann Machine (RBM) from the bottom up, which can feature information in the original data and is extracted layer by layer to abstract the high-level feature representation of the data [13]. Fine-tuning adopts a supervised learning algorithm to adjust the parameters of the network to complete classification and recognition. RBM is a generative model with strong unsupervised learning ability. It consists of two parts: visible layer and hidden layer. Units between different layers are connected by full connection [14]. The structural framework of the DBN network is shown in Fig. 1.

Fig. 1. Structure framework of DBN network

The visible layer consists n of neurons, $v = (v_1, v_2, \dots, v_n)$, where $v \in \{0, 1\}^n$; the hidden layer consists m of neurons, $h = (h_1, h_2, \dots, h_m)$, where $h \in \{0, 1\}^m$. A value of 1 indicates that the neuron is activated, otherwise it is not activated. The parameter $\theta = \{w, b, a\}$ determines the RBM model, in which w is the weight between the visible layer unit and the hidden layer unit, a representing the offset of the visible layer unit and the offset of the b hidden layer unit. The structure of the RBM is shown in Fig. 2.

Fig. 2. Structure of RBM

The joint probability distribution of the visible layer and hidden layer units of RBM is shown in formula (1).

$$P(v, h) = \frac{1}{N} e^{-E(v, h)} \quad (1)$$

In formula (1), $N = \sum_{v, h} e^{-E(v, h)}$ is the normalization factor, which $E(v, h)$ is the energy function. It is assumed that the visible layer and the hidden layer of the RBM model obey the Bernoulli distribution, and the energy function is defined as shown in formula (2).

$$E(v, h) = -\sum_{j=1}^n a_j v_j - \sum_{i=1}^m b_i h_i - \sum_{i=1}^m \sum_{j=1}^n w_{ij} v_j h_i \quad (2)$$

Exponentiate and regularize the energy function to obtain the joint probability distribution formula, and sum up the states of all neurons in the hidden layer and the visible layer respectively to obtain the edge probability distribution of the visible layer and the hidden layer, as shown in Equation (3).

$$\begin{cases} P(v) = \sum_h P(v, h) = \frac{1}{N} \sum_h e^{-E(v, h)} \\ P(h) = \sum_v P(v, h) = \frac{1}{N} \sum_v e^{-E(v, h)} \end{cases} \quad (3)$$

After the state of the visible layer unit is obtained, i the conditional probability that the first unit of the hidden layer is activated can be calculated as shown in equation (4).

$$P(h_i = 1|v) = \sigma \left(b_i + \sum_{j=1}^n w_{ij} v_j \right) \quad (4)$$

After the state of the hidden layer unit is obtained, j the conditional probability that the first unit of the visible layer is activated can be calculated as shown in formula (5).

$$P(v_j = 1|h) = \sigma \left(a_j + \sum_{i=1}^m w_{ji} v_i \right) \quad (5)$$

where σ represents the sigmoid function, $\sigma(x) = \frac{1}{1 + e^{-x}}$. The mean square error is used to measure the difference between the reconstructed output of the hidden layer to the visible layer and the input of the RBM.

Set a sample set $v = \{v_0, v_1, \dots, v_K\}$ and train the RBM model. In order to make the joint probability distribution fit the distribution of the input samples as much as possible and make the system energy stable, it is necessary to find a suitable parameter $\hat{\theta} = \{w, b, a\}$. The maximization likelihood function is used $L(\theta)$, which is equivalent to maximizing the log-likelihood function $\ln L(\theta)$, as shown in equation (6).

$$\hat{\theta} = \arg \max_{\theta} L(\theta) = \arg \max_{\theta} \sum_{t=0}^K \ln P(v_t | \theta) \quad (6)$$

The gradient ascent method is used to update the parameters as shown in equation (7).

$$\theta^* = \theta + \eta \frac{\partial \ln P(v)}{\partial \theta} \quad (7)$$

Equation (7) η represents the learning rate, $\eta > 0$. The log-likelihood function for a single sample is shown in Equation (8).

$$\ln P(v_0) = \ln \frac{1}{N} \sum_h e^{-E(v_0, h)} = \ln \sum_h e^{-E(v_0, h)} - \ln \sum_{v, h} e^{-E(v, h)} \quad (8)$$

The gradient formula of this sample is shown in formula (9).

$$\frac{\partial \ln P(v_0)}{\partial \theta} = -\sum_h P(h|v_0) \frac{\partial E(v_0, h)}{\partial \theta} + \sum_{v, h} P(v, h) \frac{\partial E(v, h)}{\partial \theta} \quad (9)$$

The joint probability distribution cannot be directly calculated, and it needs to be approximated by the sampling method, which $P(v, h)$ can be expressed as $P(h|v)P(v)$, and substitute it into the gradient formula, as shown in formula (10).

$$\frac{\partial \ln P(v_0)}{\partial \theta} = -\sum_h P(h|v_0) \frac{\partial E(v_0, h)}{\partial \theta} + \sum_v P(v) \sum_h P(h|v) \frac{\partial E(v, h)}{\partial \theta} \quad (10)$$

The update formula of the three parameters of the RBM is obtained. The traditional parameter update formula is more complicated and requires a large amount of calculation. Therefore, the Contrastive Divergence (CD) algorithm is used to update the parameters, usually only one step is needed to achieve better results. Using the k-CD algorithm, set a training set v , $\forall v \in v$ take the initial value v^0 , and perform k step Gibbs sampling. When the first t step ($t = 1, 2, \dots, k$) is reached, it is obtained by sampling, $P(h|v^{(t-1)})$ obtained $h^{(t-1)}$ by $P(v|h^{(t-1)})$ sampling $v^{(t-1)}$, and obtained after k

sub-Gibbs sampling, $v^{(k)}$ and an approximation of the parameters can be obtained. The gradient formula is as formula (11).

$$\begin{cases} \frac{\partial \ln P(v)}{\partial w_{ij}} \approx P(h_i = 1 | v^0) v_j^0 - P(h_i = 1 | v^k) v_j^k \\ \frac{\partial \ln P(v)}{\partial b_j} \approx v_j^0 - v_j^k \\ \frac{\partial \ln P(v)}{\partial c_i} \approx P(h_i = 1 | v^0) - P(h_i = 1 | v^k) \end{cases} \quad (11)$$

The update formula of the parameters can be estimated by Equation (12).

$$\begin{cases} w_{ij}^* \approx w_{ij} + \eta (P(h_i = 1 | v^0) v_j^0 - P(h_i = 1 | v^k) v_j^k) \\ b_j^* \approx b_j + \eta (v_j^0 - v_j^k) \\ c_i^* \approx c_i + \eta (P(h_i = 1 | v^0) - P(h_i = 1 | v^k)) \end{cases} \quad (12)$$

Set up a l DBN network with one hidden layer and calculate its joint probability distribution as Equation (13).

$$P(v, h_1, h_2, \dots, h_l) = P(v | h_1) P(h_1 | h_2) \dots P(h_{l-2} | h_{l-1}) P(h_{l-1}, h_l) \quad (13)$$

Equation (13) $P(h_{l-1}, h_l)$ represents the probability distribution of the top layer of the RBM, which represents $P(h_k | h_{k+1})$ the conditional probability ($k = 0, 1, 2, \dots, l-1$, where $h_0 = v$) of the hidden layer of h_k each RBM layer when the visible layer is known. h_{k+1} For a n training sample set with one sample $X = \{x_0, x_1, \dots, x_n\}$, the data label set of the sample is $Y = \{y_0, y_1, \dots, y_n\}$. The input of the pre-training process X does not require data labels. The k-CD algorithm is used to train the network parameters unsupervised, and the output value obtained by each layer of RBM is input into the next layer of RBM, and the feature vector set of the sample is obtained layer by layer. The pre-training process adjusts the RBM model of each layer to ensure the optimal output of this layer, but cannot guarantee the optimal output of the entire DBN. Therefore, the DBN network parameters need to be adjusted, and the network parameters Y are supervised top-down using the sample data label set [15].

There are two types of Elliott wave cycle modes: driving and adjusting. An impulsive wave is a homeopathic wave that pushes the market to change in the direction of the main trend. It is generally composed of five sub-waves with a simple form,

and can be divided into conventional impulsive waves and unconventional impulsive waves. A regular motive wave consists of five waves 1-2-3-4-5 directed upwards or downwards. After the fifth wave ends, there will be a movement in the opposite direction of the trend. This movement is a corrective wave, which is a partial retracement of the driving relative to the previous driving wave of the same level. The structure of corrective waves is more complex than that of driving waves, mainly including three forms: zigzag, flat and triangle [16-17].

B. 2.2 Establishment of PVD Prediction Model based on Deep Belief Network

When analyzing and forecasting financial markets, financial time series are often used to extract financial transaction data. Time series is a collection of measured values obtained over time. The core is to use reasonable technical methods to ignore the small fluctuations of the time series to obtain the concept of data sawtooth, and to identify the corresponding time series on different time scales pattern [18]. Time variables and data variables together make up each data unit of the time series. The research uses deep learning combined with Elliott wave theory to establish a financial market prediction model, extracts transaction price information and abstracts it as a time series, extracts features through deep learning model and obtains the Elliott wave pattern corresponding to the original time series [19]. Since the lengths of the time series corresponding to the same wave pattern are different, but the length of the input sequence needs to remain the same, the length of the input data needs to be fixed, and the original data is preprocessed before input, that is, the data is processed Dimensionality reduction and compression, discarding parts that have less impact on the global. The research uses the PLR_VIP algorithm to process the original data [20].

The basic principle of piecewise linear is to set a n dimensional time series $S = \{s_1, s_2, \dots, s_n\}$ and extract a new series S of k ($k \ll n$) pieces that construct an approximate series according to it $S^* = \{s^*_1, s^*_2, \dots, s^*_{k+1}\}$.

Using the PLR method, the adjacent continuous line segments can be approximated as the original time series. The selection of segment points has different degrees of influence on the time series structure, and the degree of influence can be expressed as importance. Select important points on the original time series, keep important points and discard unimportant points. In order to fix the step size of the time series, the segmentation condition is set to a fixed number of segments. When the interval of the time series is fixed, the importance of a point is measured by the distance of the point from the endpoint of the region where the point is located. The raw time series is preprocessed with vertical distance as a measure. An example of the PLR_VIP algorithm is shown in Fig. 3.

Fig. 3. PLR_VIP algorithm example

The time series shown in Fig. 3 takes the VIP_1 sum as the end VIP_2 point, and the vertical distance between the d calculation point and the two end points is p_3 shown in formula (14).

$$d = \left| \left(y_1 + (y_2 - y_1) \frac{x_3 - x_1}{x_2 - x_1} \right) - y_3 \right| \quad (14)$$

VIP_1 sum VIP_2 is two important points, find the point with the farthest vertical distance from the two endpoints P_3

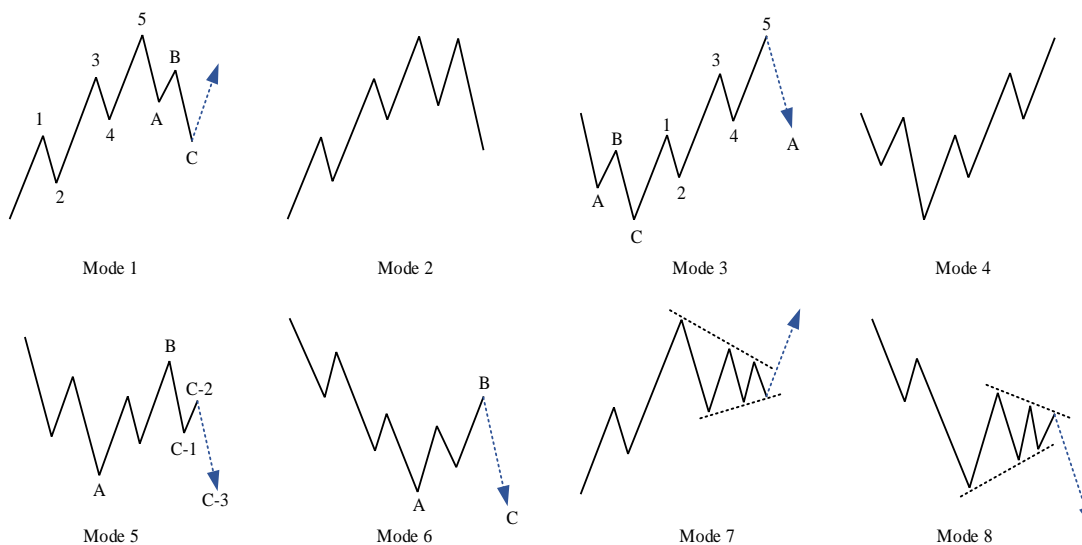

Fig. 4. 8 Elliott Wave Model

Pattern 1 consists of driving waves and zigzag waves. When the financial time series is identified as pattern 1, it means that the market is about to enter a rising stage, and there may be a new round of bull or bear market upward adjustment. Wave 3 is the key sub-wave of the bull market, and wave C is the key sub-wave of the bear market, both of which are the strongest waves under normal conditions. Pattern 2 consists of motive waves and flat correction waves. The types of correction waves are different from those of pattern 1, including spread and trend. When the financial time series is identified as mode 2, it means that the market has

as the next important point VIP_3 , find the point with the farthest vertical distance in the area with the VIP_1 sum VIP_3 as the endpoint and the VIP_2 sum VIP_3 as the endpoint respectively and mark it For important points, the above process is iterated until the number of important points reaches a predetermined number. During the training process of the network, the data of the order of magnitude will mask the contribution of the data of the smaller order of magnitude to the network, thus affecting the accuracy of the network, and the cardinality of the sample and the average value are quite different, which will reduce the convergence speed of the network. Therefore, standardize the sample data, use the min-max normalization method to map the data to the interval [0, 1], and x perform min-max normalization on the first i data of the sample as shown in formula (15). x_i

$$x_i' = \frac{x_i - \min(x)}{\max(x) - \min(x)} \quad (15)$$

The study designed eight types of Elliott wave patterns, each of which consists of eight sub-waves, as shown in Fig. 4.

entered a rising period and will usher in a trading opportunity. The attribute of the market rising is the same as that of mode 1. Pattern 3 consists of ZigZag and Motivation. When a financial time series is identified as pattern 3, it indicates that the market will enter a downward phase. The falling phase may result from a pullback from the previous driving wave, or it may usher in a new bear market. Pattern 4 is composed of a flat adjustment wave and a driving wave. The type of adjustment wave is different from that of pattern 3. The flat adjustment wave of pattern 4 includes spread and trend. When the financial time series is identified as pattern 4, it means that

the market will enter an adjustment phase, and the property of the market falling is the same as that of pattern 3. Pattern 5 represents part of a flat correction, its role is to predict the main decline in the market, and its end indicates the beginning of the main decline. Pattern 6 is an inversion of Pattern 1 and appears as part of a ZigZag. When the financial time series is identified as pattern 6, it means that the financial market is about to enter the main down stage. The purpose of model prediction is to judge the future trend of the financial market, so there is no need to consider whether the triangle is an unconventional driving wave or a corrective wave. When the financial time series completes pattern 7, the financial market will start to rise, and after pattern 8 it will start to fall.

The PVD prediction model proposed by the research mainly includes three parts: PLR_VIP algorithm, min-max normalization processing and DBN network. PVD forecasting models can identify and judge Elliott wave patterns in

financial time series. The PLR_VIP algorithm can retain the important points of the original financial time series and standardize the step size of the financial time series. The min-max normalization method can standardize the range of data changes and improve the accuracy and convergence speed of the network. Perform PLR_VIP algorithm calculation and min-max normalization on the original financial time series to obtain a training sample set and a test sample set, train and test the DBN network to obtain appropriate network parameters, and then predict the Elliott wave pattern of the financial time series. The specific process of the PVD prediction model is shown in Fig. 5.

To test the prediction accuracy and performance of the proposed model, four performance indicators are selected as evaluation criteria. The lower the indicator value, the more accurate the prediction results of the prediction model are, as shown in Table I.

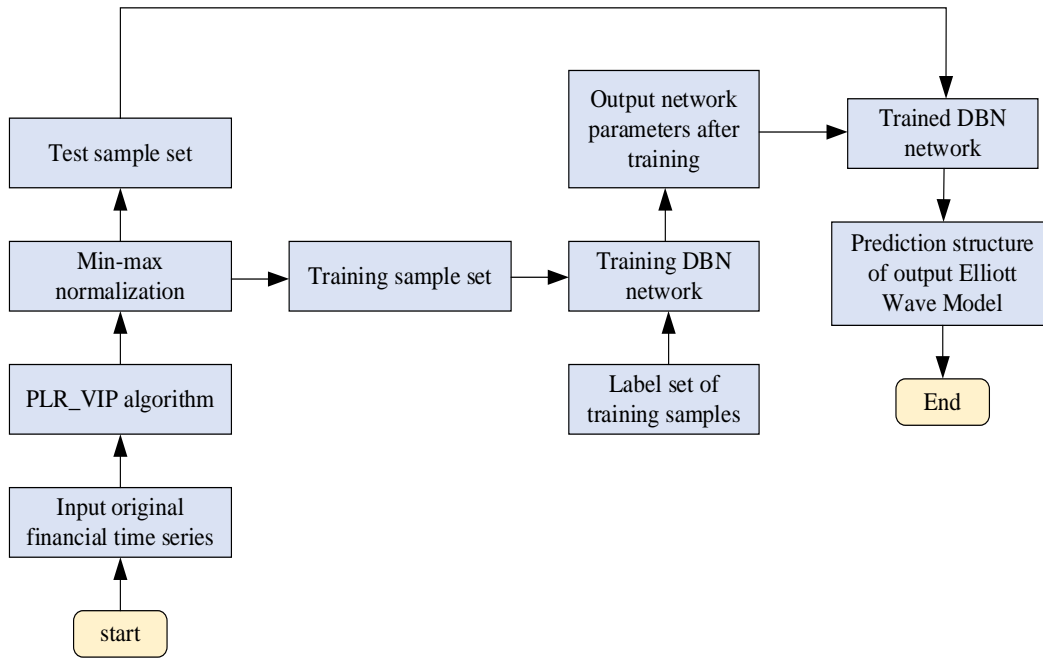

Fig. 5. Specific process of PVD prediction model

TABLE I. PERFORMANCE INDEX

Performance index	Calculation formula
RMSE	$RMSE = \sqrt{\frac{1}{n} \sum_{i=1}^n (T_i - P_i)^2}$
MSE	$MSE = \frac{1}{n} \sum_{i=1}^n (T_i - P_i)^2$
MAE	$MAE = \frac{1}{n} \sum_{i=1}^n T_i - P_i $
ER	$ER = \frac{\sum \{1 Model_p \neq Model_T \}}{\sum \{1 Model_p = Model_p \}} \times 100\%$

Table I shows that root mean square error (RMSE), mean square error (MSE), mean absolute error (MAE) and relative error (ER) are used to evaluate the prediction performance of the model.

The study selected some data from the historical price data of more than 10 trading varieties in the global stock index, foreign exchange market and bulk commodity markets for the experiment. A total of 6000 relevant financial data were collected in this experiment, 4829 of which were from Internet data and 1171 from books, newspapers and other tools. Take 20% of all data as the test set and the remaining 80% as the training set.

IV. EXPERIMENTAL ANALYSIS OF PVD PREDICTION MODEL BASED ON DEEP BELIEF NETWORK

After preprocessing through the PLR_VIP algorithm and the min-max normalization method, the original financial time series sample data of the DBN network for training and testing are obtained. The obtained sample data is input into the DBN network for iterative training. As the number of iterations increases, the training error of the DBN network is shown in Fig. 6.

Using the PVD forecast model to classify and predict the Elliott wave pattern of the financial time series, the classification results show that the MSE is 0.4015, and 70.21%

of the financial time series in the sample have obtained the correct classification result, that is, the prediction accuracy of the model is 70.21%. It shows that the PVD forecasting model can effectively identify the Elliott wave pattern of financial time series, and can more accurately predict the trend of the financial market. Taking the S&P 500 index, the US dollar index and WTT crude oil as examples, the prediction effect of the model is shown in Fig. 7.

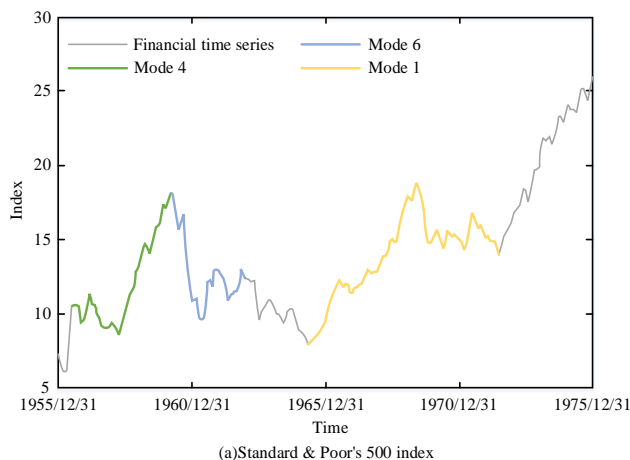

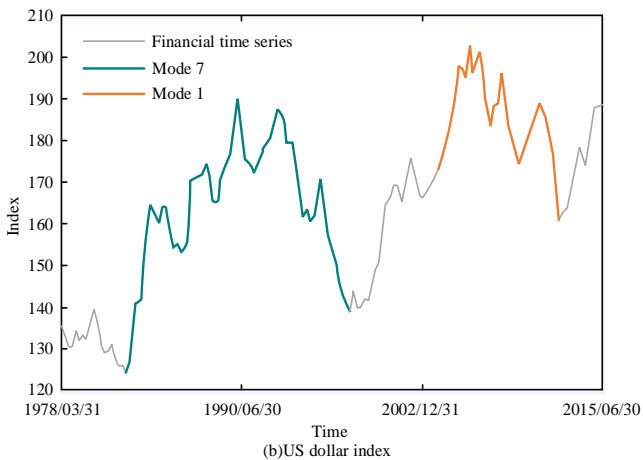

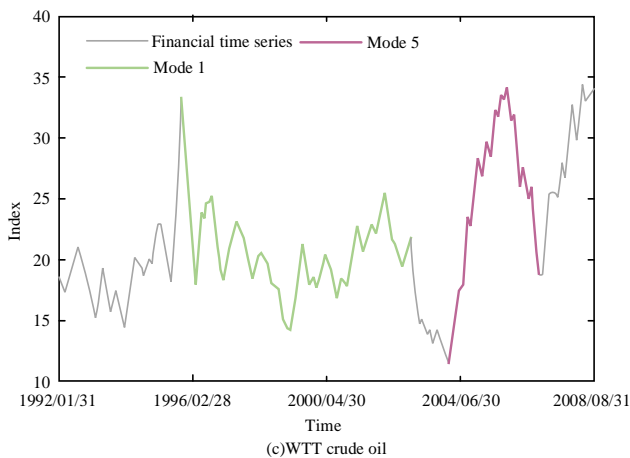

Fig. 6. Training error of DBN network

(a) Standard & Poor's 500 index

(b) US dollar index

(c) WTT crude oil

Fig. 7. Prediction effect of the model

The S&P 500 index has a monthly cycle, and its price data is shown in Fig. 7(a). The PVD model accurately discriminates the financial time series between June 1956 and February 1960 as mode 4, and the 1960-2. The financial time series between March 1965 and May 1972 is identified as mode 6, and the financial time series between March 1965 and May 1972 is identified as mode 1. The U.S. dollar index takes a quarterly cycle, and its price data is shown in Fig. 7(b). The PVD model accurately discriminates the financial time series from June 1982 to December 1997 as mode 2, and from December 2003 to 2012. The financial time series June of

2008 is identified as mode 7. WTT crude oil has a monthly cycle, and its price data is shown in Fig. 7(c). The PVD model discriminates the financial time series from September 1995 to September 2002 as mode 5. The financial time series between months is identified as mode 1. A comparative experiment was carried out on the PVD prediction model and the other five models, and the validity of the six prediction models was verified, but the prediction effect of each model was different. The performance comparison of the six models is shown in Table II.

TABLE II. PERFORMANCE COMPARISON OF MODELS

Model	Deep network model			Shallow network model		
	PVD	SAE	MLP	BP	SVD-BP	PCA-BP
RMSE	0.6336	0.6653	0.8367	0.8634	0.9312	0.8314
MSE	0.4015	0.4426	0.7001	0.7455	0.8671	0.6912
MAE	0.9052	0.9648	1.4671	1.4702	1.6310	1.3064
IS	29.79%	35.86%	44.35%	48.49%	78.23%	56.85%

It can be seen from Table II that the deep network model performs better than the shallow network model on the four evaluation indicators, and the mean values of RMSE, MSE, MAE and ER of the deep network model are 0.7119, 0.5147, 1.1124 and 36.67%, respectively. The mean values of RMSE, MSE, MAE and ER of the shallow neural network are 0.8753, 0.7679, 1.469 and 61.19%, respectively. The prediction effect of the deep network model is significantly better than that of the shallow network model. Compared with the four indicators of the shallow network model, the deep network models are reduced by 18.67%, 32.97%, 24.27% and 40.07%, respectively. Among the six prediction models, the values of the four evaluation indicators of PVD are the lowest among all models, which are 0.6336, 0.4015, 0.9052 and 29.79%, respectively, indicating that its prediction performance is the

best and significantly better than other models. The values of RMSE, MSE, MAE and ER of the SVD-BP model are the highest, indicating that its prediction effect is the worst and the prediction accuracy is the lowest. Although the training error of the PCA-BP model is smaller than that of the BP network model, its error rate is higher than that of the BP network model, indicating that the algorithm has over-fitting; weaker ability. The main reason why the prediction accuracy of PVD model is significantly higher than that of other models is that the research has introduced in-depth learning into the prediction model, so it can achieve real-time analysis with the help of financial data, and the prediction results will be more accurate. The variation of training error between the deep belief network in the PVD model and other models is shown in Fig. 8.

Fig. 8. Comparison of training error changes

It can be seen from Fig. 8(a) that the error curves of the DBN network and the SAE network are not much different, but the error curve of the DBN is smoother, indicating that the DBN has better stability. The error curve of the MLP network is very flat, indicating that it has higher stability and faster convergence speed, but its training error is higher than that of the DBN network, which is caused by the network falling into a local optimum. It has higher reliability and accuracy, and can effectively improve the local optimal problem caused by the BP algorithm. Compared with the shallow network model, the DBN network has faster convergence speed and higher accuracy. In the classification training process, compared with other models, the DBN network has the fastest convergence speed, the smallest training error and good stability. In general, the PVD forecasting model proposed in this study has high reliability and stability, and can efficiently and accurately identify Elliott waves of various patterns in financial time series. Compared with the other five models, the PVD model has higher stability and accuracy, faster convergence speed due to the use of DBN network, and also has excellent performance in feature extraction. The PVD model improves the prediction performance of the traditional BP network and multi-level classifier, reduces the error of the deep network model, and improves the accuracy of the model with high-frequency trading as the decision criterion. Experiments show that under the background of sustainable development, the PVD forecasting model proposed in the study performs well in financial investment forecasting, which provides a reference for the development of financial investment forecasting in the e-commerce industry.

V. CONCLUSION

With the rapid development of the e-commerce industry, the financial investment forecast of the e-commerce industry has gradually become a concern of people, and how to do a good job of financial investment forecast in the context of sustainable development is the focus of the industry. Researched and proposed a PVD prediction model based on DBN, and used the deep learning model to model the financial time series to achieve financial investment prediction. The experimental results show that the MSE of the PVD model is 0.4015 and the prediction accuracy is 70.21%, indicating that it can efficiently and accurately identify the Elliott wave pattern of financial time series. The PVD model is compared with the other five models. Among all the prediction models, the values of the four evaluation indicators of PVD are the lowest among all models, which are 0.6336, 0.4015, 0.9052 and 29.79% respectively, indicating that its prediction effect is the best, with the highest prediction accuracy, with good accuracy and stability, and significantly outperforms other models. Compared with the training error changes of other models, it can be seen that the error curve of the DBN network is smoother and the training error is smaller, indicating that it has higher stability, faster convergence speed, and higher reliability and accuracy. Experiment shows that under the background of sustainable development, the PVD prediction model proposed in the study has excellent stability and reliability in financial investment prediction, and can effectively predict the trend of financial investment. However, the research fails to realize the fractal level concept of Elliott

wave theory. If the neural network can be combined with the fractal level concept, the prediction performance and prediction accuracy of the model will be effectively improved. Therefore, in the follow-up work, the research will try to combine the concept of neural network and fractal level, propose a more perfect prediction model, and hope to achieve accurate prediction of financial investment in e-commerce industry, and provide strategies for the development of China's economic market.

Embedded Monitoring Method of Greenhouse Environment based on Wireless Sensor Network

Weixue Liu

Chifeng University, Teaching Staff Development Center, Chifeng, 024000, China

Abstract—Aiming at the problem of low accuracy of greenhouse environmental monitoring, an embedded monitoring method of greenhouse environment based on wireless sensor network is studied. The embedded microprocessor S3C2410 is selected as the control chip of greenhouse environmental monitoring. The wireless sensor network is composed of wireless detection node, sink node and remote-control terminal. The temperature and humidity sensor, CO₂ concentration sensor and light intensity sensor are set as the detection nodes of the wireless sensor network. Each detection sensor node is configured with wireless communication module to form a wireless sensor network to realize data communication of environmental monitoring. The distribution map method is selected to eliminate the missing data of greenhouse environmental monitoring data collected by wireless sensor network, and the weighted average method is used to fuse the monitoring data after eliminating the missing data to obtain the final greenhouse environmental monitoring results. The experimental results show that this method can effectively detect the environmental data such as temperature, humidity and light intensity of greenhouse, and the relative error of each data is less than 1%.

Keywords—Control chip; Detection node; embedded; greenhouse environmental monitoring; missing data; wireless sensor networks

I. INTRODUCTION

Facility agriculture is a modern form of agriculture that uses engineering techniques for the efficient production of plants and animals under relatively controlled environmental conditions. Facility agriculture covers facility farming, facility breeding and facility edibles. In addition to this, facility agriculture can improve or create environmental meteorological factors on a local scale to provide good environmental conditions for plant growth and efficient production. Facility agriculture is represented by the intelligent greenhouse, which embodies the direction of modern agriculture. Through greenhouse monitoring methods, various greenhouse environmental factors affecting plant growth can be obtained [1], which plays an important role in improving the yield and efficiency of crops in greenhouses. Among them, how to obtain accurate and reliable greenhouse environmental information is the basis for realising intelligent greenhouses, so information transmission is an indispensable and important link. According to different information transmission methods, greenhouse environmental information can be transmitted via wired communication or wireless communication [2].

Wiring is an unavoidable problem in wired communications. Due to the increasing complexity of the overall structure of modern greenhouses, the use of wired

communication will significantly increase the complexity of design, installation and maintenance. Once a node is damaged, it can lead to the collapse of the entire communication network. Compared to wired communication, wireless communication offers better prospects for application. Infinite communication not only requires no wiring and is easy to maintain at a later stage, but also has the advantage of being able to delete measurement nodes at will [3].

In greenhouse environmental monitoring, the monitoring of various greenhouse environmental factors that affect plant growth is the most critical. The accurate monitoring of various greenhouse environmental parameters can effectively automate and efficiently produce the greenhouse environment [4]. Because facility agriculture gets rid of the constraints of natural climate conditions in traditional agricultural production and overcomes the constraints that traditional agriculture is difficult to solve, it is necessary to monitor greenhouse environmental factors such as temperature, humidity, light intensity and carbon dioxide concentration. China's greenhouse environment has the characteristics of high humidity, high acidity, less infrastructure, many kinds of crops and dynamic changes [5]. Through investigation and analysis, greenhouse monitoring needs mainly include: real-time data acquisition, display and processing of environmental factors such as atmospheric temperature, humidity, light intensity and CO₂ concentration. Traditional sensors are connected by wires, which are very troublesome to wire a large number of wires in greenhouses and are not conducive to agricultural cultivation. Therefore, the application of wireless transmission technology in greenhouses helps to solve the limitations of wired transmission [6]. On the other hand, many agricultural monitoring systems use microcomputers as central controllers, which occupy large space, are costly, and have high environmental requirements [7].

Wireless sensor networks are a research hotspot in the field of information technology in recent years, integrating technologies from many fields, such as sensing technology, computer science, signal and information processing, and communication. The fact that wireless sensors are so obviously interdisciplinary [8] has led researchers formerly working in some specialized fields to start intervening in this field from different perspectives and studying wireless sensor networks from different aspects.

With the development of wireless communication technology, the information transmission method of wireless sensor network began to be applied to the remote monitoring of greenhouse environment. Wireless sensor networks have the characteristics of wide coverage and low influence by the

environment, and can be applied to distributed remote data collection and monitoring. Wireless sensor networks transmit data in the form of short messages, which have the advantages of flexible node deployment and small regional restrictions [9]. As long as there is wireless sensor network signal coverage, nodes can be deployed to collect data. As a new information acquisition and processing technology, wireless sensor network has gradually penetrated into the field of agriculture with its advantages of low power consumption, low cost and high reliability. Greenhouse is a relatively closed environment with limited self-regulation ability. In order to meet the requirements of agricultural production, it is necessary to artificially regulate various environmental parameters of greenhouse in order to create a more suitable environment for crop growth [10]. Monitoring greenhouse environmental information has become a key means to realize the automation and efficiency of greenhouse production. The traditional greenhouse monitoring method is based on wired communication, which has a series of problems, such as complex wiring, difficult maintenance, unable to flexibly deploy sensor nodes and so on, which limits the popularization and application of greenhouse detection methods to a certain extent. With the rapid development of modern information technology, WiFi, Bluetooth, UWB, RFID, ZigBee and other wireless communication technologies have emerged one after another. Among them, WiFi and Bluetooth cannot be popularized and applied on a large scale in the field of greenhouse monitoring due to their high cost and high-power consumption [11].

The history of embedded chips is inevitable, because embedded chips have many advantages. Non-embedded computing chips have good real-time performance, but embedded chip solutions have better advantages in terms of development cost, hardware resources and performance, in line with the development trend. Currently, embedded controllers are used almost everywhere [12]. Mobile devices, represented by cell phones, are the fastest growing embedded industry in recent years. At present, the application of embedded technology has penetrated into various fields such as industry, agriculture, education, national defense, scientific research and daily life. It has played an extremely important role in promoting technological transformation, product upgrading, accelerating the automation process and improving productivity in various industries.

There are many studies on greenhouse environmental monitoring. Pisanu et al. designed a low-cost electronic platform for greenhouse environmental monitoring based on the perspective of agriculture 4.0[13]. This platform can effectively monitor the greenhouse environment, but it has the drawback that the monitoring data cannot be transmitted to the control platform in time; Khan et al. applied the Internet of Things technology to greenhouse plant environment monitoring [14]. The accuracy of greenhouse environment monitoring is low because the sensors set cannot meet the needs of greenhouse environment monitoring.

For the shortcomings of the above two methods, an embedded greenhouse environment monitoring method based on wireless sensor network is studied. As a new information collection and processing technology, ZigBee-based wireless

sensor network has the characteristics of large node size, small size, low cost and ad hoc network. Therefore, it has a broad application prospect in the field of agricultural environment monitoring. This research collects greenhouse environment information through temperature sensors, humidity sensors and other sensors, and transmits the collected information to remote monitoring center through ZigBee wireless sensor network, which is convenient for greenhouse managers to monitor greenhouse environment remotely and in real time and provide a good environment for crop growth.

II. MATERIALS AND METHODS

A. Overall Structure of Embedded Greenhouse Environmental Monitoring based on Wireless Sensor Network

The overall structure of the embedded greenhouse environmental monitoring method based on wireless sensor network is shown in Fig. 1.

Fig. 1. The overall structure of the embedded greenhouse environmental monitoring method

As can be seen from Fig. 1, the wireless sensor network applied to embedded greenhouse environment monitoring mainly consists of wireless detection nodes, sink nodes and remote control terminals. Each detection sensor node is equipped with a wireless communication module and organized into a wireless sensor network, thus enabling mutual communication and greenhouse environment monitoring. The transmission of information in the network is achieved by "multi-hop" routing, which helps to improve the wireless communication distance and reliability. Each greenhouse has a sink node, which is equipped with a wireless communication module to realize data transmission for remote monitoring of the greenhouse environment network.

B. Wireless Sensor Communication Module

The functional structure of wireless sensor network for monitoring greenhouse environment is shown in Fig. 2.

Fig. 2. Functional structure diagram of wireless sensor network

In wireless sensor networks, end nodes are responsible for collecting greenhouse environmental data and sending it to routing nodes. The routing node aggregates the data and sends it to the coordinator node, which then sends the data to the server using the router node [15]. The coordinator node receives action instructions from the server and transmits them to the routing node, which then sends the data in the form of broadcasts to the corresponding terminals for control operations. Throughout the network communication process, each node determines whether the command executor is the node based on its own 16-bit short address. If it is the node, it performs the corresponding execution action; otherwise, it ignores the command.

1) *Communication chip*: The CC2530 chip from TI was selected as the wireless communication module. 8051 CPU used in the CC2530 chip is a single-cycle 8051-compatible core that integrates 8KB of SRAM, Flash memory and an XREG/SFR register. The CC2530-F256 chip of the CC2530 series is selected as the communication chip for greenhouse environment monitoring. The CC2530 chip is very suitable for ultra-low-power greenhouse environment monitoring. The circuit composition of the CC2530 chip includes clock circuit and reset circuit. The clock circuit frequency of the CC2530 chip is composed of two borderless when the communication module is operating normally, the function of Y1 (33.549 KHz) crystal oscillator is to provide low-power mode for the node; the function of Y2 (33MHz) crystal oscillator is to provide clock for the node; the reset circuit is composed of resistor and on/off key. When the on/off key is pressed, the wireless sensor network will return to the initial state. The RF part of the CC2530 chip is responsible for transmitting and loading RF signals. The enhanced 8051 CPU core integrated in the chip is responsible for controlling the RF, peripherals and running the ZigBee protocol stack.

2) *Building zigbee wireless sensor networks*: When building a ZigBee wireless sensor network, the coordinator needs to be powered on while the communication module initializes the protocol stack and hardware. The coordinator sends a BEACON frame from the first channel. If BEACON

responds, it can be concluded that there is another coordinator on this channel. If this occurs, it indicates that the channel is occupied and the coordinator sends BEACON frames to the next channel. This is repeated until no corresponding event for a BEACON frame occurs in a channel. After an empty channel is found, a wireless sensor network can be established. Once the network is established, the coordinator can connect to the device and then the coordinator assigns the network address. The coordinator can then read the data information and then send the transmitted or collected data information to the main control computer. When the coordinator receives an ASSOCIATION_REQ network access request from a ZigBee device, it will send the BEACON signal in response to the node's request [16] and then send the request signal ADDRESS_REQ; if the coordinator receives it, it will send the ADDRESS_ASSIGN signal and wait for an acknowledgement; if the coordinator receives ADDRESS_ASSIGN, the address list will be updated automatically. After power-up, the node will scan the channel to find an available coordinator in the network. After monitoring the beacon signal, the node will send the address assignment request signal ADDRESS_REQ, and then the node will search for the ADDRESS_ASSIGN signal. If it does not find one, it will continue to send the ADDRESS_REQ signal until it receives the ADDRESS_ASSIGN signal. After receiving the signal, the node will send ADDRESS_AK to the coordinator to confirm the signal address.

3) *CSMA / CA protocol and network interception strategy*: Since the commonly used CSMA / CD protocol may be difficult for the adapter to detect whether there is channel conflict for wireless products, this wireless sensor network adopts a new protocol, Carrier Sense Multiple Access with Collision Avoidance (CSMA / CA). CSMA /CA protocol solves the conflict problem caused by multiple wireless devices transmitting data at the same time, and brings convenience to the construction of ZigBee wireless sensor network. CSMA / CA protocol needs to complete the following two tasks: the first is to find the idle channel (carrier listening); the second is to wait for random time (avoiding collision).

a) *IEEE802. 15.4 CSMA / CA classification*: In IEEE802 15.4 in the protocol, there are two ways of multiple access / collision avoidance mechanism for carrier frame: CSMA / CA with time slot and CSMA / CA without time slot. Generally speaking, CSMA / CA with time slot is used for beacon trigger mode, and CSMA / CA without time slot is used for beacon trigger mode. The two algorithms used in CSMA /CA are based on backoff, and the time unit is the backoff period.

b) *CSMA / CA without beacon*: The operation modes of the two protocols of IEEE802. 15.4 are similar, but the backoff time is different. In the network, if there is no super-frame structure, there will be no beacon (time slot) and no network coordinator for signal use. The sensor needs to wait for random time to listen to the activity of the channel. If the channel is

idle, it can send information. Otherwise, the device needs to wait for random time again.

c) *CSMA / CA with beacon*: CSMA / CA with beacon limits the space occupied by the backoff cycle boundary, and the backoff cycle boundary must be at the super-frame cycle boundary, so as to ensure normal operation.

d) *IEEE802. 15.4 CSMA / CA process*: CSMA / CA protocol is mainly used for data transmission of ZigBee devices to avoid mutual interference of signals sent by different ZigBee devices. When the ZigBee device transmits data, it needs to find an idle channel, and it will send a signal for channel competition. If an idle channel is found, the ZigBee device will send a backoff delay time, which is used to prevent other ZigBee devices from occupying this channel at the moment and avoid interference caused by the collision of signals sent by the two devices. However, if the channel found by ZigBee device is busy, the device needs to listen to the channel again and repeat the above process until it finds a free channel.

C. Embedded Control Chip

S3C2410, a 32-bit RISC embedded microprocessor based on ARM920T core, is selected as the embedded chip of greenhouse environmental monitoring. The ARM920T core consists of ARM9TDMI, memory management unit (MMU) and cache. The core board integrates Samsung's S3C2410 processor (32-bit ARM920T core), 16M FLASH and 64M SDRAM, JTAG2ICE debugging interface, etc. The resources of the core board include: 2 UARTS, 1 USB port, data cable and LCD interface. The backplane includes: power circuit, various interface circuits, touch screen, keypad, USB storage circuit, etc. The structure diagram of embedded control chip is shown in Fig. 3.

Fig. 3. Embedded control chip hardware structure

The power supply circuit provides the required power supply for each part of the greenhouse monitoring controller [17], and the selected chips are LT1764 and MIC29302. Among them, LT1764 is divided into adjustable and non-adjustable, providing 3.3V and 5.0V voltage respectively; MIC29302 provides a voltage of 4.2V. The voltage of 5.0V is mainly used for LCD circuit and USB circuit, the voltage of 4.2V is used for GPRS circuit, and the other circuits use the voltage of 3.3V. The power supply of the core board is 3.3V, which also comes from the backplane, while the S3C2410 core voltage and I / O voltage require 1.8V and 3.3V respectively. Therefore, AIC1117A is used on the core board to reduce the

3.3V voltage provided by the backplane to 1.8V and provide it to the processor core.

The function of serial interface is to act as an encoder converter between CPU and serial equipment. There are three kinds of asynchronous serial receiving devices provided by the S3C2410 general-purpose serial port and the asynchronous serial port. Each serial port contains a baud rate generator, a transmitter, a receiver and a control unit. The greenhouse controller uses the two serial port resources provided by the core board. According to the design requirements, the two serial ports are set as the standard RS2232 serial port. In addition to the function of ordinary serial port, serial port 1 also undertakes the task of wireless sensor network communication and acts as the debugging terminal of embedded control chip. Since the core board provides TTL level, MAX3232 chip is used to convert the voltage into a voltage conforming to RS2232 standard.

D. Greenhouse Environmental Monitoring Sensor

As a monitoring device to help people understand the external environment, sensors can detect and perceive the surrounding environmental information, and express various abstract environmental factors in the environment in the form of electrical signals according to certain rules. At the same time, as a machine, there is no subjective feeling, and the perception of the external environment can be expressed more accurately. Therefore, sensors are widely used in current industrial production. In the process of sensor selection, many factors need to be considered, including measurement range, working temperature, measurement accuracy, cost and matching degree with the chip. At the same time, combined with the particularity of greenhouse environment, the appropriate device can be selected. The corresponding sensor is selected according to the environmental parameters to be collected for greenhouse environmental monitoring, and the sensor is selected considering the cost, sensor accuracy and matching degree with the main control module.

1) *Temperature and humidity sensor*: Among AM2302 air temperature and humidity sensor is selected as the sensor for temperature and humidity collection in greenhouse environmental monitoring. It is characterized by not only capacitive humidity sensing elements, but also high-precision temperature sensing elements. Each element is calibrated with specific temperature and humidity, and can be used only after passing the inspection. AM2302 air temperature and humidity sensor has an 8-bit single chip microcomputer, so the response speed is relatively fast and the anti-interference is also very good. Because of its small size, it has low energy consumption. In addition, it has a series of advantages of single bus interface, so it can be widely used in meteorological stations and other places where temperature and humidity monitoring is needed. Due to the integrated packaging, the signal strength and anti-interference ability of the air temperature and humidity sensor are greatly enhanced [18]. The chip provides a two-wire serial interface similar to I2C bus, which is connected with the input interface of the host through bidirectional serial data line data and serial clock input SCK.

It not only inherits the characteristics of simple use of I2C interface, but also supports CRC verification of data transmission results to ensure the reliability of data transmission.

The air temperature and humidity sensor use single bus to communicate with MCU, and only one I / O port is needed to realize data transmission. The temperature and humidity data inside the sensor is transmitted to the single chip microcomputer at one time through the pin. The data is composed of 40bit, and the data is divided into decimal part and integer part. The transmission format is: 8bit humidity integer data + 8bit humidity decimal data + 8bit temperature integer data + 8bit temperature decimal data + 8bit verification data. The check data is the last eight bits of the sum of the first four bytes. The data output by the air temperature and humidity sensor is eight-bit binary data, which represents the real temperature and humidity.

When the bus is idle, it is high level. When the embedded control chip sends the start signal to AM2302, it pulls down the bus for at least 18ms to ensure that the AM2302 chip can detect the start signal. After detecting the start signal, AM2302 will convert from low-speed mode to high-speed mode. Then, the bus will be pulled up by the pull-up resistance for 20-40us, to read the response signal of AM2302, wait for it to pull down the data line and keep it for 80us, and then pull it up for 80us, finally start data transmission. The data of each bit starts with a 50us low-level slot. Whether the data bit is "0" or "1" is determined by the length of the high-level. If the high-level is 26-28us, the data "0" is sent, and if the high-level is 70us, the data "1" is sent. After all data is transmitted, AM2302 pulls down the bus by 50us, and then pulls up the bus through the pull-up resistor to enter the idle state.

2) *CO₂ Concentration Sensor*: MH-Z14CO₂ concentration sensor is used as the concentration acquisition sensor for greenhouse environmental monitoring. MH-Z14CO₂ concentration sensor integrates the A / D conversion module and comparator. The conductivity of the module can be enhanced with the increase of gas concentration. The A / D conversion circuit in the module can convert this change into voltage change. The single chip microcomputer can directly read the voltage value or digital switching value. The module directly converts the gas concentration into the corresponding voltage value. The single chip microcomputer collects and reads the voltage through A / D, and then obtains the gas concentration value in proportion. The detected concentration is 100-10000ppm. MH-Z14 sensor has a long service life, which reduces the cost to a certain extent. At the same time, it also has the performance of temperature compensation to ensure the measurement accuracy. Based on the above advantages, MH-Z14 sensor is widely used in the production environmental monitoring of industrial and agricultural equipment.

3) *Light intensity sensor*: The regulation of light in the greenhouse environment is mainly to increase the light intensity in the warm room. The demand for light intensity varies greatly among different crops. Generally, when the light intensity in the warm room decreases to 1000 lux, the crops in

the warm room should be supplemented with light. According to the requirements of greenhouse crops for light intensity [19], the illuminance sensor BH1750fvi produced by Rohm company is selected. The high resolution of BH1750 can detect a wide range of light intensity changes (1lx-65535lx), and the visible light in 400nm-700nm band has excellent sensitivity. Logic+I2C Interface is the interface between light intensity calculation and I2C bus. PD is a photodiode, and its sensitivity is similar to that of human eyes; AMP integrated operational amplifier can convert PD current into PD voltage; ADC analog-to-digital conversion obtains 16-bit digital data. The ADDR port of register accumulator of BHT1750 illuminance sensor is grounded, and the two serial ports of clock end SCL and data end SDA are connected with CC2530. The working principle of the light intensity sensor is to convert the light intensity value into voltage value. Firstly, it initializes the program, then configures the input mode, collects data and carries out A / D conversion. After the conversion, the single chip microcomputer reads the conversion directly.

E. Sensor Data Fusion Method

The temperature in the greenhouse is described by multiple measurement points. The temperature in the greenhouse changes with space. At the same time, the temperatures measured in different places in the greenhouse are also different. In order to control the temperature, humidity and other factors in the greenhouse, we must give an equivalent value to describe the temperature, humidity and other states of the current greenhouse consistently. Therefore, we use data fusion method to determine the effective value, which is used to control the greenhouse, such as rolling shutter, heating equipment, ventilation equipment, etc. Data fusion makes full use of multiple sensor resources. Through the reasonable control and use of these sensors and their observation information, the redundant or complementary information of multiple sensors in space or time is combined according to some criteria, so as to obtain better performance than the subset of its components.

After using wireless sensor network to collect greenhouse environmental monitoring data, we should first eliminate the missing data. There are many methods to eliminate the missing data, and select the distribution map method to eliminate the missing data.

The main parameters used in the distribution map are: median X_M , upper quartile F_u , lower quartile F_l , quartile dispersion dF and elimination point ρ . Their definitions and usage are as follows:

Firstly, it can carry out multiple independent measurements on a tested object, and arrange the measured data in the order from small to large:

X_1, X_2, \dots, X_N , then X_1 is called the lower limit and X_N is called the upper limit.

Secondly, the median value X_M is defined:

$$X_M = \frac{(N+1)X}{2} \quad (1)$$

$$X_M = \frac{\left(\frac{N+1}{2} + \frac{N}{2}\right)X}{2} \quad (2)$$

Thirdly, in the partition map method, if the median of interval $[X_M, X_N]$ is F_u , F_u is the upper quartile, and the lower quartile F_l is the median of interval $[X_1, X_M]$

Fourthly, the dispersion dF of the quartile is defined as:

$$dF = F_u - F_l \quad (3)$$

It is stipulated that the data whose distance from the median is greater than βdF is divorce data, that is, the judgment interval of invalid data is:

$$X_i - XM > \beta dF \quad (4)$$

Where, β is a constant, and its size is determined according to the accuracy requirements of greenhouse monitoring. The elimination point is defined as:

$$\rho_1 = \frac{(F_l - \beta) dF}{2} \quad (5)$$

$$\rho_2 = \frac{(F_u - \beta) dF}{2} \quad (6)$$

The measurement data outside the interval $[\rho_1, \rho_2]$ is considered as the elimination point.

After the above steps, the remaining data are consistency measurement data. We can fit the consistency data. The weighted average method is selected to fuse the data collected by the sensor. Since many sensors are placed in the greenhouse, the greenhouse data collected by each sensor is different [20], so it is necessary to fuse the data collected by wireless sensors to give users an effective value to guide users to operate the greenhouse. The problem is described as follows: there are n temperature wireless sensors in the greenhouse, and the greenhouse data collected by each wireless sensor at t time is t_1, t_2, \dots, t_n . Firstly, the distribution diagram method is used to eliminate the missing data, and the data are sorted to obtain the consistent data columns t_e, \dots, t_p . Weight is represented by w_i . w_i is usually selected as

$\frac{1}{p-e}$, and the average value of the temperature in the greenhouse is calculated by the weighted average method:

$$\bar{T} = \sum_{i=e}^p \frac{t_i}{p-e} \quad (7)$$

The weighted average method is simple, easy to implement and occupies less resources. When the wireless sensor network is used to monitor the embedded greenhouse environment, the weighted average method is used to fuse the data collected by the sensor to obtain the final greenhouse monitoring parameters such as ambient temperature and ambient humidity.

III. RESULTS

In order to verify the effectiveness of the embedded environmental monitoring method of greenhouse based on wireless sensor network, the method in this paper is applied to the greenhouse environmental monitoring of an agricultural production. The average communication distance between the deployed nodes of the wireless sensor network is about 20m, and the nearest distance between the monitoring node and the gateway node is about 100m. After installation and operation, after the gateway is started, the average time required for node binding and ad hoc network establishment is less than 1min. The sampling frequency setting scheme of sensor nodes is: air temperature and humidity for 2min, soil temperature and humidity for 10min, light intensity for 3min and CO2 concentration for 30min. After completing data collection and transmission, each node will automatically enter the sleep state until the next sampling cycle wakes up.

In order to verify whether the communication stability between nodes of wireless sensor network is good and whether the communication quality is qualified, the packet loss rate of wireless sensor network is tested. Packet loss rate refers to the proportion of data packets not received in a certain period of time in the total data packets sent. If the packet loss rate is too high, it indicates that a large number of temperature and humidity, smoke concentration and light intensity data have not been collected, which will lead to the control node cannot accurately turn on and off the relevant equipment, cannot accurately monitor the environment in the shed, resulting in measurement failure. To ensure the reasonable distance between network nodes, it needs to try to ensure a low packet loss rate and enhance the accuracy of measurement. The greenhouse in the study area is selected as the test site. The coordinator is placed in the monitoring room, adjacent to the upper computer, and the terminal equipment is placed in different positions in the greenhouse. The transmit power of CC2530 processor is -3dBm; the total number of single packet test is set to 2000, and the packet sending speed is one group per second, with 5 packets per group. This speed fully meets the needs of the actual project. After fixing the coordinator position, it can send the same number of data packets at the terminal nodes in different positions of the greenhouse, to measure the number of received data packets, and calculate the packet loss rate. The calculation of packet loss rate is shown in the following formula:

$$A = \frac{B - C}{B} \times 100\% \quad (8)$$

In formula (8), *B* and *C* represent the transmitted data packet and received data packet of wireless sensor network respectively.

Using the method in this paper to collect greenhouse environment data, the communication performance of wireless sensor network is shown in Table I.

TABLE I. WIRELESS SENSOR NETWORK COMMUNICATION PERFORMANCE

Sensor terminal serial number	Distance from gateway node	number of packets sent	Number of received packets
1	5	2000	1999
2	10	2000	1999
3	15	2000	1999
4	20	2000	1997
5	25	2000	1995
6	30	2000	1991
7	35	2000	1987
8	40	2000	1985
9	45	2000	1981
10	50	2000	1976
11	55	2000	1961
12	60	2000	1958

Fig. 4. Statistics of packet loss rate

The data of greenhouse environment monitored by wireless sensor network used in this paper are statistically analyzed and the packet loss rate results of collecting different types of greenhouse environmental data are shown in Fig. 4.

According to the experimental results in Fig. 4, the wireless sensor network is greatly affected by the transmission distance. Within the short range of 10 meters, the data packet loss rate maintains a low value within 0.1%. However, when the

distance between the sensor terminal and the coordinator is more than 10 meters, the packet loss rate increases sharply, which is caused by the great irregularity of the communication link of the low-power module. Through the experimental test, even when the packet loss rate of 80m is the largest, the packet loss rate of ZigBee wireless communication is still less than 1%, which meets the needs of greenhouse environmental monitoring.

In the greenhouse monitoring area, each monitoring point is equipped with three sensors. The method in this paper is used to fuse the greenhouse environmental data collected by the three sensors to improve the accuracy of greenhouse environmental data collection. The temperature data of different monitoring points in the greenhouse are collected by this method, and the results are shown in Fig. 5.

Fig. 5. Temperature data collection results

Fig. 6. Collection results of ambient humidity

The humidity data of different monitoring points in the greenhouse are collected by the method in this paper, and the results are shown in Fig. 6.

The experimental results in Fig. 5 and Fig. 6 show that the method of this paper is used to monitor the greenhouse environment, and the collected temperature and humidity data of the greenhouse environment is close to the actual

environmental temperature and humidity data of the greenhouse within a reasonable range of error, which indicates that the data collected by the temperature and humidity sensor is accurate and reliable, and the sensor used in this method can effectively monitor the temperature and humidity data of the greenhouse environment. The error is within a reasonable range, which indicates that the data collected by the temperature and humidity sensor is accurate and reliable.

During the experiment, a full spectrum LED lamp is set in the greenhouse to gradually shorten the distance between the full spectrum LED lamp and the lighting intensity measuring equipment, and increase the lighting intensity. The average value of five groups of data is taken for each measurement and compared with the data measured by the digital illuminance meter. The comparison of light intensity data is shown in Fig. 7.

Fig. 7. Comparison of light intensity data

According to the experimental results in Fig. 7, the difference between the greenhouse light intensity data monitored by the method in this paper and the actual light intensity data of greenhouse is small. From the above data, the designed light intensity acquisition circuit is very close to the actual light intensity value, and the error is within a reasonable range. The data collected by the light sensor is accurate and reliable.

The CO₂ concentration data collected at different monitoring points by the method in this paper are counted, and the collected CO₂ concentration data are compared with the actual CO₂ concentration data. The comparison results are shown in Fig. 8.

Fig. 8. Comparison of CO₂ concentration data

The experimental results in Fig. 8 verify that the method in this paper can effectively collect CO₂ concentration data, and the collected CO₂ concentration data is very close to the actual CO₂ concentration data of greenhouse environment. The experimental results in Fig. 8 verify that the method in this paper can effectively collect the CO₂ concentration data of greenhouse environment by using wireless sensor network. At the same time, the collected CO₂ concentration data is in good agreement with the actual CO₂ concentration data, indicating that the method in this paper has high accuracy in collecting CO₂ concentration data.

The relative errors between the temperature data, humidity data, light intensity data and CO₂ concentration data collected by the method in this paper and the actual data are counted. The statistical results are shown in Table II.

TABLE II. COMPARISON OF RELATIVE ERRORS OF ENVIRONMENTAL MONITORING

Monitoring points	Temperature/%	Humidity/%	Light intensity/%	CO ₂ concentration/%
1	0.25	0.34	0.29	0.74
2	0.34	0.47	0.43	0.56
3	0.28	0.29	0.28	0.42
4	0.13	0.36	0.16	0.61
5	0.25	0.48	0.34	0.53
6	0.34	0.35	0.28	0.48
7	0.29	0.48	0.17	0.34
8	0.34	0.29	0.26	0.52
9	0.19	0.35	0.23	0.64
10	0.52	0.41	0.45	0.51

From the experimental results in Table II, it can be seen that the method in this paper uses wireless sensor network to

collect greenhouse environment data, and the relative error between the collected data and the actual data is less than 1%.

The experimental results show that the method can achieve effective monitoring of the greenhouse environment with high monitoring accuracy. According to the collected greenhouse environment data of each monitoring point, the greenhouse environment can meet the growth needs of crops. Through experimental verification, the research method can receive and display environmental data such as temperature and humidity, light intensity, and CO₂ concentration collected by sensor nodes in real time, and can view the real-time operation status of each node. During the test period, the sensors operated stably and all functions worked normally, and played an important role in the daily management of the greenhouse environment, achieving the expected results.

IV. DISCUSSION

Existing Research: wireless sensor networks have brought a revolution in information sensing due to their low power consumption, low cost, distributed and self-organizing features. Wireless sensor network consists of a large number of inexpensive miniature sensor nodes deployed in the monitoring area, which is a multi-hop self-organized network formed by wireless communication. ZigBee is a local area network protocol based on IEEE802.15.4 standard, which has the features of low cost, simplicity, short distance, automatic networking of nodes, low power consumption and low data transmission rate, and can be applied to various applications by embedded devices in automatic control field. Currently, many scholars have applied wireless sensors in greenhouse environmental monitoring. Benahmed K et al. proposed an algorithm based on wireless sensor network technology for monitoring microclimate in greenhouses and developed a linear equation model for optimizing plant production and material costs [21]. Given that subsurface soil sensing uses several types of sensors and devices that can help to monitor soil fertility in real time, Ghosh D et al. investigated the existing subsurface sensing technologies used to monitor soil fertility in agriculture using underground IoT[22]. Abbasikesbi R et al. proposed a wireless sensor network based on the proposed algorithm to improve tomato crops in greenhouses. The developed sensor nodes have low power consumption and low cost to monitor parameters such as temperature, humidity, CO, CO₂ and light intensity[23]. In all of the above studies, wireless sensors were used to monitor the greenhouse environment, but the accuracy of greenhouse environment monitoring was low because the sensors set up did not meet the needs of greenhouse environment monitoring.

Research results of this paper: Results of this study: Based on the previous research, this paper proposes an embedded greenhouse environment monitoring method based on ZigBee wireless sensor network. The ZigBee-based wireless sensor network has the features of large node size, small size, low cost and ad hoc network, which can not only realize the rapid automatic networking of sensor nodes, but also has the ability to collect, transmit, store and process various greenhouse environmental data in real time. The ZigBee-based wireless sensor network has the advantages of low cost, low power consumption, no wiring, flexible networking and friendly human-machine interface, which makes a useful exploration for the application of wireless sensor network and embedded technology in the field of greenhouse management. This

research collects greenhouse environment information through temperature sensors, humidity sensors and other sensors, and transmits the collected information to remote monitoring center through ZigBee wireless sensor network, which is convenient for greenhouse managers to remotely monitor greenhouse environment in real time and provide a good environment for crop growth.

Research limitations: Limitations of this research: Although the embedded greenhouse environment monitoring method based on ZigBee wireless sensor network used in this research can overcome some defects of traditional greenhouses in structure and performance and help to establish large-scale intelligent greenhouse clusters, there are still some shortcomings. In the actual greenhouse environment monitoring, the monitoring error is difficult to be completely eliminated because of the influence of many factors. Besides, the interaction between different influencing factors should be considered, and in addition to the monitoring of individual factors, joint analysis should be conducted in subsequent studies.

Future work: The Future of Work: Today's Internet applications are penetrating into the embedded space. 5G technology is enabling the rapid spread of smartphones. Due to the rapid development of embedded technology, web servers can run on single-chip microcomputers with high-capacity flash memory. Embedded technology will develop rapidly as various electrical devices become intelligent and Internet-enabled. With the application of these intelligent technologies in the field of environmental monitoring, the level of environmental monitoring will be greatly improved. Today, with the development of embedded intelligent technology and "5G technology", the greenhouse monitoring based on wireless sensor and network technology network has a better technical design basis than the traditional greenhouse monitoring method. The future direction of sensor technology research will be supported by 5G technology to get more development.

V. CONCLUSION

Through greenhouse environment monitoring, the indoor environment can be automatically monitored to provide suitable greenhouse environment for crops according to the requirements of different crops, thus meeting the needs of scientific research and production and accumulating rich data for intelligent agriculture experts to develop new technologies. The embedded greenhouse environment monitoring method based on wireless sensor network overcomes some defects of traditional greenhouses in structure and performance, and also has some significance for establishing large-scale intelligent greenhouse clusters. Through this research method, the parameters of temperature, humidity and light intensity in different areas of the greenhouse are obtained in real time, so that the crops can achieve a suitable growth environment and provide a convenient, efficient, adaptable, simple and practical monitoring scheme for greenhouse managers. The experiments show that the method is effective in monitoring temperature, humidity and other parameters and has high applicability.

Abstract—With the socio-economic development, the national demand for playing leisure sports has increased, and swimming is one of the popular choices. To help swimming beginners understand the correct swimming posture more quickly and directly, hybrid neural network algorithms based on sliding window detection and deep residual networks are designed in this study, and two corresponding virtual image classification models of swimmer's posture are designed based on these algorithms. In order to reduce the noise of the input data and reduce the cost of data collection, the virtual reality technology is used to convert the swimmer's swimming pose image into the image model in the virtual reality space as the input data of the algorithm. The performance test experimental results show that the classification accuracy of the swimmer pose recognition models based on PTP-CNN algorithm and SW-CNN algorithm designed in this research are 97.48% and 96.72% respectively on the test set, which are much higher than other comparison models, and the model built based on PTP-CNN algorithm has the fastest computation speed. The results of this research can be applied to assist participants in swimming pose recognition in teaching beginner swimmers.

Keywords—Virtual reality; pose recognition; swimming; neural network; sliding window

I. INTRODUCTION

Swimming has both leisure and physical exercise attributes, making it a better form of exercise for adults with a certain financial base [1]. In fact, the middle class population in China has grown significantly in the last decade, which has directly led to an increase in the number of people learning to swim in their spare time. However, it is difficult for beginners to distinguish between accurate and incorrect common swimming positions, but the ability to accurately judge and master scientific swimming positions is important to learn to swim and reduce the risk of personal safety during exercise [2]. In the past, beginners often need to spend a lot of time and energy on learning to identify and practice various correct swimming postures, which is inefficient, and may even make learners lose interest in swimming [3]. At the same time, the emergence of high and new technologies, including virtual reality and artificial intelligence, provides new ideas for automating traditional physical education teaching tasks. These technologies can free teachers from repetitive low-end teaching tasks, and the teaching efficiency and error rate are far lower than those of the teaching system based on traditional machine

learning algorithms [4]. Aiming at this problem, this research tries to use virtual reality technology and artificial intelligence technology to design a model that can intelligently judge whether the swimmer's posture in the swimming image is correct, so as to provide timely and accurate feedback for beginners to learn the project. It is assumed that it may play a role in shortening the learning cycle of swimming learners and reducing the learning difficulty, this is also the contribution and value of this paper to the field of swimming teaching.

II. RELATED WORK

A large number of related studies have been conducted by experts in different fields about virtual reality technology, bit-posture detection technology, and smart sports teaching involved in this research. Elbamby M S et al. discussed the challenges faced in achieving ultra-reliable and low-latency virtual reality by addressing the shortcomings of virtual reality technology in terms of high throughput, low latency, and reliable communication, thus finding that the use of millimeter wave communication, edge computing, and Intelligent networks with active caching techniques can solve the above problems of virtual reality technology applications to a certain extent [5]. Chen M et al. studied the resource management problem of networks with wireless virtual reality users communicating over small cell networks and proposed a virtual reality model based on multi-attribute utility theory, and simulation test results showed that the model has faster convergence than the traditional model and provides lower latency of virtual reality services [6]. Thies J et al. proposed an image processing algorithm based on virtual reality technology to build a more realistic virtual meeting environment in video teleconferencing [7]. Du et al. found that virtual reality technology has been gradually and widely used in the architecture, engineering, construction, and facilities management industries in recent years, because it can improve the workflow of teams by enhancing the consensus of team members. However, the current virtual reality application suffers from the difficulty of generating a virtual reality dialogue environment from input data. Therefore, the research team designed a synchronous communication system based on virtual reality technology, and the test results showed that the system has higher utilization value and communication efficiency than traditional virtual reality communication systems [8].

*Corresponding Author.

Cga B et al. found that obtaining accurate information about students' posture during learning is important for assessing students' learning status and improving teaching methods, but the presence of various occlusion elements in the educational environment makes it more difficult to carry out current student posture detection. So this study proposes a new posture detection method based on a single-stage object detector, which uses an adaptive fusion mechanism to learn complementary. This method uses an adaptive fusion mechanism to learn complementary spatial features to make the feature extractor more discriminative. Experimental results show that the student pose detection capability of the method is significantly better than other single-stage target detection methods on a real classroom pose dataset [9]. Lin G et al. found that fruit detection is necessary for automatic guava harvesting under real outdoor conditions, and that the branch-related pose of the fruit is also essential to guide the robot to approach and separate the target fruit without colliding with its parent branch. In order to perform automatic, collision-free harvesting, this research team designed a fruit detection and pose estimation method based on sensors with four channels of red, green, blue, and depth data images from cell phones. Quantitative experimental results show that the method has an accuracy and recall of 0.983 and 0.948 for guava fruit detection, respectively, which can be applied to improve the control of automatic guava harvesting machinery [10]. Tang L's research team found that it is difficult to detect the bit pose of small targets under poor imaging conditions such as severe occlusion and low resolution, and proposed a bit pose detection algorithm that combines merged region of interest pools and local static. Therefore, a pose detection algorithm combining merged region of interest pool and local static learning is proposed. Experimental results show that the method outperforms existing methods for pose recognition [11]. Zhou L et al. found that existing fabrication methods cannot produce flexible sensors that match the shape of soft robots. Therefore, a new 3D printed multi-functional inductive flexible stretchable liquid metal sensor was designed using the posture detection algorithm, and the test results showed that this sensor has a higher perception of deformation than the conventional sensors, which also means that the posture detection algorithm improves the manufacturing accuracy of the sensor components [12].

In summary, it can be found that virtual reality and posture detection techniques have been increasingly applied to industrial and educational fields, and some economically valuable and educational results have been achieved. However, studies combining virtual reality and posture detection technology to build a swimming stance recognition model with high recognition accuracy are still rare, so it is really necessary to use virtual reality technology to reduce the noise of training images and improve the data scaling effect when building this teaching aid model, while the posture detection work can help swimming beginners to learn swimming posture better, which is the reason for conducting this study.

III. DESIGN OF SWIMMING POSITION DETECTION ALGORITHM FOR SWIMMING SCENE

A. Design of Bit Pose Detection Algorithm Incorporating Sliding Window Detection and Convolutional Neural Network

The dataset used for training and testing the pose detection algorithm in this study is a virtual model image of a swimming scene and its swimmer's swimming pose constructed by virtual reality technology. Before designing the pose detection algorithm, it is necessary to design the pre-processing process of the dataset [13-15]. The preprocessing of virtual image of swimmer's pose mainly includes image cropping, grasping rectangle frame extraction, image normalization and homogenization [16]. In order to reduce the content of irrelevant information in the image and the computational effort of the algorithm, the virtual model image needs to be cropped to a uniform size (640 480 size is chosen here) [17]. The purpose of homogenization and normalization of the virtual model images is to eliminate the negative impact of different inter-feature scales in the image data on the training results. The range of RGB (Red Green Blue) channel values in the image data is [0,255], and the normalization operation can be completed according to equation (1) to compress the range of values to [-1,1].

$$I_{i,j,k}^{(n)} = \frac{2I_{i,j,k}^{(n)} - 255}{255} \quad (1)$$

$I_{i,j,k}^{(n)}$ represents the pixel values of row, column and channel numbers i , j and k positions in the n image before normalization. $I_{i,j,k}^{(n)}$ represents the pixel values of row, column and channel numbers i , j and k positions in the n image after normalization. When constructing a virtual model of the swimmer using virtual technology, the original physical image is a depth map, and the depth value is used to describe the distance between the camera and the photographed object. But the index is mainly distributed in the middle part of the image, which needs to be mapped and processed according to the camera desktop distance and the range distance, see equation (2).

$$d = \begin{cases} 1.4m, & d < 0.8m \\ 0.8m, & d > 1.4m \\ d, & d \in [0.8m, 1.4m] \end{cases} \quad (2)$$

d is the depth value after the mapping process, and m is the ratio of the camera range distance to the camera desktop distance. Then use equations (3) and (4) to normalize and homogenize d .

$$d_i = \frac{d_i - d_{\min}}{d_{\max} - d_{\min}} \quad (3)$$

$$d_i = d_i - \frac{\sum_{i=0}^n d_i}{n} \quad (4)$$

In equation (3), d_i is the depth value of the i row, d_{\min} and d_{\max} are the minimum and maximum values of the depth value of the i row, and n is the number of pixels of the i row. This time, the sliding window method is chosen to generate the rectangle to be selected. However, the number of selected rectangles generated by the image is too large, which makes the algorithm computationally inefficient, so it is necessary to filter out some of the rectangles. First of all, the background image can be removed using the background difference method, and then the image is divided into a grid of specified distances, and the detection frame containing the smallest object is set as the detection range of the sliding window, and the center point of the rectangular frame can only be in the intersection of the restricted range [18]. According to the size statistics of the dataset, it is need to set the pixel point taking steps for the rotation angle θ , length h , and width w of the grasping rectangle, and the range of values which are shown in equations (5), (6), and (7).

$$\theta = 0^\circ : 15^\circ : 180^\circ \quad (5)$$

$$h = 10 : 10 : 90 \quad (6)$$

$$w = \min(10, h - 50) : 10 : \max(90, h + 50) \quad (7)$$

Equation (5) represents the interval θ in the range 0° to 180° taken by 15° , and the meanings of equation (6) and equation (7) can be analogously derived in turn. Since convolutional neural network can generalize and extract features in images with high recognition accuracy, this study chooses it to build a swimming pose detection model based on the mature AlexNet, and the core hierarchy in AlexNet is designed below. In general, if there is an input image of size $n \times n \times n_c$ and its convolutional kernel size is $f \times f \times n_c$, and f are the number of image channels and convolutional kernel size respectively, and the convolutional step parameter is s , then the size of the output value of the convolutional layer can be obtained by equation (8).

$$((n + 2p - f) / s + 1) \times ((n + 2p - f) / s + 1) \times m_c \quad (8)$$

p and m_c represent the size of the edge filling layer and the total number of convolutional kernels used, respectively. The activation functions of the convolutional layers are used to perform nonlinear mapping of the output elements of each layer. The commonly used activation functions are relu function, elu function, tanh function, and sigmoid function. However, for neural networks with more layers, using the tanh function and sigmoid function as the activation function may

cause the gradient disappearance problem and reduce the overall convergence speed of the algorithm, so the relu function and elu function are more widely used. The function graphs of the above four activation functions are shown in Fig. 1.

Fig. 1. Function curve of common activation functions

The role of pooling layer in AlexNet is to extract the high-latitude features in the images and reduce the size of the dataset. Depending on the processing method, there are two types of pooling layers, average pooling and maximum pooling. The maximum pooling method is chosen to construct the pooling layer in AlexNet in this study, and the calculation method of maximum pooling is shown in Fig. 2.

Fig. 2. Schematic diagram of the calculation rules for maximum pooling

According to the content above, based on the simplified AlexNet, a neural network is designed to judge whether the swimmer's swimming posture in the generated rectangular box is accurate. The input is the preprocessed RGD (Red Green Depth) three channel data, and the computational flow of the algorithm is shown in Fig. 3.

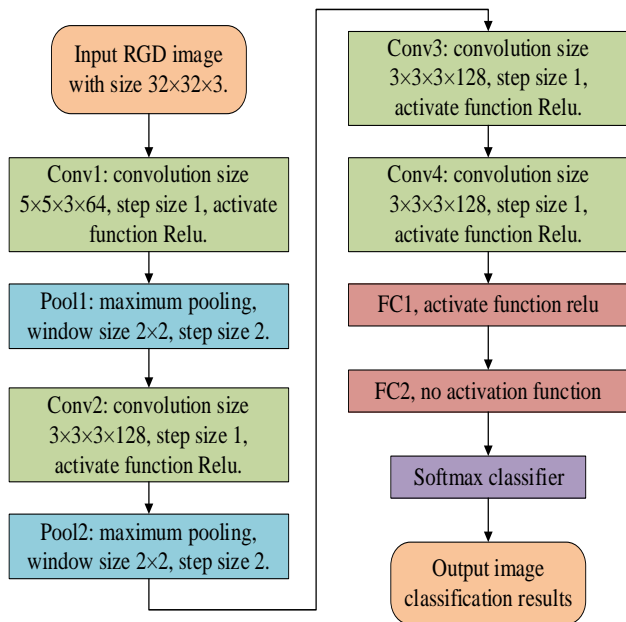

Fig. 3. Flow chart of the bit pose detection algorithm combining sliding window detection and convolutional neural network

As shown in Fig. 3, the algorithm contains four convolutional layers, two maximum pooling layers and two fully connected layers. The size of the convolutional kernel is 5×5 , and the output data size is $16 \times 16 \times 64$ after the maximum pooling process, and then the output data size is $8 \times 8 \times 128$ after three convolutional layers with the convolutional kernel size of 3×3 and the maximum pooling layer. The size of the output data is adjusted to 2. Finally, the data is input to the softmax classifier for binary classification, and the judgment result of whether the object pose of the rectangular box in the input image data is correct is output.

B. Design of Swimming Pose Detection Algorithm based on Deep Residual Network

The pose detection algorithm designed in this study, which combines sliding window detection and convolutional neural network (SW-CNN), has many layers of networks and complex processing, so it may have a problem of slow detection speed in actual use, which can't meet the timeliness requirements of its application in swimming teaching. Therefore, in order to further improve the recognition accuracy of virtual swimming stance images, a virtual model recognition algorithm of swimmer's stance that integrates end-to-end idea and convolutional neural network (PTP-CNN) is proposed. Unlike the SW-CNN algorithm, the former trained neural network can directly reflect the RGB image and its corresponding standard swimming pose mapping relationship, so the input data of the PTP-CNN algorithm in the training phase is the image and the corresponding standard swimming pose information in the figure. In addition, since the PTP-CNN algorithm removes the sliding window detection link, and the learning ability of the neural network with the requirement of diversity of input image data is increased. Therefore, migration learning and data augmentation, deep residual network methods are needed to learn swimming pose features.

Due to the inefficiency of constructing virtual models based on physical images of swimmers' swimming stance and the complexity of computational processing, the data set that can be used for training the algorithm is often small in number and cannot well meet the training requirements of the algorithm, and overfitting may even occur. Therefore, before designing the PTP-CNN algorithm, it is necessary to expand the dataset and increase the size of the dataset appropriately through data augmentation techniques to make up for the lack of data and the problem that the data diversity and feature information are relatively single, so that the neural network can learn to master more important image features. In this study, considering the type of task of the algorithm, we choose to use data augmentation methods that do not change the features themselves but only the pixel distribution to process the dataset by flipping transformation, rotation transformation, translation transformation, contrast transformation, color transformation, sharpening, adding noise disturbance, adding blurred information, etc. The program selects one or more measures to process the original dataset in a random way.

Even with data augmentation, the total number of samples in the dataset is still relatively limited, which makes it difficult and inefficient to obtain more data. And using the existing dataset directly for training may lead to overfitting of the model. In addition, training the whole neural network algorithm from scratch will consume a lot of computer and time resources. Therefore, the PTP-CNN algorithm is built using the migration learning approach. There are three common applications of transfer learning, as a feature extractor for the algorithm to be trained, as a pre-trained model for the algorithm to be trained, and as an aid for fine-tuning the model parameters. The most central step in the algorithm training here is to improve the image feature extraction capability of the algorithm, therefore, the convolutional neural network trained with Imagenet dataset is selected as the image feature extractor in PTP-CNN algorithm. Then the fully connected layer is set after the convolutional neural network, and the output of the last layer is changed to the position and stance parameters that measure the swimmer's stance. That is, the parameters of the layers within the migrated convolutional neural network remain unchanged, and only the parameters of the fully connected layer behind are fine-tuned to achieve migrated learning.

When the neural network has too many levels, its recognition accuracy will be degraded, and some scholars have proposed the use of central normalization and normalized initialization methods, which can solve the problem to some extent, but the effectiveness of these methods is also poor if the neural network has too many levels, and the residual neural network is more effective in dealing with the problem. In this study, a residual network module constructed by constant mapping is introduced into the ResNet network of PTP-CNN algorithm to solve the degradation problem of deep convolutional neural networks.

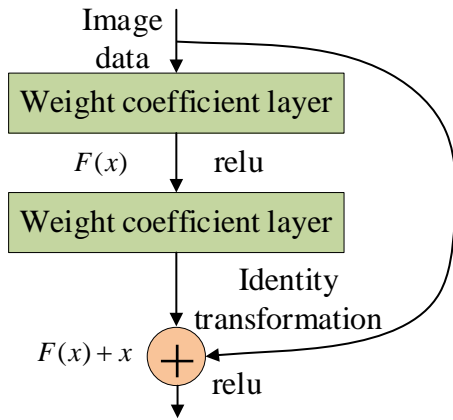

Fig. 4. Structure of residual neural network based on constant mapping

As shown in Fig. 4, the output of the residual module is obtained by superimposing the output of multiple convolutional layers and then performing ReLU processing, as shown in Equations (9) and (10).

$$F = W_2 \times \text{relu}(W_1 x) \quad (9)$$

$$y = F(x, W_1) + x \quad (10)$$

In equation (10) $F(x, W_1)$ is the residual mapping function constructed based on the input x , residual matching weights W_1 , W_2 , and y is the output data after the resultant residual processing. Here ResNet-50 containing 50 computational layers is used as the basis for forming the PTP-CNN algorithm, and the image data size of the input network needs to be adjusted to 224×224 , then the convolutional kernel and input feature data of each core level in the network are shown in Table I.

TABLE I. CONVOLUTIONAL KERNEL AND INPUT FEATURE PARAMETERS AT THE CORE LEVEL IN THE RESNET-50 NEURAL NETWORK

Layer Name Type	Output Data Size	Number of computing layers	Convolution kernel or pooling window size	Number of convolution kernels
C1	112×12	1	7×7	64
P1	112×12	1	3×3 (maximum pooling)	/
C2_X	56×56	3	1×1, 3×3, 1×1	64, 64, 256
C3_X	28×28	4	1×1, 3×3, 1×1	128, 128, 512
C4_X	14×14	6	1×1, 3×3, 1×1	256, 256, 1024
C5_X	7×7	3	1×1, 3×3, 1×1	512, 512, 2048
P5	1×1	4 (average pooling, connected, softmax)	3×3	/

After completing the above preparatory work, we started to formally design the virtual model recognition model of swimmer's stance based on PTP-CNN algorithm, the input image in this model needs to be pre-processed and data augmented, the feature extractor in the model is ResNet-50 convolutional neural network trained by ImageNet dataset, followed by docking pressure leveling layer, deletion layer, SoftMax, and finally, the overall structure of the model is shown in Fig. 5.

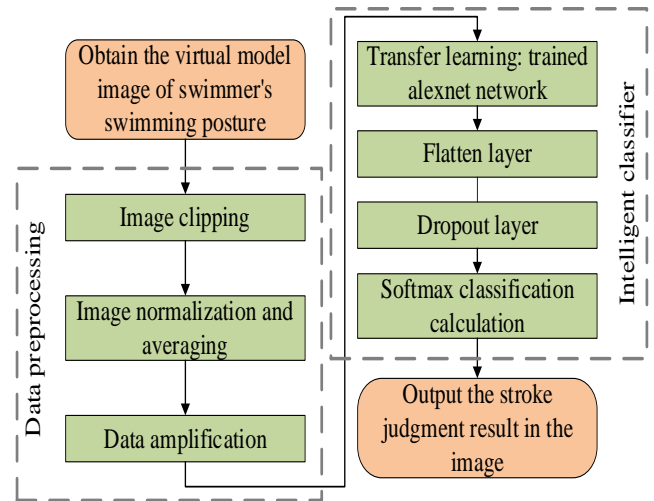

Fig. 5. Structure of virtual image recognition model of swimmer's position pose based on PTP-CNN algorithm

As shown in Fig. 5, the last layer of the standard ResNet network is the SoftMax classifier. But, in order to downscale the dimensionality of the data by one dimension for classification, a flattening layer needs to be added before, and a deletion layer is subsequently added to prevent overfitting of the model. Finally, the PTP-CNN algorithm is trained by using the cross-entropy loss function $loss(x)$, which is given in equation (11).

$$loss(x) = -\frac{1}{n} \sum_{i=1}^n [y_i \ln y_{ip} + (1 - y_i) \ln(1 - y_{ip})] \quad (11)$$

In equation (11), y_i and y_{ip} are the label value and algorithm prediction of the image i , respectively.

IV. PERFORMANCE VERIFICATION EXPERIMENT OF SWIMMING POSTURE DETECTION ALGORITHM

A. Model Parameter Setting and Performance Verification Experimental Design

The experiments were designed to verify the recognition performance of the two virtual image recognition models of swimmer's stance designed in this study, and to build a comparative classification model based on the common SVM (Support Vector Machine) algorithm and AlexNet neural network. The data set used for model training is the images of different swimming stances purchased by the research team from a third-party data agency in China, and the images are labeled as "correct stance" and "wrong stance". The data set

contains 1843 images, and after data expansion, it reaches 15442 images, which are divided into training set and test set (containing 4632 images) according to the ratio of 7:3. The model based on SW-CNN algorithm also uses cross-entropy loss function and Adam optimization method, and the learning rate is determined to be 0.001 after multiple debugging, and the exponential decay rates of β_1 and β_2 for first-order and second-order moment estimation are 0.9 and 0.998, respectively, and the batch size is 64. The model based on PTP-CNN algorithm is also optimized using Adam, and the learning rate is determined to be. The exponential decay rates of β_1 and β_2 are 0.88 and 0.999 for first-order and second-order moment estimation, respectively, and the batch size is set to 32. The common evaluation indexes of image classification accuracy are Accuracy, Precision, Recall, and F1 value, which are calculated in equations (12) to (15).

$$Accuracy = \frac{TP+TN}{TP+TN+FP+FN} \quad (12)$$

$$Precision = \frac{TP}{TP+FP} \quad (13)$$

$$Recall = \frac{TP}{TP+FN} \quad (14)$$

$$F1 = \frac{2 * Precision * Recall}{(Precision + Recall)} \quad (15)$$

In Eqs. (12)~(15), TP represents the number of samples that are actually positive classes are predicted to be positive classes, referred to as the true positive number, and so on TN , FP , FN are the true negative number, false positive number, and false negative number, respectively. Considering the importance of identifying correct and incorrect postures in swimming teaching, the accuracy rate was chosen as the performance evaluation index of each model.

B. Analysis of Experimental Results

After completing all the performance test experiments, the Excel software and SPSS23.0 software were used to count the changes of the loss function values during the training process for the virtual image recognition models of swimmer's position pose constructed based on SW-CNN algorithm and PTP-CNN algorithm designed in this study, and the comparison models constructed based on SVM algorithm and AlexNet algorithm, as shown in Fig. 6.

Fig. 6. Loss function value change curve of virtual image recognition model for each swimmer's position pose during training

In Fig. 6, the horizontal axis represents the number of iterations of the core algorithm in each model, the vertical axis represents the loss function value of each algorithm, and different colors represent different virtual image recognition models of swimmer's position pose. As we can see in Fig. 6, the model built based on PTP-CNN algorithm has the fastest convergence speed during the training process and the smallest loss function value after convergence, while the model built based on SVM algorithm has the slowest convergence speed and the largest loss function value after convergence. Specifically, when all the models finished training (i.e., the loss function values converged), the loss function values of the virtual image recognition models constructed based on the PTP-CNN algorithm, AlexNet algorithm, SW-CNN algorithm, and SVM algorithm were 3.49, 4.86, 7.13, and 19.85, respectively. The detection accuracy of each model on the test set is analyzed below. The statistical results are shown in Fig. 7.

Fig. 7. Recognition accuracy of virtual image recognition models for each swimmer's position pose on the test set

The horizontal axis in Fig. 7 represents the number of samples used to test each model, and the vertical axis represents the classification accuracy of each model on image data in %, with two valid digits retained. Since the accuracy of each model changes slightly after the number of samples exceeds 200, only the test results before the number of test samples is not higher than 200 are retained here. It can be seen from Fig. 7 that the classification accuracy fluctuation degree of the model changes with the number of test samples. The descending sorting results are SW-CNN, PTP-CNN, AlexNet and SVM. However, from the perspective of the overall classification accuracy, the descending sorting results are PTP-CNN, SW-CNN, AlexNet and SVM. When the number of test samples is 200, the classification accuracy of each algorithm is 97.48%, 96.72%, 93.60% and 91.39%, respectively. The image recognition speed of each trained model with different test samples is then analyzed and shown in Fig. 8.

Fig. 8. Computational speed of the virtual image recognition model for each swimmer's position pose on different number of test samples

In Fig. 8, the horizontal axis is the number of samples used to test the model, and the test step size is 500 samples in line with the scale. The circle and "TC" represent the computation time, and the data line and "CS" represent the computation speed. As can be seen in Fig. 8, when the training samples are small, the computational speed of each model is high because the algorithm takes a relatively constant time to start. From the model perspective, the model based on the SVM algorithm has the slowest computation speed due to the high computational complexity of its own algorithm, while the computation speed of the other three models remains roughly stable as the number of samples grows. When the number of test samples is 4500, the computation time of the models built based on PTP-CNN algorithm, AlexNet algorithm, SW-CNN algorithm and SVM algorithm is 24 ms/sheet, 19 ms/sheet, 34 ms/sheet and 45 ms/sheet, respectively. Finally, the computer memory occupancy of each algorithm during operation is analyzed in Fig. 9. It is need to note that five parallel experiments were conducted for each experimental scheme to ensure the reliability of the test results.

Fig. 9. Memory consumption of the virtual image recognition model computed for each swimmer's position pose

In Fig. 9, the horizontal axis is the number of test samples, the vertical axis is the computational memory consumption in MB, and the vertical coordinate of the center point of the circle in the figure is the mean computational memory consumption of multiple experiments, and the upper and lower limits represent the upper and lower deviation of memory consumption. As we can see in Fig. 9, the computational memory consumption of each model tends to increase as the number of test samples increases, but the memory consumption of the model built by the SVM algorithm grows the fastest, the memory consumption of the model built by the AlexNet algorithm grows the slowest, and the model built by the PTP-CNN algorithm grows the second. When the number of test samples is 4500, the memory consumption of the models constructed based on the PTP-CNN algorithm, AlexNet algorithm, SW-CNN algorithm, and SVM algorithm are 225MB, 105MB, 269MB, and 438MB, respectively.

V. DISCUSSION

For the purpose of helping swimmers learn swimming postures by themselves, this research uses sliding window and depth residual network to build a hybrid neural network algorithm, and based on this algorithm, two corresponding virtual image classification models of swimmers' postures are designed. At the same time, in order to reduce the noise of the input data and reduce the cost of data collection, virtual reality technology is used to convert the swimming pose image of swimmers into an image model in the virtual reality space as the input data of the algorithm. The performance test experiment results show that the model based on PTP-CNN algorithm designed in this study is the first to complete convergence in the training phase, and the loss function value

after convergence is also significantly lower than all the comparison models, which is 3.49. The research results of X. Tong et al. also show that the convergence speed of the pose detection neural network incorporating sliding window technology in the training phase is significantly faster than that of the neural network before improvement [19]. From the perspective of the pose recognition accuracy index of the test set, the classification accuracy of the model built based on the PTP-CNN algorithm designed in this study is 97.48%, which is the highest among all the comparison models, while the classification accuracy of the recognition model built based on the SW-CNN, AlexNet and SVM algorithms is 96.72%, 93.60% and 91.39%, respectively. The research results of J. M. Liang et al. also show that the use of virtual reality technology to convert teaching material images into virtual reality models is conducive to improving the work progress of the teaching assistance system [20]. From the perspective of computing efficiency, when the number of test samples is 4500, the computing speed and memory consumption of the model based on PTP-CNN, SW-CNN, AlexNet and SVM algorithms are respectively 24 ms/piece, 34 ms/piece, 19 ms/piece, 45 ms/piece and 225 MB, 269MB, 105 MB, 438 MB. This is mainly because the deep residual network consumes more computing resources than the general convolutional neural network, slowing down the computing speed of the entire model.

VI. CONCLUSION

To solve the problem of swimming teaching, beginners' learning progress of swimming skills is affected due to insufficient knowledge of correct swimming posture. This study uses virtual reality technology to convert physical images of swimmers' swimming posture and position into models in virtual space, and constructs two hybrid convolutional neural network-based image classification models for virtual models of swimmers' position posture. The performance test results show that the model based on PTP-CNN algorithm designed in this study has the fastest convergence speed in the training phase, and the loss function value after convergence is the smallest than the comparison model, 3.49. The classification accuracy of the models based on PTP-CNN, SW-CNN, AlexNet and SVM algorithms on the test set is 97.48%, 96.72%, 93.60% and 91.39% respectively. When the number of test samples is 4500, the calculation speed and memory consumption are 24 ms/piece, 34 ms/piece, 19 ms/piece, 45 ms/piece and 225 MB, 269MB, 105 MB and 438 MB, respectively. The experimental data shows that the model based on PTP-CNN algorithm and SW-CNN algorithm designed in this study is higher than the common neural network algorithm and machine learning algorithm in the virtual image recognition accuracy of swimmer's swimming posture, but the former has faster computation speed and consumes less resource for computation. However, due to the limitation of experimental conditions, further classification and recognition of swimmer's swimming posture by joints were not carried out, which could help learners to use the recognition model in more cases, and this is also a point for improvement in the subsequent research.

Serdang, Malaysia

Abstract—Through the growth of portals and venues to publish academic publications, the number of academic publications is growing exponentially in recent years. An effective exploration and fast navigation in the collection of academic publications become an urgent need to help academic researchers find publications related to their research and the surrounding community. A scholar network visualization approach is proposed to help users to explore a large number of academic publications concerning the strength of the relationship between each publication. The approach is realized by creating a web-based interface using D3 JavaScript algorithm that allows the visualization to focus on how data are connected to each other more accurately than the conventional lines of data seen in traditional data representation. The proposed approach visualizes data by incorporating a force-directed graph with weighted nodes and vertices to give more descriptive information of millions of raw data such as author names, publication title, publication year, publication venue and number of citations from the scholar network dataset. By introducing a weighted relationship in the network visualization, the proposed approach can give a more insightful detail of each publication such as a highly cited publication by looking at and exploring the generated interactive graph. The proposal is targeted to be incorporated into a larger-scale scholar network analytical dashboard that can offer various visualization approaches under one flagship application.

Keywords—Force-directed graph; weighted network; citation network; D3 algorithm

I. INTRODUCTION

The existence of numerous academic social networking websites such as Google Scholar and ScienceDirect has accommodated scholars to publish their scientific publications to the public effortlessly. The purpose of this platform is to acknowledge people about a specific topic in certain disciplines.

A concern regarding academic social networking websites is how to handle the flood of information offered by the websites. People can no longer rely on traditional ways to deal with the outgrowth of scientific publications. Traditional searching and browsing functions at academic social networking websites have become outdated as more time is needed to browse through each publication to see their relevancy.

The overload of information could lead to a lack of efficiency and a lengthy period of time spent searching for valuable information. It will lead to failure in receiving a full, in-depth overview of the desired topics and domains.

Therefore, a mechanism to efficiently handle the flood of information needs to be introduced, as it would speed up the process of searching and understanding the scientific network and communities in one specific discipline. An efficient search and analysis of academic networks can also help non-specialists from other disciplines quickly find existing networks that they are interested in.

In general, on academic social networking websites, the browsing function has a fixed classification algorithm that cannot provide a user with desired topics and domains. Some non-specialist users are not able to understand the jargon used in domains unfamiliar to them. Fortunately, humans are intensely visual creatures. Normally, people can read a pattern of the growth of diseases by looking at a chart, and even children can describe a bar chart and extract information from it. For that reason, an efficient scholar network visualisation approach can be an alternative way for users to replace traditional searching and browsing functionalities on academic social networking websites.

The scholar network visualization approach is considered part of data analytics and visualization, which has become a highly active field of research in recent times due to the information overload all around us. Data visualization, which deals with brain psycho-visual vision and cognitive capacities, is a privileged tool to analyze one's environment. Network visualization research can be defined by the techniques that allow humans to visualize data through a network graph that presents a network of connected entities and nodes visually.

Many visualization tools have been introduced in recent years [1,2]. They offer many useful functions, such as data processing and visual analytics. Therefore, it has simplified the process of data visualization for users, whether they have any programming knowledge or not. The tools give users the capability to transform the data into interactive charts that are more understandable and readable by everyone. Data visualization is commonly utilized in business intelligence, scientific visualization, and analytical analysis. There are two types of visualization tools: visualization tools with programming languages and visualization tools without programming languages.

Fig. 1. Network visualization generated in VOSviewer

Tableau [3] is a software that is used mainly in business intelligence and analytics. It supports various file formats, such as txt, xlsx, csv and json. Data can also be imported from online servers such as MySQL and Oracle. Tableau can generate a suitable graph automatically by extracting the header of each variable in our dataset. Users can also use the drag-and-drop feature to add rows and columns and select a chart type. A web-based application called Infogram [4] can complete data visualization quickly; first-time users just need to register, and they can upload their own data files in various formats, such as xlsx or csv to the website. Users can also import data from Google Drive, Dropbox, OneDrive, or a JSON feed. One of the disadvantages of Infogram is data privacy. An open-source JavaScript library, D3.js [5] combines HTML and CSS methods. On D3.js official website, it provides plenty of examples with the source code to inspire users to create their own data visualization. All the graphs generated will be in svg format.

R programming also provides a package called Ggplot2 [6], which is an open-source package to visualize by generating charts. Compared to basic R graphs, the Ggplot2 package allows the user to edit the plotting component of the graph. Ggplot2 also has its own repository on Github that provides the user with an annual case study competition to show their skills. Users have a chance to use the package, and in return, they can contribute codes back to ggplot2.

Fig. 2. Chinese Academy of Science Co-author network generated in Sci2

Fig. 3. Mapping papers with highest local citation score generated in HistCite

Another free visualization and analysis tool called VOSviewer [7] is able to construct and visualize bibliometric networks. It visualizes scholarly data into bibliometric networks by clustering solutions. Users can visualize their data by importing the data files from Web of Science (WOS), Pajek, and Graph Modelling Language (GML). The networks can be saved as a bitmap file or in vector format. Fig. 1 shows network visualization generated in VOSviewer. Sci2 [8] that represents The Science of Science is an open-source tool that supports temporal, geospatial, topical, and network studies. It also generates different kinds of networks. The network that generates from small datasets can be explored interactively and the network from large datasets can be rendered in Postscript files that users can convert. Fig. 2 shows a co-authorship network from the Chinese Academy of Science generated in Sci2.

HistCite [9] is used to visualize scholarly data and bibliometric analysis, including the productive authors, the scale of journals, the frequency of words, the types of documents, and the ranking of institutions. A bibliography's dataset will be converted into time-based networks called historiographs by HistCite. The historiograph assists the user in understanding the subject's main publishing events as well as the impact of the chronology on networks. Fig. 3 shows the mapping of 45 papers with the highest local citation score generated in HistCite.

BibExcel [10] is used to do multiple types of bibliometric analysis, such as citation analysis, cluster analysis, and co-citation analysis. The system allows users to select a catalogue from their data and add it as a variable in the data matrix of output files. Users can also export the files that include the data matrix and import them into other visualization tools such as Gephi, Pajek, and VOSviewer to continue their analysis. Fig. 4 shows the mapping science using BibExcel and Pajek.

Fig. 4. Mapping science using BibExcel and Pajek

Fig. 5. Visualizing patterns and trends in scientific literature using CiteSpace

A Java application called CiteSpace [11] facilitates the user by detecting, visualizing, and analyzing increasing trends and critical changes in scientific literature. It combines information visualization methods and bibliometrics with the algorithm of data mining to read the pattern in citation data. Fig. 5 shows the visualizing patterns and trends visualised in the scientific literature using CiteSpace. A fuzzy-based clustering visualization approach, Bibliographic Big Data Visualization [12] offers a hybrid fuzzy clustering-based visualization by applying the Fruchterman-Reingold algorithm. The visualization can divide the nodes into soft clusters, but they lack the strength of the connection between the clusters. Fig. 6 shows the fuzzy clustering in Bibliographic Big Data Visualization.

By implementing query optimization and the spectral centrality measure [13], an improved scholar data visualisation was proposed, in which the scholar data is visualised in a network diagram using the centrality measure for better and faster decision making. By using the concept of a word cloud, the visualization offers a weighted network visualization. Fig. 7 shows the enhanced bibliographic data retrieval using query optimization and the spectral centrality measure. Table I compares existing scholar network visualisation approaches, including their functions and limitations.

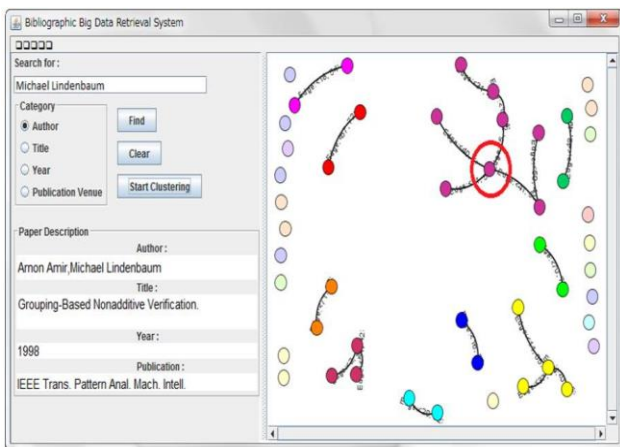

Fig. 6. Fuzzy Clustering in Bibliographic Big Data Visualization System

Fig. 7. Enhanced Bibliographic Data Retrieval Using Query Optimization and Spectral Centrality Measure

TABLE I. COMPARISON OF EXISTING SCHOLAR NETWORK VISUALIZATION APPROACHES

Name	Main function	Data format	Platform	Limitation
Tableau[3]	General data analysis	.txt .csv .xlsx	Windows Mac OS	Not programmable to improve to algorithm
Infogram[4]	General data analysis	JSON	Windows Mac OS	Not programmable to improve to algorithm
D3[5]	General data analysis	JSON	Windows Mac OS	Limited data size
Ggplot2[6]	Chart visualization	.csv	Windows Mac OS	Slow to create graphics
VOS Viewer[7]	Citation analysis	WOS Pajek,GML	Windows Mac OS	Only support node network diagram and heat map
Sci2[8]	Network analysis	.txt .csv	Windows Mac OS X Linux	High memory footprint when process large datasets.
HistCite[9]	Static analysis	WOS	Windows but only on IE	Only support data from WOS.
Bib Excel[10]	Process scholar database	WOS Med-line	Windows	Not easy to use without its help document
Cite Space[11]	Co-citation analysis	WOS Pub-Med & arXiv	Windows	Cannot delete irrelevant node

Bibliographic Big Data Visualization [12]	Fuzzy Citation Network analysis	AMiner	Java	Takes more than 2 minutes to produce visualization result due to clustering process.
Bibliographic Data Retrieval Using Spectral Centrality Measure[13]	Hybrid Clustering Citation Network analysis	AMiner	Python MongoDB	Only supports JSON/XML format dataset

Most recently, NetV.js [14] high-efficiency visualization approach was introduced for large-scale graphs. It is an open-source JavaScript library that supports the fast visualization of large-scale graph data at an interactive frame rate with a commodity computer. It consists of the Graph Model Manager, the Rendering Engine, and the Interaction Manager. While D3.js library can support up to 20,000 nodes and 400,000 edges, NetV.js can support up to 50 thousand nodes and 1 million edges. For the scholar network dataset used in this study, D3.js is sufficient to produce the visualization as the dataset only has 800 nodes, but to produce large scale graphs, NetV.js is more suitable to be used as the visualization approach.

Another recent approach for visualizing large real-world (social) network data on a high-resolution tiled display system was introduced on a tiled display system consisting of multiple screens [15]. The high resolution tiled display approach used GPUs to ensure an interactive setting with real-time visualization. GPUs are gaining popularity for large-scale datasets because they can process visualization much faster.

Section II describes the scholar network dataset from AMiner and the Fruchterman-Reingold force-directed graph applied in this study. The application of Fruchterman-Reingold to the scholar network dataset and color scheme for graph nodes and vertices visualization is presented in Section III. Section IV discusses the scholar network visualization produced from the analytics, and the research conducted in this study is summarized in Section V.

II. MATERIALS AND METHOD

A. Scholar Network Dataset from AMiner

This section describes the dataset used in the proposed approach. The dataset is acquired from the AMiner website [16-21]. AMiner is a free online web service used to index, search, and mine big scientific data. Data acquired from AMiner is suitable for data analytics operations on academic publication information to identify connections between researchers, conferences, and publications. Some of the insights that can be produced are expert findings, geographic search, trend analysis, reviewer and examiner recommendation, association search, course search, academic performance evaluation, and research domain modeling.

The Scholar network dataset from AMiner consists of eight attributes. Table II shows the data schema of the Scholar network dataset. The citation data is extracted from DBLP, ACM, MAG, and other sources. The dataset attributes include

publication id, publication title, publication authors, publication venue, published year, citation number, citing publications' id, and abstract.

B. Fruchterman-Reingold Algorithm for Vertices and Edges Visualization

Force-directed graph [22-25] is used to visualize the scholar network as it provides the ability to convey the relationship between data, the weightage of the relationship, and the flow often brings out the untold insights into the limelight.

The advantages of a force-directed graph include its flexibility to adapt to increasing criteria, its intuitiveness to make a graph easy to be predicted and understood, and its simplicity in terms of fast implementation using minimal lines of code. The interactivity a force-directed graph can offer is also a big advantage as users prefer to interact with the interface for a deeper understanding of the visualization. Lastly, the force-directed graph has a strong theoretical foundation due to its usefulness in multiple fields such as physics and statistics.

In the proposed study, the Fruchterman-Reingold [26] algorithm is selected to become the visualization approach for the scholar network. The Fruchterman-Reingold algorithm offers a dynamic force-directed graph suitable for edge crossing reduction and planar graph drawing. The algorithm introduces two principles, which are the vertices connected by an edge should be drawn near each other and the vertices should not be drawn too close to each other.

TABLE II. DATA SCHEMA OF THE SCHOLAR NETWORK DATASET

Field Name	Description	Example
Id	Publication ID	013ea675-bb58-42f8-a423-f5534546b2b1

Venue	Publication venue	Journal of Computational Chemistry
Year	Published year	2017
Citation	Citation number	0
Reference	Citing publications' id	["4f4f200c-0764-4fef-9718-b8bccf303dba", "aa699fbffabe-40e4-bd68-46eaf333f7b1"]

Suppose f_a and f_r are the attractive and repulsive forces respectively, with d as the distance between the two vertices and k as the radius of the empty area around a vertex, then

$$f_a(d) = d^2k \quad (1)$$

$$f_r(d) = -k^2 \quad (2)$$

Given a graph $G = (V, E)$, the combined force applied on vertex v is:

$$(v) = \sum_{(u,v) \in E} f_a,uv + \sum_{(u,v) \in V * V} f_r, uv \quad (3)$$

Fig. 8 shows the general flow of the Fruchterman-Reingold algorithm. In Fruchterman-Reingold, each node applies a repellant force on other nodes that are inversely proportional to the distance between those nodes, and each arc applies an attractive force on its endpoints proportional to the square of the distance between those nodes. Therefore, as linked nodes grow more distant from one another, the attractive force activates quickly and the repellant force drops off, so linked nodes will have the tendency to get back closer to one another. Similarly, as the nodes get increasingly close, the repellant force activates rapidly while the attractive force ceases, and the nodes will be pushed away from each other. Only when the nodes are at a well-adjusted distance from one another, the forces begin to balance; therefore the nodes will slowly stop moving. To keep track of the forces on each node, a Δx and Δy value for each node is maintained, where they store the gain forces on that node along the x and y axes. The algorithm is constantly tracking the location of each node since it's possible that a node might be repelled entirely vertically, in which case it will have a strong force in the y direction but no force in the x direction, or horizontally, where strong force in the x direction, no force in the y direction. The gain forces in each direction beginning at zero but will be adjusted by the interactions of each node with each other node. Fig. 9 depicts the pseudocode of the Fruchterman-Reingold algorithm.

Fig. 8. Flow diagram of the Fruchterman-Reingold algorithm

```

area := W * L; {W and L are the width and length of the frame}
G := (V, E); {the vertices are assigned random initial positions}
k := sqrt(area/|V|);
function fa(x) := begin return x^2/k end;
function fr(x) := begin return k^2/x end;
for i := 1 to iterations do begin
    {calculate repulsive forces}
    for v in V do begin
        {each vertex has two vectors: .pos and .disp}
        v.disp := 0;
        for u in V do
            if (u ≠ v) then begin
                {δ is the difference vector between the positions of the two vertices}
                δ := v.pos - u.pos;
                v.disp := v.disp + (δ/|δ|) * fr(|δ|)
            end
        end
    end
    {calculate attractive forces}
    for e in E do begin
        {each edges is an ordered pair of vertices .vand.u}
        δ := e.v.pos - e.u.pos;
        e.v.disp := e.v.disp - (δ/|δ|) * fa(|δ|);
        e.u.disp := e.u.disp + (δ/|δ|) * fa(|δ|)
    end
    {limit max displacement to temperature t and prevent from displacement outside frame}
    for v in V do begin
        v.pos := v.pos + (v.disp/v.disp) * min(v.disp, t);
        v.pos.x := min(W/2, max(-W/2, v.pos.x));
        v.pos.y := min(L/2, max(-L/2, v.pos.y))
    end
    {reduce the temperature as the layout approaches a better configuration}
    t := cool(t)
end
    
```

Fig. 9. Pseudocode of the Fruchterman-Reingold algorithm

The Fruchterman-Reingold algorithm is applied in the experiment through a plugin in D3.js [5].

III. RESULTS

A. Data Preprocessing and Exploration on the Scholar Network Dataset

The initial data consists of academic publications from 1936 to 2018. To ensure that the visualization process is fast and the graph produced is manageable, data earlier than 2010 is excluded from the experiment. Only data from 2010 and above will be visualized in the final visualization. The initial attributes of the dataset include publication id, publication title, authors' name, publication venue, published year, citation number, citing publication ID, and abstract. In the experiment, only 5 attributes are included: the authors' name, publication ID, title, number of citations, and year of publication. From the scholar dataset exploration, there is an increasing number of academic publications from year to year. Fig. 10 shows the histogram of publications from 2010 to early 2018.

A network graph has two key data elements, nodes/vertices, and links/edges. All nodes must have unique identifiers. In each node, it is possible to add as many custom variables as necessary. Links must have a valid node id as a source and a target, and they can be text or numbers. Fig. 11 shows a snapshot of the cleaned dataset ready to be visualized in the D3 algorithm. The intention is to develop a node-to-node relationship to emphasize the relationship between authors and their publications. Every node is connected to the target node with the same relationship. Another feature of the proposed approach is that every node will have a different color based on the year it was published to the public, and the radius of the node will correspond with the number of citations in every academic publication. If the user enters the author's name in the space provided, it will highlight the other nodes that are related to it. If users hover the mouse over one of the nodes, they can see the details for every academic publication they want. The information will be displayed on the left side of the graph.

B. Color Scheme for Graph Nodes and Vertices Visualization

The color palette for the nodes and vertices was chosen according to the Web Content Accessibility Guidelines (WCAG) [27] which suggests the minimum contrast ratio between text or image and background is 4.5:1. Table III describes the color ratio for every color used in the force-directed graph visualization. Ten colors are chosen to represent 10 different clusters of the scholar network to be visualized in the graph. If more than 10 network clusters exist, the same color will be repeated in other clusters.

TABLE III. COLOR RATIO FOR EVERY COLOR IN THE FORCE-DIRECTED GRAPH

Color Code	Contrast Ratio	Color
#ffffff	18.37	
#ffb646	10.52	
#ff863d	7.63	
#ff8882	7.57	
#00aa9f	6.34	
#1d9c3d	5.14	
#ff352e	5.07	
#c06c30	4.74	
#9262f8	4.65	
#0781df	4.56

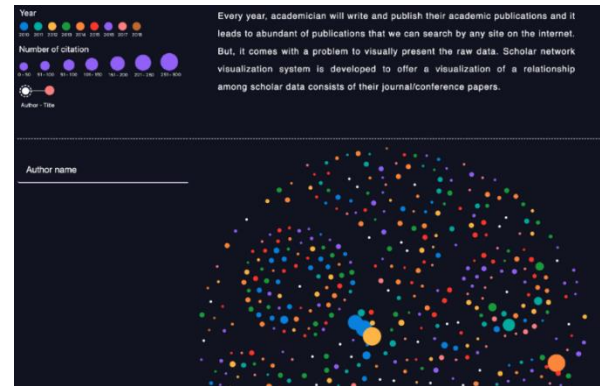

Fig. 11. The visualization of the Scholar Network Visualization approach (Initial Graph)

IV. DISCUSSIONS

This section discusses the scholar network visualization produced using the D3 library based on the experiment done on the scholar network dataset.

The Fruchterman-Reingold algorithm analyses the scholar network dataset to produce a dynamic force-directed graph visualization, and the visualization is created using the D3 algorithm [28]. D3 is a JavaScript library for manipulating documents based on data. It can bring data to life using HTML, SVG, and CSS. D3's emphasis on web standards offers the full capabilities of modern browsers without tying the data to a proprietary framework, combining powerful visualization components with a data-driven approach to DOM manipulation. It is an increasingly popular approach to data analytics visualization as it can produce sophisticated data visualization that is fast, interactive, and shareable across many platforms.

The graph produced contains nodes linked by lines that represent the relationship between the nodes. D3 implements the Fruchterman-Reingold algorithm to give the user more control over the layout. It implements three primary forces upon the nodes at each tick:

- The sum of the forces acting on each node by all other nodes
- The force pushing and pulling between two linked nodes
- The force pulling each node to a focal point, usually the center of the user-defined space.

Fig. 12. The highlighted nodes after the user search for “Gregor Kennedy”

Fig. 13. Visualization of academic publications from author name “Maslina Zolkepli”

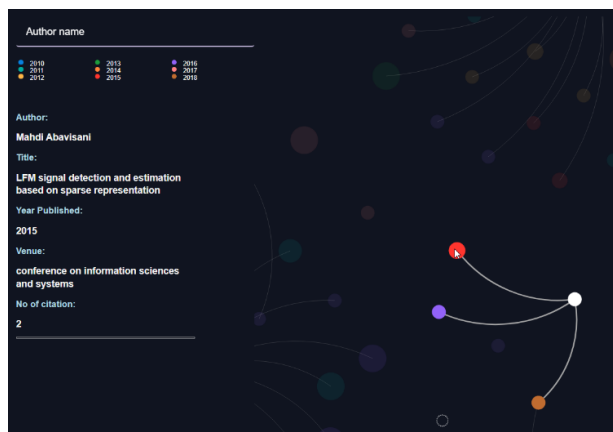

Fig. 14. Visualization of academic publications from author name “Mahdi Abavisani”

Fig. 12 shows the live interface of the D3 algorithm. Initially, when no keyword is supplied by the user, the generated graph consists of all the data that exists in the scholar network dataset. This is feasible when the dataset has between 50 and 500 nodes. If the number of nodes gets larger than 500, the graph becomes too crowded and difficult to comprehend and understand. To ensure that the graph is manageable, data cleaning and pre-processing are required to ensure only recent data is included in the dataset.

Fig. 13 shows the live interface when the keyword "Gregor Kennedy" is supplied by the user. Based on the keyword, a new graph is generated with only data that is related to "Gregor Kennedy". The nodes are weighted according to the number of citations. The larger the node, the higher the number of citations each publication has. Each node is also linked to other nodes that show the link between a publication and its citations. Fig. 14 shows the scholar network visualization result for the keyword "Maslina Zolkepli". Only vertices that contain the information related to the supplied keyword will be highlighted, and users can focus on the highlighted note. Unrelated vertices will be disabled, thus saving resources and time to produce the visualization and speeding up the process for further actions. Fig. 15 shows the scholar network visualization result for the keyword "Mahdi Abavisani". When the mouse cursor is placed on the node, the description of the publication is displayed in the left-hand corner of the page.

V. CONCLUSION

The abundance of scholarly data that is available right now brings a variety of opportunities and challenges for scholarly data analysis. Users are more aware of the significance of applying visualization technologies to different datasets to comprehend the science itself. Thus, the scholar network visualization approach plays a role in addressing the problems that arise from large volumes of diverse and important data.

In this paper, a scholarly network visualization approach is proposed by incorporating weighted nodes and vertices in a dynamic force-directed graph generation. By offering weighted nodes and vertices, users can get an informative view of the visualization. The network graph is dynamic and responds to the user's action in order to focus on several important nodes as requested by the user. The nodes can be further explored by clicking on them, and the related information will be displayed. The proposed approach is expected to increase the significance of data visualization and highlight some insights for people.

Some of the suggestions for the improvement of the scholar network visualization approach in the future are that it should be able to categorize visualization into specific fields and domains to decrease the visualization complexity. It also should be able to use various visualization techniques that can handle large-scale graphs, such as NetV.js and network visualization using a tiled display system, to deal with the ever-increasing complexity of the data. By exploring more ways to visualize data, the scope of the data can also be increased to show more relationships between the data in the best way possible.

Abstract—Agricultural drought is still difficult to anticipate even though there have been developments in remote sensing technology, especially satellite imagery that is useful for farmers in monitoring crop conditions. The availability of open and free satellite imagery still has a weakness, namely the level of resolution is low and coarse with atmospheric disturbances in the form of cloud cover, as well as the location and period for taking images that are different from the presence of weather stations on Earth. This problem is a challenge for researchers trying to monitor agricultural drought conditions through satellite imagery. One approach that has recently used is high computational techniques through machine learning, which is able to predict satellite image data according to the conditions of mapping land types and plants in the field. Furthermore, using time series data from satellite imagery, a predictive model of crop cycles can be regarding future crop drought conditions. So, through this technology, we can encourage farmers to make decisions to anticipate the dangers of agricultural drought. Unfortunately, exploration of the use of machine learning for classification and prediction of agricultural drought conditions has not conducted, and the existing methods can still improve. This review aims to present a comprehensive overview of methods that used to monitor agricultural drought using remote sensing and machine learning, which are the subjects of future research.

Keywords—Drought monitoring; exploration of the use of machine learning; Landsat imagery; remote sensing

I. INTRODUCTION

One of the problems of rainfed agriculture productivity is prolonged drought, lack of rainfall, and lack of water supply in the soil during the vegetative growth phase [1], [2], [3], [4]. In addition, high temperatures during the ripening phase can reduce the conversion yield of sucrose to fructose and glucose [5]. Climate change can also cause diseases and pests [6]. Therefore, it is essential to monitor drought conditions to schedule appropriate irrigation based on the response of plants to drought at various stages of vegetation [7], [8].

However, measuring plant response to drought is very difficult and complex [9], [10], [11], [12], [13], [14]. Detecting and integrating crop water deficits is still complex based on single plant responses [15]. Until 2017 [16] grouped four methods to monitor plant response to drought, namely, (1) Groundwater measurement; (2) Groundwater balanced approach; (3) Plant-based approach; (4) Remote sensing methods. The approach (4) remote sensing is based on the spectral index of vegetation obtained from the Unmanned Aircraft Systems (UAS) hyperspectral sensor, which is the best considering the cost of the sensor is not expensive; the determination of leaf moisture status indicators and plant stomata conductance is high. Non-destructive and non-labor intensive is suitable for automation. The remote sensing method can be adopted as an irrigation scheduling decision [17].

The fact there is an abundance of free Landsat satellite data with open access globally by the US Geological Survey (USGS) starting in 2008 [18] on the Earth Resources Observation and Science (EROS) Center website has attracted researchers from various countries to apply it as a producer of

land use land cover (LULC) maps in their respective regions [19], [20]. However, constructing medium and high-resolution land cover maps in cloud-prone areas is still challenging due to infrequent satellite visits and the lack of cloud-free data. It is both an opportunity and a challenge for researchers to accurately map plant droughts with hyperspectral indices through machine learning classification methods for persistent cloud areas with high temporal dynamics of land cover types that require further investigation. Overall, there have been numerous former studies showing that the use of remote sensing to monitor drought has increased significantly in recent times. Still, the application of machine learning to remote sensing for drought monitoring has not been well-diversified, so there are still numerous exploration gaps that show that its application has not been thoroughly assessed or utilized for drought monitoring purposes.

As a result, in this article we attempt to conduct a systematic review utilizing the meta-analysis method of prior studies using machine learning techniques in remote sensing for agricultural drought monitoring. Meta-analysis methods and systematic reviews can aid in the creation of evaluations that are clearer and more succinct [21]. If there are more studies on similar subjects, the advantages of systematic reviews can be further extended [22]. Systematic reviews can help scientists uncover factors faster, lessen data bias, more accurately define variables, spot trends that previous researchers might have missed, and choose the direction of future study topics [23]. Additionally, systematic reviews can assist researchers in comparing, debating, and choosing from the larger body of literature in order to obtain more trustworthy results [24].

II. RELATED WORK

The use of machine learning techniques to categorize satellite imaging data in remote sensing applications has gained popularity in recent years. On this subject, several research studies have been released, some of which are listed in the paragraphs below.

- Various formalisms are used in applications of machine learning and signal/image processing, including classification and clustering, regression and function approximation, image coding, recovery and enhancement, source separation, data aggregation, and feature selection and extraction [25].
- Machine learning techniques have recently been used in various ways to process data from multispectral and hyperspectral remote sensing [26].
- Using the input data from the satellites Spot5, Sentinel1, and Sentinel2, a Symbolic Machine Learning (SML) classifier with spatial generalization treatment, random theme noise, and spatial displacement noise was created. It made use of multiple Maximum Likelihood Supervised Algorithms, Logistic Regression, Linear Discriminant Analysis, Naive Bayes, Decision Trees, Random Forests, and Support Vector Machines [27].

- Training data needs, user-defined parameter selection and optimization, impact and attenuation feature space, computing costs, and choice of k-nearest neighbor algorithms, enhanced DT, single decision tree (DT), Random Forest, and somewhat mature support vector machine (k-NN) approaches are all taken into account [28].

These studies have shown how well machine learning algorithms work for categorizing remote sensing images and the possibility for further improving the precision and effectiveness of these algorithms through on-going study and development. Previous studies on machine learning in remote sensing have concentrated on a range of methods, such as deep learning algorithms and other supervised and unsupervised approaches, and have investigated their application to various types of remote sensing data and application domains. Overall, applying machine learning to remote sensing has the potential to dramatically increase this field's capabilities and open up a number of new and enhanced applications for satellite data.

III. MATERIALS AND METHODS

The aim of this work is expected to be able to answer the following four research questions (*RQ*):

- RQ1: What publications are the main targets of machine learning based remote sensing drought monitoring?
- RQ2: What kind of environment observed for drought monitoring? What types of remote sensing data have been used?
- RQ3: Which is the most widely used and most accurate machine learning algorithm for the drought monitoring approach?
- RQ4: How does machine learning play a role in drought monitoring?

After determining the research question (*RQ*) of interest, selecting a candidate paper, and performing data extraction, the last step of a systematic literature study is to synthesize the results. For each *RQ*, the inclusion results are classified into categories corresponding to the *RQ*, and the results are presented in graphs or tables. Furthermore, the results are discussed using various evaluation approaches. Finally, the narrative summary describes the main findings of the systematic literature study.

In this work, we collect and determine the most relevant literature for this particular study with the PRISMA method [29] search strategy to provide a comprehensive and systematic review of relevant previous studies related to the role of machine learning algorithms in remote sensing for drought monitoring on crop land cover maps. Food, semi-arid plantation is suspected to experience drought. A recent search was conducted on Harzing's Publish or Perish search engine with open data sources Google Scholar and Crossref based on the title text "Drought monitoring" with keywords "remote sensing" and "machine learning" in the publication period between 2010 and 2021.

This study eliminates research that does not use remote sensing and machine learning approaches from the collection of articles obtained. Each article is rated based on the use of remote sensing databases, machine learning methods, accuracy of results, and year of publication. There are about 1147 articles on remote sensing drought monitoring published from 2010 to 2021 (Fig. 1). The search for literature was conducted on July 6, 2022, through the search engine Harzing's Publish or Perish on two open-source articles, namely Google scholar and Crossref with the context of the article title "drought monitoring" and the keywords "remote sensing" and "machine learning," with the limitation of the publication period between 2010 and 2021.

The literature search selection process in Fig. 1 is conducted according to the PRISMA concept, as follows:

1) *Identification*: initial search obtained 147 articles from open-source Google Scholar and one thousand articles from open-source Crossref. Our next step is to limit the selected articles based on the number of citations in each article to at least twenty citations. This is done to select articles that have referenced popularity by researchers. The results of this limit of twenty citations selected thirty-four articles from the open-source Google Scholar and 171 articles from the open source Crossref, so that the initial number of identified article data containing the context of the article title "drought monitoring" and the keywords "remote sensing" and "machine learning" was as much as 205 articles.

2) *Screening*: 205 articles from the previous stage (Identification) were checked for duplication of articles, and it turned out that there were 11 related articles, so that they were obtained ($n = 194$). The process at this stage is conducted on the Microsoft Excel application. Next is the excluded process, namely, discarding a number of articles that do not contain relevant text related to "remote sensing" and "machine learning" in the Abstract section. The results excluded at this stage are $n = 166$, so the remaining $n = 28$ articles.

3) *Eligibility*: at this stage, the articles are examined in full text with the aim of finding research articles that consistently apply machine learning algorithms and the studies carried out contain quantitative analysis or accuracy values. The results are discarded ($n = 8$ papers without the use of machine learning algorithms); ($n = 5$ types of paper reviews); ($n = 3$ papers without quantitative analysis or accuracy scores), leaving ($n = 12$) articles using machine learning algorithms. The process at this stage is conducted on the Zotero and Mendeley application.

4) *Included*: from $n = 12$ selected articles containing the context of "drought monitoring", "remote sensing", and "machine learning", with the type of research article based on observation or experimentation, not a review article. This is done because of a systematic review and meta-analysis, not a narrative review. Furthermore, the selected articles are used as a reference for the main systematic review or meta-analysis.

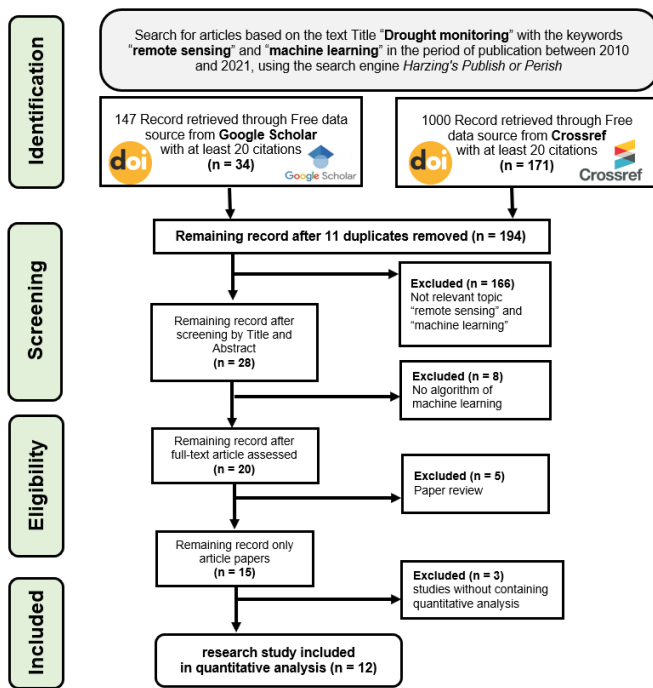

Fig. 1. PRISMA workflow diagram for new systematic review which included search of free database.

IV. RESULT AND DISCUSSION

The inclusion of the PRISMA strategy brief yielded the results of twelve articles that were then analyzed in depth for the content of a meta-analysis that could answer four research questions (RQs).

In response to RQ1, Fig. 2 demonstrates that out of a total of 194 papers, the publishers who publish the most scientific journals mention remote sensing-based drought monitoring. The breakdown is as follows: MDPI 50% (n = 97), Elsevier 30% (n = 57), Taylor & Francis 10% (n = 20), IEEE 3% (n = 7), Springer and Wiley both 2% (n = 4), and the remaining 3% from various publishers (n = 5).

Details of the names of the candidate publication journals are listed in Table I.

Fig. 2. Publication sources of selected study works.

TABLE I. PUBLICATION SOURCE SELECTED PAPERS

Journal Name	Publisher	Total
Remote Sensing	MDPI	97
Remote Sensing of Environment	Elsevier	42
International Journal of Remote Sensing	Taylor & Francis	13
GIScience & Remote Sensing	Taylor & Francis	5
Journal of Applied Remote Sensing	Other	5
Agricultural and forest meteorology	Elsevier	4
Water Resources Research	Wiley AGU	4
Environmental monitoring and assessment	Springer	4
IEEE Geoscience and Remote Sensing Letters	IEEE	3
IEEE Journal of Selected Topics in Applied Earth Observations and Remote Sensing	IEEE	3
International Journal of Applied Earth Observation and Geoinformation	Elsevier	3
ISPRS Journal of Photogrammetry and Remote Sensing	Elsevier	3
Computers and Electronics in Agriculture	Elsevier	2
Journal of Hydrology	Elsevier	2
Remote Sensing Letters	Taylor & Francis	2
Science of The Total Environment	Elsevier	2

The list of journal names in Table I can be used as a reference source. It is remarkably interesting to observe that all these journals are indexed in the Journal Citation Report, mostly in the Q1 and Q2 quartiles.

Fig. 3 presents the trend in the number of articles published per year from 2010 to 2019. This graph shows that there has been a significant increase in the number of publications in the area of Remote Sensing for Drought monitoring. Since 2010, this growth has followed a linear trend. Although the number of selected papers is not too many, it does not rule out the possibility of many publications at the end of 2021.

In order to respond to the RQ2 questions, we looked through the chosen articles and then searched for metadata pertaining to each paper's research location and the environmental state of the area covered. Table II lists the location, the surrounding environment, and remote sensing data for observations of regions thought to be experiencing drought conditions. We also complete the dryness index that was utilized in each chosen publication.

Fig. 3. Publication trends throughout the years 2010 – 2021.

TABLE II. ENVIRONMENT AND REMOTE SENSING DATA

Ref.	Environment	Data	Index	Validation
[30]	Basin area (Iran)	NOAA-AVHRR, Landsat ETM	VCI, NDVI, AVI	NDVI from Landsat+ETM 18 years (1982 - 1999)
[31]	Climate (China)	GRACE	TWSA	TWSC, SWS, SMS, GWS. Fifty-five stations in Yunnan and Guizhou (1950 – 2012)
[32]	Corn and Soybean (USA)	NDVI (MOD16A2 ET and MOD13A3); LST (MOD11A2 and MOD09A1); TRMM 3B43	LST, NDVI, NDWI, NMDI, ET, and TRMM	SPI at 54 stations (28 stations in the arid region and twenty-six stations in the humid region) from 1975 to 2012. NDMC
[33]	Sierra Nevada Forest Tree (California, USA)	MODIS Terra and Aqua observations (MCD43A4, collection 5); DEM	NDVI, EVI, NDWI	reserved validation dataset from USDA Forest Service (USFS) Aerial Detection Surveys (ADS)
[34]	Nineteen percent rice paddies and 64% forests (South Korea)	TRMM 3B43, GPM IMERG , MCD43C4 , MYD11C3 , MYD13C2	SPI and SPEI from ASOS	SPI and SPEI calculated from 61 ASOS weather stations, with 3-, 6-, 9-, and 12-month time scales.
[35]	crop yield and land cover (Korea)	AMSR-E, MODIS, TRMM	High resolution Soil Moisture Drought Index (HSMDI)	SPIs for March to November (2003–2011); twenty-nine stations (1973 to 2011)
[36]	agriculture (East Asia)	ESA-CCI for soil moisture; MOD11C1 for LST and NDVI; TRMM 3B42 for precipitation	PCI, TCI, VCI, SDCI, SMCI, MIDI, VSDI; Madden–Julian Oscillation (MJO) Index;	Three satellite-based drought indices SDCI, MIDI, and VSDI
[37]	three distinct climatic regions including the mountainous area (Iran)	GPCP, CMAP, CHOMPS, PERSIANN-CDR, TRMM, MERRA-2 and GLDAS-2	nonparametric-SPI; ORNESS-OWA; ORLIKE-OWA; K-nearest neighbors' algorithm (KNN)	Precipitation data for twenty-four stations (1981 - 2011); the Fars Meteorological Organization and Fars Regional Water Organization
[38]	pasture (Kenya)	MODIS and TAMSAT	NDVI, VCI, RFE, RCI, SPI	Precipitation data from TAMSAT
[39]	terrain mountains, plains, basins, valleys, and River (China)	Vegetation index product (MOD13A3), surface temperature product (MOD11A2), land use product (MCD12Q1), and TRMM, SRTM-DEM.	NDVI, EVI, LST, TCI, CI, SPEI, AWC, VSWI, Percentage of precipitation anomaly and TRMM-Z index	_Fifteen major meteorological stations and nine agricultural meteorological stations in Henan Province, (http://data.cma.cn/). _soil Available Water Capacity (AWC), (http://globalchange.bnu.edu.cn/).
[40]	Bare land, Woodland, Water, and Winter wheat (China)	MODIS NDVI, MODIS LST, Sentinel-2 NDVI, Sentinel-2 biophysical, ASTER GDEM	VCTI	Daily precipitation data in eighteen selected counties of the Guanzhong Plain
[41]	Darling River Basin (Australia)	SMAP, GLDAS, Soil attribute product, GPM, ISMN.	SWDI, SMDI	ISMN provides in situ Soil Moisture (SM) measurements of 1400 stations and thirty-five international SM networks available from 1952 to the present. https://ismn.geo.tuwien.ac.at

Data are gathered from Table II. It turns out that the majority of studies employ MODIS satellite data products to gauge the extent of drought in different types of ecosystems. However, some studies use validation data received from data centers, while the majority of research is based on observations from ground observation stations.

On the basis of the metadata analysis of the selected papers shown in Table III, RQ3 may be addressed by stating that the following categories can be used to categorize the application of machine learning in remote sensing for agricultural drought monitoring. The potency of each machine learning method is shown in Table III. There is evidence that ANN (91.00 percent in [31]), BRT (93 percent in [32]), GA (95.73 percent in [37]), and RF are algorithms with accuracy values of more than 90 percent (93 percent in [32] and 96.30 percent in [33]).

Although the GA method competes with RF among other algorithms for the second-best accuracy value, in actuality, researchers frequently choose for the RF approach. This could be the result of a number of problematic situations and different facts.

Responding to RQ4 based on an analysis of the metadata of a few articles as indicated in Table IV. The following four categories describe how machine learning is used in remote sensing to monitor agricultural drought. First, for prediction NDVI [30], waves [31], unmeasured area [34], drought [36], np-SPI [37], vegetation condition [38], and vegetation temperature [40]. Second, detect tree death [33]. Third, it measures degree of correlation (sixteen drought factors [32], various hazard factors [39]). Fourth, down-scaling (AMSR-E and TRMM [35], SMAP-SM [41]).

TABLE III. MACHINE LEARNING ALGORITHM FOR THE DROUGHT MONITORING APPROACH

Algorithm	Ref.	Accuracy			
ANFIS	[37]	85.72			
ANN	[30], [31], [38]	79.00	91.00	83.00	
BRT	[32]	93.00			
CUBIST	[32]	60.00			
DFNN	[39]	85.60			
DT	[34]	15.92			
ERT	[34]	32.01			
ESTARFM-SVM	[40]	83.00			
GA-ORNESS-OWA	[37]	95.73			
GAM	[38]	86.00			
GMDH	[37]	88.21			
KKN	[37]	89.68			
MSP model tree	[37]	89.78			
MLP	[37]	90.47			
PERSIANN	[41]	80.00			
RF	[32], [33], [35], [36]	93.00	96.30	69.00	70.00
SVM	[40]	83.00			
SVR	[37]	83.57			

TABLE IV. ROLE OF MACHINE LEARNING IN REMOTE SENSING FOR AGRICULTURE DROUGHT MONITORING

Ref.	Algorithm	Role
[30]	ANN	Forecast of NDVI
[31]	ANN	Forecasting future waves
[32]	RF; BRT; Cubist	Model of the relationship
[33]	RF	Detection trees mortality
[34]	DT; RF; ERT;	Models for decision making drought in unmeasured areas
[35]	RF	Downscale AMSR-E soil moisture and TRMM precipitation
[36]	RF	Developed drought prediction models
[37]	KNN; MLP; ANFIS; MSP; GMDH; SVR; GA	Estimating np-SPI based on remotely sensed data
[38]	GAM; ANN	To predict vegetation conditions
[39]	DFNN	To construct models by considering a number of various hazard factors
[40]	SVM; ESTARFM	Developing a fused vegetation temperature condition index (VTCI)
[41]	PERSIANN	Downscaled SMAP-SM as well as GLDAS-SM against the in-situ SM

Our review of the two literature with the highest yields [33], [37] showed that the results of the CRF model analysis [33] found that baseline summer NDVI or EVI was one of the key variables to differentiate significant tree mortality. Higher ground may be denser or have higher biomass, resulting in more opportunities to obtain more water during prolonged dry seasons, and thus more resistant to stressors and mortality. The model also reveals that altitude also plays a significant

role in the vulnerability of the Sierra Nevada Forest to surviving drought conditions. Altitude affects the local climate and water availability, and thus affects the distribution and drought tolerance of forest types. Vegetation index Z-scores, such as NDVI, proved to be another important variable for detecting tree mortality. The NDVI z-score in a given year represents the cumulative impact of drought on vegetation activity, while the NDWI z-score shows reduced water content. Single-dated mid-resolution imagery from MODIS and VIIRS is limited for monitoring forest health and detecting mortality, particularly at finer scales, but higher temporal frequencies, e.g., daily coverage, are a major advantage for monitoring forest health and potential forecasting capabilities across the globe (big landscape).

Meanwhile, the second-best body of research [37] demonstrates that the ORNESS-OWA fusion approach considerably enhances estimates compared to other models and that ORNESS-OWA performs better for long-term timelines than for short-term estimates. CHOMPS, GPCP, CMAP, PERSIANN-CDR, TRMM, GLDAS-2, and MERRA-2 are some examples of remote sensing precipitation products that can be used to estimate np-SPI. Three sophisticated data fusion approaches (ORNESS-OWA, ORLIKE-OWA, and KNN) are also tested against ground-based np-SPI estimations.

Even though they both employ various methodologies and observational settings, each with their own set of limitations, the two literatures produce the finest results to date. However, further research is still required to achieve results with higher spatial and temporal resolution, wider coverage, and more cost-effective operation. Future study will likely integrate satellite imagery data with field camera and aerial photography in order to provide a more comprehensive strategy that takes into account all factors, including the plant cycle. This will undoubtedly present new challenges.

V. CONCLUSION

This systematic review has provided sophisticated quantitative and qualitative analysis in this fast-growing field. Since 2010, more than 1147 journal and conference papers were found, and this trend is expected to continue in the future. A selection of the 12 most cited papers was undertaken to obtain an in-depth view of the state of the research. Drought monitoring based on remote sensing is a very active area of research with a significant impact on enhancing global sustainability and optimizing natural resources. This is supported by sensor observation technology with open access to satellite data and advances in digital machine learning computational techniques. The role of Machine learning methods has proven to be effective in prediction, detection, correlation and downscaling tasks when processing satellite imagery data.

Research on Intellectual Dichotomiser 3 Decision Tree Algorithm Model for Financial Analysis of Colleges and Universities

Sujuan Guo

Smart Finance Industry College, Shandong Institute of Commerce and Technology, Jinan, 250103, China

Abstract—The rapid development of college information construction has promoted the processing and analysis of a large number of data in the college system. Decision tree algorithm is often used in the field of financial data analysis, but it has a bias in the selection of attributes. Aiming at the defects of the decision tree algorithm in attribute selection, ID3 algorithm in the decision tree algorithm is selected for weighted improvement, and it is optimized based on Synthetic Minority Oversampling Technique (SMOTE) algorithm and Bagging algorithm to balance the positive and negative data of its training samples, thus obtaining the DSB-ID3 financial analysis model. Using this model to analyze the financial data of a university, its G value and F value are both about 0.78, the recognition accuracy rate for normal samples is 0.7345, and the total recognition accuracy rate is 0.7893, which are the highest among the four models. Compared with other models, model designed in this study has significantly improved classification performance, and its distribution is the most centralized, showing superior stability. The experimental results show that the classification effect of model designed in this study is the best, and it shows superior accuracy and stability in the analysis of financial data. Its superior classification performance shows the potential of decision tree algorithm optimization and the feasibility and necessity of improving it. From the experimental data, it can be seen that the service life and parameters of the model designed in this study are obviously better than those commonly used in the financial analysis industry of colleges and universities. It can be seen from the overall analysis that this model provides a practical reference for the application of decision tree optimization in college financial analysis, and greatly improves the accuracy of financial system data analysis.

Keywords—Financial analysis; ID3; Decision tree; model; colleges and universities; machine learning

I. INTRODUCTION

With the gradual deepening of higher education reform and the introduction of higher education into the market as an industry, the financial management of colleges and universities has also changed. The financial analysis and management work in colleges and universities has gradually shifted from accounting to analytical, but the existing financial analysis and management system cannot meet the requirements of precision and real-time [1-2]. With the rapid development of information technology, the scale of financial informatization in colleges and universities is also expanding. The college information system can easily collect relevant financial data [3-4]. However, massive data brings

management difficulties to data managers. Lack of data mining means and tools will result in a huge waste of data resources, and financial analysis cannot be carried out in a normal and orderly manner. Therefore, computer technology is integrated into financial analysis to effectively analyze and manage data, so as to improve the application level of financial data, optimize the financial structure of the school, and promote the healthy development of the financial management system [5-6]. Decision tree algorithm is often used in the field of data analysis. Research will also establish a university financial analysis model based on decision tree. However, the decision tree has the defect of attribute selection, so this research will select ID3 (intelligent dichotomy 3) algorithm in the decision tree to improve, and based on DSR (Differential Sampling Rate Resampling, DSR) technology, SMOTE (Synthetic Minor Over Sampling), so as to improve its noise resistance and balance its attribute selection, which is also the main contribution of this research.

II. RELATED WORK

Scholars such as Febriantono MA proposed a C5.0 deciMany scholars have done a lot of research on decision tree algorithm in financial analysis and other fields. Luo X et al. proposed an initialization method of dendrite neuron model (DNM) based on decision tree to trim those neurons that contribute less to the network output, aiming at the problem of insufficient calculation accuracy of decision tree model. This method can reduce the number of dendrites in DNM and improve the training efficiency, and can select appropriate initialization weight and neuron threshold, thus enhancing the classification accuracy of the algorithm. Experiments show that this method is significantly superior to the original DNM model with the lowest complexity and the fastest training speed, without loss of accuracy [7]. Podhorska I et al. believed that the non-linear data calculation ability of the decision tree model was insufficient, so they combined BP neural network with ID3 decision tree model to build an improved decision tree model, and applied it to predict financial distress. They also established a prediction model for enterprise financial distress, mined and analyzed enterprise financial data, and used it to predict enterprise financial development. The test results showed that the financial data prediction accuracy of the improved algorithm is significantly higher than that of the decision tree model before improvement [8]. Sion tree algorithm based on cost sensitivity, established a model, learned to use the Metacost Method (MM) to get the minimum cost model, and used it to solve multi-class imbalance

problems. The performance of the algorithm is better than the C4.5 and ID3 algorithms [9]. Maulana MF et al. used two model classifications for the evaluation of students' learning time, namely Logistic Model Tree (LMT) and Decision Tree J48 Algorithm (DT J48), using the model to predict the effect of students' learning time and find out the influencing factors. The prediction accuracy of LMT is 71% higher than that of DT J48 [10]. Xia Y and other scholars proposed a SurvXGBoost model based on the Gradient Boosting Decision Tree (GBDT) method, and applied it to the consumer loan dataset. The performance is excellent [11].

Researchers such as Balta M proposed a three-level fuzzy decision tree model for Vehicle Ad-Hoc Networks (VANET) system based on Software Defined Networks (SDN). The physical structure of urban intersections often lead to traffic jams, delays, and accidents. Previous studies usually choose the VANET architecture, which can communicate between vehicles and road edge devices. SDN has also become a common research method in this domain, it can solve the performance, programming, scalability and security problems in traditional networks. The proposed model utilizes the architectural recommendations of both SDN and VANET network paradigms to optimize traffic management problems based on three-level fuzzy decision tree algorithm classification [12]. Qiu T et al. proposed a Directed Edge Weight Prediction (DEWP) model based on decision tree integration. It extends the local similarity index to the Directed Weighted Network (DWN), and extracts the similarity index to construct a mixed regression model [13]. In order to explain the underpricing event of Initial Public Offering (IPO) during the epidemic, Keuangan J and other scholars built a decision tree algorithm model and tested the latest 45 action data using more than 100 previous action data. The model can interpret IPO performance according to specific classification scope. [14]. Researchers such as L Xue proposed a Privacy-Preserving Decision Tree Classification (PDTC). First, customize an encryption primitive and a secret sharing technology to design a new secure bilateral comparison protocol, in which the digital inputs of each party are compared privately. Then, based on the protocol, PDTC is constructed using decision tree structure. The customer's input and the service provider's model parameters are hidden from the counterparty, and the classification results are only displayed to the customer. The results show that PDTC achieves ideal safety [15]. Ziweritin S and other scholars established the K-nearest neighbor and decision tree model to forecast the numeric value in the one pound table under a given interest rate and life. Cross validation was performed using the R-squared test to detect fit and summarize model function on the test data set. The model is robust and competitive, and has reference value for financial analysis and its application [16].

In addition, in terms of college financial management, Natawibawa IWY team applied multiple linear regression method to analyze the financial management system of state universities, and the research results show that the availability of financial reports has a significant impact on the transparency of college financial management [17]. The Min Du team has carried out informatization reform on the

traditional financial management model of colleges and universities, and the research results show that with the help of informatization, the financial management level of colleges and universities has been effectively improved [18]. The Na Sun team started from the financial position i and staffing of colleges and universities, analyzed the current situation of colleges and universities emphasizing accounting over management, and proposed strategic management and post balance strategy [19]. It can be seen that in the application of decision tree algorithm, there have been some precedents in applying decision tree algorithm to the economic and financial fields. At the same time, in the financial management of colleges and universities, there is still a lack of appropriate information technology to provide a technical basis for the development of financial management of colleges and universities. Therefore, in order to avoid the waste of financial data resources, the research provides data mining means and tools so that the financial analysis work of colleges and universities can be carried out normally and orderly. The research is oriented to college financial analysis, and the ID3 algorithm is weighted. Based on the DSRR technology, SMOTE algorithm and Bagging algorithm, ID3 is optimized, and the DSB-ID3 model is established to overcome the defect that the ID3 algorithm tends to select attributes with more values but not necessarily optimal. This technology can monitor the financial situation of colleges and universities in real time from a dynamic perspective, carry out meticulous financial management according to the financial characteristics of colleges and universities, and improve the efficiency and quality of financial management of colleges and universities.

III. ID3 DECISION TREE OPTIMIZATION ALGORITHM MODEL FOR UNIVERSITY FINANCIAL ANALYSIS

A. Improved ID3 Algorithm based on Attribute Selection Weighting

The ID3 algorithm is a decision tree algorithm based on information entropy. It introduces information theory, uses information entropy as a criterion for selecting test attributes, divides the training set, constructs a decision tree to predict according to the test attributes, and divides the instance space [20-21]. To build a decision tree, first measure the attributes of each node using the maximum information gain from top to bottom, and obtain the corresponding attribute values, which are used to segment the target object. This step is repeated until all objects in the node are judged to be of the same type according to the classification criteria. The features with more attribute values in the decision tree have a greater impact on the calculation of information gain, however, features with more values are uncertain optimal attributes, and the algorithm has poor noise resistance, making it difficult to control the positive and negative examples in data set, so the research improves the algorithm by weighting. The main principle of the information theory introduced by the algorithm is to regard the communication process as a process of transmitting information in an environment of random interference. In order to obtain mutual information, the posterior entropy is first calculated. When the channel receiver receives the output

symbol $V_j = \{V_1, V_2, \dots, V_m\}$, the input symbol is calculated.

The information measure of $P(U|V_j)$ is as formula (1).

$$P(U|V_j) = \sum_j P(V_j) \sum_j P(U|V_j) \lg \frac{1}{P(U|V_j)} \quad (1)$$

Before receiving the symbol set V , the average uncertainty of the input symbol set is expressed as $D(U)$. After receiving the symbol set V , the average uncertainty of the input symbol set is expressed as $D(U|V)$, the relationship between the two is shown in Eq.

$$I(U, V) = D(U) - D(U|V) \quad (2)$$

In formula (2), $I(U, V)$ is the average mutual information between U and V , which represents the amount of information V about U obtained after receiving the symbol set U . In order to avoid the ID3 algorithm to select attributes with many values but not necessarily optimal as test attributes, the research introduces risk weights. Given the user's risk weights for uncertain knowledge $\max(-a_1, -a_2, \dots, -a_i, \dots, -a_n) \leq b \leq 0$, a_i it represents the conditional probability of attributes, which b is a dynamic variable whose value Depends on the conditional probability

of the attribute obtained each loop. If there are several conditional probabilities in the calculation process a_1, a_i, \dots, a_n , it is $-b$ equal to the minimum value among them. Introducing risk weights into the algorithm, the calculation of conditional entropy is as formula (3).

$$D_b(U|V) = \sum_{j=1}^n (P(V_j) + b) \sum_{i=1}^n P(U_i|V_j) \lg \frac{1}{P(U_i|V_j)} \quad (3)$$

The corresponding mutual information calculation is shown in formula (4).

$$I_b(U, V) = D(U) - D_b(U|V) \quad (4)$$

Equations (3) and (4) are used as criteria for selecting test attributes when constructing a decision tree. The research uses the AHP method to assign weights, compares and judges the importance of indicators at the same level, and constructs a judgment matrix to represent the judgment value of their relative importance. In the measurement process, the scale of the ninth is leaded into form a judgment matrix G . Each element in the g_{ij} matrix represents G the comparison value of the relative importance of the g_{ij} row index C_i to each column index, indicating the relative importance of C_j a certain index and another index, and its scale is shown in Table I.

TABLE I. RELATIVE IMPORTANCE BETWEEN TWO INDICATORS

Ratio of index 1 to index 2	extremely important	Important	Slightly important	Identical	Slightly unimportant	Unimportant	Extremely unimportant
Indicator 1 Evaluation	7	5	3	1	1/3	1/5	1/7
Intermediate value	Take 6, 4, 2, 1/2, 1/4, 1/6 as the intermediate value						

The principle of the AHP method used in the research is to judge the matrix, obtain the matrix sorting vector according to the sorting rules, and use the obtained results to calculate the weight coefficients of each index. Find the product of the elements of each row of the judgment matrix as in formula (5).

$$P_i = \prod_{j=1}^n c_{ij}, i = 1, 2, \dots, n \quad (5)$$

Calculate the square root value of each row P_i as n formula (6).

$$\bar{p}_i = \sqrt[n]{P_i}, i = 1, 2, \dots, n \quad (6)$$

Formula (6) is n the order of the matrix. The vector is normalized as in formula (7).

$$p_i = \frac{\bar{p}_i}{\sum_{j=1}^n \bar{p}_j} \quad (7)$$

P_j is the weight coefficient value of each indicator of demand. The maximum eigenroot of the judgment matrix is calculated as in Equation (8).

$$\lambda_{\max} = \sum_{i=1}^n \frac{(Gw)_i}{nw_i} \quad (8)$$

Compared with other methods for determining the weight coefficient of indicators, the AHP method can pass the consistency test and maintain the consistency of thinking logic. When judging the importance of indicators, when there are more than 3 indicators, the coordination among the judgments is the logical consistency of thinking. Let the maximum eigenroot of the λ_{\max} judgment matrix be G , when the

matrix G passes the consistency, $\lambda_{\max} = n$, otherwise $\lambda_{\max} \neq n$. To test G the consistency, the consistency index of the judgment matrix is established as formula (9).

$$CI = \frac{\lambda_{\max} - n}{n - 1} \quad (9)$$

TABLE II. AVERAGE RANDOM INDEX RI OF JUDGMENT MATRIX

Order	1	2	3	4	5	6	7
RI	0	0	0.65	0.98	1.15	1.34	1.47

The consistency ratio of the judgment matrix is CR shown in formula (10).

$$CR = \frac{CI}{RI} \quad (10)$$

$CR < 0.1$ At that time, the matrix is consistent, and the relative importance calculated using this matrix is reasonable. When this condition is not met, the matrix needs to be modified until it passes the consistency check. The comprehensive formula of multiple evaluation opinions is shown in formula (11).

$$Y_j = \frac{\sum_{i=1}^N (W_{ij} \times S_{ij})}{\sum_{i=1}^N S_{ij}} \quad (11)$$

In formula (11), N represents the number of evaluation opinions, generally $N \geq 5$. Y_j Indicates N the calculation weight value of the W_{ij} evaluation opinion for the first indicator, indicates i the j calculation j weight value of the evaluation opinion for the first indicator, and indicates the familiarity coefficient of the S_{ij} evaluation opinion i to the first j indicator, generally a dynamic value between 0 and 4, and the evaluation The familiarity of the opinion i to the first j indicator is proportional, and the same evaluation opinion has different familiarity coefficients for different evaluation indicators. After the weights are set, the evaluation results are dynamically generated by expert evaluation, so that the results can change with the environmental conditions.

When the judgment matrix passes the consistency check, $CI = 0$. The average randomness index of the judgment matrix is introduced RI to measure whether the matrix passes the consistency test. For the judgment matrix whose order is between 1 and 9, its RI values are shown in Table II.

B. DSB-ID3 Model Optimized by Three Algorithms

When the ID3 algorithm is used alone, there is a defect in the classifier itself. When selecting the relevant classification attributes, it will not select the optimal attributes, but select attributes with more values [22-23]. On the basis of the weighted improvement of the algorithm, the random oversampling technology (Over Sample, OS) is used to optimize the algorithm, so that the number of samples in the two data sets is basically equal, so that the sample balance can be better obtained. The classification performance can reduce the deviation of sample attributes to a certain extent. The specific process of the OS-ID3 model is shown in Fig. 1.

Fig. 1. Specific process of OS-ID3 model

The algorithm has a simple structure and fast calculation speed, which changes the state of imbalance between classes and makes up for the classification defects of the ID3 algorithm to a certain extent. Overfitting phenomenon. The algorithm is optimized using the Over-Under Sample (OUS) technique. When processing samples, the oversampling technique is used to add the quantity of positive samples, and the undersampling technique is used to reduce the quantity of negative samples, so as to balance the two types of samples. The specific process of the OUS-ID3 model is shown in Fig. 2.

Fig. 2. Specific process of OUS-ID3 model

The structure and steps of OUS-ID3 algorithm are simple, and the calculation speed is fast. To some extent, it avoids the problem that too many positive samples lead to over fitting of the classifier. However, when the quantity of negative samples decreases, some important information will be ignored and the function of the classifier will be degraded. In view of the shortcomings of simple sampling technology, DSR technology gives different sampling ratios to different classifiers according to the algorithm set internally in the sampling process, so that the number of sample data trained by each classifier is different. Statistically calculate the number of positive samples P_s and negative samples N_s , and calculate the difference between the two types of samples as shown in formula (12).

$$Value = N_s - P_s \quad (12)$$

Assuming that the number of classifiers is M , the sampling coefficient is calculated as shown in formula (13).

$$Coefficient = \frac{Value}{M} \quad (13)$$

Assuming i the sampling rate R of the the classifier, the number of positive samples of the the classifier is calculated i as shown in formula (14).

$$P_{S_i} = P_s + Coefficient \times R_i \quad (14)$$

In formula (14) $1 \leq i \leq M$. Aiming at the defects of random sampling, the SMOTE algorithm can effectively improve it. The principle of this algorithm is to assume that two positive samples close to each other are also positive samples between them. If the sampling rate is α , each positive class sample point is x_i , its positive class neighbor point is $y_{ij} (j=1, 2, \dots, l)$, $l = x * \alpha$ is the number of positive class neighbor points, and find all positive class neighbor points. A new negative class sample is generated q_j as shown in equation (15).

$$q_j = x_i + rand(0,1) \times (y_{ij} - x_i) \quad (15)$$

formula (15), it means that the $rand(0,1)$ value is randomly selected q_i in the interval $(0,1)$, which will be mixed with the original positive sample to form a minority class sample. According to the difference in the quantity of samples, the balance rate of the two types of samples can be obtained. The sampling principle of the algorithm is shown in Fig. 3.

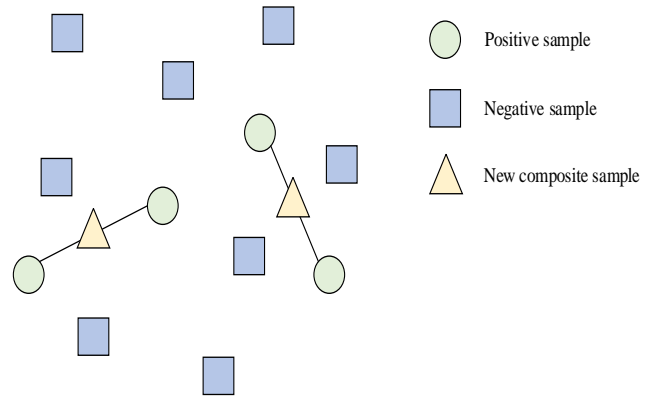

Fig. 3. Sampling principle of SMOTE algorithm

On the premise of retaining the original information and distribution of the minority class, the SMOTE algorithm constructs new samples without repetition, and can overcome the shortcomings of simple oversampling while completing the same task. The Bagging algorithm draws on the replacement sampling method in probability theory. The principle is that after each extraction, the extracted samples are put back into the original data set, so the sample sets extracted each time are the same size, the extracted samples are trained to get the same classifier with different parameters, and the prediction results are obtained. When building a model, small changes in the training samples will lead to significant changes in the classification model, resulting in large differences in the classification results. By training the ID3 algorithm through the Bagging algorithm, multiple different classifiers will be obtained. Different classifiers get different results because the built-in parameters of the ID3 algorithm have changed, resulting in changes in the internal operation of the model and changes in the results obtained. But for multiple classifiers, the majority weighted voting method does not affect the final result due to the result of a single classifier, which strengthens the generalization performance of the ensemble classifier. Assume the training set $T = \{(x_1, y_1), (x_2, y_2), \dots, (x_n, y_n)\}$, use the single-classification algorithm to perform T operations on the training set Z , extract different training subsets from it, and use it as a sample for each training to obtain $T Z$ a classifier with different results. The test set is classified, the Z results are weighted and voted, and the class that appears multiple times in the classification result is used as the final result.

Randomly select T' a subset of training samples, put them into a given single-classification algorithm for training, and obtain a model h_t , and loop through the steps z to obtain a set $\{h_1, h_2, \dots, h_t\}$. Each model h_t gets a classifier, and the unknown samples are classified to get a result, and the category to which they belong is judged according to the principle of getting the most votes. Bagging algorithm overcomes the instability of classifier classification prediction to a large extent, and can reduce a lot of time and cost in the operation process.

The ID3 algorithm model based on DSRR, SMOTE and Bagging uses DSRR technology, SMOTE sampling method and Bagging algorithm combined with ID3 decision tree algorithm to form an integrated classification model based on ID3 classifier. The DSRR technique and the SMOTE sampling method are effectively combined to generate minority class samples according to the sampling rate. The SMOTE sampling method has superior sampling characteristics, and no overfitting occurs during the sampling process, which increases the number of minority class samples and narrows the gap with the majority class samples. On the basis of retaining the original information of the samples, DSRR technology uses the changed sampling rate to establish a sub-classifier with the difference in the number of samples of the majority class and the minority class. The Bagging algorithm combines DSRR technology to generate majority class samples that match the minority class samples. The combination of the two highlights the technical superiority. After removing the weak classifiers, they are integrated into DSB-ID3 (DSRR, SMOTE and Bagging ID3) combined classifier to improve the accuracy of the algorithm based on unbalanced characteristics. The DSB-ID3 model is shown in Fig. 4.

In Fig. 4, the model determines the sampling rate of two samples through DSRR technology, and uses the SMOTE algorithm in the training set to generate several non-repetitive samples according to the determined sampling rate. From the generated samples, DSRR technology is used to extract n samples with different numbers $[X_1, X_2, \dots, X_n]$, and they are combined with the samples extracted by the Bagging algorithm according to the sampling rate X_f to form n new sample training sets. If the sampling rate is the same, the quantity of two samples is the same, and if the sampling rate is different, the number of two samples is different. The ID3 algorithm is used to train n sample training sets, and n ID3 sub-classifiers with different numbers are obtained $[K_1, K_2, \dots, K_n]$. According to the training results of each sub-classifier, extract 20 classifiers with the best classification effect from the results, obtain 20^n sub-classifiers, calculate the mean of the results obtained by the 20^n sub-classifiers, and compare the results of the sub-classifiers with the obtained mean. Compare, if it is greater than the mean, keep the sub-classifier, otherwise remove the sub-classifier.

Fig. 4. DSB-ID3 model

The classifiers with different numbers are obtained according to different sampling rates (n_1, n_2, \dots, n) , the remaining classifiers are integrated to obtain the combined classifier N , and different weights are given according to the quantity of remaining classifiers under different sampling rates, and finally the results are obtained by voting. The DSB-ID3 model overcomes the shortcomings of simple sampling technology, and assigns different sampling rates to different classifiers according to the internal algorithm, which makes the number of sample data of the classifiers different. The model also takes advantage of SMOTE sampling, increases the scale of sample data and avoids repeated results, and uses Bagging technology to significantly improve stability. The obtained negative samples are independent of each other and run fast.

IV. EXPERIMENTAL ANALYSIS OF DSB-ID3 MODEL FOR FINANCIAL ANALYSIS OF COLLEGES AND UNIVERSITIES

The experimental data comes from the financial analysis report of 2021 of a university, which includes the daily operating expenses and income of the university, the current assets and liabilities of the university, and the change

information of the cash flow of the university. This research mainly selects the student payment information in this report for experimental analysis. Student payment information includes student basic information data, student payment information data, receivables information data and fee reduction and exemption information data. The dimensions of defining information include the dimension of student information, the dimension of academic year and semester, the dimension of payable fees, and the dimension of reduced fees. The study used G-mean and F-value as the evaluation index of classification effect. The calculation of the G value is

measured by the geometric mean of the classification accuracy of positive and negative samples. In order to reach the maximum value, the classification accuracy of positive and negative samples needs to be larger. The F-value is a combination of precision and recall, where a parameter is introduced to ω reflect the relative importance of precision and recall. The experiment is realized by Matlab and decision tree tools. The DSB-ID3 model and other models are run 100 times in the same environment, and each training set and test set are randomly divided and samples are randomly selected. The G value results of each model are shown in Fig. 5.

Fig. 5. G-mean results of each model

As shown in Fig. 5, with the increase of experimental time, the G value of each model fluctuates repeatedly, but the G value of Weighted ID3 model, OS-ID3 model, and OUS-ID3 model, except for DSB-ID3 model, shows a general downward trend, and their linear regression slopes are 1.74×10^{-4} , 1.32×10^{-4} and 1.25×10^{-4} . However, the G-value curve of DSB-ID3 model has no overall downward trend. In Fig. 5, the G value of the weighted ID3 model is around 0.66, which is the lowest among all models, and its distribution is also the most dispersed. The G value of the OS-ID3 model is about 0.69, which is improved compared to the weighted ID3 model, but its distribution is also relatively scattered, which is

not much different from the weighted ID3 model. The line graph of the OUS-ID3 model is more concentrated than the previous two models, but its G value is basically not improved. The G value of the DSB-ID3 model is about 0.78, which is a significant improvement compared to other models, and the polyline distribution is concentrated. Among the four models, the weighted ID3 model has the worst classification effect, the OS-ID3 model and the OUS-ID3 model have similar classification effects, and the DSB-ID3 model has the best classification effect, and the classification results are accurate and stable. The F value results of each model are shown in Fig. 6.

Fig. 6. F-value results of each model

As shown in Fig. 6, the F value of each model fluctuates repeatedly with the increase of experimental time, and the change rule of each model is generally similar to that in Fig. 5. Specifically, the F values of Weighted ID3 model, OS-ID3 model, OUS-ID3 model and DSB-ID3 model show a downward trend in general, and their linear regression slopes are 0.82×10^{-4} , 0.94×10^{-4} and 0.71×10^{-4} , 0.35×10^{-4} , it can be seen that the overall descending speed of DSB-ID3 model is the slowest. In Fig. 6, the F value of the weighted ID3 algorithm is about 0.65, and its distribution is as scattered as the G value. Due to the improvement of the balance of sampling rate, the OS-ID3 model has a slight improvement in the F value, which fluctuates around 0.67. Compared with the OS-ID3 model, the F value of the OUS-ID3 model is basically not improved, still fluctuating around 0.67, and the distribution is relatively scattered. The F value of the DSB-ID3 model is around 0.78, which is significantly improved compared to other models, and its distribution is also the most concentrated, showing excellent stability. Among the four models, the weighted ID3 model has the worst classification effect, the OS-ID3 model and the OUS-ID3 model have similar classification effects, and the DSB-ID3 model has the best classification effect. The classification effect of the combination on the data is significantly improved. The mean values of G and F values for each model are shown in Fig. 7.

Fig. 7. Mean value of G-mean and F-value of each model

In Fig. 7, the mean G value of the weighted ID3 model is 0.6602, and the mean F value is 0.6523; the mean G value of the OS-ID3 model is 0.6875, and the mean F value is 0.6718; the mean G value of the OUS-ID3 model is 0.6881, and the mean F Value The mean value of the value is 0.6724; the mean value of the G value of the DSB-ID3 model is 0.7795, and the mean value of the F value is 0.7813. The G value and F value of each model are not much different. With the further improvement and optimization of ID3, the G value and F value of the model continue to increase, and its classification effect is also significantly improved. The G value and F value of the DSB-ID3 model largest, and its classification effect is also the best. The recognition accuracy of each model to the data is shown in Fig. 8.

Fig. 8. Data recognition accuracy of each model

In Fig. 8, Accuracy+ represents the recognition accuracy of the model for positive data, and Accuracy represents the recognition accuracy of the model for all data. The accuracy of the weighted ID3 model for the positive data is 0.5421, and the total accuracy is 0.7864; the accuracy of the OS-ID3 model for the positive data is 0.5687, and the total accuracy is 0.7882; The accuracy of class data is 0.5824, and the total accuracy is 0.7428; the accuracy of DSB-ID3 model for positive class data is 0.7345, and the total accuracy is 0.7893. It can be seen that among the four models, DSB-ID3 model has the highest recognition accuracy and total recognition accuracy for regular data, indicating that its classification effect is the best, and it shows superior accuracy and stability in the analysis of financial data. The final student classification accuracy is shown in Fig. 9.

Fig. 9. Student classification accuracy

It can be seen that, for different types of students, the model has a classification accuracy of 99.2% for students with good payment history, 99.3% for students with arrears history, and 99.1% for poor students, all above 99.0%. At the same time, in terms of the classification of historical students in arrears, the classification accuracy reached 99.4% for all students in arrears and 99.6% for some students in arrears. In terms of poor students, the classification accuracy of all students who have paid all the fees has reached 99.1%, and the classification accuracy of students who have paid part of the fees has reached 99.5%. It can be seen that the model designed in this study can obtain good classification effect in practical application, has feasibility and practicality, and has high operational accuracy.

V. DISCUSSION

With the development of management informatization of higher education structure, the demand for financial intelligent management in colleges and universities is growing day by day. The main goal of financial work has also changed from the original accounting type to the analytical type. ID3 algorithm itself has a significant disadvantage, that is, it tends

to choose more values rather than the optimal attribute. Therefore, this research introduces risk weight to improve ID3 algorithm, and designs DSB-ID3 model based on SMOTE algorithm and Bagging algorithm. The analysis results show that with the increase of experimental time, the G value of each model fluctuates repeatedly, but except for DSB-ID3 model, the G value of weighted ID3 model, OS-ID3 model and OUS-ID3 model shows a general downward trend, and the linear regression slope is 1.74×10^{-4} , 1.32×10^{-4} and 1.25×10^{-4} . The F value of each model fluctuates repeatedly with the increase of experimental time, and the change rule of each model is roughly similar to that in Fig. 5. Specifically, F values of weighted ID3 model, OS-ID3 model, OUS-ID3 model and DSB-ID3 model show a downward trend in general, and their linear regression slopes are 0.82×10^{-4} , 0.94×10^{-4} and 0.71×10^{-4} , 0.35×10^{-4} , it can be seen that the overall decline speed of DSB-ID3 model is the slowest. It can be seen that using DSB-ID3 model to analyze college financial data, its G value and F value are the highest among the four models, with the best classification effect. Compared with other models, it has significantly improved, and its distribution is the most centralized. The

research results of Apalkova V and others also show that the classification ability of the decision tree model can be improved to a certain extent after using SMOTE algorithm to improve the decision tree model [24]. Among the four models, DSB-ID3 model has the highest accuracy, with a recognition accuracy of 0.7345 for positive data and a total recognition accuracy of 0.7893. In the final classification accuracy rate of students, the classification accuracy rate of this model for different types of students exceeds 99%. The classification effect of DSB-ID3 model is the best, showing superior accuracy and stability in financial data analysis. The research results of Podhorska I also show that the classification accuracy of the improved integrated algorithm using SMOTE algorithm is higher than that of the original algorithm [25].

VI. CONCLUSION

In order to overcome the disadvantage that ID3 algorithm tends to select more values but not necessarily the optimal attribute, this study introduces risk weight to improve ID3 algorithm and designs DSB-ID3 model. Using this model to analyze the financial data of colleges and universities, its G value and F value are the highest among the four models, about 0.78. The classification effect is the best. Compared with other models, it has significantly improved, and its distribution is the most centralized. For superior stability. Among the four models, DSB-ID3 model has the highest accuracy, with a recognition accuracy of 0.7345 for positive data and a total recognition accuracy of 0.7893. In the final classification accuracy rate of students, the classification accuracy rate of this model for different types of students exceeds 99%. The classification effect of DSB-ID3 model is the best, showing superior accuracy and stability in financial data analysis. The DSB-ID3 model of financial analysis in colleges and universities shows excellent classification performance in financial data analysis. The accuracy and stability of its classification effect provide practical reference for the application of financial analysis in colleges and universities. This research uses the annual financial report data of the real university to carry out the research, which ensures the rationality of the research results. However, the model still has many shortcomings in practical application. For example, this study only uses student payment data for experiments, and the application of school financial reports is relatively low.

Abstract—The benefits of requirement traceability are well known and documented. The traceability links between requirements and code are fundamental in supporting different activities in the software development process, including change management and software maintenance. These links can be obtained using manual or automatic means. Manual trace retrieval is a time-consuming task. Automatic trace retrieval can be performed via various tools such as Information retrieval or machine learning techniques. Meanwhile, a big concern associated with automated trace retrieval is the low precision problem primarily caused by the term mismatches across documents to be traced. This study proposes an approach that addresses the term mismatch problem to obtain the greatest improvements in the trace retrieval accuracy. The proposed approach uses clustering in the automated trace retrieval process and performs an experimental evaluation against previous benchmarks. The results show that the proposed approach improves the trace retrieval precision.

Keywords—Requirements traceability; information retrieval; term mismatch problem; trace retrieval; TraceLab; clustering

I. INTRODUCTION

Many software development standards have been proposed in response to the high rate of software project failures. These standards include SEI's CMMI and IEEE's JSTD-016. A common feature of these standards is that they all impose requirement traceability (RT) practices on the software development process [1]. RT is an important quality factor of software development that intends to ensure a continued alignment between stakeholder requirements and various outputs of the system development process. In addition [2], RT makes it easy to determine what software artifacts must be updated to fulfill a change request made during the maintenance phase of the software project.

In 2014, members of the Center of Excellence for Software traceability (CoEST) established a roadmap for advancing the state of practice in software traceability and presented a focused research agenda for software traceability. They identified seven broad research focus areas and outlined the specific research needed in each of these areas. Under the umbrella of one of these research areas, that is, *Creating & Maintaining Traces*, we focus herein on trace retrieval, which is concerned with dynamically generating trace links between source and target artifacts [3]. Researchers utilized different algorithms to infer the trace links between related artifacts based on the assumption that related artifacts contain related terms [4]. The underlying concept behind this was that these

algorithms could be used to estimate the similarity between two documents.

A big concern associated with trace retrieval research is the low precision problem. Precision is the percentage of correct traces over all retrieved traces. "Low precision" indicates that many false traces have been incorrectly retrieved, and the user must manually evaluate the retrieved links to identify the correct traces. This leads to an emphasis on precision. Accordingly, some researchers examined ideas on how to increase it [4] [5]; however, these ideas resulted in only a minor increase in precision. The problem is primarily caused by term mismatches across documents to be traced. The reason for choosing the proposed approach is to enhance trace retrieval precision. Therefore, the authors formulated the problem by choosing an intelligent solution based on unsupervised learning using clustering. The datasets have a limited number of labels. These labels are provided for testing only. So, the suggestion for addressing this problem is by choosing an intelligent solution based on unsupervised learning to find similarities in the data point and group similar data points together to enhance trace retrieval precision.

In this work, to address the term mismatch problem in automated trace retrieval, we follow the proposed research direction toward achieving automated trace retrieval, that is, to develop intelligent tracing solutions, "which are not constrained by the terms in source and target artifacts, but which understand domain-specific concepts, and can reason intelligently about relationships between artifacts" [3]. We lay down the foundations needed to use clustering in automated trace retrieval between *source code* and *requirements*.

Clustering, which relies on unsupervised machine learning, is the task of grouping a set of objects in such a way that objects in the same group, called a cluster, are more similar in some sense to each other than to those in other groups or clusters [6]. In this study, we used K-means++, Hierarchical, Gaussian mixture model (GMM), and Density-based Spatial Clustering of Application with Noise (DBSCAN) algorithms. Clustering algorithms can be summarized in three steps:

- 1) *Inputs*: dataset after preprocessing and other steps related to the dataset type.
- 2) *Applying* suitable models.

A. *Outputs*: evaluating the results after the clustering processes; for this, we decided to use clustering to cluster the dataset into two: clusters 0 and 1. Cluster 1 means the

items are similar. Cluster 0 means the items are different. All clustering steps are described in Section IV. We present an overview of these methods below.

The K-means is a partition-based iterative clustering algorithm, in which each cluster is characterized by its center point. It is widely used because of its implementation simplicity and effectiveness. It assumes that the number of clusters represented by “K” in K-means is already known. This algorithm aims to minimize the distance inside the same cluster and maximize the distance between the clusters [7].

Hierarchical clustering divides the data set at different levels to form a tree-shaped cluster structure that naturally defines clusters by branches in the hierarchical tree. It makes a few assumptions regarding the overall data point distribution; hence, it is suitable for datasets of many different shapes. Hierarchical clustering has two main implementations: agglomerative and divisive clustering [8].

In model-based clustering, each cluster is considered as a generative model with mean and variance. Instances arise from a distribution that is a mixture of several components. Gaussian (normal) distributions are the most used representation in model-based clustering. The mixture model is the GMM, whose components are Gaussian distributions with different means and variances [9].

The density-based clustering algorithm, called DBSCAN, recognizes arbitrary-shaped clusters under a high noise level of the studied data. The efficiency of DBSCAN depends on the parameter values set up at the initial step of the algorithm usage [10].

In this paper, we adopted four widely used metrics to evaluate the new proposed approach, precision, recall, F-score, and accuracy. Both precision and recall are used to assess the effectiveness of the requirement tracing tools [11]. **Precision** is defined as the percentage of correct retrieved candidate links and measures the fraction of retrieved documents which are relevant [12]. **Recall** is the percentage of the found correct links [13]. **F-score** is used to provide a balance between recall and precision [14]. It is the harmonic mean of recall and precision [15] and used to aggregate both measures into a single value [16]. Finally, **accuracy** measures are the rate of normal and outlier values correctly classified between the total number of classifications [17].

The remainder of this paper is structured as follows: Section II describes the related works in the trace retrieval field; Section III presents the proposed approach; Section IV explains the obtained results; Section V includes a result evaluation; and Section VI provides the conclusions and future work.

II. RELATED WORKS

This section reviews some methods used to solve the term mismatch problem in automated requirement trace retrieval.

In the paper [19] titled “Automatic traceability link recovery via active learning”, the authors proposed a new traceability link recovery approach based on active learning (AL). They evaluated their approach on seven datasets used in traceability and compared them with an information retrieval

(IR)-based approach and a state-of-the-art machine learning approach, called traditional supervised learning. The used datasets are available from the CoEST website (<http://www.CoEST.org>). The results showed that the AL-based approach outperforms the other two in terms of the F-score.

In the paper [20] titled “Traceability Transformed: Generating more Accurate Links with Pre-Trained BERT Models”, the authors proposed a framework, called Trace BERT (T-BERT), to create trace links between the source code and the natural language artifacts. They then applied the T-BERT framework to recover links between issues and commits in open-source projects. The evaluation results as regards the accuracy and efficiency of three BERT architectures indicated that the Single-BERT architecture generated the most accurate links, while the Siamese-BERT architecture produced comparable results with significantly less execution time. By learning and transferring knowledge, all three models in the framework outperformed classical IR trace models.

In the paper [21] titled “Analyzing close relations between target artifacts for improving IR-based requirement traceability recovery”, the authors proposed a method for trace link recovery by combining the IR method and the close relations between the target artifacts. This approach was referred to as IR_CRT. Aside from textual similarity, the close semantic relations between the target artifacts were considered. Experiments on five public datasets indicated that the precision on these datasets improved by 15.6% on average, showing that their method outperformed the baseline when working under the same conditions.

In the paper [22] titled “Ontology-based Trace Retrieval”, the authors solved the term mismatch problem in automated requirement trace retrieval by incorporating information from the general and domain-specific ontologies into the tracing process. They used ontologies to identify relationships that would not be recognized by standard IR techniques. They then experimentally evaluated their approach against the standard vector space model (VSM). Their results showed that a domain ontology combined with a generalized ontology returns the greatest improvements in trace accuracy.

In the paper [23] titled “Towards an Intelligent Domain-Specific Traceability Solution”, the authors solved the term mismatch problem in automated requirement trace retrieval by presenting the domain-contextualized intelligent traceability (DoCIT) solution. This approach mimicked some of the higher-level reasoning that a human trace analyst performs. The authors focused their efforts on the complex domain of communication and control in a transportation system and found that their approach can significantly improve the quality of the generated trace links. They illustrated and evaluated DoCIT with examples and experiments from the control and communication sector of a transportation domain.

In the paper [24] titled “Combining Machine Learning and Logical Reasoning to Improve Requirements Traceability Recovery”, the authors proposed a novel traceability link recovery approach that measures the similarity between requirements and the source code by exploring their features.

They combined machine learning and logical reasoning models and conducted a series of experiments on four datasets to evaluate the performance of their method against existing approaches. Their experiments showed that their approach is substantially better than other methods.

III. PROPOSED APPROACH

In this section, we divided the task of the proposed approach using clustering to improve the recovery of links between source code and requirements, into two main phases. Fig. 1 illustrates the two phases of the proposed trace retrieval approach.

B. Phase 1: Choosing Suitable Datasets

Research on automated requirement traceability relies on the availability of different dataset types. In general, obtaining datasets has been one of the reported barriers for researchers in the software engineering domain [25]. This phase introduces the three datasets used in this study to evaluate automated trace retrieval between the source code and requirements. Table I defines the characteristics of the datasets used in the proposed approach. These datasets are available from <http://www.CoEST.org>.

TABLE I. DATASET CHARACTERISTICS [25],[26],[27], [28][29][30]

Dataset description	Freq	Traceability details	Trace space	CC	UC	Trace links
eTour: "an electronic tourist guide developed by students"	10	Use cases to code	6728	116	58	366
SMOS: "an application that is used to monitor high school students (e.g., absence, grades)"	7	Use cases to classes	6700	100	67	1044
eANCI: "system providing support to manage Italian municipalities"	3	Use cases to classes	7645	55	140	567

The above-mentioned datasets were chosen because they are available for all researchers and compatible with TraceLab's environment.

With these datasets, we ran into some issues related to the two artifacts (requirements and source code). For example, all three datasets are imbalanced datasets. They included useless words, with some words starting with extra letters and ending with extra letters without meaning. A few single characters can be found between the lines of the files that did not have a clear meaning. According to the Answer set of the dataset, some source codes did not have any requirements, which affected the links between the two artifacts and gave wrong similarities. Some words and sentences were written in different languages. Some of them were in English, while others were in Italian.

C. Phase 2: Choosing and Applying Clustering Models

Clustering is an unsupervised machine learning task used to gather data into many collections or clusters according to the similarities of the data point features and characteristics [31]. In this phase, we followed seven main steps to apply clustering models to the three datasets:

Fig. 1. Proposed trace retrieval approach

Step 1, Feature extraction: The requirements (source artifact) and the source code (target artifact) were written in natural and programming languages, respectively. Hence, they included different types of information that were not all useful for identifying the traceability links between the two artifacts. For that, we extracted the most important source code feature, namely (*class_name, class_attribute, class_comments, method_comment, method_name, method_parameter, method_return*). We also extracted the two main features related to the requirements (i.e., Title and Description) as shown in Fig. 3.

Step 2, Translation: The content of the two artifacts (i.e., UC and CC files) included Italian words and sentences in some files and some parts of the file lines. Therefore, the content of the two artifacts was translated into English. To this end, we leveraged the advanced translation engine to translate documents into English if they were originally unspecified in English. We used one of the tools used for translation into the English language namely Google Translate [32], which enables a method of translating text from one language to another.

Step 3, Preprocessing: We followed a classic process to pre-process the contents of the software artifacts, UC and CC. The preprocessing comprised the following steps: removing the camel case, splitting the words, converting to a lower case, and removing punctuations, Stop Words, and numbers. We performed lemmatization for all words to facilitate natural language analysis, such as transforming the verb, noun, adjectives, and adverbs into their bases and examining the study of word texts with the intention of finding something that adds meaning to the word text [33] and removing any single character from both artifacts.

Step 4, Query expansion using WordNet: WordNet is an online lexical system (database) for the English language that provides diverse and wide-ranging semantic information [34]. We used query expansion to add related words to a query to increase the number of returned documents and improve the recall accordingly. In most cases, all words in each query should first be extracted. For each word, the synonyms were automatically selected.

Step 5, Text encoding: Many methods can be used to convert text into numerical vectors, such as TF-IDF encoding, Dec2Vec, Word2Vec, and Bag of Words (BOW) [35]. We experimented Dec2Vec and Word2Vec, but they did not improve experiments results, so we used the TFIDF to have better results.

Step 6, Computing similarity: Using the cosine similarity [36], we computed the similarity between two vectors after converting the corresponding contents of each feature into a vector by using the TFIDF algorithm. The cosine similarity algorithm measures the similarity between two vectors, which can represent paragraphs, sentences, words, or the entire document.

Step 7: In this step, four types of clustering models were used, namely K-means++, GMM (hard clustering type), Hierarchical, and DBSCAN. After the previous steps, we first prepared the dataset. Fig. 2 illustrates the total columns and rows of the dataset which are 14 columns. Second, we chose the clustering type. Third, evaluating the results, we performed external evaluation criteria and computed the confusion matrix (i.e., precision, recall, F-score, and accuracy measures). Table II shows the meaning of the confusion matrix symbols that are used for precision, recall, F-Score, and accuracy. The mathematical formulas of accuracy, precision, recall, and F-score are as follows:

$$\text{Accuracy} = (TP + TN) / (TP + FP + FN + TN).$$

$$\text{Precision} = TP / (TP + FP)$$

$$\text{Recall} = TP / (TP + FN)$$

$$\text{F-score} = 2 * (\text{precision} * \text{recall}) / (\text{precision} + \text{recall}).$$

TABLE II. MEANING OF THE CONFUSION MATRIX SYMBOLS [18]

Symbol	Description
TP	The number of data pairs found in the same cluster, both in C and in P.
FP	The number of data pairs found in the same cluster in C but in different clusters in P.
FN	The number of data pairs found in different clusters in C but in the same cluster in P.
TN	The number of data pairs found in different clusters, both in C and in P.

C means the actual cluster and P means the prediction cluster.

IV. RESULTS

In this section, we present the results of applying the Proposed Trace Retrieval Approach described in Section 3, which consists of two main phases as shown in Fig 1.

As mentioned in Section III, we applied four clustering models (i.e., K-means++, GMM, Hierarchical, and DBSCAN) to the three datasets described in Phase 1 of the proposed trace retrieval approach.

The results of the new proposed trace retrieval approach are presented here which include four measures: Precision, recall, F-score, and accuracy as shown in (Table III).

Comparing the proposed approach with two experiments, namely TraceLab and IR as shown in Tables IV (A) to (C). Tables V (A) to (C) show the comparison results of the proposed method and the two studies (i.e., studies [19] and [24]).

First, Table III and Fig. 4 present the results of K-means++ for three datasets: eTour, SMOS, and eANCI achieved high values compared to GMM, hierarchical DBSCAN results. The proposed trace retrieval approach is effective in improving precision, recall, F-score, and accuracy. The extent of improvement differed from one dataset to another depending on the dataset type. We used accuracy as an additional measure, whereas TraceLab and Information retrieval R and two studies [19] and [24] did not. The proposed approach achieved highest results using accuracy with the three datasets (i.e., eTour = 0.91, SMOS = 0.66, and eANSI = 0.60). Three parameters used in the experiments: max_feature with a value of 400 for the eTour dataset, SMOS, featurewiz when (corr_limit values) equal 0.5, and corr_limit values equal 0.5 for eANSI.

TABLE III. SUMMARY OF THE RESULTS OF THE PROPOSED TRACE RETRIEVAL APPROACH USING TWO CLUSTERING ALGORITHMS FOR THREE DATASETS

eTour dataset:				
Model Name	Precision	Recall	FScore	Accuracy
K-means++	0.93	0.97	0.94	0.91
SMOS dataset				
K-means++	0.73	0.76	0.74	0.66
eANCI dataset				
K-means++	0.64	0.77	0.70	0.60

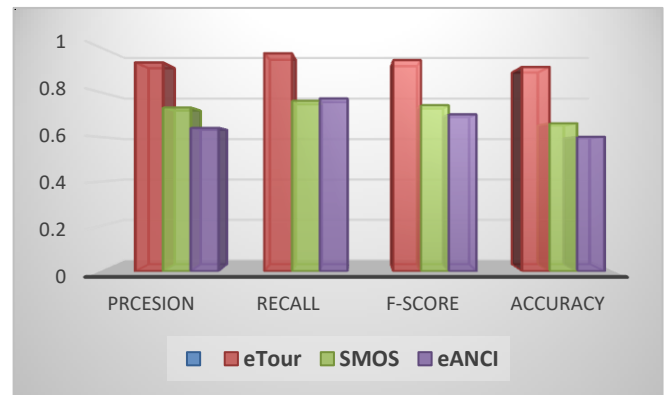

Fig. 4. Summary of the results of the proposed trace retrieval approach using two clustering algorithms for three datasets

Second, presenting a comparison between the proposed trace retrieval approach and two experiments, namely *TraceLab* and *IR*. Table IV (A) to (C) and Fig. 5(a) to (c) present a comparison of the proposed approach and the two experiments. The results showed that the former returns the greatest improvements in the trace measures.

Fig. 5. (a) eTour result comparison: clustering, IR, and TraceLab (b) SMOS result comparison: clustering, IR, and TraceLab (c) eANCI result comparison: clustering, IR, and TraceLab

1) *Experiment one (TraceLab):* Study [37] designed to help and support the reproducibility of experiments in software engineering and maintenance. In TraceLab’s visual modeling environment [38], IR algorithms are implemented as experiments using a library of reusable and user-defined components [39]. An already existing experiment, called Basic IR [40], which is a standard support vector model experiment, was conducted to implement the VSM/TF*IDF algorithm.

2) *Experiment two:* four steps were applied. *The first step* was preprocessing, which included transforming the upper case to the lower case, removing the punctuations and digits, converting plurals to singulars, and transforming verbs into infinitives. *The second step* was getting the weight of each term into artifacts using TFIDF. *The third step* was computing the similarity between the source and target artifacts using the cosine similarity. *The fourth and final step* was computing the precision, recall, and F-score.

TABLE IV. (A). eTOUR COMPARED WITH IR AND TRACELAB

Measure	Clustering	IR	TraceLab
Precision	0.93	0.39	0.046
Recall	0.97	0.07	0.98
F-score	0.94	0.11	0.088

(B). SMOS COMPARED WITH IR AND TRACELAB

Measure	Clustering	IR	TraceLab
Precision	0.73	0.24	0.19
Recall	0.76	0.14	0.99
F-score	0.74	0.18	0.32

(C). eANCI COMPARED WITH IR AND TRACELAB

Measure	Clustering	IR	TraceLab
Precision	0.64	0.31	0.03
Recall	0.77	0.11	0.95
F-score	0.70	0.16	0.06

Tables IV (A) to (C) and Fig. 5(a) to (c) show that the proposed trace retrieval approach achieved high results with three datasets in the precision measure, which was the concern in this work. TraceLab achieved high results in recall because the precision and F-score measures were very low, and the false negative (FN) of the links was more than the true positive with the three datasets. The proposed approach achieved high results with the three datasets in F-score compared to the IR and TraceLab.

Third, compared the results of the proposed approach and those of other studies. Tables V (A) to (C) and Fig. 6(a) to (c) present the results obtained from applying clustering models into the three datasets. The performance of the proposed approach was compared to those of studies 19 and 24, which addressed the same problem and used the same datasets. Four measures were used: precision, recall, and F-score as the comparison metrics. The two studies used precision, recall, and F-score, but not accuracy.

Tables V (A) to (C) and Fig. 6(a) to (c) depict that the proposed trace retrieval approach achieved high results with precision, recall, and F-Score in the eTour dataset than in the two studies. In the SMOS dataset, the proposed approach trace retrieval achieved high results using precision, recall, F-Score than in the two studies. Meanwhile, in the eANCI dataset, the proposed approach obtained low results using precision than in the two studies and highest results in recall and F-Score.

TABLE V. (A). eTOUR COMPARED WITH THE TWO STUDIES

Measure	Clustering	Study [19]	Study [24]
Precision	0.93	0.68	0.66
Recall	0.97	0.34	0.59

Measure	Clustering	Study [19]	Study [24]
F-score	0.94	0.46	0.61

(B). SMOS COMPARED WITH THE TWO STUDIES

Measure	Clustering	Study [19]	Study [24]
Precision	0.73	0.57	0.75

Measure	Clustering	Study [19]	Study [24]
Recall	0.76	0.29	0.33

Measure	Clustering	Study [19]	Study [24]
F-score	0.74	0.39	0.51

(C). EANCI COMPARED WITH THE TWO STUDIES

Measure	Clustering	Study [19]	Study [24]
Precision	0.64	0.73	0.62

Measure	Clustering	Study [19]	Study [24]
Recall	0.77	0.44	0.54

Measure	Clustering	Study [19]	Study [24]
F-score	0.70	0.55	0.58

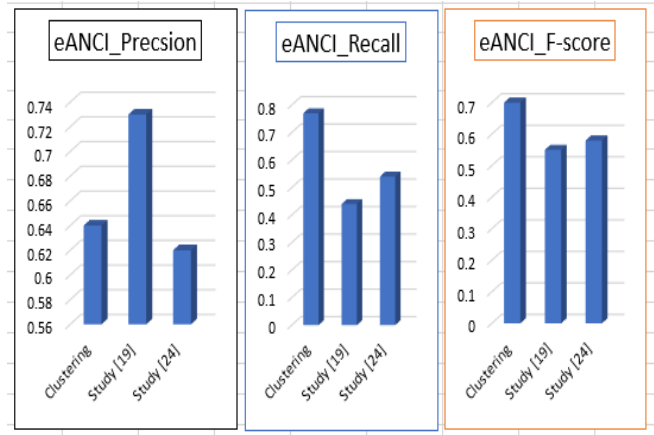

Fig. 6. (A). eTour result comparison: clustering and studies [19] and [24] (B). SMOS result comparison: clustering and studies [19] and [24] (C). eANCI result comparison: clustering and studies [19] and [24]

Finally, the authors will present all the experimental results obtained from K-means++, hierarchical, and DBSCAN as shown in (Tables VI-XVII). Those tables include different results using various parameters used during running the experiments such as (max_features). The max_features set the maximum number of features to be used by specifying the value between (100 and 900). Also, featurewiz package was used. The package is available at <https://pypi.org/project/featurewiz/>. featurewiz package is used for selecting the most important features using different parameters like *corr_limit* parameter using different values (0.1 – 0.9) as follows:

```
features, train = featurewiz (data, target, corr_limit=0.9,
verbose=2, sep=",", header=0, test_data=" ",
feature_engg=" ", category_encoders="")
```

First: eTour dataset, (Tables VI and VII) presents the results of the experiments obtained from K-means++ and hierarchical.

Table VI shows the result of the proposed trace retrieval approach using K-means++ based on max_feature values (100,300,400,800). The Table indicated that the precision achieved the highest value with all max_feature values. Recall achieved the highest results when is max_feature values=400 and 800 and F-Score with max_feature values=300 and 400.Finally, the accuracy achieved highest results when is max_feature values=300,400, and 800.

TABLE VI. ETour_K-MEANS ++ (MAX_FEATURE)

Measure's name	max_feature values			
	800	400	300	100
Precision	0.93	0.93	0.93	0.93
Recall	0.97	0.96	0.96	0.95
F-Score	0.93	0.94	0.94	0.93
Accuracy	0.91	0.91	0.91	0.90

(a)

(b)

According to Table VII, the proposed trace retrieval approach using hierarchical based on the max_feature values achieved the highest results with precision, recall, F-Score, and accuracy when is max_feature value =950.

TABLE VII. eTOUR_HIERARCHICAL (MAX_FEATURE)

Measure's name	Max_feature vlues			
	800	400	300	950
Precision	0.91	0.91	0.91	0.93
Recall	0.56	0.56	0.56	0.95
F-score	0.69	0.69	0.69	0.93
Accuracy	0.56	0.57	0.56	0.90

Second: SMOS dataset, (Tables VIII–XII) presents the results of the experiments obtained from K-means++ and hierarchical.

Table VIII indicates the results of the proposed trace retrieval approach using K-means++ based on max_feature values (100 - 500). Precision achieved the highest results when are max_feature values=400. Both Recall and accuracy achieved the highest results when is max_feature values=500, and F-score achieved the highest results when are max_feature values=300

TABLE VIII. SMOS_K-MEANS++MAX_FEATURE (MINMAX_SCALARE)

Measure's name	max_feature values				
	500	400	300	200	100
Precision	0.71	0.72	0.71	0.71	0.71
Recall	0.80	0.74	0.79	0.73	0.69
F-score	0.75	0.73	0.77	0.70	0.68
Accuracy	0.66	0.65	0.65	0.64	0.62

The authors inferred that the corr_limit values enhance precision, recall, F-Score, and accuracy with different values as shown in Table IX. Precision achieves the highest results when the corr_limit values =0.7 and 0.5. Recall and accuracy obtain the highest results when the corr_limit values = 0.7. F-Score obtains the highest result when corr_limit values=0.7 and 0.5.

TABLE IX. SMOS_KMEANS++ USING FEATURE_WIZ (MIN, AXSCALER)

Measure's name	Corr_limit values			
	0.7	0.5	0.4	0.3
Precision	0.72	0.72	0.71	0.71
Recall	0.71	0.70	0.67	0.67
F-score	0.71	0.71	0.69	0.69
Accuracy	0.64	0.63	0.61	0.61

As shown in Table X, the proposed trace retrieval approach using K-means++ based on standard scalar (corr_limit values). Precision and accuracy achieve the highest results when corr_limit value=0.5. Also, the recall and F-

Score achieved the highest results when is corr_limit value=0.3.

TABLE X. SMOS_KMEANS++ USING (STANDARD SCALAR)

Measure's name	Standard scalar (corr_limit values)			
	0.5	0.4	0.3	0.6
Precision	0.73	0.70	0.66	0.71
Recall	0.76	0.75	0.96	0.77
F-score	0.74	0.72	0.78	0.74
Accuracy	0.66	0.63	0.65	0.64

Table XI lists the results of the proposed trace retrieval approach using hierarchical based on max_feature values (100,200, 300, and 500). The precision achieved the highest value with all values of the max_feature. Recall, F-Score, and accuracy obtains the highest value when is max_feature values =500.

TABLE XI. SMOS_HIERARCHICAL MAX_FEATURE(MINMAX_SCALARE)

Measure's name	max_feature values			
	500	300	200	100
Precision	0.71	0.71	0.71	0.71
Recall	0.80	0.79	0.73	0.77
F-score	0.76	0.75	0.72	0.74
Accuracy	0.66	0.65	0.64	0.64

Table XII presents the proposed trace retrieval approach using hierarchical based on featurewiz using (corr_limit values). Precision achieved highest results when is corr_limit value=0.5. The recall, F-Score, and results enhance when corr_limit values equal 0.6. Accuracy when corr_limit equal 0.5 and 0.6

TABLE XII. SMOS_HIERARCHICAL USING SELECT FEATURES (FEATUREWIZ)

Measure's name	Standard scalar (corr_limit values)			
	0.5	0.6	0.4	0.8
Precision	0.73	0.67	0.71	0.71
Recall	0.75	0.94	0.68	0.76
F-score	0.74	0.78	0.69	0.73
Accuracy	0.66	0.66	0.62	0.65

Third: eANCI dataset, (Tables XIII–XVII) presents the results of the experiments obtained from DBSCAN, K-means++, and hierarchical.

The proposed trace retrieval approach using DBSCAN achieved the highest value in precision when is corr_limit values=0.5 and 0.7. Recall F-Score, and accuracy achieved the highest value when is corr_limit values=0.7 as shown in Table XIII.

TABLE XIII. EANCI_DBSCAN USING FEATUREWIZ

Measure's name	Standard scalar (corr_limit values)		
	0.5	0.6	0.7
Precision	0.64	0.61	0.64
Recall	0.71	0.53	0.77
F-score	0.67	0.57	0.70
Accuracy	0.57	0.51	0.60

As shown in Table XIV, the proposed trace retrieval approach using K-means++ based on standard scalar achieves highest precision with all values of the Max_feature. Recall-Score, and accuracy achieves the highest results when are Max_feature =200.

TABLE XIV. EANCI_KMEANS ++ USING MAX_FEATURE

Measure's name	Max_feature		
	100	200	300
Precision	0.63	0.63	0.63
Recall	0.82	0.84	0.84
F-Score	0.71	0.72	0.72
Accuracy	0.59	0.60	0.72

From Table XV, the authors inferred that the proposed trace retrieval approach using K-means++ based on standard scalar (corr_limit values) achieves the highest results with precision when is corr_limit value=0.5 and 0.7. Recall, F-Score, and accuracy achieved the highest results when is the corr_limit value=0.7.

TABLE XV. EANCI_KNEAMS USING FEATURERWIZ

Measure's name	Standard scalar (corr_limit values)		
	0.5	0.6	0.7
Precision	0.64	0.61	0.64
Recall	0.71	0.53	0.77
F-score	0.67	0.57	0.70
Accuracy	0.57	0.51	0.60

According to Table XVI, the proposed trace retrieval approach using hierarchical achieves the highest results for precision, Recall, F-Score, and accuracy when is MinMax scalar = 100.

TABLE XVI. EANCI_HIERARCHICAL USING MAX_FEATURE

Measure's name	Standard scalar = 400	Standard scalar = 100
	Precision	0.62
Recall	0.68	0.77
F-score	0.65	0.69
Accuracy	0.56	0.59

As shown in Table XVII, the proposed trace retrieval approach using a GMM based on a standard scalar achieves

the highest value in precision, Recall, F-Score, and accuracy when is corr_limit values = 0.5.

TABLE XVII. EANCI_GMM_ USING FEATUREWIZ

Measure's name	Standard scalar (corr_limit values)	
	0.5	0.6
Precision	0.63	0.61
Recall	0.65	0.52
F-score	0.63	0.56
Accuracy	0.56	0.50

Regardless of the results, the suitable intelligent solution for addressing the term mismatch problem between requirements and source code for a few labels or unlabelled data is UNSUPERVISED machine learning using clustering, which is the only way to solve the problem of labels and enhance low precision.

V. EVALUATION

This section presents the evaluation method of the retrieved links evaluated with respect to two criteria. The first criterion is the performance of the three measures (i.e., precision, recall, and F-score), when evaluating the traceability links between the source and target artifacts. The second criterion is the comparison of the proposed trace retrieval approach with two experiments (IR and TraceLab) as shown in Tables IV (A) to (C) and two studies ([19]and [24]) as shown in Tables V (A) to (C). The proposed trace retrieval approach achieved high results compared to the two experiments and the two studies.

VI. CONCLUSION AND FUTURE WORK

This study presented new clustering-based approach that addresses the term mismatch problem to obtain the greatest improvements in precision. The study followed the proposed research direction toward realizing automated trace retrieval by developing intelligent tracing solutions. Then the authors applied the intelligent solution that is based on unsupervised learning using clustering. After that, evaluate the proposed approach results with respect to two criteria: performance of the confusion matrix (i.e., precision, recall, F-score) and comparison of the proposed trace retrieval approach with two experiments and two studies. Clustering yields high results in precision with other measures (i.e., recall, F-score, and accuracy), which is a big concern associated with trace retrieval precision.

In the future work, the authors will look for another intelligent solution that can be applied to the same datasets (i.e., eTour, SMOS, and eANCI) for improving trace retrieval precision.

Application of Multi-Scale Convolution Neural Network Optimization Image Defogging Algorithm in Image Processing

Weihan Zhu

School of Electrical and Information Engineering-Jiangsu University, Jingjiang College, Zhenjiang, 212000, China

Abstract—To improve the ability to detect and identify smog images in complex road traffic scenes, smog images need to be defogged, and an optimized image defogging algorithm on the basis of multi-scale convolutional neural network (MCNN) is proposed. The physical model of road traffic scene smog scattering is constructed, and the image is divided sky area, road surface area and road sky boundary area. The road sky boundary line is the boundary line between road surface and sky area. The dark channel of traffic scene smog image is established by Canny edge detection and MCNN optimization, and the smog image is subjected to detail compensation and gray enhancement processing through prior knowledge. After substituting the atmospheric light value and transmittance map into the atmospheric scattering model (ACM), the MCNN learning model is combined to realize the filtering processing and defogging optimization of smog images in complex road traffic scenes. The color saturation, defogging degree, peak signal-to-noise ratio (PSNR), texture effect as well as other aspects of the image are taken as test indexes for the simulation experiment. The simulation results show that the color saturation, defogging degree and image definition of the defogged haze images in complex road traffic scenes are higher by using this method, which improves the output PSNR of the defogged haze images in complex road traffic scenes, and has a good application value in image defogging.

Keywords—Multi-scale convolution neural network; complex road traffic scene; Image defogging; dark passage; Gray enhancement

I. INTRODUCTION

Nowadays, the society has entered the information age, and the way that human beings know and transform the world depends not only on language and characters, but also on images, which gradually become the main medium for transmitting real-world information. According to scientific statistics, in the process of people learning and recognizing social changes, most of the effective information comes from images, which means that image research has a significant role in production and life. In actual scenes, image semantics is often changed due to the introduction of some noises, and some directions related to computer vision are just born for solving this kind of image tasks, such as common image denoising and image enhancement, etc. This paper mainly focuses on the research of the related methods of image defogging. Recently, daily transportation, aerospace and road monitoring are all seriously affected by smog weather due to rapid development of domestic industrial production. Fog

refers to tiny water droplets suspended in the air, which are formed by condensation of water vapor in the ground layer; Haze, which consists of dust, sulfuric acid, organic hydrocarbons and other particles in the air, leads to atmosphere turbid. In foggy scenes, natural light will be absorbed or scattered by these suspended water droplets and particles in the process of transmission, which will cause the outline of the shot scene to be blurred, the image clarity and color saturation to decrease, thus affecting the overall visual effect of images. Especially when the smog concentration is high, the information of the real image will be seriously lost. Hinder the subsequent application of images. For example, in daily traffic

The main goal of image defogging algorithm is to reduce the noise caused by haze impurities to the image, increase the image's clarity and color saturation, and repair the image details. Traditional image defogging methods are mainly divided into two types. The first type is the defogging algorithm on the basis of non-physical model, which only depends on enhancing the image to enhance the image visual effect. This kind of method does not involve the principle of fog formation and the process of image imaging, but only enhances some information in the foggy image according to the actual needs. The second kind is the defogging algorithm on the basis of physical model. This method, on the basis of the ACM, estimates the undetermined parameters in the model by statistical methods to recover the fog-free image. Recently, the deep learning theory has been extensively applied in image defogging. Some scholars use a large number of foggy image data sets to train and learn, so that they can achieve defogging more efficiently.

The early defogging algorithm did not consider the objective physical model of image degradation in foggy environment, but was guided by the subjective feeling of human vision. By enhancing the contrast of foggy images, the visual feeling of images was natural and clear, and the details of images were richer. This kind of method can improve the subjective quality of images to some extent[1]. However, there is no fundamental analysis of the factors affecting image degradation, so some prominent information may cause some losses. This kind of algorithm mainly includes: histogram equalization algorithm. And wavelet homomorphic filtering algorithm, Retinex algorithm, etc. Among them, literature [2] puts forward an image defogging algorithm for complex road traffic scenes, which adopts the smooth transition of abrupt points in the image. Because of the unknown a priori, it is

difficult to build a statistical model. Literature puts forward a simple defogging model on the basis of physical laws. Through constructing the scene's physical texture features, the atomization points are virtually reconstructed. The method is simple and easy, but the accuracy is not high. Literature analyzes the defogging algorithm of atomized images collected on the water surface, and mainly adopts the defogging algorithm of complex road traffic scenes on the basis of constrained evolutionary time-frequency weighted filtering. The algorithm is limited by the scattering interference of edge fog points, so the defogging effect of complex road traffic scenes and other images is not good.

To solve the above problems, this paper puts forward a haze image defogging algorithm on the basis of MCNN. Firstly, the paper builds a physical model of haze scattering in road traffic scenes, and builds an ACM according to the sky brightness estimation and road sky line segmentation method. By using MCNN method, the largest line segment is found out based on the calculated length of each straight line segment, so as to recover the image scene and defog the image in complex road traffic scenes. Finally, the performance of this algorithm is checked by simulation experiment, indicating that his algorithm has superior performance.

II. RELATED WORKS

The work of removing smoke from traffic scene images belongs to image denoising, and people have carried out a lot of research in this field before. With the development and maturity of artificial intelligence technology, it is increasingly used in image denoising. Jian J et al. found that the image denoising algorithm based on sparse expression has good denoising effect. Therefore, a convolutional neural network algorithm based on sparse expression is designed and applied to image denoising. The experimental results show that the algorithm significantly improves the image quality and the denoising effect is significantly better than the algorithm model without sparse expression [3]. Jh A et al.'s desert images tend to contain noise caused by large amounts of sand and dust in the air. In order to improve the quality of images taken in desert areas, an improved neural network algorithm was designed. The test results show that the algorithm has better image denoising effect than the current algorithm [4]. Liu Y's research team found that the quality of polarized images is easily affected by the noise in the images obtained by the polarization camera. A denoising method using pulse coupled neural network to optimize polarization images is proposed. The calculation results show that compared with the most advanced image denoising algorithm, the proposed optimized image denoising method effectively suppresses the noise in polarized images [5]. Golilarz NA et al. designed a neural network algorithm incorporating adaptive Gaussian distribution to solve the noise problem in remote sensing satellite images. The test results show that, compared with the common denoising algorithm, the denoised image signal-to-noise ratio of this algorithm is significantly higher [6].

To sum up, in order to denoise the image to improve the image quality, people have proposed many improved image appearance processing methods, but few studies have involved

removing the influence of fog caused by weather in the image, which is crucial to improve the image recognition quality of the transportation industry, which is the main purpose of this study.

III. CONSTRUCTION OF ATMOSPHERIC SCATTERING PHYSICAL MODEL AND IMAGE PRE-PROCESSING OF IMAGE ENVIRONMENT ON THE BASIS OF GIS

A. Physical Model of Haze Scattering in Road Traffic Scenes

Firstly, a physical model of smog scattering in road traffic scenes is established[7]. When light travels, some of it will deflect due to contact with suspended particles in the atmosphere[8-9]. Besides, the deflection intensity is closely related to the suspended particle's size, type and distribution. Generally, the camera equipment receives two types of light sources: one is the reflected light of the target object. During reflected light propagation from the target object to the imaging equipment, the light received by the equipment is attenuated due to the absorption and scattering of impurities, resulting in the decrease of imaging brightness and contrast; Second, the ambient atmospheric light, the main sources of which are direct sunlight, atmospheric scattered light and ground reflected light, etc. Atmospheric light will also experience the process of being absorbed or scattered by particles, but when it propagates to the imaging equipment, the original image may be blurred because the intensity of this split light is larger than the target's reflected light. Therefore, the light intensity which is received by the imaging sensor is mainly from the superposition of the above two remaining light intensities after being influenced by impurities. They can be respectively expressed by the incident light attenuation model (ILAM) and the atmospheric light imaging model. Seen from image processing, the contrast of degraded images in foggy days is enhanced. Aiming at the characteristics of clear boundary line between highway and sky and large sky area, the image is segmented first, and the pre-processing of image defogging is realized [10]. The schematic diagram of the physical model of water surface atmospheric scattering is shown in Fig. 1.

Fig. 1. Physical model of atmospheric scattering

Fig. 1 shows Narasimhan ACM. On the basis of this, a monochromatic ACM under fog and haze weather conditions is obtained. Depending on the physical model, the weather degradation image restoration method, the human eye observes the object depending on the reflection phenomenon formed when the light meets the target scene[11-12]. During the reflection process, the light will collide with the suspended impurities in the atmosphere, resulting in the deflection of

some light propagation directions and attenuation of the incident light actually entering our eyes or imaging equipment[13]. At the same time, the scattering degree of the incident light is relevant to the distance between the measured object and the imaging equipment. The larger the distance, the stronger the scattering ability, and the less the light that finally enters the camera[14]. The atmospheric scattering process and image degradation process during the generation of the incident ACM are described by the model state equation:

$$I(x) = J(x)t(x) + A(1-t(x)) \quad (1)$$

Wherein, A indicates the environmental light effect component of smog image in complex road traffic scene, $t(x)$ indicates the atomization transmittance of smog image in complex road traffic scene, and $J(x)t(x)$ indicates the attenuation factor of smog image atomization process in complex road traffic scene. According to the above equation, it is assumed that A represents the sky brightness, $\rho(x)$ represents the scene albedo of the smog image of the complex road traffic scene at the spatial coordinate $d(x)$, and S^x represents the spatial coordinate, so that the pixel of the smog image of the complex road traffic scene captured by $I(x)$ is expressed as:

$$I(x) = A\rho(x)e^{-\beta d(x)} + A(1 - e^{-\beta d(x)}) \quad (2)$$

Wherein, β represents the scattering degree of incident light. In the complex road network environment, the transmission wavelength coefficient of smog image imaging in the atmosphere of complex road traffic scenes is:

$$L = J(w, e) - \sum_{i=1}^N a_i \{w^T \varphi(x_i) + b + e_i - y_i\} \quad (3)$$

Wherein, $J(w, e)$ represents the distance between the measured object and the imaging equipment, a_i represents the unit cross-sectional thickness through which the incident light vertically passes, b represents the wavelength of the incident light, and e_i is the scene depth. When the reflected light of the target scene propagates to the imaging equipment, the impurities suspended in the natural environment will scatter the reflected light, resulting in the attenuated incident light, direct sunlight and scattered light of other objects entering the image acquisition equipment simultaneously. This process is named atmospheric light imaging. Therefore, contrary to the ILAM, the acquisition equipment in the atmospheric light imaging model can not only receive the target object's reflected light, but also have more types of atmospheric light. With the fluctuation of light and the change of probability density distribution model, the objective optimization function of atomization image processing and defogging is expressed as:

$$\left. \begin{aligned} J_1(w, e) &= \frac{\mu}{2} w^T w + \frac{1}{2} \gamma \sum_{i=1}^N e_i^2 \\ s.t. y_i &= w^T \varphi(x_i) + b + e_i, \quad i = 1, \dots, N \end{aligned} \right\} \quad (4)$$

In the above formula, $\varphi()$ is the wavelength kernel space mapping function of the local light spot information of the haze image in the complex road traffic scene, and $w^T \varphi(x_i)$ is the atmospheric penetration factor of the haze image in the complex road traffic scene. The partial derivative of the above formula is obtained as follows:

$$\left. \begin{aligned} \frac{\partial L}{\partial w} = 0 &\rightarrow w = \sum_{i=1}^N \alpha_i \varphi(x_i) \\ \frac{\partial L}{\partial b} = 0 &\rightarrow \sum_{i=1}^N \alpha_i = 0 \\ \frac{\partial L}{\partial e_i} = 0 &\rightarrow \alpha_i = \gamma e_i \\ \frac{\partial L}{\partial \alpha_i} = 0 &\rightarrow w^T \varphi(x_i) + b + e_i - y_i \end{aligned} \right\} \quad (5)$$

In the above formula, $i = 1, \dots, N$, streamline amplification processing is performed on the smog image of complex road traffic scene in the Z-axis direction of each vertex of the entity constructed by the atomized environment model, and the LOD with the highest resolution is used to form the entity environment object model of the smog image of complex road traffic scene. During the propagation of the reflected light of the smog image of complex road traffic scene, because of the scattering effect of atmospheric particles, some reflected light on the surface of the object is lost due to the scattering of the particles of the smog image of complex road traffic scene, and the fog point scattering loss of the smog image of complex road traffic scene is obtained as follows:

$$J(x) = \frac{I(x) - A}{\max(t(x), t_0)} + A \quad (6)$$

Wherein, A represents the opposite of the ILAM, which is collected in the atmospheric light imaging model, $I(x)$ represents the reflected wavelength of the received target object, and $\max(t(x), t_0)$ is the wavelength of the reflected light scattered by the suspended impurities in the natural environment. Therefore, through the ACM, a scene picture is formed, and the reflected light intensity will decrease exponentially with the propagation distance. On this basis, this paper adopts the defogging method on the basis of the physical model, which essentially uses the ACM to solve the scene albedo and realize the image defogging.

B. Mathematical Model Construction and Preprocessing of Image

On the basis of the prior knowledge, the smog image is subjected to detail compensation and gray enhancement. After substituting the atmospheric light value and transmittance map into the ACM, the MCNN learning model is combined to

construct the defogging processing model of the smog image in the complex road traffic scene, and the mathematical model of the image is obtained. Collecting image information by block processing method, and selecting initial block size as a fixed value: 15*15; determining the image processing template by the image size m*n. And solving the dark primary color of the scattered atomized image in the 3*3 template of the haze image of complex road traffic scene, where $t(x) = e^{-\beta d(x)}$ indicates the propagation function or transmittance of the medium at the image position $0 < t(x) < 1$, so as to obtain the new features of the haze image of complex road traffic scene. The solution process is described as follows: Assume that the signal form of the haze image information of a complex road traffic scene is:

$$s(t) = \sum_{m=-\infty}^{\infty} \sum_{n=-\infty}^{\infty} a_{mn} g_{mn}(t) \quad (7)$$

Wherein, a_{mn} is the extra luminous flux of the imaging acquisition equipment, $g_{mn}(t)$ is haze images of miscellaneous road traffic scenes, the included angle projected in the imaging acquisition equipment is fixed, and the atmospheric light source is the cross section of the vertebral body, and the largest pixel value of the imaging acquisition is determined as the estimated value of sky brightness, which is expressed as:

$$J^{dark}(x) = \min_{c \in \{r, g, b\}} (\min_{y \in \Omega(x)} (J^c(y))) \quad (8)$$

Wherein, J^c represents a channel of smog image information of complex road traffic scene. A dark original smog image distribution area is set in the 3*3 template with X as the center. The edge of the smog image of complex road traffic scene is detected by Canny operator, and the smog image of complex road traffic scene is counted in blocks to find out the candidate sky area, and the intensity of the smog image of complex road traffic scene is close to 0. Based on the above processing, the haze image mathematical model in complex road traffic scene is obtained, and the atmospheric dissipation function is further defined, and the haze image in complex road traffic scene is defogged. The atmospheric dissipation function represents the extra part of ambient light to the image. In this way, the atmospheric dissipation function is simplified to $U(x) = 1 - e^{-\beta d(x)}$, which apparently has the characteristic resolution of the haze image in complex road traffic scene. Therefore, the captured image pixels is simplified as follows:

$$I(x) = J(x)t(x) + AU(x) \quad (9)$$

Wherein, $J(x)$ is the regular quantity of incident light attenuation of a point light source, A is the illumination amplitude and $U(x)$ is the radiance of the light source. For a color image, J^c is defined to represent a certain color component J , namely one of the three channels of RGB. The global non-significant mutation information extraction method

is adopted to increase the sampling accuracy. The information sampling plane of smog image in complex road traffic scene is composed of single-layer square grid in color space. In the above-mentioned modeling coordinate system of background information of smog image in complex road traffic scene, the formula for collecting atomization information of smog image in complex road traffic scene is as follows:

$$y = \bar{y} + R_t d, \quad z = \bar{z} + R_h d \quad (10)$$

Among it, R_t indicates the transmittance estimation value of the haze image in the complex road traffic scene, R_h is the estimation of the edge change pixels of the haze image. Grid structure in the complex road traffic scene is the change rate of the abrupt information texture after the image is disturbed by haze. Through the above processing, the ACM is constructed according to the sky brightness estimation and highway sky line segmentation method, and the haze scattering image of road traffic scene is defogged.

IV. SCALE CONVOLUTION NEURAL NETWORK METHOD AND IMPROVED IMPLEMENTATION OF DEFOGGING ALGORITHM

A. MCNN Learning

Narasimhan and Nayar explained the elements contained in foggy images and the imaging process by establishing a mathematical model. The model considered that the reasons for the image quality degradation in foggy days mainly included two aspects: first, the energy attenuation caused by the influence of suspended particles in the atmosphere on the absorption and scattering of the target's reflected light, and finally reduced the imaging brightness; Second, atmospheric light imaging, where ambient light like sunlight is scattered by atmospheric media to form background light, and its intensity is too high, which affects the imaging clarity and causes the image color to be unnatural. Therefore, the MCNN learning method is applied to learn the image defogging. Fig. 2 shows the MCNN learning model.

Fig. 2. MCNN

In this study, a smog image defogging algorithm on the basis of MCNN for complex road traffic scenes is adopted. The improved idea and key technology realization of the

algorithm are described as follows. Firstly, the texture information features of smog images in complex road traffic scenes are calculated. Assuming that the transmittance of smog in complex road traffic scenes is the same in a local area, the 3*3 median filter is used to preprocess the smog in complicated scenes of road traffic and filter out the noise in the smog in complex road traffic scenes, and the texture information of smog in complex road traffic scenes is obtained as follows:

$$pk = \left\langle x_0, (x_i)_{0 \leq i \leq \tau}, (x_i)_{0 \leq i \leq l-1}, (\Pi_i)_{0 \leq i \leq l-1} \right\rangle \quad (11)$$

Wherein, x_0 is the transmittance of the window, x_i is the selected brightness in the dark channel diagram of the foggy image, Π_i is the pixel point at the same position, and the error vector of random logarithmic fluctuation is used to obtain integer vectors of haze fluctuation and cutoff as follows:

$$\mathbf{b} = (b_i)_{1 \leq i \leq \tau} \in (-2^\alpha, 2^\alpha)^\tau \quad (12)$$

Wherein, b_i is the atmospheric light value, and the image S is decomposed into an orthogonal projection sequence of smog in complex road traffic scenes by one-dimensional wavelet decomposition method. The learning function of neural network of smog in complex road traffic scenes is:

$$c = \left[\sum_{1 \leq i, j \leq \mu} m_{i,j} \cdot x_{i,0} \cdot x_{j,1} + \sum_{1 \leq i, j \leq \mu} b_{i,j} \cdot \Pi_{i,0} \cdot \Pi_{j,1} + \sum_{1 \leq i, j \leq \beta} b_{i,j} \cdot x_{i,0} \cdot x_{j,1} \right]_{x_0} \quad (13)$$

Wherein, $b_{i,j}$ is the transmitted light intensity of smog in complex road traffic scene, and for the point set in the edge center area, in a local sub-block area in any channel of the original road fog image, it satisfies:

$$\min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} (I^c(y)) \right) = \tilde{t}(x) \min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} (J^c(y)) \right) + (1 - \tilde{t}(x)) A^c \quad (14)$$

: Wherein, A^c represents the sky brightness of a certain color channel component, which is known from the previous sky brightness estimation algorithm as A^c , and $A > 0$. The texture features of the haze image of the complex road traffic scene in the haze obtained above are uniformly traversed and addressed, and the haze on the water surface is segmented by the highway sky line to obtain two parts, the regional difference $Dif(C_1, C_2)$ of which is larger than the internal difference $Int(C_1)$ or $Int(C_2)$ of no less than one part. In the area near the highway sky boundary line, the target search area can be reduced through detecting the highway sky line, which can reduce the subsequent target detection and recognition. Here, the estimated value of transmittance is expressed by. Because of $A > 0$, equation (14) is equivalent to:

$$\min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} \left(\frac{I^c(y)}{A} \right) \right) = \tilde{t}(x) \min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} \left(\frac{J^c(y)}{A} \right) \right) + (1 - \tilde{t}(x)) \quad (15)$$

In the sky area of the complex road traffic scene smog image, the intensity value of the complex road traffic scene smog image with the smallest channel tends to the sky

brightness A , that is, $\min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} \left(\frac{I^c(y)}{A} \right) \right) \rightarrow 1$, then $\tilde{t}(x) \rightarrow 0$ at this time, because of $A > 0$, so

$$\min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} \left(\frac{J^c(y)}{A} \right) \right) = 0 \quad (16)$$

Substituting the formula (16) into the formula (15) gives:

$$\tilde{t}(x) = 1 - \min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} \left(\frac{I^c(y)}{A} \right) \right) \quad (17)$$

$$\tilde{U}(x) = 1 - \tilde{t}(x) = \min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} \left(\frac{I^c(y)}{A} \right) \right) \quad (18)$$

Edge detection is used to get the smog image of complex road traffic scene, and Hough transform is used to detect the straight line, and the straight line segment is extracted. Here, the expression is the estimated value of atmospheric dissipation function.

A. Haze Image Defogging Processing in Complex Road Traffic Scenes

According to the above algorithm, the prior defogging algorithm flow of dark channel can be obtained. Firstly, the foggy image is used as input, and the dark channel map is obtained in accordance with the ACM deformation. Then, the atmospheric light value is estimated, thus obtaining the transmittance map; at last, on the premise that $I(x,y)$ is known, the clear image is inverted by $t(x)$ and A . The defogging algorithm can restore the image color and visibility, and at the same time, it can estimate the distance of the object by using the fog concentration, which have important applications in computer vision. However, according to the experimental statistics, if the image to be searched contains a large sky scene, the restored fog-free image will have obvious excessive areas. Realize the restoration of the image scene, and realize the image defogging processing in the complex road traffic scene. The estimated atmospheric dissipation function is:

$$U(x) = 1 - \tilde{t}(x) = \omega \tilde{U}(x) = \omega \min_{c \in \{r,g,b\}} \left(\min_{y \in \Omega(x)} \left(\frac{I^c(y)}{A} \right) \right) \quad (19)$$

In some scenes, it is difficult to extract features manually. Convolutional neural network is used to learn image features automatically. The influence weight in the field of image vision is gradually increasing. Following the example of human visual system, CNN obtains local features of data through local receptive fields, and gradually expands receptive fields by convolution kernel stacking. The restored image can be expressed as follows:

$$\begin{aligned} J(x) &= [I(x) - AU(x)] / (1 - U(x)) \\ &= [I(x) - A\omega\tilde{U}(x)] / (1 - \omega\tilde{U}(x)) \end{aligned} \quad (20)$$

Wherein, $I(x)$ is the convolution layer parameter, A is the input feature map size, the output feature map size size, $U(x)$ is the convolution kernel size, $U(x)$ is the abstract feature and context information. The convolution layer plays an important role in feature extraction of the input data information, and it contains multiple filters. The convolution kernel's each element has its corresponding weight coefficient and bias constant, which is similar to the forward propagation neuron. Each neuron in the convolution layer is associated with multiple neurons, and the associated area is defined as "receptive field". To restore the haze image of complex road traffic scenes more naturally, a constant ω is introduced here to improve the estimation of transmittance, where $0 < \omega \leq 1$, and

$$\tilde{t}(x) = 1 - \omega \min_{c \in \{r, g, b\}} \left(\min_{y \in \Omega(x)} \left(\frac{I^c(y)}{A} \right) \right) = 1 - \omega \tilde{U}(x) \quad (21)$$

Wherein, $\tilde{t}(x)$ is the estimated value of the improved transmittance, and the value of ω relies on the fog concentration and the size of the sky area in the specific complex road traffic scene. For the atomized image, in the convolution layer, the step parameter S transformation can affect the size of the feature map. It can be seen that when S increases, the network parameters of the complex road traffic scene fog will decrease. However, setting the S value is complicated, and the pool layer can be used to achieve the same function, that is, the pool layer can also change the image size, so it is also called the sampling layer. It can not only reduce the data size, but also detect more abstract features and contextual information, thus enriching semantic information. The pool layer is generally used behind the convolution layer, and two ways of maximum pool and average pool are often adopted. Maximum pooling refers to selecting the largest element value from locally related elements, while average pooling refers to calculating the average value from these elements and returning it. The adjacent gray levels of image pixels obtained by constraining evolutionary conditions are:

$$P(t, f) = \int_{-\infty}^{\infty} s^* \left(u - \frac{\tau}{2} \right) \alpha(\tau, v) e^{-j2\pi(vt + f\tau - vu)} dudvd\tau \quad (22)$$

In the above formula, when there is large sky area and thick fog, the light transmittance of smog in complex road traffic scenes is generally 0.75. When the fog is thick, the ω value is larger, and the value is smaller when the proportion of smog image features in complex road traffic scenes is larger in the sky area. Because the fog concentration of the smog in the complex road traffic scene in the same background has little change, we can only get the fog distribution map of one of the video frames in the same background, and use the MCNN to directly subtract the fog noise of other frames from this fog distribution map to achieve the effect of video clarity. To sum up, the algorithm implementation process is shown in Fig. 3.

Fig. 3. Flow chart of defogging and clearing processing of road surface scattering image

V. SIMULATION EXPERIMENT AND RESULT ANALYSIS

To test the algorithm's defogging and clearing performance after collecting smog images of complex road traffic scenes under smog, a simulation experiment was carried out. The hardware environment of the simulation is PC, the operating system is Windows 7, and the system memory is 4GB. The algorithm simulation is realized by Matlab 2012. To prove the image defogging effectiveness, it is evaluated from objective and subjective perspectives. According to the subjective visual perception of the observer, evaluate the color saturation and clarity of the restored image. Evaluation indexes are used to quantitatively analyze the restoration effect of fog-free images. Subjective evaluation refers to the subjective evaluation of the defogged image by observers on the basis of its color saturation, defogged degree and texture effect. Generally, the scoring criteria for comparison between fog-free images and restored images include: whether the color is distorted, whether the image is clear, whether there is exposure problem, and whether the information of the image is lost. Image subjective evaluation can not only reflect subjective feelings, but also the evaluation results are authentic and effective, which has certain reference significance. Although the subjective evaluation is intuitive, there are still many problems, which require repeated observation of fog-free images, and it is time-consuming. Firstly, the images in the road traffic scene under the fog scattering environment are collected. Figure shows the collected original image information, which is used as a sample for image defogging. In Fig. 4, when the road empty background image is viewed from a long distance, the image is divided into sky area, road surface area and road sky boundary area. The road sky boundary line is the boundary line between road surface and sky area, and the Canny edge detection and Hough line detection are combined to obtain the image detail enhancement image in Fig. 5.

Fig. 4. Original image sample

Fig. 5. Image feature enhancement extraction diagram

Using the prior information of the sky area position, a connected component above the image is selected as the sky area to segment the road sky, and the final road sky boundary line graph is obtained, so as to pre-process image defogging. Through the above processing, on the basis of this, the fog processing of road fog image is carried out. To compare the performance of the algorithm, this algorithm is compared with the traditional Retinex algorithm and MCNN algorithm.

The analysis results in Fig. 6 show that most of the fog in the image is removed by using this algorithm, and the image is realistic with good visual effect. The algorithm in this paper has obvious defogging effect on smog, especially suitable for the processing of images with obvious road-sky boundary lines. Test the convergence of the image and get the convergence curve as shown in Fig. 7.

(b) Time-frequency weighting algorithm

(c) Algorithm in this paper

Fig. 6. Comparison of simulation results of image defogging algorithm

Fig. 7. Convergence test of image defogging

The output SNR is tested. The comparison results are shown in Fig. 8 and Table I. The results in Fig. 8 and Table I show that this method has higher color saturation, higher defogging degree and better image definition, which improves

the peak SNR of the defogged haze images in complex road traffic scenes, and has a good application value in image defogging.

VI. DISCUSSION

The existence of smoke in complex traffic scenes will further reduce the image clarity, which will affect the efficiency of the image recognition system in traffic scenes. In this study, a smoke denoising algorithm for traffic scene images is proposed, which combines multi-scale idea and Canny edge detection. The test results show that, from a qualitative point of view, the part of the image that is occluded by smoke using the improved algorithm is clearer by naked eyes, and the definition and color saturation of the entire image are significantly higher than those of the image denoised by the contrast algorithm. The research results of WANGFS also show that the denoising ability of the denoising algorithm has been improved to a certain extent by using the fusion multi-scale idea [15].

From a quantitative perspective, as the number of training iterations of each algorithm increases, the peak signal-to-noise ratio of the denoised image of each algorithm gradually

increases, but on the whole, the peak signal-to-noise ratio of the image processed by the improved algorithm designed in this study is the highest. When the number of iterations exceeds 100, the peak signal-to-noise ratio of the test set image after denoising based on the improved multi-scale convolutional neural network algorithm, Retinex algorithm, and MCNN algorithm is about 94dB, 81dB, and 65dB respectively. This is mainly because Canny edge detection can retain more feature information of the original image. Suyu WANG's research results show that the improved algorithm using Canny edge detection has a lower peak signal to noise ratio, which is mainly because the algorithm has too few computational levels to fully extract image features [16].

VII. CONCLUSION

In the haze scene, the images taken by the imaging equipment will have some problems. Therefore, the research of fog removal technology is of great significance. An image defogging optimization algorithm based on MCNN is

proposed. In the real fog image experiment, qualitative observation with the naked eye shows that the defogging image processed by the improved MCNN algorithm can better process the details on the basis of maintaining the integrity of the image information, and the defogging effect is better than the comparison algorithm. In addition, the contrast and brightness of the real fog image can be closer to the natural and clear image. From a quantitative point of view, the improved algorithm designed in this study has the highest peak signal to noise ratio of the image after processing. When the number of iterations exceeds 100, the peak signal-to-noise ratio of the test set image after denoising based on the improved multi-scale convolutional neural network algorithm, Retinex algorithm, and MCNN algorithm is about 94dB, 81dB, and 65dB, respectively. The above research results show that the image smoke removal algorithm based on the improved MCNN algorithm proposed in this study for the application of traffic scenes has certain application potential. However, due to the limitations of research conditions, this study failed to select more data sets for experiments, which is also the part that needs to be improved in subsequent experiments.

Abstract—Visualization is a process of converting data into its visual form as such data patterns can be extracted from the data. Data patterns are knowledge hidden behind the data. However, when data is big, it tends to overlap and clutter on visualization which distorts the data patterns. Data is overly crowded on visualization thus, it has become a challenge to extract knowledge patterns. Besides, big data is costly to visualize because it requires expensive hardware facilities due to its size. Moreover, it is timely to plot the data since it takes time for data to render on visualizations. Due to those reasons, there is a need to reduce the size of big datasets and at the same time maintain the data patterns. There are many methods of data reduction, which are preprocessing operations, dimension reduction, compression, network theory, redundancy elimination, data mining, machine learning, data filtering and sampling techniques. However, the commonly used data reduction technique is sampling technique that derives samples from data populations. Thus, sampling technique is chosen as a study for data reduction in this paper. However, the studies are scattered and are not discussed in a single paper. Consequently, the objective of this paper is to collect them in a single paper for further analysis in order to understand them in great detail. To achieve the objective, three interdisciplinary databases which are ACM Digital Library, IEEE Explore and Science Direct have been selected. From the database, a total of 48 studies have been extracted and they are from the years 2017 to 2021. Other than sampling techniques, this paper also seeks information on big data, data visualization, data clutter, and data reduction.

Keywords—Sampling technique; probability sampling; non-probability sampling; data clutter; big data; data visualization; data reduction

I. INTRODUCTION

Data visualization is a technique to convert data to a visual form to extract knowledge hidden behind the data through data patterns. According to [1], data visualization involves a combination of people with distinct visualization-related skills. Data visualization is also a technology to explore data interactively. Through data exploration, various data patterns can be revealed.

Big data plays a bigger role in our latest technologies today. Communities are particularly depending on the data to gain more information for decision making [2]. The advantage of data visualization is that it supports analysis, identifies issues and tackles problems faster through data patterns [3].

Big data technology is designed to process an enormous dataset for process optimization and decision making [4, 5]. However, an enormous dataset, both structured and

unstructured are complex as they deal with an extensive amount of data. Thus, consistently, they are inadequate to operate with conventional processing techniques and algorithms [2, 6]. This is true when data is from various sources with various forms and format and yet they need to be integrated prior to processing.

Other challenges when dealing with big data are the effectiveness and efficiency in understanding, storing, managing, and developing data visualization [7]. Plotting these big data to form visualizations, require high end and expensive hardware and software facilities.

Nevertheless, when data have been successfully plotted and converted to visualization forms, it is common for the data to overlap on top of each other which could lead to data clutter issues. Data clutter can be defined as data that overlapping on top of each other which can lead to a massive number of false detections over the search space that relies on pixel patterns [8]. Fig. 1 below show the example of data clutter.

Fig. 1. Example of data clutter (Source: [51])

Another issue of concern regarding data clutter is plotting efficiency. It takes a longer time to plot data into its visual and is defined as computational overhead which is costly [9].

Data clutter also leads to unrecognized data patterns when in fact extracting the patterns is the main objective of data visualization [10] for strategic planning and decision making. In other words, the whole point of data visualization is to extract data patterns in order to uncover the gems of knowledge hidden behind the data.

Thus, there is a need to overcome data clutter and one of the techniques is through data reduction. Data reduction is one of the methods to shrunk computational overhead [11]. Although the dataset is reduced, the original information in the dataset should be preserved without scarifying any data patterns. However, data reduction could somehow remove some information from an original dataset that can lead to an unknown output of the dataset [12]. Nevertheless, data reduction can solve the difficulties that both data and visualization scientists suffer [13].

By reducing data in a dataset, data visualization can be more comprehensible with clearer data patterns. With proper data processing, data reduction can generate accurate visualization without changing data patterns [14].

The sampling technique is about choosing a subgroup from a large dataset and at the same time maintaining its properties or attributes [15, 16]. The sampling technique is a crucial way to analyze a massive dataset where its size is reduced for effective use of equipment and space [17].

Moreover, sampling techniques can lower data error that happens due to human factors when dealing with a large dataset [18]. The sampling technique is an outstanding technique to handle large datasets and when the resources are restricted. It generates results rapidly and accurately as data are smaller in size [19]. Normally, data reduction is implemented along with a machine-learning technique to analyze the size of the dataset to find an accurate output [14].

During analysis, it is common to visualize and analyze smaller datasets at a time as it is easier to identify data patterns [7, 20]. On the other hand, a larger dataset is explored at an early stage of data analysis to get a bird eye view and to identify interesting patterns for further analysis [13, 21]. Besides that, a larger dataset is used to understand the structure and the flow of the dataset [13]. However, it is burdensome for the researchers and the algorithms if a large dataset is used to discover data patterns.

Various techniques have been used for data reduction such as pre-processing operations, dimension reduction, compression, network theory, redundancy elimination, data mining, machine learning, data filtering and sampling technique. However, in this study, the sampling technique is chosen as a data reduction technique. It is chosen because it is a well-known technique and consistently gives a positive result in scaling down the number of massive datasets [11].

However, there are various types of sampling techniques. Each is with its own strength and weakness. However, the discussion of these sampling techniques is scattered and not in a single paper. It is inconvenient to gather information from different papers. Thus, this review paper combines various sampling techniques into a single paper to ease their comparison and contrast for further analysis. Besides, the analysis could be used in choosing the right sampling technique for optimum outcome.

To be specific, the objective of this review paper is to understand the various sampling techniques for data reduction. This study is intended to find the answers to three main research questions (RQ) which are: RQ1: What are the various types of sampling techniques to reduce data clutter? RQ2: What are the distinct behaviors of these sampling techniques? Finally, RQ3: What is the outcome of these techniques in various dataset and applications?

To achieve the objectives, this paper starts with an introduction, followed by research method. Then, the paper continues with the synthesis of results, followed by discussion. Finally, the last section summarizes and presents conclusions.

II. RESEARCH METHOD

The aim of this paper is to explore the various types of sampling techniques that can assist in encountering the problem of data clutter and provide a snapshot to a direct future design and research.

Since there are huge research papers available in various areas of research, they need to be filtered in order to focus only on related papers that give most input. Thus, this section focuses on the three steps on how the filtering process is designed.

The first step is to identify research questions, followed by a description for each of the questions. This phase is vital as it gives direction to the filtering process. Next, is to identify related keywords based on the research questions. These keywords become the basis for research paper filtering. Three online databases have been identified that are suitable for cluster analysis. They are ACM Digital Library, IEEE Explore and Science Direct. Lastly, inclusion and exclusion criteria for the research paper are identified. These criteria are used to further filter research papers based on the keywords selected. It is to ensure that the research papers are qualified and within the scope of the research.

A. Research Questions

The first step of the research paper filtering process is to formulate research questions. Thus, to achieve this paper's objectives, it has to answer three research questions as depicted in Table I.

TABLE I. THE RESEARCH QUESTIONS ADDRESSED

Research Questions	Motivation
RQ1: What are the various types of sampling techniques to reduce data clutter?	To identify various sampling techniques that have been used to reduce data.
RQ2: What are the distinct behaviors of these sampling techniques?	Identify the distinct behaviors or attributes of these sampling techniques and how they are different from each other.
RQ3: What are the outcomes of these techniques in various dataset and applications?	Find out how these sampling techniques are being applied in previous research to view it from a bigger perspective.

B. Search Strategy

This paper covers English language articles that have been published from 2017 to 2021. The primary collection method is through online databases. Three popular online research databases have been selected which are ACM Digital Library, IEEE Explore, and Science Direct.

The next step is to identify keywords. There are several sets of keywords that have been built based on the research questions.

Next, the keywords are embedded with Boolean operators which are 'OR' and 'AND' operators. Table II shows the research questions and their related keywords.

TABLE II. KEYWORDS FOR RESEARCH QUESTION

Research Question	Keywords
What are the various types of sampling techniques to reduce data clutter?	"Types" OR "Sampling techniques" AND "Reduce" AND "Data clutter" OR "Data overlap"
What are the distinct behaviors of these sampling techniques?	"Distinct" OR "Behaviors" AND "Sampling techniques"
What are the outcomes of these techniques in various dataset and applications?	"Sampling Techniques" AND "Application"

After the keywords have been built, they are then used to filter the three online databases. The first search string retrieves 85,729 search results on ACM Digital Library, IEEE Explore returns 97,668 search results and Science Direct fetches 2,218,712 results. The second search string receives 138,341 from ACM Digital Library, IEEE Explore returns 241,709 results and Science Direct fetches 2,648,324. The last search string receives 144,579 from ACM Digital Library, IEEE Explore fetches 680,554 results and Science Direct receives 11,397 results. The total for all keywords in three different online databases is 6,267,013 articles.

C. Inclusion and Exclusion Criteria

Once the databases have been filtered, the next stage is to further filter the articles through inclusion and exclusion criteria. This step is to ensure the articles fall within the paper scope. Table III shows the inclusion and exclusion criteria for this research.

TABLE III. CRITERIA OF INCLUSION AND EXCLUSION

Inclusion Criteria	Exclusion Criteria
The research papers published in the English language are included	Papers written other than English language are not included
Primary studies like original research papers are selected	Papers that fail to answer the research questions are excluded
Research papers, book chapters that are relevant to the main topic are selected	Elimination of duplicated papers
Research papers ranging from 2016 to 2021 are included in the studies	Research paper less than two pages are removed

The inclusion and exclusion criteria are applied to the 6,267,013 articles filtered earlier. Then, the references from previous systematic reviews are also added, in order to collect as many papers as possible. Finally, a total of 52 papers have been identified suitable for the review. From the 52 articles, they are then grouped into their related sampling techniques. Fig. 2 shows the tabulation of the papers and their topics on sampling techniques.

The total number of papers on simple random sampling is nine while six papers focusing on systematic random sampling. Stratified random sampling is found in seven papers. Moreover, multi-stage sampling has been discussed in three papers while convenient sampling appears in four papers as well as seven papers on snowball sampling. Lastly, quota and judgmental sampling are each discussed in other two papers.

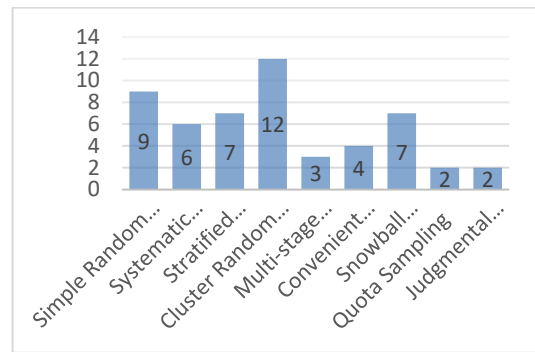

Fig. 2. Histogram for the articles used for each sampling technique

III. SYNTHESIS OF RESULTS

This section answers the research questions as depicted on Table I, by synthesizing and analyzing the knowledge collected from the filtered research papers.

A. RQ1: What are the Various Types of Sampling Techniques to Reduce Data Clutter?

Sampling technique can be divided into two types which are probability sampling and non-probability sampling. Probability sampling is also known as random sampling or representative sampling.

Unlike probability sampling, non-probability sampling does not have a random selection of the sample.

1) *Probability sampling*: Probability sampling chooses the sample data randomly. The data population must be defined precisely to make the sample selection process easier. The advantage of probability sampling is that it can reduce the chances of systematic error during the sampling process [22]. A systematic error is caused by incorrect measurement of data. Moreover, the sampling technique under-probability sampling can reduce bias that is a common problem in sampling technique [22]. It can select sample data fairly without bias. Moreover, sampling techniques in probability sampling can generate a better sample as compared to non-probability sampling [22].

However, probability sampling demands a lot of training. In addition, to ensure the sample data collected is fair and generates the desired outcome, some calculations need to be applied to the technique. Other than that, probability sampling is timely to generate samples because of the calculation and the implementation of the technique happens layer by layer [23]. There are a few techniques that fall under probability sampling which are simple random sampling, systematic random sampling, stratified random sampling, cluster sampling, and multi-stage sampling.

2) *Simple random sampling*: One of the sampling techniques that fall under probability sampling is simple random sampling. Simple random sampling is a sampling where each data in the population has a similar chance to be selected as the sample. Each data in the population can participate to be selected as a sample without exception. Usually, the researcher uses computer-generated random numbers to select the sample. Simple random sampling is

suitable to be used when the entire population is available and the researcher has a list of all subjects from the population [23]. Fig. 3 below shows how the simple random sampling selects samples from the population.

Fig. 3. Selection of sample using simple random sampling

However, using simple random sampling techniques may reduce the possibilities of bias. It is because the dataset is selected randomly, hence there is no bias. The sample from the population is a righteous representative of the whole population [22]. For example, if there exist a few categories in the dataset, all the categories will reform to represent the whole categories. Simple random sampling lowers the vulnerability suitable to the finite size of the sample [23].

Simple random sampling might be pricey and time-consuming if the population involved a broadly spread geographical location. It needs a lot of attempts when a dataset used is large [22]. However, if there is a minority in the population, they will be diminished.

3) *Systematic random sampling*: The next technique of probability sampling is systematic random sampling which makes use of a specific formula to select the sample. The formula is also known as regular interval [24]. The process of data selection is initiated by selecting a random data and then the selection continues at regular intervals [23].

A population can be described based on any characteristics that are suitable for the studies. The characteristics can be age, gender, race, location, and others, as long as there are different characteristics.

Fig. 4 below shows how systematic random sampling selects the sample from the population.

Fig. 4. Selection of sample using systematic random sampling

Systematic sampling is to ensure that the whole population participates in the sampling selection and there is no exception [22]. Thus, there is certainly a sample from each data category since all the categories are involved. Similar to simple random sampling, systematic sampling chooses the sample randomly and the location of the sample is not important as long as all the elements are included [22]. Systematic sampling is less expensive [24].

Due to the calculation that is needed for this technique, it might be timely and requires lots of effort especially if the population involved is scattered in the widely spread geographical area and it is also a challenge to access the population [22].

4) *Stratified random sampling*: One of the sampling techniques that uses strata or subgroups of the population is stratified random sampling. Stratified random sampling uses a subgroup to give an equal possibility to select data randomly from the strata [21]. The population is grouped into similar characteristics and the sample is selected randomly from the subgroup [22]. Stratified sampling is derived from the simple random sampling; hence the sample frame is needed. Fig. 5 below shows how stratified random sampling is selected from the population.

Fig. 5. Selection of sample using stratified random sampling

The advantage of stratified random sampling is the researcher can collect samples from each of the strata and the sample size will be different from each stratum [22]. Stratified random sampling also collects samples from the minority population, hence there is no exception between the majority population and minority population [22]. Thus, stratified sampling can represent the actual data population [25].

However, stratified random sampling is costly, timely and requires a lot of effort due to the subgroup process and randomly selected samples [20, 25]. If the population is not subgrouped into the same characteristic, the entire research may be useless [20]. Hence, before proceeding to select the samples, the researcher must make sure that the population has been subgrouped correctly based on the characteristics.

5) *Cluster sampling*: Cluster sampling is a sampling technique where the samples of the population are from a geographical area that is spread and possible to be accessed simultaneously [21]. The researcher splits the population into clusters based on the geographical area and later extracts the sample from the cluster. Cluster sampling is similar to simple random sampling as the samples are randomly selected from the cluster. Fig. 6 shows how samples are selected from the population using cluster sampling.

Fig. 6. Selection of sample using stratified random sampling

If the population is widely spread over a geographical area, cluster sampling can lessen the cost, time, and efforts

compared to other sampling techniques [26]. Cluster sampling requires less effort and time because the population can be visited once. Moreover, cluster sampling does not need to define the number of clusters prior to processing [27]. The number of clusters is defined after the whole population has been clustered. According to [28], cluster sampling does not require additional information while the algorithm is applied to the population. By using hybrid models, it can enhance the variances for the data [29].

However, cluster sampling might not perform the true diversity of the population [30]. Moreover, biases and systematic errors could happen sometimes. In addition, after the cluster sampling has been applied to the population, it might be challenging to do a correction to the sample [27, 28].

6) *Multi-stage sampling*: The last sampling technique of probability sampling is multi-stage sampling. Multi-stage sampling is similar to cluster sampling where the population is sub grouped into the same cluster and a sample from the cluster is selected in the next process [21].

The advantages of multi-stage sampling are time and cost efficiency. This is because the population is sub grouped into the same category and samples from the subgroup are selected at a later stage [22] which reduced the process flow. The disadvantage of multi-stage sampling is the sample does not represent the population if the selected clusters do not capture the characteristics of the population [22].

7) *Non-probability sampling*: Another type of sampling technique is non-probability sampling where selection is not random. The dataset for this type of sampling does not need to be precisely defined. Unlike probability sampling, non-probability sampling can be used either for specific and general categories.

The advantage of using the non-probability type of sampling is that they require less effort and less time to generate the sample [22]. However, their disadvantage is that they are easily exposed to systematic errors and bias issues [20]. Thus, the samples at times might not be an accurate representation of the population [20].

There are a few sampling techniques that fall under non-probability sampling, which are convenient sampling, snowball sampling, quota sampling, and judgment sampling.

8) *Convenient sampling*: Convenient sampling is the process of selecting sample subjects based on their availability and accessibility [24]. It is common for researchers to conduct interviews from the available pool of respondents as shown in Fig. 7. It is not the researchers' concern if the selected data fail to represent the population.

Fig. 7. Selection of sample using convenient sampling

With this kind of method, data could be collected through online channels where respondents are those who are willing to spend time in the data collection process [31]. Thus, it takes less effort. However, convenient sampling is easily facing problems of biasness and systematic error.

9) *Snowball sampling*: Another non-probability sampling technique is snowball sampling. Snowball sampling is where the researcher makes the first arrangement with a small group of people that are relevant to the subject and uses them as the criterion to contact other people [21]. In other words, data are collected from a small group of respondents and through them, more respondents are identified as illustrated in Fig. 8.

Fig. 8. Selection of sampling using snowball sampling

The technique is suitable when the population is not located in a particular area [24]. It is also suitable for scarce and very small population [22]. Thus, there may occur biases and systematic errors due to non-random network connection [20].

10) *Quota sampling*: Quota sampling is also categorized as non-probability sampling. Quota sampling is commonly used if the elements of the population is not matched with another characteristic of the criteria that has been defined. The population is sub grouped into its same elements and the quota is set for each subgroup.

The advantage of quota sampling is every single subject in the population has its own subgroup. Compared to stratified sampling, quota sampling is less time consuming and inexpensive [22]. However, quota sampling might not be the best method to represent the whole population. Hence, it cannot counter issues where generalizability needs to be made [20].

11) *Judgmental sampling*: Judgmental sampling is the sampling where the subjects of the population are selected by the researcher [20]. The process starts with the researcher generally evaluating the population's characteristics. From there, samples are selected with the aim that they represent the whole population as illustrated in Fig. 9.

There are not many researchers who use this sampling technique because the researcher's judgment might be biased [22].

Fig. 9. Selection of sample using judgmental sampling

In short there are various sampling techniques, and they can be grouped into probability and non-probability. Each has its own behaviors and characteristics. Thus, the next section answers the RQ2 where the sampling techniques differences are analyzed.

B. RQ2: What are the Distinct behaviours of these Techniques?

To answer research question 2 (RQ2) about the distinct behaviors of the sampling techniques, this section compares and contrasts these sampling techniques. Table IV shows their comparison.

TABLE IV. COMPARISON OF SAMPLING TECHNIQUES

Behaviors Sampling Techniques	Use sample	Costly	Bias problem	Timely	Sample represent population	Lots of efforts	Systematic error	Size of population
Simple Random Sampling	Yes	Depends	No	Depends	Yes	No	-	Large
Systematic Random Sampling	Yes	No	-	Yes	Yes	Yes	-	Large
Stratified Random Sapling	Yes	Yes	-	Yes	Yes	Yes	-	Large
Cluster Sampling	Yes	No	Yes	No	Yes	No	Yes	Large
Multi-stage Sampling	Yes	-	-	-	-	-	-	Large
Convenient Sampling	No	No	-	-	-	No	-	From small to large
Snowball Sampling	No	No	Yes	Yes	-	Yes	Yes	From small to large
Quota Sampling	Yes	No	-	No	No	No	-	Small
Judgmental Sampling	No	No	-	No	-	Yes	-	From small to large

The comparison involves a group of probability and non-probability sampling techniques which have been introduced in the earlier sections. The comparison involves a few attributes which are sample, cost, bias problem, time-consuming, population representation, efforts used, systematic error and size of population.

In terms of costing, stratified technique is more costly as compared to others. On the other hand, costing for simple random sampling depends on the dataset size. The bigger the size the more cost involved. Sampling techniques that are less costly are systematic random sampling, cluster sampling, convenient sampling, snowball sampling, quota sampling and judgmental sampling.

Next attribute that is important in the area or sampling is bias. Sampling techniques that are prone to bias are cluster sampling and snowball sampling. Meanwhile, simple random sampling is the least with the issue of bias.

Timely is another attribute for comparison. Sampling techniques that are timely to be executed are systematic random sampling, stratified random sampling and snowball sampling. On the other hand, sampling techniques that are not commonly related to timely issues are cluster sampling, quota sampling and judgmental sampling. While simple random sampling depends on the size of population or dataset. The bigger size, the longer sampling process.

In terms of accurately representing population, the sampling techniques are simple random sampling, systematic random sampling, stratified random sampling and cluster

sampling. Meanwhile, quota sampling is not included in this group of accurately representing the population.

Besides, effort is another attribute of sampling techniques that differ from each other. Systematic random sampling, stratified random sampling, snowball sampling and judgmental sampling require more effort for implementation. On the contemporary level, simple random sampling, cluster sampling, convenient sampling and quota sampling are categorized as less effort when it comes to implementation.

Systematic error is another vital attribute of sampling technique that needs to be compared. Cluster sampling and snowball sampling are prone to systematic error. While for other sampling techniques, it could not be identified whether they are prone to systematic error.

Lastly, population size varies with sampling techniques. Different techniques are suitable for different population sizes. Techniques that use large populations are simple random sampling, systematic random sampling, stratified random sampling, cluster sampling and multi-stage sampling. On the other hand, quota sampling is suitable for a small population. However, convenient sampling, snowball sampling and judgmental sampling need two steps. Thus, the first step is to make use of the small population and the population will grow with time.

C. RQ3: What is the Outcome of these Techniques in Various Dataset and Application

This section is to identify the various applications of the sampling techniques based on the previous research.

The discussion starts with probability sampling and continues with a non-sampling group of techniques.

1) *Probability sampling*: This section discusses the application of various probability sampling in various areas.

2) *Simple random sampling*: Many previous studies used simple random sampling as the technique in their studies. According to [32], to find the random information that is adjacent to the expected distribution, the anticipated distribution and the sampling distribution are extricated frequently by using simple random sampling. The purpose of extracting frequently is to make sure that the population is placed randomly and not follow any arrangement. By combining the simple random sampling technique with Arithmetic Mean which is then known as Random Sampling-Arithmetic Mean (RS-AM), it could reduce the data conflict and increase the sampling accuracy [32]. The benefit of using RS-AM is that an efficient calculation method could be achieved if the distance function is used effectively [32].

Based on [33], block pool is the output of I-sampling. It is also known as the block-based sampling method. It is used with data that has almost similar probability distribution.

The sampling process start with splitting a large dataset into non-overlap data. Next, block pools are created. Finally, the data blocks are randomly be selected from the block pool. This is to ensure data are selected fairly and without bias.

In addition, by using distinct data sizes to randomly extract the documents especially in medical, the chances of certain words appearing in the documents and sentences are high. Identifying the distance between target words in different dimensions is used to categorize the documents and to differentiate the documents. Each alphabet has its own size and distance between each stroke. For the word centroids distance training, random sampling is applied to verify the accuracy of the output and the variety of the selected documents [30, 48].

Simple random sampling can also be used to allocate resources to the network and all subsystems in the Markov chain [31, 34]. It has been proven that simple random sampling can be used in the network and not limited to dataset. Due to the power supply and network restraint, it is suitable to make a schedule especially a wireless network system that incorporates the immense number of nodes. Scheduling is used to ensure the stability of performance specification in the network systems. Scheduling performs independent control loops based on the requirement and overall network supplies.

3) *Systematic random sampling*: Systematic sampling technique is used in an alternative method to estimate the Banzhaf-Owen value in a large class of TU games with scientific [32, 34]. The systematic sampling technique is suitable with the arrangement of a priori unions. Systematic sampling is used as a technique in this study because this technique can handle memory size issues and can reduce massive situations.

In addition, Stochastic bilevel programming is a program that has randomness in the problem, hence it will face problems with computationally expensive and challenging [33, 34]. The randomness that happens in bilevel programming is

the randomness property and hierarchical nature of optimization. Systematic sampling is chosen as the algorithm because this technique will determine a representative from the leader's opinion and hybrid particle swarm optimization procedure.

Another application of systematic sampling is to measure the correlation of two objects. The correlation is defined as the max-min distance between two points set and could identify the parallel between two points [34, 48]. A Measure two-point set is known as Hausdorff distance or HD. HD is difficult to figure out because of a very massive scale point set and at the same time to assure the certainty of HD. Systematic sampling is chosen as the algorithm because it spends less time to choose the sample and achieve maximum dispersion of the sample and the starting point of this sampling is selected random samples [34, 48].

4) *Stratified random sampling*: Stratified sampling is a widely used tool for variance reduction used for failure probability estimation. This study merges the stratified sampling with importance sampling and stratified importance sampling. Stratified sampling is used to reduce the samples to approximately a failure probability with the same coefficient of variation [34, 35].

The common use of stratified sampling is to subgroup the population [34, 36]. Then samples are selected from the subgroup. The sample size is to resolve the strata by acknowledging the compatibility between sampling design and load research objectives. The population from the study consists of electricity tariffs, contract power, geographical area, and region type. Stratified random sampling subgroups the population into the same categories.

In the study conducted by [37, 48], stratified sampling is used to preprocess the wastewater condition dataset that has a sophisticated nonlinear relationship, performance, and MLR models that are not good. The researcher partitions the dataset into different subgroups and selects data points from distinct strata for different purposes. Stratified random sampling trains and tests the dataset that contains the same proposition of each class label [37].

5) *Cluster sampling*: A study conducted by [38] stated that the cluster sampling technique is applied to get a sample from Java software that consists of a similar system and to display the differences between the clusters. The software is grouping into the cluster using the CrossSim algorithm to observe the similarities. After finding out the similarities, the software is clustered using cluster sampling. Lastly, to extract the description of the project and group the systems based on the extraction, Python implementation of the Latent Dirichlet Allocation (LDA) is used.

Moreover, the clustering technique can be used as an alternative technique for subdividing the input space especially involving the high-dimension input spaces and to model MFs into partitions. This study uses the cluster sampling approach initialized ANFIS and MF which can take the entire advantage of intrinsic data distribution. The cluster sampling is used to develop ANFIS nearest-neighbourhood and to allow the online

generation of advanced rules by excluding the nearest-neighbourhood that is not effective anymore [20, 39].

On the other hand, conditional cluster sampling is used as the approach for the current pandemic around the world that is COVID-19. This study is conducted by [40] where conditional cluster sampling is used to test patients in pools rather than individual testing by using a numerical method, statistical data, and machine learning. After the output has been generated for each pool, the researcher makes a decision either to continue the testing or abort it. Conditional cluster sampling is applied to cluster the population depending on the patients' condition. The major reason behind this study is the possibility of COVID-19 critical patients is higher than other patients' diseases.

Lastly [41] stated that the cluster sampling is not efficient as SRS, but it is cost-efficient in the statistical information that is to come across a wide geographical area. Cluster sampling is the most economical when a group of the population element establishes a sampling unit than a single element [41].

6) *Multi-stage sampling*: There are a few studies that used multi-stage sampling as the approach. One of the studies is conducted by [42], where the multistage sampling is the extension to the acceptance sampling technique where the inspection happened several times and only accepted if it travelled as such it covered all stages. This approach is called the multi-stage acceptance technique when the starting test is pursued by the next inspections.

7) *Non-probability sampling*: This section discussed the non-probability type of sampling technique.

8) *Snowball sampling*: The study conducted by [43] stated that snowball sampling is used when it is difficult to approach subjects with distinct characteristics. The study used qualitative research which coordinates the approach of describing people's experiences and internal feelings. This research collects data with a different approach such as interviews, observations, focus groups, narratives, notes, reports, and a review of archives. Snowball sampling assembles the information to approach specific groups of people.

Moreover, [44] using snowball sampling to create samples from simulated networks and cut down the distance from network statistics across network sizes. In this study, snowball sampling generates samples with an identical number of waves and seeds as the samples taken from simulated population networks.

Besides, snowball sampling is used to identify the effectiveness of assumptions about the existence of effects such as network closure and attribute homophiles [45]. This study uses snowball sampling to generate specimens of nodes in a network by applying the network structure itself that can be represented as follows.

Lastly, snowball sampling starts with the entity that has preference characteristics and uses that individual's connection to attract other people with the same characteristics [46]. This study uses a snowball sampling to gain information about the mothers with children that have developmental disabilities.

Mothers are requested to pass the information to other mothers that might have a child that suffered from developmental disabilities. However, previous studies for judgmental sampling, quota sampling, and convenient sampling are quite difficult to find.

IV. CONCLUSION

There are two main types of sampling techniques which are probability sampling and non-probability sampling. The sampling techniques that fall under probability sampling are simple random sampling, systematic random sampling, stratified random sampling, cluster sampling, and multi-stage sampling.

The population involved in the probability sampling can be large as the sampling techniques take the samples directly from the population. Hence, the large population should ensure that the output generated is correct and accurate. Each sampling technique in probability sampling has its methods or calculation to take samples from the population.

The sampling techniques for the non-probability sampling are convenience sampling, snowball sampling, quota sampling, and judgment sampling. The majority of the sampling techniques in the non-probability sampling are suitable for small populations. Thus, most researchers use this sampling technique in their research because of the population size.

On the other hand, non-probability sampling is not quite popular among researchers because of the small population. This can lead to inaccurate output. Therefore, in this paper, there are sampling techniques in non-probability sampling that do not have previous studies. Besides, non-probability sampling majorly uses primary data which could become a burden to researchers.

Probability sampling is usually used by the researcher because the data can be primary and secondary. Hence, the researcher can choose how to gather the data (primary or secondary). Moreover, probability sampling uses a large population that can lead to accurate results because of the number of the population involved in the research.

To make researchers to understand the pattern well, researcher can visualize the graph. One of the well-known visualization graphs is parallel coordinates as it can be used for large and multi-dimensional data set visualization [46, 47]. One of benefits of using parallel coordinates graph is the ability to identify the relationship of multivariate data [20].

Research on the Optimization Problem of Agricultural Product Logistics based on Genetic Algorithm under the Background of Sharing Economy

Na Wang

College of Humanities and Management
Xi'an Traffic Engineering Institute, Xi'an, 710300, China

Abstract—China's national development and reform commission issued the "logistics industry adjustment and revitalization plan" in 2009 to support the development of agricultural product logistics and distribution centers. China's agricultural product logistics and distribution have entered a stage of rapid development. With the rise of the sharing economy, logistics has become a bottleneck restricting the further development of agricultural product distribution. In order to realize the effective cooperation among the main body of agricultural product logistics distribution, improve the distribution efficiency and reduce the distribution cost, a logistics distribution optimization model based on the two-layer planning idea and genetic algorithm is proposed. A two-level programming model is constructed by combining qualitative and quantitative methods, theory and examples, and insertion and deletion operators are introduced to optimize the genetic algorithm. The research results show that the optimized genetic algorithm has a 54.55% increase in convergence speed, 1.08% in performance, and a 54.231% reduction in path length compared to the benchmark algorithm. It effectively improves the efficiency of path planning and saves the planning cost, and the final target value is reduced by 48.19%.

Keywords—Sharing economy; two-level programming; genetic algorithm; path optimization

I. INTRODUCTION

With the rise of the sharing economy, urban residents in my country have higher requirements for the distribution of perishable agricultural products, and relevant online platforms need to have more professional logistics and distribution planning [1]. Due to the late start of the perishable agricultural product distribution network in China, the lack of infrastructure and equipment, and the lack of relevant technical and legal support are discussed in [2]. In addition to strengthening the construction of perishable agricultural product distribution infrastructure and improving relevant laws, it is also necessary to establish an efficient logistics network system for the distribution of perishable agricultural products [3]. In China, the distribution network of perishable agricultural products usually adopts the network model of a single economy. The production base is directly connected with the sales terminal, and the merchant arranges the delivery order according to the user's order delivery time. The lack of overall planning in each link of this model will not only result in waste of transport capacity, but once traffic congestion and other problems occur midway, the goods may not be delivered in time. In order to

build a more reasonable logistics network and solve the problems existing in the layout of the existing logistics network, a genetic algorithm (GA) optimization logistics distribution model for two-level planning is proposed. The upper model is to determine the optimal location of logistics distribution nodes, and the lower model is to determine the best path for logistics distribution. For the optimization of the genetic algorithm, insertion operator and deletion operator are introduced to increase the coherence constraint of path planning and reduce the path mutation before and after the current planning. The combination of node location selection and distribution path optimization in the logistics distribution network can fundamentally realize the coordination and cooperation of various subjects, so as to improve logistics distribution efficiency, reduce distribution costs, and meet consumer demand for quality, time and price.

II. RELATED WORK

The State Information Center of China mentioned in the "China Sharing Economy Development Report (2019)" released on February 28, 2019 that the transaction volume of China's sharing economy market exceeded three trillion yuan, a year-on-year increase of 41.6%, and the number of relevant participants was close to 800 million. The "sharing economy" has become a new economic growth point with huge potential in China [4]. The transaction scale of fresh agricultural products is about 162 billion yuan, maintaining a steady growth of 29.2% [5].

In order to solve the problems of high cost and low resource utilization in the process of logistics distribution under the sharing economy, many domestic and foreign scholars have carried out related research. Scholars such as Lv proposed a linear multi-objective bi-level programming method, the core of which is to replace the lower-level problem with optimal conditions, and use the complementary constraint as the penalty term for the upper-level objective. And introduce the concept of problem equilibrium point and analyze its characteristics, and propose an equilibrium point algorithm based on the penalty method [6]. Scholars such as Zeng proposed a two-level programming model with equilibrium constraints to optimize the planning and design of renewable energy electric vehicle charging stations. The lower-level problem is used to confirm the user's charging strategy [7].

Scholars such as Moon K proposed a two-level programming model to find a single minimum genetic variation by studying the logical reasoning of Boolean networks, and developed a branching and constraint algorithm, which can effectively find all the minimum mutations. The effectiveness of this model is validated through computational studies on a variety of Boolean networks [8]. Song et al. constructed an energy optimal scheduling model based on uncertain two-level programming. The upper model takes the transition matrix of the energy hub as the upper decision maker, and the minimum operating cost in the form of confidence as the objective function; the lower model uses the power subnet, the optimal operation scheme of the thermal energy sub-network and the gas sub-network is the lower-level decision-maker, aiming at the operation economy of each sub-network and taking its operation as a necessary constraint [9]. Aboelnaga Y and other scholars proposed an improved genetic algorithm and chaotic search to solve the two-layer programming problem, which improved the performance and convergence speed of the algorithm, and successfully got rid of the local optimum, allowing the algorithm to solve the global optimum [10].

Scholars such as Zhu believe that a genetic algorithm model based on the attention mechanism is proposed, and the attention mechanism is used to assign different weights to each feature, so that the model can focus more attention on key features. And through the genetic algorithm to optimize the structure of the model and the parameter selection of the data, the global search ability of the model is improved [11]. Wang et al. proposed a multi-objective trajectory planning method based on an improved elite non-dominant sorting genetic algorithm. The trajectory function is composed of a quintic polynomial and a cubic Bezier curve, and then three genetic operators are introduced: sorting group selection, direction-based crossover and mutation with adaptive precision control. The optimal solution of the algorithm is determined through fuzzy comprehensive evaluation to obtain the optimal trajectory [12]. Huang et al. (2022) proposed an adaptive optics technique based on genetic algorithm to detect the twisted wavefront of a laser beam, and then perform aberration correction, which has optimized the performance of two-photon fluorescence microscopy. With the spatial light modulator acting as a wavefront controller, the corrected phase is obtained through a signal feedback loop and a natural selection process [13]. Scholars such as Zemliak (2022) introduced the generalized optimization idea of circuit into the optimization of genetic algorithm, changing the control vector that determines the method of calculating the fitting function makes it possible to bypass the local minimum and find the global minimum, and the accuracy is high, and the central processing unit Time is also greatly reduced [14]. Scholars such as Al-Obaidi et al. (2021) incorporated the developed and validated process model into an optimization framework based on species conservation genetic algorithms to optimize the design and operating parameters of the process. And a multi-objective function is proposed to optimize the membrane design parameters, xylenol repulsion and required energy consumption [15]. Scholars at home and abroad have used two-level programming and genetic algorithm in the field of path planning, and achieved certain results. However, in terms

of genetic algorithm optimization, only the smoothness of a single planned path is considered, but the coherence of multiple planned paths is not considered, and it is impossible to guarantee that the planned path has no mutation [16]. Aiming at the incoherence problem of common genetic algorithms in path planning, this paper proposes an optimization method that introduces insertion operator and deletion operator, and adds coherence constraints in the fitness function, in order to reduce the probability of path mutation and ensure the path Coherence and smoothness of planning.

III. GENETIC ALGORITHM OPTIMIZATION AND TWO-LAYER MODEL CONSTRUCTION

A. Eight-neighborhood Path Selection Genetic Algorithm with Insertion Operator and Deletion Operator

The GA algorithm is an optimization algorithm based on a biological optimization mechanism. It has strong global search ability and scalability, but has problems such as weak local search ability and high randomness [17]. In order to reduce the path length of the transport vehicle, and improve the stability of the vehicle during driving. The research introduces genetic operators such as deletion and insertion on the basis of standard GA algorithm, and correlates with the last path planning result. The main idea is to compare the angle difference between candidate paths. The larger the difference, the lower the weight given to the path and the smaller the probability of being selected. Assume that each path is a chromosome, and each individual in the population corresponds to only one chromosome, and the genes on the chromosome are path grounding singles. Compared with the coordinates, the grid number of the grid is simpler in form, which is convenient for the operation of the genetic operator, so the sequence number of the grid is used to encode the chromosome. Let any $P = [p_1, p_2, \dots, p_n]$ path be a node on the path. $p_i (i = 1, 2, \dots, n)$ As shown in Fig. 1.

Fig. 1. Path coding of improved genetic algorithm.

In Fig. 1, S is the start point of the path and E is the end point of the path. On the node, the p_1 path is chosen $p_1 \rightarrow p_2$ instead $p_1 \rightarrow p'_1$ of, because of $\angle Sp_1p_2 < \angle Sp_1p'_1$. The quality of the initial population of the GA algorithm determines

the quality of the final output of the GA algorithm, and the diversity and randomness of the initial population are important factors affecting the quality of the initial population [18]. The research uses two methods of directed search and random search to generate candidate paths, and the weights of the two methods are equal. When a path node is near the end, no new path nodes are generated and the current path is preserved. When there is an obstacle in front of the generated path node, the path is re-planned. As shown in formula (1) and formula (2).

$$\begin{aligned} x_{i+1} &= (x_G - x_i) \cdot rand + x_i \\ y_{i+1} &= (y_G - y_i) \cdot rand + y_i \end{aligned} \quad (1)$$

$$\begin{aligned} x_{i+1} &= N \cdot rand \\ y_{i+1} &= (y_G - y_i) \cdot rand + y_i \end{aligned} \quad (2)$$

In formula (1) and formula (2), (x_{i+1}, y_{i+1}) is the Cartesian coordinate of the candidate path node, is p_{i+1} the Cartesian coordinate (x_i, y_i) of the current path node p_i , (x_G, y_G) is the coordinate of the coordinate end point, and $rand$ is 0 : 1 a random number between. Genetic manipulation refers to the use of a series of genetic operators to perform operations [19]. Due to the randomness of path and path node generation, there is a probability of adjacent node breakpoints in the path, which is not conducive to genetic operations. And there are redundant path nodes in the randomly generated path, which is not the optimal path.

Research on adding an insert operator to connect breakpoint path nodes, and a new delete operator to delete redundant path nodes. In the GA algorithm, the roulette algorithm is a commonly used selection operation, but the roulette algorithm may lead to a large selection error due to its strong randomness, resulting in the frequent occurrence of individuals with large offspring fitness and falling into a local optimum [20]. The study introduces the deterministic sampling selection method to replace the roulette algorithm, and first calculates the expected survival number of the next generation of individuals, as shown in formula (3).

$$N_i = \frac{M_p f_i}{\sum_{i=1}^{M_p} f_i} \quad (3)$$

In formula (3), M_p is the number of individuals in the population, N_i where i is the expected survival number, f_i of the i th individual, and is the fitness value of the th individual. The integer part is taken N_i as the survival number of individuals in the next generation, the fractional part is sorted in descending order, and the top $M_p - \sum_{i=1}^{M_p} [N_i]$ individual is selected to join the next generation population, which $[N_i]$ is rounded.

In order to avoid the breakpoint path generated by the crossover operation, a single-point crossover method is used for crossover. When there are redundant path nodes in the path, a crossover is randomly selected, and when the path has no redundant path nodes, no crossover is performed. Compared with roulette algorithm, deterministic sampling selection method adopts single point crossing in the crossing process. The algorithm reduces the frequency of individuals with large fitness, effectively avoids falling into local optimum, and improves the local search ability of GA algorithm. In the GA algorithm, the most commonly used mutation method is the random mutation method. In practical problems, however, random variation may lead to poor or even impassable logistics paths. The study adopts the eight-neighbor random non-obstacle node method, as shown in Fig. 2.

In Fig. 2, the path nodes with higher fitness are selected in the eight neighborhoods near the mutation point. When the obtained path is better than the original path, it is replaced with the mutated path, otherwise the original path remains unchanged.

It should be noted that when there is an obstacle between the path node with higher fitness and the target node, another path node with higher fitness needs to be selected. Since the mutation operation will not produce a worse path, the research only performs mutation operation on the optimal path in each generation, which can greatly improve the efficiency and performance of the algorithm. When there is a breakpoint path, the insertion operator fills it with free grids to make it a feasible continuous path, as shown in formula (4).

$$V = \max \{abs(x_{i+1} - x_i), abs(y_{i+1} - y_i)\} \quad (4)$$

In formula (4), at that time, it is determined that the two path nodes are continuous, otherwise it is determined to be discontinuous. $V=1$ When the path is discontinuous, the average method is used to fill the discontinuous path, as shown in formula (5).

$$\begin{aligned} x'_{i+1} &= \frac{(x_{i+1} + x_i)}{2} \\ y'_{i+1} &= \frac{(y_{i+1} + y_i)}{2} \\ n_i &= x'_{i+1} + Ny'_{i+1} \end{aligned} \quad (5)$$

Fig. 2. Eight-neighborhood random non-obstacle node method.

In formula (5), it (x_{i+1}, y_{i+1}) is the coordinates of the free grid, and when it n_i is an obstacle grid, it is n_i filled with the nearest grid grid. In order to reduce the length of chromosomes and improve the efficiency of the algorithm, a deletion operator is introduced. Retrieve all path nodes from the starting point. If the weak current path node and the end point are connected without obstacles, it means that the path nodes in between are redundant nodes. These redundant path nodes should be deleted and the path should be re-planned, as shown in Fig. 3.

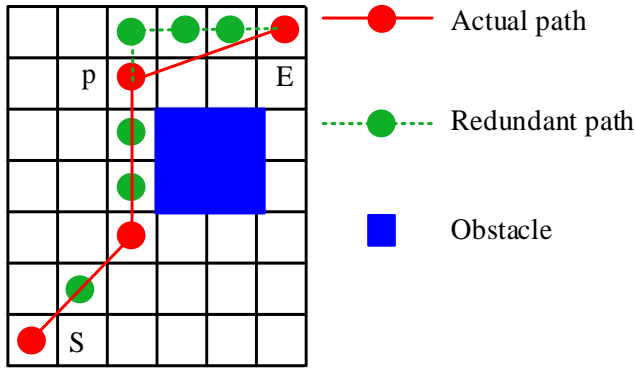

Fig. 3. Paths before and after deleting redundant nodes.

In Fig. 3, redundant path nodes are meaningless and only add computational burden to the algorithm. In particular p , the redundant path nodes between the path node and the end point not only reduce the operating efficiency of the algorithm, but also directly cause the algorithm to fail to select the optimal path. E The elite retention strategy is a commonly used strategy in GA algorithms to ensure that individuals with the highest fitness can be retained after each iteration. Assume that the individual with the highest fitness in the current candidate path is a , compare the fitness of the candidate path a with the fitness of the optimal path so far A , and then use it $a > A$ instead A . The fitness function is a performance index to evaluate the fitness of an individual, which directly affects whether the final output of the GA algorithm is the optimal solution. The purpose of the research is to find the most suitable logistics distribution path and distribution node, so it is necessary to optimize the length and coherence of the path at the same time. The fitness function is shown in formula (6).

$$f(x) = Inf - w_1 \cdot f_1(p) - w_2 \cdot f_2(p) \quad (6)$$

In formula (6), Inf is a large enough real number, w is $f(p)$ the weight, $f_1(p)$ is the path length function, $f_2(p)$ is the path coherence function. As shown in formula (7) and formula (8).

$$f_1(p) = \sum_{i=0}^{L-1} \sqrt{(x_{i+1} - x_i)^2 + (y_{i+1} - y_i)^2} \quad (7)$$

$$f_2(p) = |\theta_k - \theta_{k-1}| \quad (8)$$

In Eq. (7), L is the number of all path nodes, in Equation (8), θ_k is the angle between the direction of the transportation vehicle at the current moment and the planned path, and θ_{k-1} is the angle between the direction of the transportation vehicle and the planned path at the previous moment. The research abstracts the transportation reserve as a mass point, which can θ also be regarded as the expected turning angle of the vehicle, as shown in Eq. (9).

$$\theta = \arctan\left(\frac{x_1 - x_s}{y_1 - y_s}\right) \quad (9)$$

In formula (9), (x_1, y_1) is the first path node after the operator is deleted, and (x_s, y_s) is the starting point coordinate.

B. Construction of Upper Model and Lower Model

Agricultural products include products with simple storage conditions and long storage time, as well as perishable products. Under the sharing economy, the logistics and distribution of agricultural products in cities are mostly perishable products such as fresh and aquatic products, so such products are mainly considered when constructing a two-tier planning model. There are many kinds of perishable agricultural products, and it is difficult to unify the storage conditions of each logistics distribution node, so it is impossible to find suitable variables to calculate the real loss during transportation. All perishable products, even with the most advanced preservation techniques, have a limited shelf life and can be roughly divided into three stages, as shown in Fig. 4.

Fig. 4. Quality-time change of perishable agricultural products.

In Fig. 4, the perishable agricultural products are divided into three stages. The first stage is when the initial time 0 arrives T_1 , the product is in a state of good quality, and the quality of the product declines slowly; in the second stage, the quality of the product is relatively obvious. In this process, the speed of quality decline is accelerated; in the third stage, the quality of the product deteriorates, and the speed of quality decline increases sharply, and it is T_3 no longer suitable for consumption at any time. In the entire logistics network, the investment and construction of distribution nodes is the focus of optimization, and reasonable distribution node construction can greatly improve the ability to collect and disperse goods. Build the upper-level model for decision-making of distribution nodes, and the cost is shown in formula (10).

$$\begin{aligned}
 H = \min & \sum_{r \in G} C_{pr} d_{pr} Z_r + \sum_{r \in G} F_r Z_r + \theta_1 \sum_{r \in G} (t_{pr} Z_r)^2 \\
 & \sum_{r \in G} Z_r \geq 1 \\
 & \sum_{r \in G} Q_r Z_r \geq \sum_{j \in H} q_j \\
 Z_r = & \begin{cases} 1, \text{Create a distribution node at } r \\ 0, \text{else} \end{cases}
 \end{aligned} \tag{10}$$

In formula (10), $\sum_{r \in G} C_{pr} d_{pr} Z_r$, $\sum_{r \in G} F_r Z_r$ and $\theta_1 \sum_{r \in G} (t_{pr} Z_r)^2$ represent the transportation cost of perishable agricultural products from the supplier p to the distribution node r , the construction and operation cost of the distribution node, and the consumption cost of perishable agricultural products in the distribution process, respectively. $\sum_{r \in G} Z_r \geq 1$

Indicates that at least one distribution node must be established, $\sum_{r \in G} Q_r Z_r \geq \sum_{j \in H} q_j$ indicating that the carrying capacity of the distribution node is greater than the demand of the terminal retailer. In actual distribution, the collection and distribution of goods need to be flexibly changed according to the specific requirements of customers. Considering the storage capacity, transportation capacity and time requirements of customers, the lower-level model of distribution path decision-making is constructed, as shown in formula (11).

$$\begin{aligned}
 U = \min & \sum_{i \in S} \sum_{j \in H} \sum_{k \in V} C_{ij} X_{ijk} d_{ij} + \sum_{k \in V} C_k X_k + \sum_{j \in H} R_j E_j + \theta \sum_{k \in V} \left(\sum_{i \in S} \sum_{j \in H} X_{ijk} t_{ij} \right)^2 \\
 & \sum_{k \in V} \sum_{j \in H} C_{ij} X_{ijk} = 1; j \in H \\
 & \sum_{j \in H} \sum_{i \in S} q_j X_{ijk} \leq Q_k; k \in V \\
 & \sum_{i \in S} X_{ijk} - \sum_{i \in S} X_{pij} = 1; k \in V, p \in S \\
 & \sum_{k \in V} X_{rmk} + Z_r + Z_m \leq 2; r \in G, m \in G \\
 & \sum_{i \in S} \sum_{j \in H} X_{ijk} \leq 1, k \in V \\
 & E_{ij} \leq T_j \leq L_{ij} \\
 X_k = & \begin{cases} 1, \text{vehicle } k \text{ is used} \\ 0, \text{else} \end{cases} \\
 X_{rjk} = & \begin{cases} 1, \text{the } k\text{-th vehicle delivers from } r \text{ to } j \\ 0, \text{else} \end{cases}, k \in V, j \in H \\
 Y_{rj} = & \begin{cases} 1, j \text{ deliver from } r \\ 0, \text{else} \end{cases}, r \in G, j \in H \\
 R_j = & \begin{cases} 1, \text{time window met} \\ 0, \text{else} \end{cases}, j \in H
 \end{aligned} \tag{11}$$

In Eq. (11), $\sum_{i \in S} \sum_{j \in H} \sum_{k \in V} C_{ij} X_{ijk} d_{ij}$, $\sum_{k \in V} C_k X_k$, $\sum_{j \in H} R_j E_j$ and $\theta \sum_{k \in V} \left(\sum_{i \in S} \sum_{j \in H} X_{ijk} t_{ij} \right)^2$ points are represented by the distribution cost of the distribution node to the retailer, the use cost of the vehicle, the penalty cost of overtime and the loss cost on the way. $\sum_{k \in V} \sum_{j \in H} C_{ij} X_{ijk} = 1; j \in H$ Indicates that each retailer has only one vehicle for distribution, $\sum_{j \in H} \sum_{i \in S} q_j X_{ijk} \leq Q_k; k \in V$ indicates that the total amount of goods in each distribution route does not exceed the maximum capacity of each vehicle, $\sum_{i \in S} X_{ijk} - \sum_{i \in S} X_{pij} = 1; k \in V, p \in S$ indicates that each distribution process is continuous, and $\sum_{k \in V} X_{rmk} + Z_r + Z_m \leq 2; r \in G, m \in G$ indicates that there is no distribution relationship between the two distribution nodes., which $\sum_{i \in S} \sum_{j \in H} X_{ijk} \leq 1, k \in V$ means that each vehicle belongs to

at most one distribution node, which $E_{ij} \leq T_j \leq L_{ij}$ is the time constraint of the retailer. It can be seen that, whether it is the upper-level distribution node decision-making model or the lower-level distribution path arrangement model, the cost of the entire logistics activity is required to be the lowest. By changing the location class of distribution nodes, the choice of distribution path is affected, and the continuous optimization of the distribution path in turn affects the choice of the location of distribution nodes. This process is a process of mutual influence. The process of solving the model is shown in Fig. 5.

The process of solving the two-layer model is shown in formula (12).

$$p_{ij}^k(t) = \begin{cases} \frac{\tau_{ij}^\alpha(t) \eta_{ij}^\beta(t)}{\sum_{s \in allowed_k} \tau_{is}^\alpha(t) \eta_{is}^\beta(t)}, j \in allowed_k \\ 0, \text{else} \end{cases} \tag{12}$$

In Eq. (12), the α sum β score is denoted by the weight of the distance-influenced heuristic factor. α The larger the value, the more inclined the shorter distance is when planning the path, the β larger the more inclined the path with fewer obstacles. $allowed_k$ Indicates k the path nodes that can be selected in the next planning of the path, τ_{ij} and η_{ij} is the amount of information obtained by the two weights when planning the path. The update of information is shown in formula (13).

$$\begin{aligned}
 \tau_{ij}(t+n) &= \rho \tau_{ij}(t) + \Delta \tau_{ij} \\
 \Delta \tau_{ij} &= \sum_{k=1}^n \tau_{ij}^k
 \end{aligned} \tag{13}$$

Fig. 5. Genetic algorithm to solve the two-layer model.

In formula (13), it $\rho(0 < \rho < 1)$ is the residual coefficient of information, and η_{ij} the update is the same as formula (13), so it is omitted. This process is repeated continuously, and the iteration is stopped when the end condition is satisfied. If it is not satisfied, a new round of optimization is started after jumping to the initialized population.

IV. PATH PLANNING MODEL TRAINING AND EXAMPLES

A. Path Planning using Different Genetic Algorithms in Simple and Complex Environments

Two training scenarios are constructed. The first environment is relatively simple, and the second environment is relatively complex. Assuming that the length of each fence grid is 1, the evaluation indicators are the path length and the number of corners. The comparison algorithms are the A-Star algorithm and the GA algorithm commonly used in path planning, and the results are shown in Fig. 6.

In the simple scenario of Fig. 6(a), all three algorithms successfully plan paths. Among them, the path length of the ImproveGA algorithm is about 13.544 and the number of corners is one. The path length of the StandardGA algorithm is 12.857, and the number of corners is three. The path length of Astar algorithm is 22, and the number of corners is 6. In the complex scene of Fig. 6(b), the path length of the ImproveGA algorithm is about 17.890, and the number of corners is 4. The StandardGA algorithm falls into a local optimal solution and

fails to plan a path. The path length of Astar algorithm is 22, and the number of corners is 7. In a simple scene, the path length of the StandardGA algorithm is 5.72% shorter than that of the ImproveGA algorithm, but the number of corners is three times. In a complex scene, the path cannot be planned because it falls into a local optimal solution. The ImproveGA algorithm can successfully plan paths in both simple and complex environments. Compared with the Astar algorithm, the paths in the two environments are 38.44% and 18.68% shorter, respectively, and the number of corners is much lower than that of the Astar algorithm. In order to further study the performance of the algorithm, the traveling salesman problem dataset maintained by Heidelberg University is used to train the algorithm, and the results are shown in Table I.

In Table I, the path length of the ImproveGA algorithm is optimized by 54.231% and 25.554% compared with the other two algorithms, the maximum yaw angle is optimized by 39.939% and 18.257%, and the sum of the absolute value of the turning angle is optimized by 46.713% and 25.779%. Combining Fig. 6 and Table I, it can be concluded that compared with the Astar algorithm, the GA algorithm has certain advantages, and it can plan the path more flexibly, reduce the turning angle, reduce the path length and the calculation amount of the algorithm, but the StandardGA algorithm is easy to fall into in the face of complexity. The ImproveGA algorithm can not only deal with complex environments, but also has better performance indicators than the StandardGA algorithm.

Fig. 6. Simulation results of path planning scenarios.

TABLE I. PATH PLANNING TRAINING RESULTS

Algorithm	Path length	Maximum yaw angle change	The sum of the absolute values of the corners
Astar	27.18km	32.8°	371.2°
StandardGA	16.71km	24.1°	266.5°
ImproveGA	12.44km	19.7°	197.8°

B. Practical Application of Two-level Planning Model to Logistics Network Optimization

In order to test the optimization effect of the two-level planning model on the logistics network, an example containing five potential distribution nodes and 20 demand points is used for testing. An enterprise selects two out of five alternative distribution nodes to serve 20 demand points, numbers the five alternative distribution nodes as A, B, C, D, E, and the 20 demand points as 1, 2, 3,..., 20. There are a total of five delivery vehicles, all of the same model, and the demand at each demand node is shown in Table II.

For the convenience of calculation, the unit transportation cost is set at 10 yuan per ton per kilometer, and the cost of using vehicles is 50 yuan per vehicle. The average driving speed of the vehicle is 20 kilometers per hour, the load capacity of the vehicle is 20 tons, and the consumption cost of perishable agricultural products is 1 yuan per hour. Since the relative positions of delivery nodes and demand nodes are

fixed, unit price and vehicle cost will not affect the results no matter how they are chosen. The total demand of all demand nodes is 370, and the coordinates and capacities of potential distribution nodes are shown in Table III.

In Table III, the total supply of any two nodes is required to be greater than or equal to 370, so the only combinations considered are point A, any point, and CD. The research uses Matlab to solve the model. Since the problem is not complicated, the fixed value method is used instead of the adaptive probability method in parameter setting. In order to better find the global solution, the initial population size is set to 100. In order to prevent falling into local optimum, the crossover probability is set to 0.5, and the mutation probability is set to 0.05. Due to the large initial population size and low mutation probability, the number of iterations is set to 500 to ensure that the optimal solution can be found. Using fitness as the evaluation index, the change trajectory of the optimal target value is shown in Fig. 7.

TABLE II. C COORDINATES AND DEMAND QUANTITY OF DEMAND NODES

Numbering	X coordinate	Y coordinate	Time window upper limit	Lower time window	Service hours	Demand
1	Twenty-three	28	0	110	10	20
2	52	34	0	120	10	30
3	27	6	0	120	10	15
4	95	38	0	100	10	25
5	64	Twenty-four	0	115	10	10
6	Twenty-three	15	0	120	10	10
7	6	16	0	140	10	15
8	41	10	0	160	10	20
9	38	26	0	105	10	30
10	91	32	0	120	10	10
11	82	14	0	110	10	10
12	64	Twenty-two	0	100	10	5
13	57	71	0	150	10	10
14	56	82	0	100	10	20
15	19	66	0	180	10	10
16	Twenty-two	9	0	105	10	25
17	13	18	0	115	10	25
18	41	35	0	110	10	15
19	69	32	0	115	10	30
20	32	91	0	155	10	35

TABLE III. C COORDINATES AND SUPPLY VOLUME OF EACH DISTRIBUTION NODE

Numbering	X coordinate	Y coordinate	Capacity	Construction Cost
A	3	38	22 0	100
B	54	32	1 70	50
C	41	7	1 90	70
D	50	80	1 80	90
E	25	71	1 70	60

Fig. 7. Trajectory of optimal target value change.

In Fig. 7(a), the two-level programming model using the ImproveGA optimization algorithm tends to converge after about 100 iterations. When the number of iterations is less than 100, the fitness value decreases rapidly. After convergence, the fitness value is 462. The value converges to 459. In Fig. 7(b), the two-level programming model using the StandardGA algorithm tends to converge at about 150 iterations, but the adaptation value will be slower before the 80 iterations. After convergence, the adaptation value is around 461, and the optimal target value converges to 458. In Fig. 7(c), the two-level programming model using the Aster algorithm tends to converge after about 220 iterations, the adaptive value after convergence is about 464, and the optimal target value converges to 464. Compared with the Asters algorithm, the ImproveGA algorithm improves the performance by 1.08% and the convergence speed by 54.55%. It can be seen that although the other two algorithms are not much worse than ImproveGA in terms of optimal target value when used in bi-level programming, there is a large gap in stability and optimization speed. It cannot meet the needs of timeliness in the distribution route planning of perishable agricultural products. The optimal distribution node location and distribution path are shown in Fig. 8.

Fig. 8. Optimal distribution node and distribution path.

Combining Table II, Table III and Fig. 8, it can be seen that if only the optimization of distribution nodes is considered, the selected distribution nodes are also points A and B. Since the distribution is not carried out in a roving manner, the total logistics cost is as high as 1072. However, if only the delivery route is considered and the delivery nodes are not considered, the final target value is 884. The bi-level programming model considers both the distribution node and the distribution route, and the final target value is only 458, which is 57.28% and 48.19% lower than the single problem.

V. CONCLUSION

On the basis of consulting relevant literature and referring to domestic and foreign research results, the distribution network of perishable agricultural products is optimized. The main optimization direction is to establish a two-level planning

model to optimize the distribution node location and route planning of the logistics network. And improve the genetic algorithm in the two-level programming model to improve its path planning ability. Compared with the standard GA, the improved GA introduces insertion and deletion operators in the crossover stage. The improved genetic algorithm, Astar algorithm and standard genetic algorithm are tested for path planning. The performance of the improved genetic algorithm is increased by 18.68% and 38.44% respectively. The maximum yaw angle decreased by 18.257% and 39.939%, respectively, and the sum of absolute angles decreased by 25.554% and 46.713%, respectively. Then, the constructed bi-level programming model is tested, and the improved genetic algorithm can plan the optimal configuration faster than the other two comparison algorithms. Speed increased by 54.55%. Finally, comparing the bi-level programming model with the single-planning model, it is found that the cost of the bi-level planning is reduced by 57.28% compared with only considering the distribution node optimization. Compared with only considering the distribution route optimization, the cost of bi-level planning is reduced by 48.19%. This model can effectively save planning costs and improve delivery efficiency. The limitation of this study is that it simplifies the calculation of consumption cost, which is not enough to fully simulate the actual situation. Therefore, future research will consider adding the loss cost in the calculation to make the experiment more realistic.

Application Research of Trademark Recognition Technology based on SIFT Feature Recognition Algorithm in Advertising Design

Weina Zhang

Department of Publishing and Communication, Shanghai Publishing and Printing College, Shanghai, 200093, China

Abstract—Now-a-days, due to the sharp increase in the number of advertising designs, creative duplication is easy to occur in advertising design. If this situation is not discovered in time, it may cause legal disputes and cause damage to the reputation and property of the enterprise. In view of the above situation, this paper proposes a trademark recognition technology based on SIFT feature recognition algorithm to avoid duplication of advertisement design and cause copyright disputes. Aiming at the defect that the dimension of the image feature vector extracted by SIFT algorithm is too high, the principal component analysis method is used to reduce its dimension. For the problem of unsatisfactory image recognition rate accuracy of SIFT algorithm, a support vector machine is used to classify the extracted feature vector, so as to improve the image recognition rate. Based on the above content, build a trademark recognition model. The research results show that the recognition accuracy of the model reaches 98.82%, 0.66% and 0.58% higher than that of Model 1 and Model 2; AUC value of model 3 is 0.962, 0.039 higher than model 2 and 0.107 higher than model 1. The above results show that the proposed trademark recognition model can better identify similar advertising designs, thereby avoiding design duplication and legal disputes.

Keywords—SIFT algorithm; trademark recognition; advertising design; support vector machine; principal component analysis

I. INTRODUCTION

Good advertising design can keep a product in the memory of consumers for a long time, thereby increasing the popularity and sales of the product. Therefore, advertising design is of great significance to the development of enterprises. Trademark design is an important part of advertising design. Due to the increase in the number of enterprises and the huge number of trademark designs, duplication of ideas is an unavoidable problem. Reputation and property have caused certain losses [1-2]. Therefore, trademark recognition technology based on computer vision technology has gradually emerged and has received extensive attention from all walks of life. It has important applications in product monitoring, trademark protection and commercial information mining. The application of trademark recognition technology in advertising design is as follows: through the identification of trademark design features, trademark images with similar characteristics are matched in the data set, so as to determine whether the design results are repeated with other trademark designs [3]. Scale invariant feature transform (SIFT)

algorithm has strong local feature extraction ability and matching ability, and is less affected by light and noise, so it has an important application in trademark recognition. However, the feature dimension extracted by the SIFT algorithm is high, which leads to long image recognition time and unsatisfactory recognition accuracy, so it needs to be improved [4-5]. The principal components analysis (PCA) is used to reduce the dimensions of the feature vectors extracted by SIFT algorithm, and the support vector machine (SVM) is used to classify the feature vectors. Through the above operations, the trademark recognition model based on SIFT-PCA-SVM is built, so as to improve the efficiency and accuracy of image recognition and matching. The results show that the precision and efficiency of the research model are significantly higher than the existing models. The research builds a trademark recognition model based on SIFT-PCA-SVM to achieve efficient trademark recognition and avoid the repetition of advertising design ideas to the greatest extent. There are three main innovations in the research. The first point is to build a trademark recognition model based on SIFT algorithm to achieve intelligent detection of plagiarism in advertising design. The second point is to use PCA to reduce the dimension of feature vectors and improve the processing efficiency and accuracy of SIFT algorithm. The third point is to introduce SVM to classify the output feature vectors, so as to improve the accuracy of trademark recognition.

II. RELATED WORKS

In today's highly developed economy and technology, the number of enterprises is increasing, and various products are emerging on the market one after another. In an increasingly fierce market environment, excellent advertising can make products more famous, thereby increasing product sales and improving corporate efficiency. Therefore, the importance of advertising design is becoming more and more prominent. In order to improve the effect of advertising design, many scholars take the advertising design of various products as an example, and put forward guiding suggestions for advertising design. Choi SJ et al. assessed the correlation between ad spend and data breaches using a gamma distribution using data from non-federal acute care inpatient hospitals as an example [6]. Kininmonth S believes that the frontier media market will have a certain impact on the advertising industry, and discusses the advertising market prospects under the trend of digital advertising [7]. Shieh CH et al. invited 363

consumers to participate in a field experiment in a shopping mall to explore the correlation between consumers' purchase intention and location-based advertising [8]. Wright MJ et al. used the logistic regression analysis method to discuss and analyze the marketing effect of digital advertising in the case of consumer distraction, and believed that the marketing effect of emotional advertising is better than rational advertising in special circumstances [9]. Lacoste-Badie S et al. took 50 French children as the research object, evaluated the children's attention to the health problems in snack advertisements, and suggested that the French authorities should take measures to strengthen the health warnings in advertisements based on the results [10]. Taking a coffee shop brand as an example, Busser JA et al. used structural equation model to study the impact of consumer-generated advertising on consumers' brand trust and brand loyalty. Brand loyalty has a positive impact [11]. Levin E et al. discussed the relationship between the service quality of advertising companies, advertising companies and customer relationship management from the social and economic aspects [12]. M Méndez-Suárez et al. used the partial least squares equation model to study the impact of Internet advertising and digital advertising on brand awareness, as well as the impact of brand awareness on product sales [13]. Basch CH et al. analyzed the prevalence of sugar-sweetened beverage advertisements on LinkNYC kiosks in New York City to evaluate and recommend the work of the New York Department of Health [14]. Sahin S et al. analyzed the influence of green advertising image on consumer psychology, and the results show that green advertising image can promote consumers' purchasing behavior [15].

The SIFT algorithm is a common algorithm in image processing, which can detect and describe the key features of the image, and is a local feature descriptor. The SIFT algorithm has the characteristics of strong discrimination, more feature vector extraction, and less influence by noise and illumination. It has a key application in digital image feature matching. A large number of scholars have conducted in-depth discussion and analysis on the application and improvement of SIFT. Combining tensor theory and based on spatial and spectral information, LI et al. proposed a tensor gradient SIFT and applied it to feature extraction and matching of hyperspectral images [16]. Li J et al. used PCA and SIFT to predict protein-protein interactions in organisms through protein sequences, and verified by five-fold cross-validation method, the accuracy of this method exceeded 97% [17]. Combining SIFT and patch matching, Henan et al. proposed a 3D view image quality improvement method. The simulation results show that the method has strong feasibility and effectiveness [18]. Raveendra K et al. optimized the performance of SIFT through the global optimization feature of ant colony optimization (ACO), and constructed a hybrid model for document retrieval in the dataset, and the accuracy of the model exceeded 95% [19]. Hwang SW uses artificial neural networks (ANN) and SIFT algorithms to build a model

to automatically classify wood knots based on macroscopic images [20]. Wulandari I et al. introduced the SIFT algorithm in the citra fusion technology and used it in treatment and medical treatment. The experimental results show that the method has good application effect in the medical field [21]. Taking the official currency of Singapore as an example, Prasasti AL [22] proposed a foreign currency identification method based on the improved SIFT algorithm based on ANDROID. Dalai R et al. introduced the SIFT algorithm into the Mask-R-Convolution Neural Network (Mask-RCNN) to extract and match the feature points of the image, thereby realizing image processing and fast detection of objects in the image [23]. Karim A et al. proposed an Arabic handwriting recognition model combining SIFT and SVM. The experimental results show that the recognition accuracy of this model reaches 99.08% [24]. Misra I et al. used the pattern-guided SIFT algorithm for feature detection, thereby improving the accuracy of remote sensing image registration and facilitating subsequent Earth observation data analysis. The experimental results show that the RMSE of this method is 0.12 [25].

As can be seen from the above content, there are many research results on advertising design and SIFT algorithm, but few people apply SIFT algorithm to advertising design. Through the feature extraction and feature matching capabilities of the SIFT algorithm, it can help advertising designers avoid creative duplication, thereby improving the effect of advertising design and increasing corporate profits. To this end, the research builds a trademark recognition model based on the SIFT algorithm, and discusses the practical application effect of the model in advertising design.

III. CONSTRUCTION OF TRADEMARK RECOGNITION MODEL BASED ON IMPROVED SIFT

A. Image Preprocessing and SIFT-Based Trademark Recognition

For the survival and development of enterprises, the use of advertisements to enhance the popularity and sales of products has become a major concern of major enterprises. Therefore, the number of advertisements is increasing, flooding all aspects of people's lives. In advertising design work, especially in trademark design, creative duplication is an unavoidable problem. When the duplication of trademark design is not discovered in time, copyright and legal disputes are likely to occur, causing damage to the reputation and property of enterprises, products and advertising designers. Therefore, it is very necessary to realize trademark recognition through image recognition technology, so as to avoid repeated plagiarism of trademark design. When performing trademark image recognition, it is necessary to extract the feature values of the image to achieve image feature matching. However, the original image has many problems, such as noise and different sizes [26]. Therefore, image preprocessing is required. First, the digital image histogram is used to process the gray value of the image, as shown in Fig. 1.

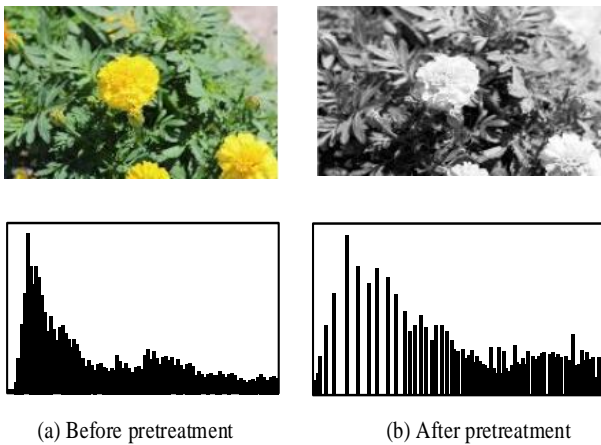

Fig. 1. Gray value processing of image by histogram

Then, a Gaussian filter is used to filter the image, and the Gaussian function is shown in formula (1).

$$g(i, j) = e^{-\frac{(i^2+j^2)}{2\sigma^2}} \quad (1)$$

In formula (3), $[i, j]$ is a certain pixel point, (i^2+j^2) is the radius of the Gaussian function, and σ is the standard deviation. Finally, the redundant data of the image is removed by the method of data compression, and the image compression is realized. Data compression refers to reducing the amount of data processed with the same amount of information. Data redundancy can be expressed as formula (2).

$$R = 1 - 1/C \quad (2)$$

Formula (2), R, C the number of bits of data redundancy and the compression rate are respectively expressed. The definition of the compression ratio is shown in formula (3).

$$C = b/b' \quad (3)$$

Formula (3), b and b' respectively represent the number of bits in the information to be processed before compression and the number of bits in the information to be processed after compression. The SIFT algorithm has strong anti-interference ability, and has excellent feature extraction and feature matching capabilities. The SIFT algorithm is used to build a trademark recognition model. First, the scale space is constructed with the help of Gaussian blur. For an image $L(x, y, \delta)$, whose scale space is set to $L(x, y, \delta)$, its size can be expressed as Equation (4).

$$L(x, y, \delta) = G(x, y, \delta) * I(x, y) \quad (4)$$

In formula (4), (x, y) is I the coordinate of the pixel point of the image, δ which is the scale space factor, and its value determines the smoothness of the image. The δ smaller

the value, the more obvious the detailed features of the image, which $*$ means convolution, which G means the Gaussian function, such as formula (5) shown.

$$G = \frac{1}{2\pi\delta^2} e^{-\frac{\left(\frac{x-m}{2}\right)^2 + \left(\frac{y+n}{2}\right)^2}{2\delta^2}} \quad (5)$$

In formula (5), it m, n represents the dimension of the Gaussian template. SIFT can use Gaussian blur to search for key feature points in each scale space. The calculation of the Gaussian blur template is mainly based on the normal distribution, as shown in formula (6).

$$G(r) = \frac{1}{\sqrt{2\pi}\delta^2} e^{-\frac{r^2}{2\delta^2}} \quad (6)$$

In formula (6), δ is the standard deviation of the normal distribution, the smaller the value, the clearer the image; r it represents the distance between the elements in the fuzzy template and the center of the template; N it represents the dimension of the space where the normal distribution is located. Gaussian blurring is performed on the image at different scales and downsampling is performed to construct a Gaussian image pyramid, as shown in Fig. 2.

Fig. 2. Gaussian image pyramid

The difference between each layer of the Gaussian pyramid is recorded as Difference of Gaussian (DOG), and the key feature points can be obtained by using the difference Gaussian to describe the image features. The extreme points in the DOG space are sampled and detected to locate key feature points. DOG is greatly affected by edges and noise. In order to obtain a more stable image feature description, it is necessary to remove low-contrast and unstable points, which are realized by using Harris Corner detector and two-dimensional Hessian matrix respectively. After obtaining the stable extreme feature points, in order to describe the rotation invariance of the feature points, the pixel gradient and direction of the feature point neighborhood are obtained by calculating the image gradient, as shown in Fig. 3.

Fig. 3. Description of feature point direction

Based on the above content, information such as the position, scale, and direction of the feature points can be obtained, so as to ensure the uniqueness of the feature points. After using the SIFT algorithm to obtain the eigenvalues of an image, the eigenvalues of the image are matched with the eigenvalues of other images to achieve image recognition. However, the eigenvalues between images are not in a one-to-one correspondence, so it is necessary to quickly match the eigenvalues between images through data indexing [27]. The research uses KD-Tree algorithm crop eigenvalue matching algorithm. For two images A and B, first obtain a set of eigenvalues from image A, denoted as $F_a = \{y_1^a, y_2^a, \dots, y_N^a\}$, and denote the set of eigenvalues in image B $F_b = \{y_1^b, y_2^b, \dots, y_N^b\}$ as.

$$d(F_a, F_b) = \sqrt{\sum_{i=1}^n (y_i^a - y_i^b)^2} \quad (7)$$

After obtaining the ratio between the closest distance and the second closest distance, compare whether the ratio satisfies the set threshold, so as to determine whether it is a similar point. Repeat the above operation to match all similar feature points. Through the above content, we can realize trademark recognition and judge whether the trademark design is repeated on a large scale.

B. Optimization path of Trademark Recognition Model based on SIFT Algorithm

When the trademark recognition model based on SIFT algorithm is used for trademark recognition, its recognition effect is more dependent on the quality of the extracted feature values. However, the feature dimension extracted by the SIFT algorithm is high, which leads to long image recognition time and unsatisfactory recognition accuracy. Aiming at the defect that the dimension of the image feature vector extracted by the SIFT algorithm is too high, the PCA algorithm is used to reduce the dimension of the feature vector. Since the image feature vector extracted by the SIFT algorithm is basically 128-dimensional, the dimension is relatively high, and it is very easy to cause a dimensional disaster, resulting in an

exponential increase in the amount of data calculation, which seriously affects the accuracy and efficiency of trademark recognition. The PCA algorithm can simplify the 128-dimensional information, thereby reducing the dimension of the eigenvalue descriptor. The dimensionality reduction process of PCA for eigenvalues is: obtaining a 128-dimensional matrix vector C_x , and each column in the matrix represents an eigenvector. Calculate the covariance of all eigenvectors Σ_x , and obtain the eigenvalues of the covariance matrix by solving Equation (8).

$$\det(\lambda_i I - \Sigma_x) = 0 \quad (8)$$

In formula (8), λ_i represents the i th eigenvector. According to the solution of formula (8), the corresponding eigenvectors are obtained W_i . Considering the acquired feature vector as a column vector W , the new transformed feature is obtained by formula (9).

$$C_Y = C_X W^T \quad (9)$$

In formula (9), W^T is the column vector matrix. Select eigenvectors with larger values and set eigenvectors with smaller values to 0, thereby reducing the eigenvector dimension. The identification and matching of trademark images can be regarded as a binary classification problem. In view of the problem of too many feature points in feature matching, which leads to low efficiency and accuracy, SVM is used to match feature values [28]. SVM is essentially a linear classifier, which has excellent performance for nonlinear identification problems in high-dimensional space. The mathematical model of SVM can be expressed as Equation (10).

$$f(x) = \text{sign}(wx + b) \quad (10)$$

In formula (10), w the normal vector of the b classification surface is represented, and the constant term of the classification surface is represented. When formula (11) is satisfied, it means that the current hyperplane is the optimal hyperplane.

$$wx + b = 0 \quad (11)$$

After obtaining the optimal hyperplane by formula (11), in order to make the model more optimized, it is necessary to find the farthest distance from the sample points of different sample classifications in the data set to the hyperplane, so as to find the maximum interval hyperplane. The specific model is shown in the Fig. 4.

Fig. 4. Schematic diagram after optimization of support vector machine

$$K(x_1, x_2) = \phi(x_i) \cdot \phi(x_j) \quad (14)$$

Through the formula (14), the inner product operation is performed in the high-dimensional space to obtain a nonlinear classification decision function. SVM mainly solves the two-class problem, and has poor performance for solving the multi-class problem. The classification of trademark image feature values is a multi-classification problem, so it is necessary to build a multi-classifier according to SVM. There are generally two ways to construct the SVM multi-classifier. The first is to modify the objective function of the multi-classification problem, so as to solve the multi-classification problem at one time. However, this method requires a huge amount of calculation, takes a long time, and the establishment of the objective function is very difficult. Therefore, another method is used to construct SVM multi-classifiers in this study, that is, construct n binary classifiers, and perform the analysis on these binary classifiers. Combinatorial solutions to solve multi-class problems. When the feature values of the image have N classes, the number of binary classifiers of SVM is shown in formula (15).

In Fig. 4, the maximum margin hyperplane solution can be transformed into the function minima problem in Eq. (12).

$$\phi(w) = \frac{1}{2} \|w\|^2 \quad (12)$$

$$n = \frac{N(N-1)}{2} \quad (15)$$

By formula (12), some linear problems can be solved. However, for nonlinear problems, SVM needs to use the conversion function to upgrade the original space to convert the original problem into a linear problem in a high-dimensional space, so as to facilitate the calculation and solution of the optimal classification hyperplane in the high-dimensional space, and finally to the non-linear problem. Solve linear problems. In SVM, the process of converting a nonlinear problem into a linear problem using a transfer function is shown in Fig. 5.

By combining the binary classifiers, the voting method is used to obtain the category of the feature value of the trademark image. Based on the above content, a trademark recognition model based on SIFT-PCA-SVM is constructed, so as to realize the recognition and matching of trademark images, prevent legal disputes caused by plagiarism and infringement, and avoid economic and reputation losses of enterprises and advertising designers.

Fig. 5. The process of transforming a nonlinear problem into a linear problem

IV. PERFORMANCE ANALYSIS OF TRADEMARK RECOGNITION MODEL BASED ON SIFT-PCA-SVM

In the research, the Sigmoid kernel function is used as the transformation function. The expression of the sigmoid kernel function is shown in formula (13).

$$K(x_1, x_2) = \tanh(\eta \langle x_1, x_2 \rangle + \theta) \quad (13)$$

In Formula (13), η is the learning rate and θ is the vector feature. Nonlinear mapping $\phi: R^d \rightarrow H$ can map the sample data in the input space to the high-dimensional feature space H, the kernel function K can be used to obtain formula (14).

Aiming at the problem that the current trademark design is prone to creative duplication and legal disputes, this paper studies the construction of a trademark recognition model based on SIFT-PCA-SVM. In order to verify the performance of the model, the research uses the FlickrLogos dataset for experiments. The FlickrLogos dataset contains images related to 32 kinds of trademarks. The study selects 3000 images, of which 2500 images are used as the training sample set to train the model, and the other 500 images are used as the test sample set to test the performance of the model. The test environment is as follows. The operating system uses Windows, OpenCV3.0 alpha as the development tool, and Python as the programming tool. The processor is Intel (R) Core (TM), and the memory is 6GB. The data of training sample set and test sample set are preprocessed by the method proposed in the study. Build a trademark recognition model based on SIFT algorithm (Model 1), a trademark recognition model based on SIFT-SVM (Model 2) and a trademark recognition model based on SIFT-PCA-SVM (Model 3), respectively, and compare the training of the above three models Effects and test effects to validate the performance of the proposed trademark identification method in the study. The three models are trained using the training sample set. During the training process, the performance of the three

models is shown in Fig. 6.

Fig. 6. The performance of the three models in the training process

As can be seen in Fig. 6, the training performance of Model 3 is significantly better than the other two models. Model 3 achieves the target accuracy when the training time is 241 seconds; Model 2 achieves the target accuracy when the

training time is 393 seconds, which is 152 seconds more than the training time of Model 3; Model 1 achieves the target accuracy when the training time is 476 seconds, more than Model 3 takes 235 seconds more to train. From the above results, it can be shown that the training performance of Model 3 is better, which can greatly save training time and improve the efficiency of trademark recognition. Aiming at the defect that the dimension of image feature vector extracted by SIFT algorithm is too high, the PCA algorithm is used to reduce the dimension of its feature vector, so as to reduce the number of invalid feature points extracted and improve the feature extraction efficiency and feature matching accuracy. In order to verify the improvement effect of the PCA algorithm on the SIFT algorithm, the study randomly selects three trademark images from the FlickrLogos data set, denoted as image A, image B and image C respectively. Three images are used to test the feature point extraction effect of SIFT algorithm and PCA-SIFT algorithm. The number of feature points extracted by the SIFT algorithm and the PCA-SIFT algorithm for the three images and the matching accuracy of the feature points are shown in Fig. 7.

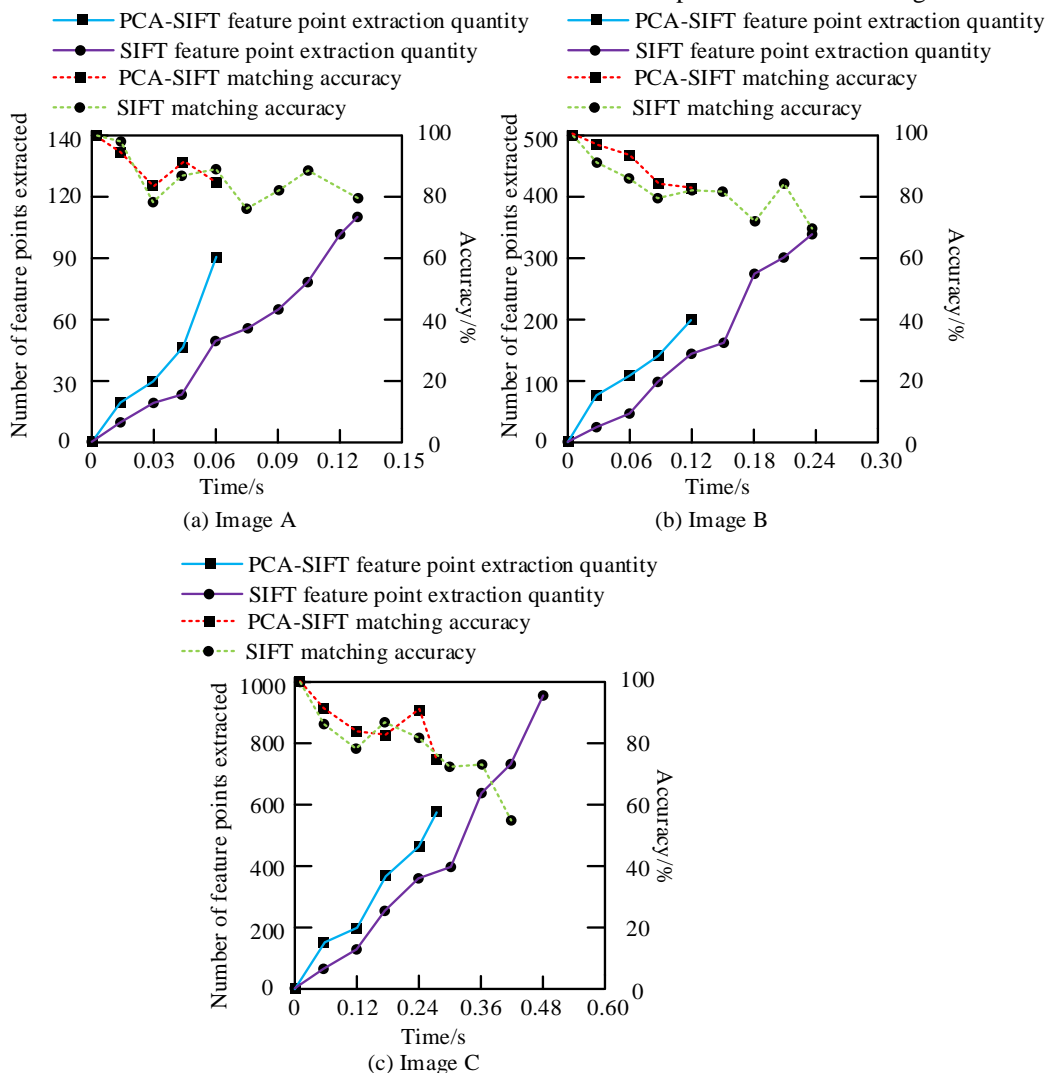

Fig. 7. Improvement effect of PCA algorithm on SIFT algorithm

In Fig. 7, it can be seen that when processing the same image, the number of image feature points and feature point extraction time of the PCA-SIFT algorithm are significantly lower than those of the SIFT algorithm, and the feature point matching accuracy is significantly higher than that of the SIFT algorithm. For the three images, the average extraction time of feature points of PCA-SIFT algorithm is 0.16s, the average number of feature points extracted is 284, and the average matching accuracy of final feature points is 80.62%; the average extraction time of feature points of SIFT algorithm is 0.31s, Compared with the PCA-SIFT algorithm, the average number of feature points extracted is 485.2, which is 201.2 more than that of the PCA-SIFT algorithm. The average matching accuracy of the final feature points is 78.41%, which is 2.21% lower than that of the PCA-SIFT algorithm. The identification and matching of trademark images can be regarded as a binary classification problem. In view of the problem of too many feature points in feature matching, which leads to low efficiency and accuracy, SVM is used to match feature values. In order to verify the recognition accuracy of the proposed trademark recognition model, a test sample set was used to test Model 1, Model 2 and Model 3 to compare the trademark recognition accuracy of the three models, as shown in Fig. 8.

In Fig. 8, the trademark recognition accuracy of Model 3 is significantly better than Model 1 and Model 2, and the number

of iterations required to achieve the best accuracy is also significantly less than Model 1 and Model 2. The trademark recognition accuracy of Model 3 is 98.82 %, which is 0.66% higher than Model 1's 98.16% and 0.58% higher than Model 2's 98.24%. In the FlickrLogos dataset, images of four trademarks including Adidas, Aldi, Apple, and Becks were selected for testing. For the above four trademarks, the recognition time and recognition accuracy of the three models are shown in Table I.

Fig. 8. Trademark recognition accuracy of three models

TABLE I. RECOGNITION TIME AND ACCURACY OF THREE MODELS

Model	Trademark	Time/s	Accuracy/%
Model 1		68.6	89.32
Model 2	Adidas	32.4	93.65
Model 3		35.3	98.42
Model 1	Aldi	76.6	86.46
Model 2		44.3	92.03
Model 3		45.6	98.14
Model 1	Apple	55.2	90.06
Model 2		24.0	96.33
Model 3		26.8	99.25
Model 1	Becks	108.4	88.44
Model 2		65.3	91.09
Model 3		70.2	98.62
Model 1	Average	77.2	88.57
Model 2		41.5	93.28
Model 3		44.5	98.61

In Table I, the trademark recognition accuracy of model 3 is significantly higher than that of model 1 and model 2, and the recognition time of model 3 is much shorter than that of model 1, slightly higher than that of model 2. Among them, in the identification of Adidas trademark, the identification time of model 3 is 35.3s, and the identification accuracy is 98.42%; The recognition time of model 2 is 32.4s, 2.9s less than model

3, and the recognition accuracy is 93.65%, 4.77% less than model 3; The recognition time of model 1 is 68.6s, 33.3s more than model 3, and the recognition accuracy is 89.32%, 9.10% less than model 3. This shows that the accuracy and efficiency of Model 3 are much higher than those of Model 1 and Model 2. In order to further evaluate the performance of the three models, the area under the ROC curve is introduced to evaluate the three models. Generally speaking, the larger the

AUC value is, the better the performance of the model is. Test the two prediction models with the test data sample set, and the AUC curves of the three models are shown in Fig. 9.

Fig. 9. AUC curve of three models

As can be seen in Fig. 9, the AUC value of Model 3 is 0.962, which is 0.039 higher than Model 2's 0.923 and 0.107 higher than Model 1's 0.855. To sum up, the proposed SIFT-PCA-SVM-based trademark recognition model can identify trademarks with high efficiency and high precision, so as to avoid legal disputes caused by infringement and plagiarism, and has positive significance for advertising design.

V. CONCLUSION

Aiming at the problem that the current trademark design pattern is easy to repeat and causes legal disputes such as plagiarism and infringement, an SIFT-PCA-SVM algorithm is proposed to build a trademark recognition model. The experimental results show that model 3 achieves the target accuracy when the training time is 241s, 152 seconds less than model 2, and 235 seconds less than model 1. The trademark recognition accuracy of model 3 is 98.82%, 0.66% higher than 98.16% of model 1, and 0.58% higher than 98.24% of model 2. The area under ROC curve is introduced to evaluate the three models. AUC value of model 3 is 0.962, 0.039 higher than 0.923 of model 2, and 0.107 higher than 0.855 of model 1. In conclusion, the trademark identification model based on SIFT-PCA-SVM proposed in the study can identify trademarks efficiently and accurately, so as to avoid legal disputes caused by infringement, plagiarism and other issues, which is of positive significance to advertising design. The trademark recognition model proposed in the study is mainly used to identify the problem of pattern type advertisement design plagiarism. The recognition effect of video and audio advertisement design plagiarism is poor, which is also the direction that needs to be improved in the next step of the study.

Abstract—The number of social media users has increased. These users share and reshare their ideas in posts and this information can be mined and used by decision-makers in different domains, who analyse and study user opinions on social media networks to improve the quality of products or study specific phenomena. During the COVID-19 pandemic, social media was used to make decisions to limit the spread of the disease using sentiment analysis. Substantial research on this topic has been done; however, there are limited Arabic textual resources on social media. This has resulted in fewer quality sentiment analyses on Arabic texts. This study proposes a model for Arabic sentiment analysis using a Twitter dataset and deep learning models with Arabic word embedding. It uses the supervised deep learning algorithms on the proposed dataset. The dataset contains 51,000 tweets, of which 8,820 are classified as positive, 37,360 neutral, and 8,820 as negative. After cleaning it will contain 31,413. The experiment has been carried out by applying the deep learning models, Convolutional Neural Network and Long Short-Term Memory while comparing the results of different machine learning techniques such as Naive Bayes and Support Vector Machine. The accuracy of the AraBERT model is 0.92% when applying the test on 3,505 tweets.

Keywords—Arabic sentiment analysis; machine learning; convolutional neural networks; word embedding; Arabic word2Vec; long short-term method; AraBERT

I. INTRODUCTION

Recently, sentiment analysis has been prioritized by researchers because it plays an important role in many domains. It is primarily used to study user feedback (user opinion) on a specific event, product or social phenomenon. Many studies have proposed models, approaches or novel databases to predicate and detect user opinions. These methods use machine learning classifiers, deep learning models and natural language techniques as pre-processing methods. Most of the sentiment analysis research focuses on languages other than Arabic. Recent Natural Language Processing research is now increasingly focused on using deep neural learning [1]. Some research initiatives are being launched in a competition funded by the King Abdullah University of Science and Technology (KAUST). They focus on the Arabic language and some individual research efforts.

Generally, in other languages, specifically English, the universal language has proven to be significant due to the vast amount of data contributed by users on social networks (Facebook, Twitter, etc.). In machine learning, a classification known as supervised learning is used in sentiment analysis. There are several methods used in sentiment analysis which can be categorized into binary classification, multi-classification, polarity, multilingual and aspect-based sentiment analysis. In binary classification, the classes can be represented only as positive and negative. In multi-class, there are more than two classes. Additionally, there are classifiers used in binary classification such as DT and TH, while KNN and LR are used in multi-classification. Polarity in sentiment analysis is based on a dictionary that assigns a score to each word. Multilingual sentiment analysis requires many pre-processing steps to be performed in option detection and aspect-based. It is focused on one aspect, concept or word.

To the best of our scholarly knowledge, less attention has been given to Arabic sentiment analysis and there are fewer public Arabic datasets [2]. Therefore, this paper proposes a model for Arabic sentiment analysis based on the proposed dataset. This work uses supervised deep learning algorithms. The original dataset before the cleaning process contains 51,000 tweets classified as 8,820 positive, 37,360 neutral and 8,820 negative. After cleaning, it contains 31,413 tweets classified as 4,855 positive, 21,842 neutral and 4,716 negative. This work introduces and applies deep learning methods on Arabic sentiment analysis text multi-classes with parameter optimization, and improves the process in the text pre-processing area. We apply the deep learning methods Convolution Neural Network (CNN) and Long Short-Term Memory (LSTM) to compare the results of different supervised machine learning techniques such as Naive Bayes (NB) and Support Vector Machine (SVM). The accuracy of the best CNN model is 95.8% and the accuracy of LSTM is 96.6%, which are better than the SVM and NB results, which are 82.5% and 69.4%, respectively. We used BERT pre-trained specifically in Arabic to achieve the same success that BERT achieved in English [3]. Based on a review of the literature and the high accuracy achieved in the deep learning models, the main contributions of this paper can be summarized as follows.

- Develop a model for Arabic sentiment analysis using machine learning and deep learning models.
- Explore the most recent approaches to Arabic sentiment analysis.
- Propose a novel dataset called ASAD that is publicly available.
- Perform a comparative analysis of the results of MLC and DLM.

The remainder of this paper is organized as follows: Section II presents an overview of related studies on sentiment analysis. Our research methods and materials are explained in Section III. Section IV presents the results. The conclusion is in Section V.

II. RELATED STUDIES

Scholars have not given enough attention to the Arabic Sentiment Analysis Dataset (ASAD). It [4] provides a comprehensive overview of a new Twitter-based benchmark dataset for Arabic sentiment analysis. ASAD is a massive, high-quality annotated dataset (including 95,000 tweets) with three-class sentiment labels, compared to other publicly released Arabic datasets (positive, negative and neutral) in [5], researched Twitter's sentiment analysis. Three machine learning algorithms are used, Logistic Regression, Aid Vector Classification, and NB, with two sets of characteristics. The word frequency approach, word embeddings, and machine learning classifiers can correctly identify rumour-related tweets with 84% accuracy, which classifies tweets into four categories: academic, media, government and health [6].

In [7], two new Arabic text categorization datasets are introduced. The first consists of Twitter, Facebook and YouTube posts from well-known Arabic news channels, and the second consists of tweets from popular Arabic accounts. In modern standard Arabic, the papers in the former are almost entirely written (MSA), while the tweets in the latter contain both MSA and dialectal Arabic.

In [8], Word2Vec models were collected from 10 newspapers in different Arabic countries from a broad Arabic corpus. The reports increased the accuracy of sentiment classification after applying various machine learning algorithms and convolution neural networks with different text feature choices (91%–95%).

In [9], an in-house-built dataset shows tweets and comments where three classifiers were applied, including NB, SVM and K-Nearest Neighbour, in particular. The findings show that SVM provides the highest accuracy, while KNN (K=10) provides the highest recall.

In [10], four classifiers were trained to incorporate a dataset consisting of 4,712 tweets to conduct a comparative study on the output of the classifiers, namely NB, SVM, Multinomial Logistic Regression and K-Nearest Neighbour. When running against the tweet's dataset, these algorithms revealed that SVM gives the highest F1 score (72.0), while KNN (K=2) achieved the best accuracy, equivalent to 92.0.0.

In [11] the processes of gathering Twitter data and filtering, pre-processing and annotating the Arabic text to create a large dataset of sentiment analysis in Arabic are summarized. In addition to deep learning and CNN, machine learning algorithms (NB, SVM, and Logistic Regression) were used on the health dataset in the sentiment analysis experiments. The keywords are Machine Learning, Deep Neural Networks, Arabic Language and Emotion Analysis.

Several versions of RNN and CNN classifiers using GloVe-based word embedding were introduced. All classifiers performed well, while the classifiers between 90% and 91% had the highest accuracy. Experimental findings indicate that BRAD 2.0 is rich and stable [12]. To encourage more study in the field of Arabic computational linguistics, the benchmark dataset was made available as the key contribution.

In [13] a new mix model from CNN and LSTM is proposed using vector representations of sentences and the SoftMax regression classifier to identify the sentiment tendencies in the text. In [14] a method for evolving the CNN and creating an Arabic sentiment classification system is proposed using the differential evolution (DE) algorithm. In [15] a novel architecture for Arabic word classification and understanding is proposed. This is based on CNNs and recurrent neural networks that address the difficulty of handling unstructured social media texts in low data availability. Therefore [16] attempts to identify expressions related to feelings, such as happiness, rage, anxiety and sadness. In addition, it presents the emotion classification in Arabic tweets by using the CNNs and compares them with the machine learning methods SVM, NB and Multi-Layer Perceptron (MLP).

In [17] an Arabic sentiment analysis corpus culled from Twitter is presented, consisting of 36,000 tweets categorized as positive or negative, plus 8,000 tweets manually annotated and used to assess the corpus intrinsically by comparing it to human classification and pre-trained sentiment analysis models, with an accuracy of 86%. In [18] a survey is proposed that focuses on 90 recent research papers (74% were published after 2015). In [19] supervised and unsupervised transformation methods, such as principal component analysis (PCA) and latent Dirichlet allocation (LDA), are presented. They are tested on five Arabic opinion text datasets of various domains and sizes (1.6–94,000 reviews). In the two-class classification problem, accuracy values range from 95.5%–99.8%, and for the three-class classification problem, accuracy values ranged from 92%–97.3%.

In [20] a new study is presented to develop a new model to predict an individual's awareness of the precautionary procedures. Tweets related to COVID-19 were collected from the five main regions in Saudi Arabia, and the accuracy level achieved was 85%. A systematic comparative overview of the most appropriate methods for analysing Arabic sentiment is presented in [21]. It carries out a thorough comparison of various machine learning methods for Arabic sentiment analysis, such as NB, SVM, CNN, LSTM and several recently developed language models. The model achieves F-scores of 0.69, 0.76 and 0.92. A method for extracting knowledge from Arabic text on social media in four stages – data collection, cleaning, enrichment and availability – is shown in [22]. It

offers an integrated solution for the challenges of pre-processing Arabic text on social media. This was undertaken to investigate the performance metrics as given in [23, 24, 25, 26, 27, 28, 29] and validates the proposed model for small-and large-scale datasets. Disambiguation using the deep learning techniques with the Arabic corpus is presented in [30]. An Arabic model for text clustering using word embedding and Arabic word net is presented in [31].

III. METHODOLOGY

This section describes the research methodology that was used to conduct this research. It consisted of six main interrelated phases: text retrieval; text pre-processing; tokenization and feature extraction; application of the deep learning model; model performance evaluation as shown in Fig. 1; and use of the transfer learning by applying the AraBERT Model.

The analysis concentrated on three cases of tweets, positive, negative and neutral. To perform the sentiment analysis experiment, the large number of collected tweets was necessary. A lot of noisy data was used in the total number of tweets (51,000 tweets). The model architecture is shown in Fig. 1. The first phase in this work is text retrieval; the second is text cleaning; the third is tokenization; the fourth is embedding the text using the Word2Vec corpus in [32]; the fifth is to apply deep learning models; and the last phase is to evaluate the results.

Fig. 1. Model architecture

A. Tweet Text Retrieval

This section describes the first phase, text retrieval. Data retrieval is performed using Tweepy API, and because the text characters are in Arabic, we implemented an Arabic text retrieval module using the Tweepy Twitter API library in Python.

B. Text Pre-Processing

Improving the accuracy of the text classification required enhancing the text features [22]. We added some feature selection improvements, such as noise removal. Removing the

noisy characters from the text enhanced the word representation. The following steps were run on the text to remove the noisy data.

- Remove the advertisement tweets.
- Remove the retweeted tweets, which started with the segment 'RT'.
- Remove the duplicate tweets, which were retrieved more than once.

1) *Normalization*: Normalization is a pre-processing method of text data cleaning, to format a sequence of texts into a standard uniform [33]. It is difficult to analyse Arabic texts because of the nuances of the language, both in terms of infrastructure and conformation. Arabic has an abundance of diverse inflexions, dialects and spellings that change the meanings of the words. Using special labels, called configuration, rather than vowels, they differ according to the shape of the word. This method is necessary and useful in word processing to minimise uncommon terms and increase classification accuracy. The following steps were applied to the stored tweets in the dataset on two levels. The first level retained the emoji and the second level removed the emoji from the data collection phase.

- Remove digits, non-Arabic letters, single letters, punctuations, diacritics and special characters (\$, %, &, #, .).
- Separate all words by spaces.
- Remove (ات, ين, ون, ان, وا, ها) from the end of the word.
- Remove (ال, تال, وكال, كال, وال, وتال, ولال, لل) from the beginning of the word except إله الله, الله, اللهم.
- Normalize some characters with a single character, such as (أ, إ, !,) with (ا), (ئ, ي) with (ى) and (ة) with (و).
- Replace repeated characters (e.g., ياااa) with a single character (e.g., يارب).

2) *Stop words removal*: Stop words are words that do not affect the meaning of the sentence, and eliminating the stop words from the text helps to identify the most important words as the following [34].

- Relative pronouns (الأسماء الموصولة)
- Referral names/determiners (أسماء الإحالة / المحددات)
- Transformers (verbs, letters) (المحولات (الأفعال والحروف))
- Verbal pronouns (الضمائر اللفظية)
- Adverbs (الاحوال)
- Interrogative pronouns (ضمير الاستفهام)
- Conditional pronouns (الضمير مشروط)
- Prepositions (حرف جر)
- Pronouns (الضمائر)

a) *Pre-processing*: We performed pre-processing operations on the data, such as removing the stop words, special characters, such as '@' and '#', URLs, non-Arabic characters and punctuation to create a clear analysis of the text. In addition, we used NLTK (<https://www.nltk.org>) word tokenization on the text data (refer Table I)

TABLE I. SAMPLES OF TWEETS BEFORE AND AFTER THE NOISE CLEANING PROCESS

#	Label	Text before cleaning	Text normalized with emoji retained	Text normalized with emoji removed	English meaning
1	Neutral	عندي @elm مشكلة لما تبي اجدد إقامة عامل حاولت اتواصل بس يفصل معي الخط من قبل مقيم	عندي مشكلة لما تبي اجدد إقامة عامل حاولت اتواصل بس يفصل معي الخط من قبل مقيم	عندي مشكلة لما تبي اجدد إقامة عامل حاولت اتواصل بس يفصل معي الخط من قبل مقيم	I have a problem when I want to find the residency of a worker, I tried to contact me, but the line was separated by a resident
2	Positive	@nas_alharbi8 والله حسب الأرقام سيكون مخيب للأمل ولكن الأهل قدها برجاله في الملعب	والله حسب الأرقام سيكون مخيب للأمل ولكن الأهل قدها برجاله في الملعب	والله حسب الأرقام سيكون مخيب للأمل ولكن الأهل قدها برجاله في الملعب	By God, according to the numbers, it will be disappointing, but Al-Ahly has led it with its men on the field
3	Neutral	الزعل بيغير ملامحك ، بيغير نظرة العين ، بيغير شكلك في الصور ، الزعل ممكن يطفيك تماما	الزعل بيغير ملامحك ، بيغير نظرة العين ، بيغير شكلك في الصور ، الزعل ممكن يطفيك تماما	الزعل بيغير ملامحك ، بيغير نظرة العين ، بيغير شكلك في الصور ، الزعل ممكن يطفيك تماما	Upset changes your features, changes the look of the eyes, changes your appearance in the photos, upset you can completely eliminate you
4	Positive	ثقي قلباً وقالياً معاك وفخورين فيك وين مرحتي وربّي يوفّقك ويسهّلك طريقك https://t.co/N8vVjcwD08	ثقي قلباً وقالياً معاك وفخورين فيك وين مرحتي وربّي يوفّقك ويسهّلك طريقك	ثقي قلباً وقالياً معاك وفخورين فيك وين مرحتي وربّي يوفّقك ويسهّلك طريقك	Trust your heart and soul with you and be proud of you. Where have you gone, and my Lord will help you and make your way

5	Negative	هذا المخلوق ينتمي إلى المجتمع الشيطاني ما في منه اي خير https://t.co/1YoS64SKJZ	هذا المخلوق ينتمي إلى المجتمع الشيطاني ما في منه اي خير	هذا المخلوق ينتمي إلى المجتمع الشيطاني ما في منه اي خير	This creature belongs to the satanic community, there is no good in it
6	Negative	ادور لعيني النوم لو كانه سلف .. من بارحة الاولى و انا اودي و اجيب	ادور لعيني النوم لو كانه سلف من بارحة الاولى و انا اولادي و اجيب	ادور لعيني النوم لو كانه سلف من بارحة الاولى و انا اولادي و اجيب	I turn to my eyes to sleep if it was an ancestor from yesterday and I am my children and I answer

Fig. 2. Dataset statistics

Fig. 2 shows the dataset before and after cleaning. As the dataset published by [34] contains IDs and annotations only, the first step must be to retrieve the tweeter text using the authorized API object from Tweepy, using the API to retrieve all IDs from the file one by one.

3) *Tokenization*: Tokenization is the method used to break down text into individual tokens separated by white space. Tokenization removes all special characters, determines phrase boundaries, and processes abbreviations and numbers [35]. Due to the morphological complexity of the language, the number of tokens in Arabic can exceed four. Since Arabic words often contain many affixes and clitics, the tokenization process was preceded by a segmentation process to eliminate suffixes.

C. Word Vectors Lookup

Word embedding [36] is a language modelling and feature learning technique, where each word is mapped to a vector of real values in such a way that words have a similar representation with similar meanings. Using neural networks, value learning can be achieved. Word2Vec, which has models such as skip-gram and continuous bag of words (CBOW), is a widely used word embedding method. The likelihood of words occurring in proximity to one another is dependent on both models. Skip-gram allows a word to begin with and to anticipate the words that are likely to accompany it. By predicting a word that is likely to occur based on particular background terms, CBOW reverses that. The CBOW model

used to learn domain-specific word embeddings from large amounts of Arabic text was collected from the free online encyclopaedia Wikipedia (2,000,000 words vectors of Word2Vec) to create the corpus defined in [31].

The Word2Vec corpus was used to look up all words' vectors from the corpus. In [11] it is suggested that pre-trained word embeddings trained on very large text corpora, such as the free Word2Vec vectors trained on 100 billion Google news tokens, can provide universal features for use in natural language processing.

D. Deep Learning Models

This section presents the two types of deep learning models used in the experiments. Using deep learning in text classification is powerful for feature extraction. In this work, we improve the CNN model in [13] as shown in Fig. 3, and the LSTM model as shown in Fig. 4 with parameter optimization to improve the classification accuracy and compare it with the different ML methods (KNN, NB and SVM). Additionally, we propose the new CNN model as shown in Table III.

Fig. 3. CNN architecture

Fig. 4. LSTM architecture

IV. RESULTS

This section presents the results of the conducted experiments. These three experiments, namely, the experiment based on the CNN model, the experiment based on the LSTM model, and the experiment based on the feature methods. These experiments were carried out based on different experiment settings.

A. Experiment Settings

This section describes the experiment settings of all three experiments. The experiment settings and hyperparameter tuning were performed to improve the accuracy of the performance model. In the first experiment, each CNN layer has various parameters such as the number of filters, kernel size, strides, padding, dropout rate, batch size and activation function. All CNN parameters are tuned and optimized to achieve high accuracy. In the second experiment, LSTM is used with the architecture. The embedding layer is used in the LSTM layers as in the CNN model. In the third experiment, the CNN and LSTM models with N-gram ranges were applied to achieve highly accurate model performance. The N-gram ranges method is applied with embedding vectors CBOW and skip-gram. All the parameters and details of the experiment are shown in Table II.

TABLE II. EXPERIMENTS SETTINGS

Parameter	Experiment 1	Experiment 2	Experiment 3
No. of layers	10	22	5
Input shape	300	300	300
Filters	64	64	64
Embedding vectors	CBOW	CBOW	CBOW
Max sequence length	300	300	300
Activation function	SoftMax	SoftMax	SoftMax
Optimization	Adam (learning rate = 0.001)	Adam (learning rate = 0.001)	Adam (learning rate = 0.001)

In these experiments, we applied the SoftMax activation function as shown in formula 1. The key benefit of using SoftMax is the performance probabilities range. The range will vary from 0 to 1, and the sum of all the odds will be equal to 1. If the SoftMax function is used for the multi-classification model it returns the probabilities of each class and the target class would have a high probability.

$$f(S)_i = \frac{e^{S_i}}{\sum_j^C e^{S_j}} \quad (1)$$

While for the loss function in all experiments a 'Categorical Cross-Entropy loss' has been utilized to train a CNN to output a probability over the C classes for each tweet, the target is three classes in the SoftMax activation function at the last layer. The mathematical formula of SoftMax activation and Cross-Entropy loss is shown in formula 2.

$$CE = -\log\left(\frac{e^{S_p}}{\sum_j^C e^{S_j}}\right) \quad (2)$$

where S_p is the CNN score for the positive class.

Before training the model, the dataset is divided into 25,130 training samples and validated on 6,283 samples.

TABLE III. LSTM ARCHITECTURE LAYERS

Layer (type)	Output Shape	Parameters #
input (Input Layer)	(None, 300)	0
embedding (Embedding)	(None, 300, 300)	17421900
LSTM	(None, 18)	22968
Batch Normalization	(None, 18)	72
Dense	(None, 3)	57
Total Parameters: 17,444,997		
Trainable Parameters: 17,444,961		
Non-trainable Parameters: 36		

In the third experiment, two experiments applied CNN and LSTM models to get a highly accurate model performance. The first experiment used the N-gram ranges method along with embedding vectors using CBOW. The second experiment used the N-gram ranges method to extract the required features, but with embedding vectors using skip-gram.

B. Experiments Results

This section explains the results of the experiments. Several experiments were conducted, and these can be categorized into three main experiments, namely, the experiment based on the CNN model, the experiment based on the LSTM model, and the experiment based on the feature methods.

1) *Experiments based on CNN model:* In this experiment, the CNN model applied two different architectures as shown in Table III, Table IV and Table V. Fig. 5 shows a scatter plot diagram for tweets labelled against the predicted labels. In addition, this figure explains the correlation with different epochs compared to the pre-processing approaches, and whether the emoji were retained or removed.

TABLE IV. CNN-1 ARCHITECTURE LAYERS

Trainable params: 17,764,815		
Non-trainable params: 128		

Fig. 5. Scatter plot diagram for tweets labels

2) *Experiment based on the LSTM model:* In this experiment, the LSTM model has been utilized. LSTM is used to enhance the memorisation of important information. In the text classification, LSTM is used in multiple word strings to identify the class to which it belongs. In this experiment, the dataset has been divided into three groups with different dataset sizes of 3,000 tweets, 15,000 tweets and 31,000 tweets, respectively. The results of this experiment are shown in Evaluation Results of Our Models' Accuracy with Different Dataset Sizes

Model	Accuracy-without emoji	Accuracy-with keeping emoji
SVM	81.79 %	82.5 %
NB	69 %	69.4 %
CNN-1	95 %	95.8 %
CNN-2	70 %	82.7 %
LSTM	96.6 %	95.5 %

TABLE VI. EVALUATION RESULTS OF OUR MODELS' ACCURACY WITH 31,000 TWEETS, WITH EMOJI RETAINED AND REMOVED

3) VI.

Model	Accuracy-without emoji	Accuracy-with keeping emoji
SVM	81.79 %	82.5 %
NB	69 %	69.4 %
CNN-1	95 %	95.8 %
CNN-2	70 %	82.7 %
LSTM	96.6 %	95.5 %

Table VII shows the results of our models' accuracy with the maximum tweets (31,000) and compares the classification accuracy when emoji are retained or removed from the content of the tweets.

TABLE VII. EVALUATION RESULTS OF OUR MODELS' ACCURACY WITH DIFFERENT DATASET SIZES

Model	Accuracy-without emoji	Accuracy-with keeping emoji
SVM	81.79 %	82.5 %
NB	69 %	69.4 %
CNN-1	95 %	95.8 %
CNN-2	70 %	82.7 %
LSTM	96.6 %	95.5 %

TABLE VIII. EVALUATION RESULTS OF OUR MODELS' ACCURACY WITH 31,000 TWEETS, WITH EMOJI RETAINED AND REMOVED

Dataset Size	SVM	NB	CNN-1(9L)	CNN-2(21L)	LSTM
Dataset-1(3000 Tweets)	81 %	23 %	93 %	89 %	90 %
Dataset-1 (15000 Tweets)	78.9 %	63 %	96 %	74.8	90 %

Dataset-1 (31000 Tweets)	82.5 %	69.4%	95.8%	83%	96.6 %
---------------------------------	--------	-------	-------	-----	--------

Training and testing accuracy for CNN and LSTM models is shown in Fig. 6, which also shows the accuracy of retaining or removing emoji. This comparison was implemented with different epochs, up to 100 epochs.

Fig. 6. Deep learning accuracy comparing retaining and removing emoji

4) *Experiments based on features methods:* In this experiment, two methods have been utilized to examine the accuracy of the model performance. In the first experiment, the two methods used are N-gram and CBOW. The experiments' results are shown in Table VIII.

TABLE IX. CBOW WITH N-GRAM RESULTS COMPARISON

Classifier	Without N-gram	N-gram range 1-2	N-gram range 1-3
SVM	82.22	82.64	83.2
LSTM	96.6	96.7	96.9
CNN-1	95.8	95.82	95.83
CNN-2	83	83.3	84
NB	69.4	69.7	70

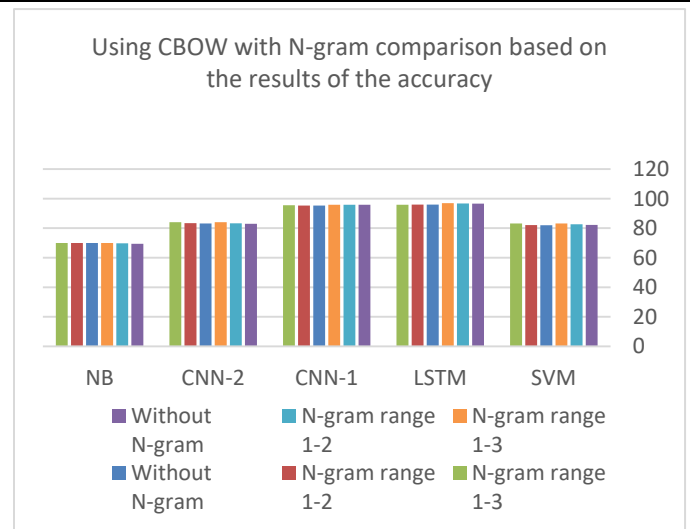

Fig. 7. CBOW and N-gram results comparison

Fig. 8. Skip-gram and N-gram results comparison

In the second experiment, skip-gram and N-gram have been utilized.

TABLE X. SKIP-GRAM AND N-GRAM RESULTS COMPARISON

Classifier	Without N-gram	N-gram range 1-2	N-gram range 1-3
SVM	82	82.06	83.2
LSTM	96	96	95.8
CNN-1	95.3	95.3	95.5
CNN-2	83.2	83.4	84
NB	70	70	70

The accuracy of CNN-1 with emoji retained is 95.8%, and with emoji removed is 95%. The accuracy of CNN-2 with emoji retained is 82.7%, and with emoji removed is 70%. The CNN-1 model is more accurate than CNN-2. The accuracy of LSTM with emoji retained is 95.5% and 96.6% with emoji removed. When applied to SVM and NB the results are 82.5% and 69.4%, respectively. Fig. 8 shows the comparison between the deep learning accuracy with emoji retained and removed. By applying the same models with N-gram and with skip-gram, the results in Table VIII and Table IX, and represented in Fig. 7 and Fig. 8, show the LSTM model is better in both CBOV and skip-gram.

5) *Experiment based on the AraBERT model:* In this experiment the AraBERT for Sequence Classification is applied (Transformer-based Model for Arabic Language Understanding) with the following parameters:

TABLE XI. ARABERT PARAMETERS

Parameter	Value
Attention probs dropout prob	0.1
Hidden act	gelu
Hidden size	768
Initializer range	0.02
Intermediate size	3072
Layer norm eps	1e-12

Max position embeddings	512
Num attention heads	12
Num hidden layers	12
Transformers version	4.17.0
Vocab size	64000

After training the dataset on the AraBERT model using the parameter list as shown in Table X. The training accuracy (Fig. 9) of the AraBERT model is 0.92% when the test is applied on 3,505 tweets.

Fig. 9. Results of the training for AraBERT Model

V. CONCLUSION AND FUTURE WORKS

Results of this work show that there is improvement in CNN model accuracy by retaining emoji in text content, and LSTM is more accurate when emoji are removed. These results are summarized in Table II. The accuracy of CNN-1 with emoji retained is 95.8%, and with emoji removed is 95%. The accuracy of CNN-2 with emoji retained is 82.7%, whereas its accuracy with emoji removed is 70%. CNN-1 outperforms CNN-2 in terms of accuracy. The accuracy of LSTM when the emoji are retained is 95.5 %, and it is 96.6% when the emoji are removed. When we use SVM and NB, the outcomes are 82.5% and 69.4 %, respectively. The accuracy of the AraBERT model is 0.92%. In this work, we have shown that the LSTM architecture is the most suitable for the analysis of Arabic tweets. In the future, we can build a new system to analyse Arabic texts using the modern model GPT-3 from Open AI and apply the sentiment analysis on this dataset.

ACKNOWLEDGMENT

The authors would like to thank the Arab Open University for supporting this research paper.

Abstract—Responding to enormous comments on social media platforms is one major challenge facing businesses in recent times, especially when dealing with irate consumers. Customers have increasingly adopted social networks as a platform for expressing their concerns and posting comments on business pages, posing a great challenge for customer support agents and digital marketers alike. Analyzing and responding manually to these enormous comments is a time-consuming task, necessitating the adoption of Artificial Intelligence (AI) tool that can complete the task swiftly — *automatic comprehension of social media posts for comment generation*. In this paper, we present algorithms and a tool for the automatic comprehension of customer tweets and generation of responses to these tweets. This was done in two-fold: using existing Natural Language Processing (NLP) libraries to preprocess and tokenize these tweets, and secondly, using rule-based algorithms to find a *matching response* to each customer, based on the array of extracted tokens from the customer's tweet. This was built into a tool called **Comment-Synthesizer**. This tool takes unfiltered tweets as input, preprocesses the tweets, and matches the tweet with predefined responses using a rule-based algorithm with a success rate of 76%. This tool, if implemented in a desktop automation application, can be used to respond automatically to a large volume of customers' social media comments/posts.

Keywords—*Natural language comprehension; social media; natural language processing; customer engagements; artificial intelligence; comment generation*

I. INTRODUCTION

In recent years, social media has become an indispensable resource for companies to incorporate into their marketing plans [1]. Social media is described as a collection of Web applications that allow people to produce and generate content through the innovative use of Internet technology [2]. The widespread use of social networks by customers influences businesses that must join to connect with customers [3]. Businesses are embracing social media for an expanding number of marketing tasks, including image, market analysis, demand planning, provision of services, and commerce. Additionally, businesses have found that social networking websites, in particular, are crucial for drawing customers to their products and brands [4]. As a result of the recent explosion of interest in social networks like Facebook, Twitter, and LinkedIn, tons of businesses are posting information to influence consumers about their products/services [5]. The number of posts and comments received every day gives a surprising indication of the enormous influence of social networks, with Facebook accounting for one billion active users, YouTube with over

four billion views, and nearly 140 million active users on Twitter [6], [7], [8]. As a means of communication, the usage of social networks is becoming significantly important, particularly because it enables firms to cultivate relationships with their clients [9]. Social networks can be used to distribute well-known e-Commerce solutions, but businesses that do not engage with their customers lose their potential [10].

In the early days of social media, PR firms would keep an eye on customer comments on a company's website to find and handle irate clients, but with the proliferation and volume use of social media platforms, this is no longer nearly adequate [6]. When a business adopts a Social Media strategy, the volume of postings increases quickly, requiring considerable human work for manual analysis [11]. Consequently, many businesses designate a human expert to constantly update their pages with relevant content, monitor comments, and respond to them on time. However, responding manually to these enormous comments is a time-consuming task, necessitating the adoption of Artificial Intelligence (AI) tool that can complete the task swiftly — *automatic comprehension of social media posts for comment generation*.

A long-standing aim of AI is the creation of programs that can understand and generate human language [12]. Natural Language Processing (NLP), an aspect of AI that deals with the interaction between machines and human language and has been around for more than four decades [13], is one of such programs. Machines are programmed to successfully process large natural language data. NLP makes it feasible for Intelligent machines to analyse the complexities of human expression in order to obtain information from numerous types of text, such as blogging, evaluation of products, as well as the numerous daily posts on Twitter, Facebook, and news feeds [14]. The digital representation and understanding of human language have recently attracted significant interest in this domain. Its applications have spread to numerous domains such as email spam surveillance, translation software, and retrieval of information, summarization, medicine, and question answering [15].

In this paper a set of rules was used to develop an algorithm that automatically comprehends social media comments and responds to them in real-time. This involves performing lexical analysis on the raw tweets with several preprocessing techniques, such as eliminating Twitter handles, URLs, whitespaces, etc. In addition, we performed sentiment analysis to identify the underlying emotions in the dataset, and then we

defined rule-based algorithms to find a *matching response* to each customer, based on the array of extracted tokens from the customer's tweet. Fig. 1 depicts the processes.

The following is a summary of the significant contributions made in this paper.

- 1) leverage the Python Natural Language Toolkit (NLTK) for the analysis of the dataset. A tool that supports NLP data structures and algorithms in Python,
- 2) design a Natural Language Generation (NLG) algorithm system that uses a rule-based approach to automatically generate social media comments,
- 3) create *Comment-Synthesizer*, a software tool that deploys the techniques described in (3) above, and
- 4) present deployment of the tool, as well as results demonstrating the social media comments generated.

The remaining sections of this paper are organized as follows. Section II provides background and discusses the related work. Section III elaborates on the design concept used in this work. In Section IV, we demonstrate the implementation of the *Comment-Synthesizer* tool and the results obtained from the synthesized comments. In Section V, the results are evaluated, while Section VI provides a summary of the work and the further study.

II. BACKGROUND AND RELATED WORK

This section examines works related to the problem domain and presents the various terms and techniques for solving the problem. It provides a definition of the terms and the motivation behind this work.

A. Social Media Marketing in the Digital Age

Social media is a dynamic and fast-moving domain across the globe. In the digital age, leveraging social media to advertise to a targeted demographic of potential customers is an effective strategy [16]. This allows a business to remain connected with customers and respond to their queries without delay. Every day, people around the world use the Web, social networks, smartphone applications, and other electronic communication systems [17]. Since the emergence of social networks, many businesses have realized that they can add value to a firm's entire business plan, particularly in terms of improving brand perception.

Businesses are leveraging alternative marketing strategies that are more cost-effective and beneficial for consumer engagement than conventional ways, as they recognize the potential of the Internet as a crucial component of their platform. They are now supporting open communication practices within the firm, such as tweeting, texting, and other methods, to promote branding outside the company [18]. It's no secret that platforms like Facebook, Instagram, and Twitter are essential tools for interacting with customers and spreading the word about a firm's products and services. Given how frequently consumers use social media for several hours each day, marketers have adopted it as a powerful marketing tool [19]. According to the statistics, the average internet user spends approximately 144 minutes every day exploring social

networks. As a result, large corporations and their strategists employ social media to create brand images [20].

B. Social Media Automation

Digital marketing has metamorphosed significantly over the past two decades. Businesses are now expected to improve their strategies to earn customers' loyalty. The social web statistics indicate that automation of digital marketing applications, especially social media, is the key as this enables firms to make effective use of their time by concentrating on the more important side of the business. Social media automation can be described as an approach to remodelling business social media campaigns by utilising automation tools, such as Hootsuite, Buffer, Social Pilot, and the like [21]). Automating social media posts reduces the time spent on maintaining and growing brand accounts. Therefore, time and resources could be allocated to other areas of the marketing budget and to meet strategic goals [22]. A significant advantage of automation is the propensity to organize the company's entire social media strategy in advance. Content or posts can be scheduled on Twitter, Facebook, Instagram, and other social networks, which are then automatically published [23].

C. Challenges of Digital Marketing

One of the most direct channels of engagement between a business and a target audience is through social media marketing — bidirectional communication. As consumers spend more time than ever online, the ability to effectively engage with them, respond to their comments, and solve their problems in real time is crucial [24]. Marketing experts have less control over the message on social networks due to its conversational nature than they do with more conventional means of marketing communication [3]. There is more exposure to digitization and social media from several consumers. Social media power is a fundamental challenge for any digital marketer. The management of customer queries is one of those challenges.

A key goal of marketers is customer engagement, a study in 2012 found that customer engagement was reinforced by 78 per cent of marketing reports when they use social media to promote their products [25]. Customer expectations must be managed to avoid harmful or negative posts. The use of negative post-reactions in social media marketing is one facet of digital marketing that can be particularly destructive to marketing campaigns. There is not much a marketer can do to prevent unfavorable comments, images, or videos from being posted online by dissatisfied consumers or competitors in the same business [26].

D. Artificial Intelligence and Automation

Artificial Intelligence is the ability to make machines execute intelligent tasks like humans. It uses intelligence to perform automated tasks. A more in-depth definition of AI describes it as the flexibility in a machine's ability to learn from experience, incorporate that knowledge into its operation, and use that performance to achieve predetermined ends [27]. As automation becomes more complex, the demand for AI is growing due to its ability to solve complex problems even with little human expertise and resources in a short timeframe [28]. With abstraction to phase out human efforts in routine tasks,

Fig. 1. Processes of social media comment generation

advancing machine learning (ML) will continuously activate paradigm shifts in multiple sectors of the technology industry. Among the components of AI is NLP, which is concerned with the interaction of machines and humans through natural language. As AI is penetrating the business arena, it has led to a fundamental change in the concept and application [29].

The application of AI is used significantly in different business domains, including healthcare, finance, manufacturing, law, education, and more. Doctors can now diagnose diseases faster than before with the assistance of ML. The application of AI in social media marketing results in spending less time on routine administrative tasks and providing customers with satisfaction. The adoption of AI can be cost effective and complement customer engagement [12]. Applications such as chatbot assist patients with invoicing and assist clients with appointment scheduling. In pedagogy, AI can provide auto-grading, assist students with learning by catering to their individual needs and ensuring that they stay on course. Artificial intelligence in the legal field has made it easier for lawyers to precisely and efficiently evaluate thousands of large legal documents, which is generally a difficult undertaking. Industrial robots have made manufacturing considerably easier and more efficient than it was only a few years ago [28].

E. Motivation

There is an increase in the number of comments available on a business social media platform every single day, especially on Twitter. It is projected that there will be 3.43 billion monthly active users on social media platforms worldwide in 2023. This figure represents almost one-third of the total population of the world [20]. Thus, it becomes a problem for a human expert to deal with a large volume of questions in different real-life data handling applications. Social media comments are important

data in social media marketing, as those comments can make or break a business. However, all posts must be evaluated to effectively utilize the data acquired in the social media posts [11]. Against this background, there is the necessity for the creation of an algorithm that can complete the task swiftly.

F. The Gap

Unprecedented social media marketing growth has led to a constant influx of customers posting a massive volume of comments on business social media platforms that may be too much for a human expert to handle. When customers do not receive a prompt response to their inquiries, there is an underlying unhappiness that exists. Therefore, it is necessary to create a novel strategy to solve this issue without involving humans in easy-to-automate tasks.

G. Why Use Rule-Based Techniques?

The rule-based system has advanced several NLP systems. Rule-based logic is at the centre of most automated processes. A rule-based system encrypts expert human knowledge in a rather narrow domain using an automated system [30]. The foundation of rule-based systems is solid language comprehension and the syntactic insights gained with an NLP system can be applied to a similar task in another system [31]. One of the simple methods to represent the human intellect in AI is to transform it into plain linguistic phrases utilizing the format IF-THEN rules [32]. The knowledge expert system is an example of a rule-based technique that uses predefined rules to make deductions and draw conclusions to perform automated tasks.

A rule-based approach consists primarily of a collection of rules, a statement of facts, and a termination criterion [30]. Despite the fact that a rule-based method is neither AI nor ML, it may be used to power certain components of AI and

ML, as it essentially follows the rules specified by humans. Although an AI can determine the action to take itself, the rule-based approach does exactly as humans instructed. ML, on the other hand, is concerned with the possibility of computer programs accessing data and using it to learn for themselves. The objective is to provide machines with the ability to learn independently of human intervention and modify their behavior as necessary. Therefore, it is essential to use an approach that is most suitable for a specific field of study as this will influence the specified result. ML components in this case lack enough data to form a proper generalization. The benefit of the rule-based system is that it offers a detailed analysis of social media comments using morphological and syntactic information, while ML approaches face some challenges with specific NLP tasks, such as detecting well-formed and poorly formed inputs [31].

H. NLP Tools and Techniques

NLP deals with computer-natural language communication. Algorithmic systems can integrate language understanding and language generation through the use of NLP metrics [15]. NLP techniques enable enormous collections of social media posts to be automatically analysed and useful information extracted. Table I illustrates some examples of NLP tools and techniques.

TABLE I. SOME EXAMPLES OF NLP TOOLS AND TECHNIQUES

Tools	Techniques
AllenNLP: Premised on PyTorch tools and frameworks to use deep learning techniques for applications in NLP research and industry [33].	Text Classification: NLP techniques to classify vast volumes of unstructured text [34].
Keras: A library for neural networks that is highly modular, which is built on top of TensorFlow [35].	Summarisation: Using an NLP system to synthesize complex text by generating a concise summary [36].
NLP Architect: A Python module for evaluating deep learning architectures and techniques for optimizing NLP and NLU neural networks [37].	Sentiment Analysis: The analysis of data to assess its positivity, neutrality, or negativity [38].
SpaCy: Open-source NLP library that specializes in syntactic analysis, word-to-vector transformations, and conversational UIs [35].	Keyword Extraction: Automatically extracting the most useful textual data employing AI and machine learning algorithms [39].
NLTK: The Natural Language Toolkit is an accessible NLP resource for tokenising, stemming, labeling parts of speech, parsing, and logic [40].	Named Entity Recognition: Tags and extracts named identities from the using NLP algorithms for further analysis [41].

I. Related Work

According to our understanding and considerable research, no effort has been attempted to automatically comprehend and generate comments for social media posts using rule-based technique. Nevertheless, there are numerous similar works in NLP, particularly in the area of tweet message analysis on social media sites like Twitter, and various works in automatic comprehension and summarisation, language generation, and synthesis of things. Several of these interrelated concepts will be covered in this section.

- 1) *Twitter Immediate Response Using NLP Techniques:* Ahmad et al [42] proposed implementing NLP algorithms to analyze and evaluate various preprocessing, data augmentation, classification, and fusion approaches to provide instant response

on water quality from social media posts.

- 2) *Social Media Posts as Programming Feedback:* Kabaso and Ade-Ibijola [43] presented a Context-Free-Grammar for automatically generating educational feedback on Twitter for novices in programming.
- 3) *Comment Generation Based on User Profile:* Zeng et al [44] proposed that each user's personalized comments be generated automatically based on the data in their profile. The work employed a large-scale and high-quality Chinese dataset as the foundation for creating a link between user profiles and the comments made on social media platforms.
- 4) *Social Media Profile Synthesis:* Ade-Ibijola [45] presented novel approaches to create imaginary social media profiles on an automatic basis utilizing probabilistic CFG.
- 5) *Financial Chat Analyzer (FINCHAN):* IMs with FX options obtained from Bloomberg Terminals were analyzed by [13] using a formal grammar-based technique. The work presented a novel algorithm to produce descriptive overviews of these financial chats by cleaning and retrieving terms from the conversations. The conversation token syntax was then specified using a CFG.
- 6) *Analysis of Tweets for Identifying Trends:* Novel algorithms were developed by [46] to identify trends in tweets related to natural disasters, such as earthquakes.

J. Definition of Terms

Definition 1: Symbol, Alphabet, and String [47]: A single element is regarded as a symbol. Any finite collection of symbols is represented by an alphabet Σ , while a string consists entirely of zero or more symbol combinations.

Definition 2: Tokenization: The process of dividing raw text into small parts is called tokenization. Raw text is divided into words and sentences and is referred to as tokens. These tokens are helpful in the creation of NLP contexts and models. Tokenizing complete sentences or individual words is possible using this method. The term "word tokenization" refers to the act of splitting a string of words into constituent lexemes. Sentence tokenization is the term used for the process of tokenizing a sentence [48].

Definition 3: Regular Languages and regular expressions [47], [13]: Languages that can be accepted by finite automata are regular languages that can be expressed by formulas known as regular expressions that use the operations of union, concatenation, and the Kleene star. An algebraic notation to describe regular language is called regular expressions (RE). The following terms apply to a regular language L over some alphabet Σ :

1. \emptyset denotes an empty set in regular language.

2. λ is a collection of all conceivable null strings in regular language.

3. For each $a \in \Sigma$, a denotes the regular language $\{a\}$.

4. Given L_1 and L_2 are R , then the following is true: L_1 and L_2 is R that combines both languages. The combined language, identified as L_1, L_2 , is considered a regular language. L_1^* is another common language that symbolizes the Kleene closure feature and is also referred to as the Kleene star.

III. DESIGN

The rules for generating comments for social media posts are described in this section. Our test case focuses on Twitter. Twitter is a social networking and microblogging platform that was launched in 2006 by a small group of people, including Jack Dorsey [49]. Every second, over 6,000 tweets are sent, equating to about 350,000 messages sent in a single minute, 500 million tweets produced in a single day, and 200 billion tweets sent in a single year [50]. To increase user and consumer participation, marketers employ Twitter and other social networking platforms in their campaigns [51]. A tweet has a structure that allows content to be shared among its audience with a 280-character limit [52]. Twitter can facilitate brand engagement with consumers by monitoring and responding to online consumer opinions [53]. In this paper, the structure of a tweet is described using the following attributes:

- 1) **Tweet Text:** it is a short message containing 280 characters or less that a Twitter user shares with a specific audience. For example, text, pictures, graphics and videos,
- 2) **Screen Name:** a Twitter handle or username that is assigned when a user creates their first Twitter account. This is followed by the "@" symbol, which your followers use when responding, mentioning, and sending direct messages (DM). For instance, @steveleo,
- 3) **Full Name:** it is a unique identifier that is different from a Twitter username. For instance, Jay Paul,
- 4) **Date:** the time and date when a tweet was published on Twitter,
- 5) **Tweet ID:** Twitter's unique identifier for each user's tweet,
- 6) **Location:** the location of the Twitter user,
- 7) **Retweet:** sharing a tweet from another account with your followers,
- 8) **Type of App:** the device that a user uses to send Tweets,
- 9) **Hashtag:** a topic or narrative preceded by the sign (#) symbol. Users can use hashtags to explore topics of interest, and
- 10) **Url:** the address to a user's profile on Twitter.

A. Tweet Extraction

To begin with, we first crawl tweets of a keyword associated with the hashtag "loadshedding". In South Africa, the country's electricity company, Eskom, frequently uses the term "load shedding" to prevent blackouts. As the primary source of electricity in South Africa, Eskom is tasked with ensuring

the reliability of the country's power supply to best support the nation's economy and society. Their main responsibilities in the country of South Africa include the generation, transmission, and distribution of electricity. Loadshedding is a well-planned response to unplanned events that is carried out with the objective of preventing the complete collapse of the energy grid [54]. The primary goal of load shedding is to ensure that the grid does not fail completely. Consumers are frequently notified of imminent load shedding, which typically takes place in a sequence of stages: 1, 2, 3, 4 etc. The tweets were extracted using Tweet Archiver API that spans a period of 12 weeks, which are then stored in Google sheets for further preprocessing.

B. Tweet Preprocessing

It is crucial to conduct a lexical analysis to parse the tweet text. Tweets are unstructured data that frequently contains graphics and abbreviations and must be converted into a format that machines can understand and analyse. Tokenization is the initial stage in any NLP pipeline. Algorithm 1 shows the tweet handling method using regex to search for the instance of tweet data in the text. A tokenizer as presented in Algorithm 2 was designed to separate the dataset into distinct pieces of information. The dataset was first preprocessed using the NLTK tool, which involves the following cleaning process: removing Twitter handles, whitespace, emojis, URLs from the tweet, hashtag and punctuation removal, converting text to lowercase, stop word removal, tokenizing the string with regular expressions into a list of words, and reducing words to their stems, i.e., buying, buys become buy. During the tokenization process, some stop words, such as "the" and "a", will be eliminated because these words do not contribute significantly to the information obtained. An illustration of a tweet preprocessing technique can be seen in Fig. 2.

Algorithm 1 : Tweet Handling

```
1: Function text_handle_remove(input_text):  
2:   using regex to search for the instance of tweet data in  
   the text  
3:   regex.sub(r'https?://[^\s\n\r]+', '', tweet)  
4:   regex.sub(r'@[^\s\n\r]+', '', tweet)  
5:   re.sub(r'#', '', tweet)  
6:   return new_tweet_text  
7:   end  
8: End Function
```

C. Sentiment Analysis

The comprehension of massive amounts of unstructured data (tweets) can be facilitated for businesses using sentiment analysis. We are primarily interested in gaining a sense of the consumer perspective with respect to the dataset and the polarity of that perspective, that is, whether it is positive, negative, or neutral. The dataset was augmented with labels to facilitate the computation of opinion scores and their classification. The results shows a slightly high positive score (35.6%) compared to the negative score (35.2%), as shown in Fig. 3. It is observable that loadshedding has a negative impact on the consumers, and they viewed it as incompetence and maladministration. In addition, we utilised a word cloud as a

Fig. 2. Raw tweets before and after tokenization

Algorithm 2 : Tweet Tokenization

```

1: Function tokenize_text(input_text):
2:   tokenized_tweet=tweet_tokenizer.tokenize(tweet)
3:   stemmer = PorterStemmer()
4:   initialise english stopwords
5:   clean_tweet list
6:   for word in tokenized_tweet:
7:     if (word not in stopwords_english and
8:         word not in string.punctuation):
9:       wordnet_lemmatizer.lemmatize(word,
pos='verb')
10:      wordnet_lemmatizer.lemmatize(lemmatizer_word,
pos='noun')
11:      add lemmatized_word to clean_tweet list
12:   return tweets_clean
13:   end
14: End Function

```

means of disseminating crucial information and developing an appealing visualisation strategy for the purpose of highlighting important textual data points, which helped monotonous data stand out as seen in Fig. 4.

IV. IMPLEMENTATION AND RESULTS

This section presents a new tool for implementing the techniques described in this article and the results obtained. The name of this tool is called Comment-Synthesizer.

A. Implementation details

We discuss the components of our technique for synthesizing comments and generating automated responses. First, we generated a list of intents and responses that spans the entire

Fig. 3. Distribution of sentiments in the tweet

category of customer posts in the dataset — preprocessed Tweets. Based on the analysis of the patterns observed in the dataset, the intent of the users was classified into 19 groups, each class representing a distinct user response. We tagged each post response based on the human expert’s estimation using the process below:

- 1) Create a list of intents and responses.
- 2) Use WordNet to find similar words with a tag of intent.
- 3) Combine words that are similar in meaning.
- 4) Use Regular Expressions (RegEx) to find similar patterns.

The tag in each intent is determined by the categorization of the dataset. For example, a question concerning power outages was tagged “outages” while inquiries from customers regarding

Fig. 6. The Comment-Synthesizer tool displays the users' tweet and the responses generated automatically (1/2)

Fig. 7. The Comment-Synthesizer tool displays the users' tweet and the responses generated automatically (2/2)

Algorithm 3 : Comment-Synthesizer Algorithm

```
1: Function get_tweet_synonyms(tag)
2:   define the list of intents, response and tag
3:   preprocess tweet
4:   for each_tag in tag
5:     get synonyms of tag from Wordnet.synsets
6:     for each_word in synonyms
7:       lemmatize each_word
8:     add user customized synonyms
9:   return processed_synonym
10: end
11: End Function
12: Function create_pool_of_intent(tag)
13:   for each_synonyms in tags_of_intent:
14:     add searchable regex function(".*\\b")
15:     Add regex compile action()
16:   return new_synonyms
17: end
18: End Function
19: Function algorithm_implementation(user_tweet)
20:   for each_word in user_tweet
21:     convert each_word to lower_case
22:     remove tweet_handle, hash_tag in each_word
23:   produce user_tweet
24:   for intent in dictionary_of_intent:
25:     regex search for user_tweet_pattern
26:   if user_tweet_pattern is found:
27:     produce the appropriate tag and response
28:   else
29:     produce unrelated message
30:   return appropriate response to the tag found
31: end
32: End Function
```

where TRUE POSITIVES are represented by the letters TP, TRUE NEGATIVES by the letters TN, FALSE POSITIVES by the letters FP, and FALSE NEGATIVES by the letters FN.

VI. CONCLUSION AND FUTURE WORK

The design of a software program called Comment-Synthesizer is described, which is designed to automatically comprehend and generate comments on social media posts. This entails performing lexical analysis on raw tweets using various preprocessing techniques, such as removing Twitter handles, URLs, whitespaces, etc. In addition, we performed sentiment analysis to identify the underlying emotions in the dataset, and then we defined rule-based algorithms to find a *matching response* to each customer, based on the array of extracted tokens from the customer's tweet. The Python library Tkinter was used to implement and build the tool into a desktop application. We demonstrate the deployment of the tool with the results of the social media comments it generated. During the testing, the Comment-Synthesizer algorithm predicted with 76 percent accuracy for the most part. This tool, if implemented in a desktop automation application, can be used to respond automatically to a large volume of customers' social media comments/posts, thereby improving customer experience. In the future, we will increase the classification of datasets to

enhance the functionality of the Comment-Synthesizer tool.

ACKNOWLEDGMENT

This research was partially supported by the Global Excellence Stature (GES) awards and National Research Fund (NRF) with grant number - 119041.

Abstract—Deep object detection models are important tools that can accurately detect objects and frame them for the user in real time. However, in low visibility conditions, such as fog or low light conditions, the captured images are underexposed and blurred, which negatively affects the recognition accuracy and is not well visible to humans. In addition, the image enhancement model is complex and time-consuming. Using the image enhancement model before the object recognition model cannot meet the real-time requirements. Therefore, we propose the Parallel Detection and Enhancement model (PDE), which detects objects and enhances poorly visible images in parallel and in real time. Specifically, we introduce the specially designed tiny prediction head along with coordinated attention and multi-stage concatenation modules to better detect underexposed and blurred objects. For the parallel image enhancement model, we adaptively develop improved weighting evaluation models for each “3D Lookup Table” module. As a result, PDE achieves better detection accuracy for poorly visible objects and more user-friendly reference in real time. Experimental results show that PDE has significantly better object recognition performance than the state-of-the-art on real foggy (8.9%) and low-light (20.6%) datasets.

Keywords—Low-visibility condition; image enhance; object detection

I. INTRODUCTION

Deep learning is used for many tasks, such as model fitting [1]–[3], object detection [4], [5], and so on. Recently, deep object detection models [6]–[8] have been widely used in daily life. These models provide accurate and 7×24 consistent object recognition, which facilitates people’s work and helps them detect inconspicuous objects. However, in most places in the world, it is dark 42% of the day and there are one to three rainy or foggy days per week. These natural phenomena inevitably affect the performance of deep object detection models [9]–[11]. In addition, object detection models must filter out objects for user reference in real time (processing more than 30 frames per second). In this context, object detection in low visibility conditions has attracted much attention in both academia and industry to enable accurate and view-friendly object detection at all times of the day and under all climatic condition [12]–[14].

To mitigate the negative effects in low visibility conditions, current research can be divided into two classes: 1) Two-stage models: Two-stage models use image enhancement models to first enhance the images with poor visibility and then train the object detection model on the enhanced images [15], [16]. For

example, [17] used “GridDehaze” to denoise foggy images, and [18] introduced a brightening step to lighten the images before object detection. 2) Joint Learning Models: Joint learning models jointly train an image brightening model and an object detection model to deal with poorly visible images [19], [20]. More specifically, two subnetworks [21] with common feature extraction layers are used to simultaneously detect the objects and brighten the images.

As shown in Fig. 1, current object detection models cannot detect and display objects well due to the following three challenges: 1) Out-of-focus and low-contrast objects. In low visibility conditions, objects are out of focus and low contrast, so their detectable areas are smaller and blurrier than in high quality images. This negatively affects the accuracy of conventional object detection methods originally developed for high-quality images. 2) Unfavorable representation in poor visibility conditions. Images captured in poor visibility conditions are not well visible to the user. It is necessary to enhance the images and frame the objects clearly for the user. 3) Real-time processing requirements. To meet real-time requirements, the entire process of image enhancement and object detection should be performed at more than 30 frames per second. In the two-stage models, the image enhancement step and the object recognition step are processed serially, which further limits the processing time of each step and results in unsatisfactory performance of both steps. In the joint learning models, the image enhancement model and the object detection model have completely different optimization objectives. The joint optimization of these two models may result in a wobble phenomenon, leading to better performance in image enhancement or recognition, but negatively affecting the other objective.

To this end, we study the problem of how to achieve better enhancement and detection while meeting real-time requirements. Specifically, we investigate the following three research questions. 1) How can the enhancement and detection steps be decoupled to improve both together? 2) How can objects with blurred edges be accurately detected? 3) How can images with poor visibility be enhanced to better present recognition results to users? By exploring the above questions, our work makes the following three contributions.

- We propose a novel parallel framework called Parallel Detecting and Enhancing models (PDE) that can solve the wobble problem while improving detection and enhancement performance.
- PDE introduces a tailored model for detecting objects

in low-visibility images by introducing a tiny prediction head to detect objects with smaller detection areas. In addition, PDE uses coordinated attention and multi-stage concatenation to further improve detection performance in low visibility.

- PDE incorporates a specially designed image enhancement model by developing an adaptively enhanced weighting model for each “3D Lookup Table” module to achieve better enhancement performance.

To prove the efficiency of our approach in object detection, we evaluate the proposed model on synthetic and real low visibility datasets. Experimental results show that PDE has significantly better object detection performance on two real datasets with fog (8.9%) and low light (20.6%). In addition, case studies show that PDE provides more accurate object detection and clearer rendering than other low visibility models.

The remainder of this article is organized as follows: Section II provides related work, including object detection, image enhancement, and multi-tasking in low visibility. Section III describes the proposed method used for low visibility images. Section IV presents the comprehensive experimental results of our method compared with other methods. Section V concludes our work.

II. RELATED WORK

A. Object Detection

CNN-based target detectors can be divided into two types according to the steps of image processing: 1) Single-stage detectors: YOLOv4 [22], YOLOv5 [23], FCOS [24], and EfficientDet [25]. 2) Two-stage detectors: R-CNN [26], R-FCN [27], Mask R-CNN [28], Fast R-CNN [29], etc. From the point of view of composition, they both consist of two parts. One part is the CNN-based basic framework, which is used to extract image features. The other part is the prediction head, which is responsible for classification and localization. In addition, existing object detectors add some layers between the basic framework and the head, which are called the neck of the detector. The three structures are described in detail below.

Backbone. The backbone often uses VGG [30], ResNet [31], EfficientNet [32], CSPDarknet53 [33], Swin-Transformer [34], etc., rather than networks designed by ourselves, since these networks have been shown to have strong feature extraction capability in computer vision tasks. However, the backbone network can be fine-tuned to make it more suitable for specific tasks.

Neck. The neck was designed to make more efficient use of features extracted from the backbone network. Its main task is to further process and use the features extracted from the backbone in different stages. The neck usually consists of several top-down and several bottom-up paths. The neck is an important component of the object recognition network and connects the backbone to the head. Commonly used linking modules for the neck include FPN [35], NAS-FPN [36], PANet [37], BiFPN [25], ASFF [38], etc. The common point of these modules is the iterative use of various upsampling, downsampling, dot-sum or dot-product methods to develop aggregation strategies.

Head. In the detection task, the backbone cannot perform the localization task. Therefore, the head network is responsible for detecting the location and class of objects based on the feature maps extracted from the backbone. Head networks are generally divided into two categories: single-stage object detectors and two-stage object detectors. The most representative two-stage object detector is the R-CNN [26], [39] series. Compared to the two-stage detector, the single-stage object detector predicts both the bounding box and the object class simultaneously. The most representative single-stage object detectors are YOLO [22], [40], SSD [41], and RetinaNet [42] series.

B. Image Enhancement

Image adjustment determines a threshold based on the gray level range of the image. If it is below the threshold, automatic color gradation enhancement is applied. On the other hand, if it is above the threshold, enhancement methods based on histogram equalization and inverse equalization are performed. The adaptive image enhancement method can enhance not only low-contrast images, but also partially dark and partially

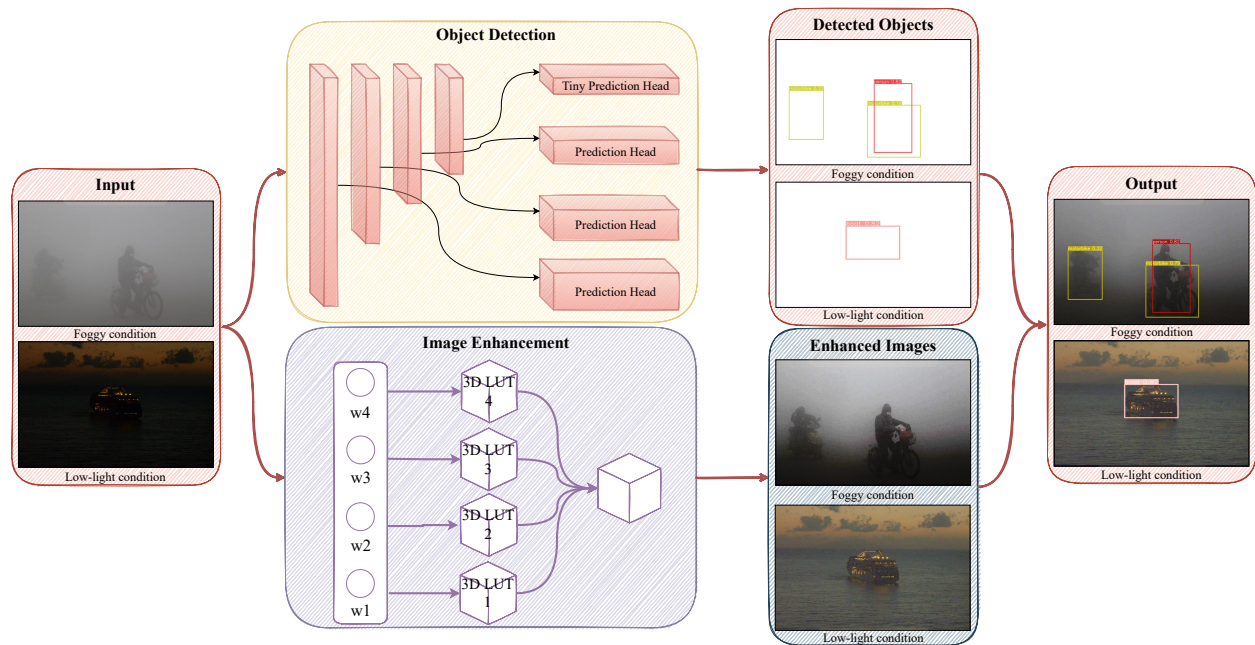

Fig. 2. An overview of the working pipeline with PDE. PDE can detect objects and enhance the low-visibility images in parallel and in real time. The label and coordinate values are obtained by the object detection model. Then we overlay the detected images with the enhanced image to get the final output.

light images with high robustness, so that the enhanced images have a better visual effect. Image adjustment is a widely used technique in image enhancement. Some classical methods [43], [44] use adaptive filters to control the contributions of the various enhancement operations so that contrast enhancement occurs in regions of high detail. [45] proposed a Deep Learning model that trains data on unpaired images. A Deep Reinforcement Learning approach is also used to decide what action to take given the current state of the images. [46] effectively transforms the color and hue of the source image by using a small CNN to learn image-adaptive 3D lookup tables.

C. Multi-Task in Low-Visibility Conditions

Existing models for object detection in low visibility include several tasks, such as image denoising and object detection. Depending on the order in which the different tasks are performed, they can be divided into two classes: two-stage models and joint learning models. Two-stage models [5], [15], [17] use classical visualization enhancement methods to process images before detection. For example, [47] proposed an AOD-Net for foggy conditions that denoises images before detection. However, the object detection models have strict requirements for deriving the time. When the image enhancement model and the object detection model are connected in series, the recognition time of both models is constrained, resulting in suboptimal performance in enhancement and detection. Joint learning models [19], [21] have performed image enhancement and object detection using a joint structure to better recognize images with low visibility. However, it is difficult to adjust the parameters to balance the completely different optimization goals of image enhancement and object detection. For this reason, [48] proposed an unsupervised adaptive system for object detection in rain and fog. After that, many works [49]–[51] emerged to improve the detection

performance by using range adaptation. [52] proposed a robust learning method to resist interference from poor visibility and reduce the information loss caused by range adaptation. [20] developed a joint learning model (IA-YOLO) that combines image matching enhancement and object detection to meet the requirements of real-time recognition. In this work, we use the classical single-stage model YOLOv5 [53] as a basis and improve its performance under low visibility conditions.

III. PROPOSED METHOD

The PDE synchronizes the input image with the object detection module and the image enhancement module, as shown in Fig. 2. First, the object detection module detects the image to obtain the coordinates and classification information of the target. Second, the image enhancement module reduces the weather noise and increases the brightness of the input image to obtain a more user-friendly reference. Finally, the coordinates and classification information of the target are written into the enhanced image to obtain the result. In this section, we introduce the object detection and image enhancement modules.

A. Detection Network Module

Images captured in low visibility conditions contain interference from environmental information that makes object detection difficult. To overcome this challenge, PDE introduces a customized model for low-visibility object detection by importing a tiny prediction head and further employing coordinated attention and multi-stage concatenation to improve the performance of low-visibility detection. As shown in Fig. 3, the object detection model is a newly developed implementation of YOLOv5. These tricks help deep neural networks accurately locate and identify objects by reducing the detrimental effects

Fig. 3. The object detection module. 1) A coordinate attention block (CoordAtt) is located at the bottom of the backbone network. 2) The multi-stage concatenation module (MSC) replaces the original concatenation module. 3) The number of prediction heads has been increased from 3 to 4.

of detectable zones that are smaller and blurrier than in high-quality images. In addition, the model combines feature maps generated by shallow and deep neural networks so that semantic information and location features can be fully utilized. Moreover, an explicit supervised learning task is formed by setting a learning weight parameter. In this way, excellent learning results are obtained by perfectly distinguishing the importance of feature maps from shallow and deep neural networks. Therefore, the representative features can be accurately retrieved and appropriately represented, which improves the overall detection performance of the model. To get a clearer picture of the core of the object recognition module, we will describe the above methods and loss functions in detail below.

Coordinate Attention. Attentional mechanisms have been shown to be effective in many visual tasks. The core of the attentional mechanism is to enhance the model's ability to extract and represent important features, similar to the way humans selectively focus on important parts rather than the totality of information. However, most attention mechanisms only consider the information between channels and not the information about spatial location. This ignores the part of the information that is hidden in space and fails to extract the optimal representation of the features. Moreover, the convolution operation can only extract local relations, but not relations over long distances. To this end, we use coordinate attention [54] to capture spatial relationships over long distances with precise location data by embedding the location information into the channel attention. Specifically, each input X is decomposed into w and h dimensions, and the decomposed tensors are processed by global pooling to generate X_w and X_h , respectively. Feeding into a convolutional block with the concatenated tensors X_w and X_h generates an encoded Y that summarizes

the extracted features of X_w and X_h . The set of operations can be formulated as follows:

$$Y = f(G(\{X_w, X_h\} \circ W)) \quad (1)$$

where $\{X_w, X_h\}$ means concatenating X_w and X_h , \circ means convolution operation, G and f denote normalization and activation function, respectively, and W is the convolution filter. Furthermore, we split Y again to obtain \hat{X}_w and \hat{X}_h :

$$\hat{X}_w, \hat{X}_h = Split(Y) \quad (2)$$

Also, \hat{X}_w and \hat{X}_h are convoluted and activated to get the final output:

$$Y_{out} = X \times \sigma(F(\hat{X}_w)) \times \sigma(F(\hat{X}_h)) \quad (3)$$

where F denotes convolution and σ denotes the sigmoid function.

By combining attention along the horizontal and vertical directions of the input sensor, each element of the attention maps can reflect in two directions whether the object of interest is present in the corresponding row and column. In this way, coordinated attention can more accurately determine the exact location of the object so that the entire model can better identify objects.

A Tiny Prediction Head. Feature sensitivity is one of the most important properties of the model for extracting key information from noisy images. The best way to achieve this is to add observations from different viewpoints and combine them to make better use of the fine-grained features from different viewpoints and achieve better feature representation.

However, we find that there are three different scales of prediction heads in the original YOLOv5 model, namely 256×256 , 384×384 and 512×512 , and the number of anchor images is 9. Although YOLOv5 has been observed from three perspectives, the recognition results are still not satisfactory for noisy images, as shown in Fig. 4. To this end, we add a tiny prediction head with a scale of 128×128 to extract features from a more microscopic perspective. We also increase the number of anchor frames from 9 to 12. Although this is only an incremental change to the detection head, the structure of the multi-detection head contributes significantly to improving the model performance, as shown in the Table IV of experimental results. We also found that the number of detection heads is not as large as possible and that the structure with four detection heads is the most stable and effective. Given the input X, the individual steps are as follows:

$$Z = \sum_{i=1}^N Anchor_i \oplus X_i \quad (4)$$

where N denotes the number of prediction heads. *Anchor* denotes an anchor frame set based on prior knowledge. \oplus denotes the matching of *Anchor* with X to obtain a set of prediction boxes. Then, the result after matching is concatenated with the original input X. Finally, the convolution operation is used to continuously traverse the entire region to obtain the final feature map. The details are as follows:

$$Out = Conv(Concat(Z, X)) \quad (5)$$

where *Out* denotes the final feature map.

Multi-Stage Concatenation. The receptive field, the most important component in CNN-based models, is used to extract abstract features layer by layer. In deep layers, the receptive field is relatively large to extract features, and conversely, it is smaller in shallow layers. In general, feature maps captured by larger receptive fields have stronger semantic representation but weaker spatial representation. In contrast, feature maps captured by smaller receptive fields have weaker semantic representation but stronger spatial representation. To this end, we combine the original concatenation module with the BiFPN algorithm [25] to fully exploit the properties of feature maps from deep and shallow layers. The importance of features from different layers is defined by a learnable weighting parameter *W*. The parameter is defined as :

$$W_i = \frac{X_i}{\sum X_i + \varepsilon} \quad (6)$$

where X_i denotes the input of each layer, and W_i denotes the weight parameter of each input layer. ε is set to 0.0001.

According to Eq. 6 the formation of the result can be formulated as follows:

$$Y = Conv(ReLu(\sum_{i=0}^{N-1} W_i \times X_i)) \quad (7)$$

where *Y* denotes the result and *Conv* denotes the convolution operation; *Relu* denotes the activation function and *N* denotes the number of input layers. Both semantic features and spatial features can be transferred to different depth layers by

feature fusion and mapping. This method improves the model's ability to extract and express features, and thus improves recognition performance.

Loss Function. The loss function of YOLOv5 divides the objective function into three subfunctions, namely object, classification, and regression. However, we found that the original loss function uses the basic Intersection-over-Union (IoU) loss, which limits the ability to measure the overall performance of the model. The total loss is calculated as follows:

$$Loss = w_{obj} \times loss_{obj} + w_{cls} \times loss_{cls} + w_{reg} \times loss_{reg} \quad (8)$$

where $loss_{obj}$, $loss_{cls}$, and $loss_{reg}$ denote the object objective function, classification objective function, and regression objective function, respectively. w_{obj} , w_{cls} , and w_{reg} denote their weighting values set a priori to 0.3, 0.05, and 0.7, respectively.

To better measure the difference between confidence in the predicted object and the true value, we construct this objective function $loss_{obj}$ based on cross-entropy loss. For a given predicted value *x* and a true value *y*, the equation is as follows:

$$loss_{obj} = -\frac{1}{n} \sum_{i=1}^n (y_i \times \ln i + (1 - y_i) \times \ln (1 - x_i)) \quad (9)$$

Although the predictions are multiclassification, there is only one positive sample, so we use the loss of cross entropy. After we use the cross entropy as the loss function, the gradient of the backpropagation is no longer associated with the derivative of the sigmoid function. This avoids the disappearance of the gradient to some extent. $loss_{obj}$ is the same as $loss_{cls}$.

In the regression task, the most direct indicator to determine the distance between the predicted box and the ground truth is the intersection over union (IoU), and $IoU = \frac{|A \cap B|}{|A \cup B|}$, however, does not accurately reflect the intersection of the two boxes and cannot be trained further due to disjunction. Therefore, we use the complete-IoU [55] to construct the objective function of the regression task. We consider the similarity of the aspect ratio between the ground truth and the predicted box.

$$loss_{reg} = 1 - IoU + \frac{\beta^2 \times (b_p, b_g)}{c^2} + \alpha \times \nu \quad (10)$$

$$\alpha = \frac{\nu}{\nu - IoU + (1 + \varepsilon)} \quad (11)$$

$$\nu = \frac{4}{\pi^2} \times \left(\frac{w_g}{h_g} - \frac{w_p}{h_p} \right)^2 \quad (12)$$

where b_p and b_g denote the centers of the prediction box and the ground truth, respectively. β denotes the Euclidean distance between the two centers. *c* denotes the distance of the diagonals of the smallest region containing both the prediction box and the ground truth. α denotes the weighting parameter. ν is used to measure the similarity between the aspect ratio of the prediction box and the ground truth.

B. Image Enhancement Module

The 3D lookup table is an algorithm that reconstructs the hue of an image by creating a color map. The essence of the 3D lookup table is a mapping relation: $(R, G, B) = f(r, g, b)$, where f represents the mapping function. Moreover, it is an intuitive idea to learn a classifier to classify the scene. Suppose M 3D lookup tables, denoted by $\{\mu_n\}_{n=1,\dots,M}$, are learned. The classifier outputs N probabilities $\{p_n\}_{n=1,\dots,N}$ for classifying the scene. The process of 3D lookup table selection can be described as follows:

$$q = \mu_i(x), \quad s.t. \quad i = \arg \max_n p_n \quad (13)$$

where x denotes an input image and q the output. Another common method for improving image quality is to manually adjust the parameters of a 3D lookup table. However, manually adjusting the parameters is extremely time consuming when processing large images. The parameters need to be adjusted based on scenarios that have different negative effects. Therefore, the applicability of the method is hindered by a lack of flexibility and practicality.

H. Zeng developed an end-to-end adaptive image enhancement method [46] based on 3D lookup tables and a convolutional network. The model learns how to improve image quality based on paired data, namely the affected images and the images optimized by experts. To this end, we propose a specific model for image enhancement by developing adaptive models for each “3D Lookup Table” to improve the weighting evaluation. Moreover, in this work, we train the image enhancement model by combining preprocessed images, i.e., foggy images and low-light images, with clear original images.

The image enhancement model introduces 4 basic 3D lookup tables along with a CNN-based model g that predicts weights for the output of each 3D lookup table. For an input image x , the final enhancement result is as follows:

$$q = \sum_{n=1}^4 w_n \mu_n(x) \quad (14)$$

where $\{w_n\}_{n=1,\dots,4} = g(x)$ are the content-dependent weights output by the CNN-based model. Specifically, we use different 3D lookup tables to enhance different images. Moreover, the color space of the image is transformed using 3D lookup tables, while the CNN weight predictor extracts information about the image content, including hue, brightness, contrast, etc. The weights obtained by the CNN predictors are assigned to the corresponding 3D lookup tables. Therefore, our model adaptively improves the image quality according to the image content and scene in low visibility conditions.

IV. EXPERIMENTS

We evaluate the effectiveness of PDE in fog and low-light conditions. We report the object detection metric mAP (average of all 10 IoU thresholds in the range of [0.5: 0.95]) and the image enhancement metrics PSNR (Peak Signal to Noise Ratio) and SSIM (Structure Similarity). We will present this section under the following aspects.

A. Experimental Details

Datasets. For the two tasks that PDE faces, i.e., target detection and image enhancement, we need to take different approaches to create datasets for the corresponding tasks so that we can effectively evaluate the performance of the model.

In object detection, we first evaluate the detection performance of the model under three conditions, including normal, foggy, and low light. We use the VOC dataset [56], [57] as a benchmark and the RTTS dataset [58] and the ExDark dataset [59] as test sets. To make better use of these datasets, we filtered out the common categories of the datasets. The VOC dataset shares five categories with the RTTS dataset, namely pedestrians, cars, buses, bicycles, and motorcycles. Similarly, the VOC dataset shares 10 categories with the ExDark dataset, namely, bicycles, boats, bottles, buses, cars, cats, chairs, dogs, motorcycles, and people. The VOC_5c training dataset and the VOC_5c test dataset, namely VOC_5c_train and VOC_5c_test, are created after screening and consist of 8111 and 2734 images, respectively.

Although we already have a dataset for normal conditions, we lack sufficient images of foggy conditions and low light conditions. Therefore, we use a weather simulation algorithm to simulate images under low visibility conditions. According [60], for the original input image $O(x)$, the foggy image $F(x)$ can be calculated as follows:

$$F(x) = O(x) \times g(x) + L \times (1 - g(x)) \quad (15)$$

where L denotes global atmospheric light, and $g(x)$ denotes the medium transmission map, which is defined as:

$$g(x) = e^{-\beta} \times s(x) \quad (16)$$

where β denotes the scattering coefficient of the atmosphere, and $s(x)$ denotes the scene depth which is calculated by

$$s(x) = -0.04 \times \rho + \sqrt{\max(\text{row}, \text{col})} \quad (17)$$

where ρ denotes the Euclidean distance from the current coordinate to the pixel coordinate of the image center, row and col represent the number of rows and columns of the images. Combining the Eq. 15, 16 and 17, we obtain the following equation for the generation of fog images:

$$F(x) = O(x) \times e^{-\beta} \times s(x) + L \times (1 - e^{-\beta} \times s(x)) \quad (18)$$

In this work, L is set to 0.5 and β is calculated using the formula $\beta = 0.05 + 0.01 \times \text{Num}$. Num is set to a random integer between 0 and 9. In this way, for each input image, we get up to 10 foggy images with different effects of fog concentration.

Similarly, we simulate low lighting conditions to create the low lighting conditions dataset. For a given input image, each pixel x in the image is transformed as follows:

$$f(x) = x^\gamma \quad (19)$$

where γ is determined randomly from a uniform distribution with a range of values of [1.5, 5].

TABLE I. AN OVERVIEW OF ALL DATA SETS USED IN THIS EXPERIMENT

Dataset	Number
VOC_5c_train	8111
VOC_5c_test	2734
VOC_10c_train	12334
VOC_10c_test	3760
VOC_fog_train	8111
VOC_fog_test	2734
VOC_low-light_train	12334
VOC_low-light_test	3760
RTTS	4322
ExDark	2563
LUTs_fog_train	20000
LUTs_fog_test	2000
LUTs_low-light_train	20000
LUTs_low-light_test	2000

To achieve ideal recognition performance under normal and low visibility conditions, we use a hybrid data training scheme for PDE. Each image in the normal datasets has a 2/3 probability of being randomly tagged with some kind of fog or converted to a low-visibility image before being input to the model for training. The hybrid data contains images from both normal and low visibility situations. The model becomes more robust when it learns with normal and low visibility images simultaneously, resulting in high performance.

Second, training an image enhancement model for image enhancement tasks requires a large amount of data to achieve an excellent result. Therefore, we extend the data again based on the simulated images in foggy and low-light conditions in the object recognition task. For the foggy conditions, we first add three random fog patches to each image in the VOC_5c_train dataset. Second, we randomly select 20,000 images from this dataset to form the fog training dataset, i.e., LUTs_fog_train. Similarly, we first randomly add fog to each image in the VOC_5c_test dataset. Second, we randomly select 20,000 images from this dataset to form the test dataset under foggy conditions, i.e., LUTs_fog_test.

In low light conditions, we perform the same steps to obtain the dataset, i.e. LUTs_low-light_train and LUTs_low-light_test.

We count the number of all records for this experiment, as shown in Table I. VOC_5c_train, VOC_5c_test, VOC_10c_train, VOC_10c_test, VOC_fog_train, VOC_fog_test, VOC_low-light_train, and VOC_low-light_test denote training and test sets, respectively, for object detection under normal, foggy, and low-light conditions. RTTS and ExDark are real-world datasets consisting of images taken under foggy and low-light conditions, respectively. LUTs_fog_train, LUTs_fog_test, LUTs_low-light_train, and LUTs_low-light_test denote training and test datasets for image enhancement in foggy and low-light conditions, respectively.

Baselines. This work focuses on improving the accuracy of object detection in low visibility conditions, complemented by image enhancement techniques to obtain more user-friendly references. Therefore, we perform comparison experiments and

ablation experiments mainly for the object recognition module, while for the image enhancement module, we only present its experimental results without detailed comparison with other excellent methods.

To evaluate the universality and effectiveness of PDE in fog and low-light conditions, we choose YOLOv5 as our baseline model. In addition, we compare our model with other excellent models for detecting objects in low visibility. We choose the real-time target detection model YOLOv3 as our comparison model. We also choose GridDehaze [35], MSBDN [5], and ZeroDCE [15], the most widely used CNN-based image enhancement methods, to process images before detection and then combine them with the object detection model YOLOv3 [43]. GridDehaze and MSBDN are both image enhancement models for removing fog by developing novel network modules to learn more effective feature representations for image unveiling. ZeroDCE achieves effective image enhancement by implementing intuitive and simple nonlinear curve mapping to adapt to different lighting conditions. For the domain adaptation approach, we choose DAYOLO [19], which combines multiple adaptation paths and corresponding domain classifiers with the YOLO object detector to produce domain-invariant features. For the multi-task learning algorithm, we choose DSNet [22], which can learn denoising and detection together. We also choose IA-YOLO [34], which can adaptively enhance each image to improve detection performance.

B. Experiments Results

To fully demonstrate detection performance, for each model we evaluate the model's ability to recognize objects under different conditions, namely normal, foggy, and low light. The improvements are calculated by comparing PDE with the best baseline (underlined). From Table II and Table III, it can be seen that PDE significantly outperforms the other SOTA models at low visibility in the detection scene in all data sets and at all settings. In particular, for the mAP metric, PDE outperforms the baseline model by 8.9% (RTTS) and 19.7% (VOC_fog_test) in foggy conditions. In low-light conditions, PDE outperforms the baseline model by 20.6% (ExDark) and 15.8% (VOC_low-light_test).

These results demonstrate the consistent superiority of our PDE in detection performance under poor visibility conditions. Moreover, the PDE also performs better than the corresponding best baselines in a normal scene. This phenomenon proves the strong scalability of PDE.

Image enhancement is a secondary task that helps improve the display for the user, as this work focuses on target detection. Therefore, we did not perform comparison experiments for the image enhancement task. We evaluate the model's ability to enhance images in fog and low-light conditions. For the PSNR metric, PDE achieves a score of 23.64 (fog test set) and 23.97 (low-light test set). For the SSIM metric, PDE achieves a value of 0.838 (fog test set) and 0.827 (low-light test set). In the following subsection IV-D, we conduct a case study to illustrate the excellent results of the image enhancement task.

C. Ablation Study

To test the effectiveness of the object detection model in PDE, we compare the detection performance of our model

TABLE II. COMPARISON OF DETECTION PERFORMANCE WITH BASELINES IN TWO SCENARIOS, INCLUDING NORMAL AND FOGGY CONDITIONS. THE IMPROVEMENTS ARE COMPUTED BY COMPARING OUR MODEL WITH THE CORRESPONDING BEST BASELINES (UNDERLINED)

Model	Train data	VOC_5c_test	VOC_fog_test	RTTS
MSBDN [5]	VOC_5c_train	-	57.4	30.2
GridDehaze [35]	VOC_5c_train	-	58.2	31.4
DAYOLO [19]	Hybrid data	56.5	55.1	29.9
DSNet [22]	Hybrid data	53.3	67.4	28.9
IA-YOLO [34]	Hybrid data	73.2	72.0	37.0
YOLOv3 [43]	VOC_5c_train	70.1	31.1	28.8
YOLOv3 [43]	Hybrid data	64.1	63.4	30.8
YOLOv5 [23]	VOC_5c_train	86.2	68.5	45.1
YOLOv5 [23]	Hybrid data	<u>85.6</u>	<u>71.4</u>	<u>50.5</u>
PDE	Hybrid data	86.7(1.3%↑)	85.5(19.7%↑)	55.0(8.9%↑)

TABLE III. COMPARISON OF RECOGNITION PERFORMANCE WITH BASELINES IN TWO SCENARIOS, INCLUDING NORMAL AND LOW LIGHT CONDITIONS. THE IMPROVEMENTS ARE COMPUTED BY COMPARING OUR MODEL WITH THE CORRESPONDING BEST BASELINES (UNDERLINED)

Model	Train data	VOC_10c_test	VOC_low-light_test	ExDark
ZeroDCE [15]	VOC_10c_train	-	33.6	34.4
DAYOLO [19]	Hybrid data	41.7	21.5	18.2
DSNet [22]	Hybrid data	64.1	43.8	37.0
IA-YOLO [34]	Hybrid data	70.0	59.4	40.4
YOLOv3 [43]	VOC_10c_train	69.1	45.9	36.4
YOLOv3 [43]	Hybrid data	65.3	52.3	37.0
YOLOv5 [23]	VOC_10c_train	78.2	60.8	43.2
YOLOv5 [23]	Hybrid data	77.1	64.5	45.0
PDE	Hybrid data	79.5(3.1%↑)	74.7(15.8%↑)	54.3(20.6%↑)

TABLE IV. ABLATION ANALYSIS OF MODULES OF OUR MODEL IN REAL DATA SETS UNDER LOW VISUAL CONDITIONS. CA DENOTES THE COORDINATE ATTENTION MODULE. MSC DENOTES THE CONCATENATION MODULE COMBINED WITH MULTI-STAGE FEATURE FUSION. MH DENOTES THE MODULE WITH MULTIPLE PREDICTION HEADS. THE IMPROVEMENTS ARE COMPUTED BY COMPARING THE VARIANTS WITH YOLOV5 (UNDERLINED)

Model	Method			RTTS	ExDark
	CA	MSC	MH	mAP	mAP
YOLOv5	✗	✗	✗	<u>50.5</u>	<u>45.0</u>
PDE w/o MH	✓	✓	✗	52.5 (3.9%↑)	49.9 (10.9%↑)
PDE w/o MSC	✓	✗	✓	52.9 (4.7%↑)	53.6 (19.1%↑)
PDE w/o CA	✗	✓	✓	55.0 (8.9%↑)	53.8 (19.5%↑)
PDE	✓	✓	✓	55.0 (8.9%↑)	54.3 (20.6%↑)

with its variants on two real datasets (RTTS and ExDark) in Table IV. In the following experiments, we use the data as our training dataset. “PDE w/o MH” means we omit the tiny prediction head in PDE. “PDE w/o MSC” means we omit the multi-stage concatenation module in PDE. “PDE w/o CA” means we omit the coordinate attention module in PDE.

As shown in Table IV, “PDE w/o MH” is 3.9% and 10.9% higher than YOLOv5 in RTTS and ExDark, respectively. However, “PDE w/o MSC” is 4.7% and 19.1% higher than YOLOv5, respectively, whereas “PDE w/o CA” is 8.9% and 19.5% higher than YOLOv5, respectively. Although the coordinate attention module can improve the performance of the model, the effect is not very large when the Table IV is analyzed. On the contrary, the tiny prediction head and multi-stage concatenation module significantly improve the performance of the model. In particular, the growth rate obtained with “PDE w/o MSC” reaches the maximum in ExDark, which proves

that the module uses the features extracted from the backbone network very effectively under low light conditions. Moreover, the growth rate of “PDE w/o CA” reaches the maximum in RTTS, where the multi-stage concatenation module fully utilizes the effective features in the images combined with the tiny prediction head to perform target detection.

According to Table IV, PDE consistently outperforms the other variants, underscoring the need for and effectiveness of these methods, as noted in III-A.

D. Case Study

In Fig. 4, we visualized the detection result on two real datasets (RTTS and ExDark). In particular, we compare the detection results of the base models YOLOv5 and PDE. As you can see in Fig. 4, PDE can achieve better object detection accuracy and user representation in low-visibility. Moreover, inference time is an important metric to evaluate

Fig. 4. Visualization. Detection results of YOLOv5 (middle row) and PDE (bottom row) on RTTS (columns 1, 2) and ExDark (columns 3, 4). PDE achieves better object detection accuracy and better visualization for the user in low visibility images.

the practicality of models. Therefore, we conduct extensive test experiments to evaluate PDE by processing 480×480 images on a single GTX 2080Ti GPU. The experiment showed that PDE can process more than 30 frames per second. Therefore, PDE can achieve better user representation and detection while meeting real-time requirements.

V. CONCLUSION

In this paper, we note that the existing low visibility models suffer from the wobble phenomenon caused by the absence of better detection and image enhancement performance. We propose the parallel detection and enhancement model (PDE) to ensure that image enhancement and object detection perform their tasks. For object detection, PDE introduces a tailored model for low-visibility object detection by introducing a tiny prediction head, combined with coordinate attention and multi-stage concatenation modules. For image enhancement, PDE proposes a dedicated image enhancement model by developing an adaptively enhanced weighting model for each “3D Lookup Table” module. By decoupling these two concepts, PDE can improve the overall performance. Extensive experiments show that PDE achieves better accuracy in detecting low-visibility objects and more user-friendly reference in real time in all situations.

Design and Implementation of an Unreal Engine 4-Based Smart Traffic Control System for Smart City Applications

Md. Imtiaz Hossain Subree¹, Md. Rakib Hasan², Maksuda Haider Sayma³
Dept. of ICT, Comilla University, Cumilla - 3506, Bangladesh

Abstract—Traffic congestion is a serious problem nowadays, especially in Dhaka city. With the increasing population and automation, it has become one of the most critical issues in our country. There can be a lot of causes of congestion in traffic, such as insufficient capacity, large red signal delay, unrestrained demand, etc, which causes extra time delay, extra fuel consumption, a speed reduction of vehicle, and financial loss. The traffic control system is one of the most important factors affecting traffic flow. Poor traffic management around these hotspots could result in prolonged traffic jams. Small critical locations that are frequent hotspots for congestion are a common byproduct of poorly constructed road networks in many developing countries. In this research, we first offer a straightforward automated image processing method for analyzing CCTV camera image feeds to determine the level of traffic congestion. Our system's design seeks to use real-time photos from the cams at traffic intersections to calculate traffic density using image processing, and to adjust the traffic signal on the data obtained based on the current traffic congestion on the road. We suggest tailoring our system to erratic traffic feeds with poor visual quality. Using live Surveillance camera feeds from multiple traffic signals in Dhaka city, we demonstrate evidence of this bottleneck breakdown tendency persisting over prolonged time frames across multiple locations. To partially address this problem, we offer a local adapting algorithm that coordinates signal timing behavior in a restricted area and can locally minimize congestion collapse by maintaining time-variant traffic surges. Using simulation-based research on basic network topologies, we show how our local decongestion protocol may boost the capacity of the road and avoid traffic collapse in limited scenarios.

I. INTRODUCTION

Within the cutting-edge generation, the exponential growth of traffic congestion is among the most vital problems facing our civilization today. Due to the rise in automobiles in urban regions, many road networks are experiencing issues with the decline in road capacity and the accompanying stage of the carrier.

Traffic congestion eats up 5 million working hours each day in Dhaka city, which costs the country 11.4B USD a year. Vehicular speed has decreased from 21kmph to 6.5kmph in the last 12 years, which causes 40% of fuel wastage. 40% of the fuel is being wasted. There are 70 signalized intersections in Dhaka city. In our country, generally, 2 types of systems are used for controlling traffic at intersections.

- 1) Manual Traffic Control System: In the manual traffic control system, to manage traffic, a certain region is

assigned to traffic police. To regulate traffic, traffic police utilize signboards, whistles, lasers, and other tools.

- 2) Automatic Traffic Control System: In an automatic system, Traffic Lights are used to control the traffic. A timer is used to control the signals of the traffic lights. The lights get off and on based on the timer value. [1]

The conventional methods have distinct drawbacks. There is a significant labor requirement for the manual controlling system. We are unable to have traffic police manually regulate traffic in all sections of a town or city due to the inadequate number of traffic officers. Conventional traffic control employs a traffic signal with a timer for each phase that is static and cannot change based on the volume of traffic on that particular road in real time. It's always fixed and do not alter or update in real-time in accordance with traffic on the roads [1].

The main problem with the conventional automatic traffic control system is, the traffic lights use a timer for every segment, which is rigid and does not update or change based on the real-time traffic on the road. During morning and evening, the majority of the traffic movement direction is always opposite. Taking into account this theory, one particular direction with heavier traffic is given the same amount of green signal time as the other direction, which has lesser traffic than the other or in some cases, no traffic at all, which is inconvenient.

So, the main problems identified by us were

- Manual Traffic control system is inconvenient and faulty.
- Automatic Traffic control system uses a fixed timer which is rigid and does not update with the real-time traffic on the road.

From this existing problems, the following research questions arise:

- Is there a better way to replace the existing system?
- Can we upgrade the existing automatic traffic control system with a timer that can adjust to the existing traffic condition and update based on that?

Our suggested method intends to provide a computer vision-based traffic signal controller that can adjust to the existing traffic condition. It makes use of actual footage from the Surveillance cameras installed at road intersections to determine the traffic density by measuring the number of cars at

the light and altering the length of the green signal accordingly. The vehicles are separated into four categories: automobiles, trucks, buses, and bikes to calculate the correct calculation of the green light time. The system employs YOLOv5 to compute the number of automobiles before modifying the traffic signal's timer in line with the suitable direction of vehicle density. In contrast to a static system, traffic is cleared significantly more swiftly thanks to this, maximizing the periods whenever the green light is on. Unwanted delays, traffic, and waiting times are reduced as a result, which also reduces fuel consumption and emissions.

The main contribution of our proposed system are as follows:

- Proposing a better solution for timer based automatic traffic control system.
- Using the existing Surveillance cameras on the road to collect the traffic info and update the signals accordingly.
- Using YOLOv5, which is 88% smaller and 180% faster than YOLOv4, to compute the number of automobiles before modifying the traffic signal's timer in line with the suitable direction of vehicle density.
- Achieving almost perfect result by counting the number of vehicles, identifying the types of vehicles, measuring the speed of each vehicle and feeding proper value to the server.

II. LITERATURE REVIEW

de Frías, C. J., Al-Kaff, A., Moreno, F. M., Madridano, Á., and Armingol, J. M. describe a cooperative system for monitoring traffic flow based on the use of unmanned aerial vehicles (UAVs) in [10]. A lightweight semantic neural network was suggested by this system, which uses RGB photos as input to produce a segmented image of the vehicles and their 2D actual positions. Then, each car receives this information so that it may fully understand its environment. The suggested approach has undergone multiple experiments with a variety of scenarios and conditions, and the outcomes demonstrate the system's effectiveness and robustness while also demonstrating how it may be used for traffic monitoring.

PJ Navarathna, VP Malagi proposed some important technology and answers to the many issues that the lack of digitalization was causing the populace in [9]. It addresses problems with the city's infrastructure, public security, and safety, and offers the best remedies. It places a strong emphasis on using AI in conjunction with other technologies, such as the Internet of Things (IoT), deep learning, machine learning, pattern recognition, big data analytics, and cloud infrastructures, to create a fully functional smart city.

Karimi, A., and Duggirala, P. S. presented a new approach to formalizing and implementing traffic rules in [12]. The DMV driver manual for California is used as a working example. Its method offers a clear mapping between the handbook's rules and their formal model, as well as between the model and implementation. They use the Clingo programming language to explicitly model the traffic regulations in the Answer Set Programming (ASP) logic programming paradigm to show

the effectiveness of this method. They later incorporate these regulations into CARLA, a computerized testing ground for autonomous automobiles. By correctly applying the right-of-way rules for autonomous cars in real-time, they replicate the behavior of autonomous vehicles at four-way and three-way uncontrolled junctions. As a result, as compared to CARLA's default FIFO controller, the behaviors of autonomous vehicles under our controller are more realistic.

Manjón Prado, Javier examined the escalating issue of traffic congestion, as well as various potential solutions, such as traffic simulation software and autonomous vehicles in [11]. The new choice for recreating a traffic scenario is Unreal Engine. Using a click-and-drag editor, a tool has been developed that enables users to build and alter road tracks and add autonomous car models to them. Different scenarios are used to evaluate the simulator while important data is collected. Finally, the results are discussed together with suggestions and directives for future improvement.

Khushi used video processing to fix the congestion problem in [1]. Before being delivered to the servers, the footage from the live stream is processed. There, a CPP-based algorithm is utilized to generate the outcome. The dynamic algorithm demonstrated a 35

Renjith Soman employed ANN and a fuzzy controller to suggest a smart traffic signal system in [2]. Images obtained from cameras placed at traffic locations are used by this system. Before further normalization, the image is initially transformed to a grayscale version. Following that, the segmented image is passed through an ANN to count the automobiles regardless of size, and the output is then used in a control scheme to set periods for the green and red lights using crisp output. Results had a 2

Chabchoub, A., Hamouda, A., Al-Ahmadi, S., and Cherif, A. designed a smart traffic light controller using fuzzy logic and image processing with MATLAB, to control movement in two ways, aided by a camera and auto sensors. in [3]. The Fuzzy logic has two inputs and six outputs designed, the console input is the number of cars on each road and the time of the assumed red, yellow and green signal according to the vehicles congestion. The simulation result is similar to the proposed control unit, as it deals with the lights simultaneously according to the number of cars in each branch of the road, which leads to the use of all the time to operate the stoplights.

A. A. Zaid, Y. Suhweil, and M. A. Yaman suggested a traffic signal that can be adjusted to the prevailing traffic conditions using fuzzy logic [4]. For the major and secondary driveways in this system, two fuzzy control systems with three inputs and one output are used. Simulated traffic conditions were improved for lower traffic density using VISSIM and MATLAB.

Al-Majhad, H. G., Bramantoro, A., Syamsuddin, I., Yuni-anta, A., Basori, A. H., Prabuwono, A. S., and Barukab, O. M. aims to benefit from the current Riyadh road infrastructure and apply the Internet of Things paradigm for detecting traffic congestion with Everything as a Service approach. in [5]. By using the services, the users are able to identify the exact location where congestion occurs and an alternate solution can be provided easily. To achieve this, Business Process Execution Language is embedded as a supporting framework layer. This

approach clearly defines how the services are executed through the proposed models.

Agrawal, Aditi, and Rajeev Paulus proposes Fuzzy Adaptive Control System (FACS) that uses fuzzy logic to decide the phase sequence and green-time for each lane based on sensed input parameters in [6]. It is designed with an aim to improve traffic clearance at isolated intersection especially in peak traffic hours of the day along with giving precedence to emergency vehicle as soon as it is detected and also assist pedestrian passage thus reducing their waiting time at the intersection. Performance of the proposed Fuzzy Adaptive Control System (FACS) is evaluated through simulations and compared with Pre-Timed Control System (PTCS) and Traffic Density-based Control System (TDCS) at a busy intersection with lanes leading to offices, schools and hospitals. Simulation results show significant improvement over PTCS and TDCS in terms of traffic clearance, immediate addressing of the emergency vehicle and giving preference to pedestrian passage at the intersection.

Adeb, Tesfanesh, Di Wu, and Muhammad Ibrar presented heuristic algorithms called Congestion-Free Path (CFP) and Optimize CFP (OCFP), in SD-VANET architecture in [7]. The proposed algorithms address the traffic congestion issue and also provide a feasible path (less end-to-end delay) for a vehicle in VANET. They used the NS-3 simulator to evaluate the performance of the proposed algorithms, and for generating a real scenario of VANET traffic; we use the SUMO module. The results show that the proposed algorithms decrease road traffic congestion drastically compared to exiting approaches.

Saili Shinde examined the various traffic signal control system techniques in [8]. This study notes that each method has a similar architecture, which includes selecting input data, extracting traffic parameters from it, processing it, figuring out density, and updating parameters. The numerous traffic signal control system methods are examined in this reference. This paper shows that the architecture of each approach is similar and consists of picking data input, obtaining traffic data from it, analyzing it, calculating intensity, and changing parameters. The first method involves the employment of VANETS to collect information on each vessel's position, which is subsequently sent via installed GPS to the nearest Intelligent Traffic Light (ITL). Additionally, these ITLs will update the vehicles around with statistics. In the event of incidents, information would be provided to drivers so they could choose an alternative path to avoid traffic. This method is not workable because of the high deployment costs. The second technique uses a transceiver to capture each car's token utilizing infrared sensor-based embedded systems. Vehicles' data lines regularity tags can be used to identify them in an emergency and let vehicles pass. By adopting this technique, red light violations are discovered. However, this strategy is not flexible because infrared sensors need to be visible. The third methodology employs a fuzzy logic approach and two probabilistic reasoning controllers, one of which lengthens the green period of a route at an intersection and the other of which optimizes the signal. The outgoing and incoming lines' record cameras act as sensors to collect data from input sources. The controller then uses the data gathered by these detectors to determine the best course of action and minimize the goal function. The fourth method uses fuzzy reason, and

the system's inputs include the number of vehicles and the average speed of movement in each route. Using sensors placed along the route, it is possible to calculate the number of cars and the cruising pace of the flow of traffic. The fifth approach makes use of spaced-apart photoelectric sensors to collect data and transmit it to the traffic panel, which weighs each road individually and adjusts the traffic light as necessary. However, maintenance is quite expensive. Video image processing is employed to detain the data in the sixth technique. Dynamic noise removal and numerous morphological processes are conducted to get a clear illustration of the automobile. A fresh rectangle is generated, and the vehicle calculation is increased each time a new car enters the subject of attention. Although the algorithm is simple to use, it does not account for shadow overlapping and occlusion.
