
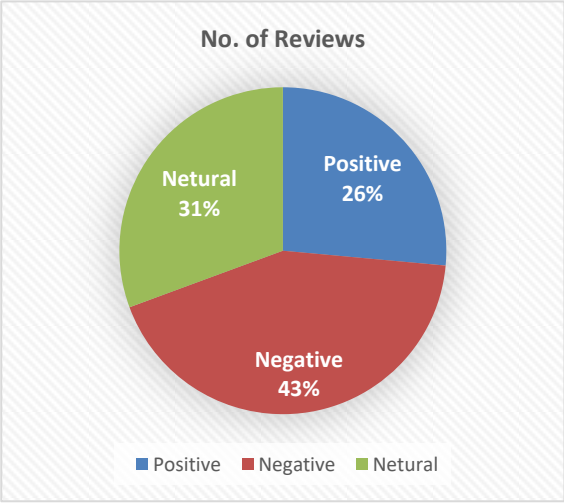

Fig. 2. MASR Dataset Polarity Distribution.

Table III represents samples of MASR datasets which contains app category, app name, review, translated review, rating, and polarity (Negative, Positive, Neutral).

4) Second phase: Text Preprocessing phase: The initial step is to implement text pre-processing so as to evolve the performance of classifiers by changing the text into a format as suitable as possible. To achieve this, many stages are executed; specifically, normalization, tokenization, stop-word removal and stemming.

5) Normalization: This stage includes the accompanying steps: Remove punctuation marks and special characters, remove tatweel kashida symbol ("--"), remove of all diacritics, remove digit numbers (0-9), remove repeated characters, remove all non-Arabic words, replace each final letter (ي) with (ى), replace initial letter alef-hamza (أ، إ،ء،ئ،ؤ، آ) with (ا), and replace each final letter (ة) with (ه).

TABLE III. MASR REVIEWS

App Category	*App Name*	*Review*	*Translated Review*	*Rating*	*Polarity*
Productivity	Ana Vodafone	معرفتش ادفع ببطاقة الائتمان	I don't pay by credit card	3	Negative
Travel & Local	EGYPTAIR	برنامج رائع برجاء اضافة صاله السفر والوصول في حالة الرحلة	Wonderful program, please add the travel and arrival hall in case of flight	4	Positive
Tools	SHAREit	طبيق ممتاااز بس احيانا لما احاول ابعت حاجه لإصدار اقل مني ميبعتش	An excellent application, but sometimes when I try to send something less than me, I need to issue it	5	Neutral

6) Tokenization: For author/s of more than two affiliations: To change the default, adjust the template as follows. By tokenizing, you can appropriately separate text by word or by sentence. This will permit act with smaller sets of text that are still comparatively meaningful regular outgoing of the context of the remainder of the text. In this research, Regexp Nltk14 method applies on MASR dataset. It divides a string into substrings utilizing a standard expression. It can utilize its regexp to look like delimiters instead.

7) Stop word removal: The second stage is to eliminate all stop-words from the reviews. Stop words are characterized as words that don't increase any sentiment value to a review; they are typically the most widely recognized words in a language. They can either be specially made or gained from the web. Unfortunately, there is no clear list accessible and there are slight lists accessible for the Arabic language. This research adjusted Arabic stopword list from many resources in addition to Egyptian stopword list from [24].

8) Stemming: Stemming is a text processing method of decreasing a word to its root. It maps various patterns of the similar word to a public "stem" - for example, the Arabic stemmer maps طفل, اطفال, الاطفال, اطفالكم, فأطفالكم, اطفالهم, والاطفال, والطفولة, وطفل, فاطفالهم, and طفلتان to طفل. In this research, Snowball[15] stemmer applies on MASR dataset.

a) Third phase: Splitting phase: MASR dataset was separated into two sections: training sets, and testing sets. The training sets represent 70% of the datasets, and the testing sets represents 30%. The training sets utilized to train models, while the testing sets utilized to evaluate models.

[14] https://www.nltk.org/_modules/nltk/tokenize/regexp.html
[15] https://git.texta.ee/texta/snowball/-/blob/master/python/testapp.py

b) Fourth phase: Feature extraction phase to estimate classifiers performance, this research utilized various variety of features. Those features can be Bag-of-Words (BOW) with TF-IDF (Term Frequency Inverse Document Frequency).

9) Bag of Words (BOW) [16]: BOW is a process of eliciting features from text for utilize in modeling, such as with ML algorithms. BOW model assigns a corpus with word counts for every document.

*10)*Term Frequency- Inverse Document Frequency (TF-IDF) [17]: Tf-IDF weight is a statistical measure utilized to estimate how significant a word is to a document in a corpus. The significance grows proportionally to the frequency of times a word represents in the document. It is formed by two sections:

$$Tfidf = \log(word, review) * \log \frac{\sum reviews}{\sum freq\ of\ words} \quad (1)$$

a) Fifth phase: Hybrid supervised classification approach phase: This phase performs two subsections: the first issue is applying ML approach which performs five selected ML classifiers which utilized extensively for ASA: Logistic Regression (LR) [25] [26] [27] [28], Naïve Bayes (NB) [29] [30] [31] [32], K-Nearest Neighbors (KNN) [33] [34] [31] [35], Random Forest (RF) [36] [37] [38] and SVM [33] [39] [40] in addition applying DL approach which performs DL classifier Multi-Layer Perceptron Neural Network (MLP-NN) which applied in [36] [37] for ASA.

For the second issue: This research intends to propose a novel Hybrid Supervised Classification Approach to automatically classify and predict the polarity of mobile apps Arabic Slang user reviews. This model mixes various supervised ML, and DL approaches. In ML approach, we suggest various modeling approaches: decision tree approach, and statistical approach. While in DL approach, we suggest linear & non-linear approach. In decision tree approach, we apply RF classifier. In Linear & Non-Linear approach, we apply MLP-NN classifier. In Statistical approach, we apply LR classifier. The reason for selecting those classifiers came after applying various ML classifiers in a previous phase. The results shows that the top classifiers that gain best accuracy for classify or predict MASR datasets are: RF, LR, and MLP-NN. Finally, we propose to apply a hybrid classification model that combines those three techniques to improve accuracy performance.

b) Six phase evaluation phase: To evaluate ML, DL, and our proposed hybrid classification approaches algorithms, this research applied 10-fold cross validation. This paper assessed performance of those models utilizing various evaluation measures: Accuracy (ACC) [41], F-measure [41], Precision (PRE) [41], Recall (REC) [41], Area Under the Curve (AUC) [42], and Ensemble classifier average [28].

$$Accuracy = \frac{\sum TP+\sum TN}{\sum TP+FP+TN+FN} \quad (2)$$

$$Precision = \frac{TP}{TP+FP} \quad (3)$$

$$Recall = \frac{TP}{TP+FN} \quad (4)$$

$$F-Measure = \frac{2*Precision*Recall}{(Precision*Recall)} \quad (5)$$

$$F\ abs = \left(\frac{AUC\ non-iv}{AUC\ iv}\right) * \left(\frac{Dose\ iv}{Dose\ non-iv}\right) \quad (6)$$

$$Ensemble(AVG) = \sum \frac{1}{n}(a1 + a2 + \cdots . + an) \quad (7)$$

IV. Results and Discussion

For empirical study, ORANGE Data Mining tool utilizes a component-based, inclusive model for DM and ML users and developers. Also, this research utilizes it for ML, and DL Models purposes. It is a combination of Python-based, and NLTK library modules which perform a set of functions such as data input, pre-processing, splitting, visualization, classification, prediction, and evaluation. Classifier methods used to classify MASR dataset utilizing: ML approach which perform KNN, SVM, NB, & LR, DL approach which perform MLP-NN for ASA. In addition, this paper suggests a novel hybrid classification technique which combined from two top ML classifiers in addition to DL classifier: LR + RF +MLP-NN to enhance accuracy for classification and prediction. k-fold cross-validation was utilized with k = 10. Accuracy, F1, Precision, Recall, AUC were utilized for evaluate MASR sentiment polarity datasets.

The results are discussed separately for each evaluation criterion. Moreover, to ensure the performance of the classifiers, this paper combined various domains to test the accuracy of various ML, DL, and our proposed hybrid approach using Arabic dialect features.

1) Accuracy (AUC): Fig. 3 represents the performance of three various classification approaches: ML classifiers (KNN, SVM, NB, RF, LR), DL classifier (MLP-NN), and our proposed hybrid classification model approach: ML+DL (LR+RF+MLP-NN).

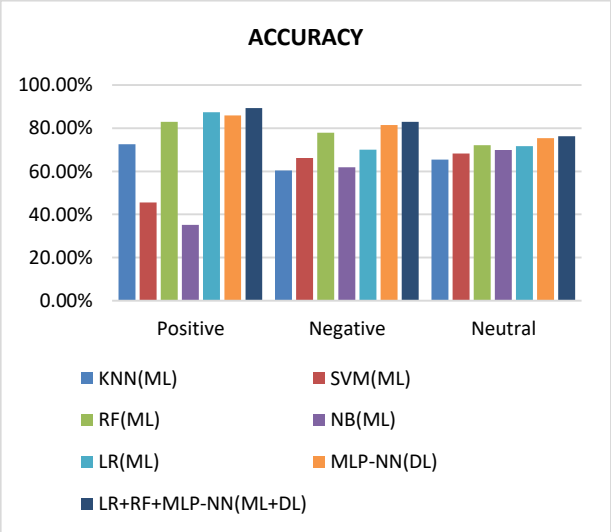

Fig. 3. Accuracy of Ml, Dl, and Hybrid (ML+DL) Approach.

[16]https://gist.github.com/mwitiderrick/363a71bc0d686383a33132aa9f896fce

[17] https://scikit-learn.org/stable/modules/feature_extraction.html

After applying ML classifiers on Positive Sentiments, results show that LR (87.5%), and RF (83%) shows better accuracy compared to a KNN (72.6%), SVM (45.5%), and NB (35.1%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that NLP-NN accuracy (86%) is approximate to ML classifiers: RF, and LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better accuracy (89.4%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

After applying ML classifiers on Negative Sentiments, results mention that RF (78%), and LR (70%) shows better accuracy compared to a SVM (66.2%), KNN (60.4%), and NB (61.9%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that NLP-NN accuracy (81.5%) perform better accuracy than top two ML classifiers LR, RF. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better accuracy (83%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

After applying ML classifiers on Neutral Sentiments, results mention that RF (72.1%), and LR (71.7%) shows better accuracy compared to a NB (69.9%), SVM (68.3%), and KNN (65.5%), and respectively. In addition, after applying DL classifier: MLP-NN, results observe that NLP-NN accuracy (75.4%) perform better accuracy than top two ML classifiers LR, RF. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better accuracy (76.3%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

2) Precision (PRE): Fig. 4 represents the various precision results of three different classification approaches: ML classifiers (KNN, SVM, NB, RF, LR), DL classifier (MLP-NN), and our proposed hybrid classification model approach: ML+DL (LR+RF+MLP-NN).

After applying ML classifiers on Positive Sentiments, results mention that LR (91%) and RF (66.3%) shows better Precision results compared to a KNN (48.8%), SVM (31.8%), and NB (29%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that Precision of LR (91%) perform better than Precision of NLP-NN (70.8%). And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that Precision result is (84.4%). So, LR performs better Precision result than our proposed hybrid approach.

After applying ML classifiers on Negative Sentiments, results mention that NB (96.3%) and SVM (73.9%) shows better Precision results compared to a RF (71.8%), LR (59.6%), and KNN (54.1%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that Precision of NB (96.3%) perform better than Precision of MLP-NN (76.1%). And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that Precision result is (79.1%). So, NB performs better Precision results than our proposed hybrid approach, and MLP-NN.

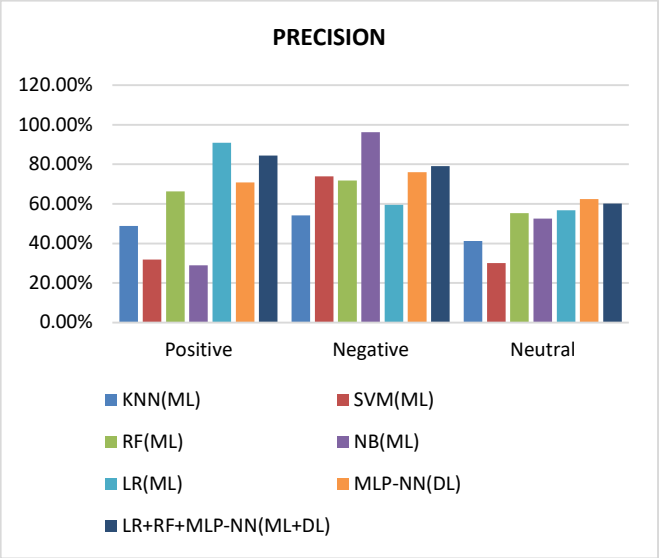

Fig. 4. Precision of Ml, Dl, and Hybrid (ML+DL) Approach.

After applying ML classifiers on Neutral Sentiments, results mention that LR (56.8%) and RF (55.3%) shows better Precision results compared to a NB (52.6%), KNN (41.3%), and SVM (30.1%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that Precision of NLP-NN (62.5%) perform better than top two ML classifiers LR, RF. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that Precision result is (60.2%). So, MLP-NN(DL) performs better Precision results than our proposed hybrid approach.

3) Recall (REC): Fig. 5 illustrates the various recall results of three different classification approaches: ML classifiers (KNN, SVM, NB, RF, LR), DL classifier (MLP-NN), and our proposed hybrid classification model approach: ML+DL (LR+RF+MLP-NN).

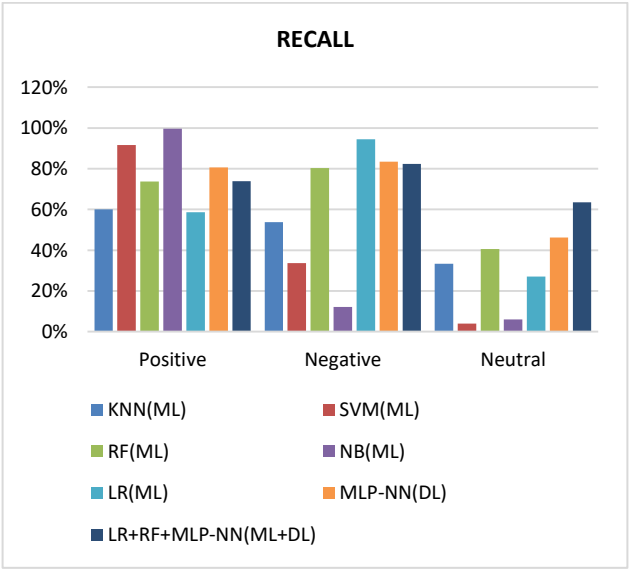

Fig. 5. Recall of Ml, Dl, and Hybrid (ML+DL) Approach.

After applying ML classifiers on Positive Sentiments, results mention that NB (99.7%), and SVM (91.6%) shows better Recall results compared to a RF (73.7%), KNN (60%), and LR (58.7%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that Recall of MLP-NN (80.6%). And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that Recall of is (73.8%). So, NB and SVM perform better recall results than DL (MLP-NN) and our proposed hybrid approach (LR+RF+MLP-NN).

After applying ML classifiers on Negative Sentiments, results mention that LR (94.5%) and RF (80.3%) shows better Recall results compared to a KNN (53.8%), SVM (33.6%), and NB (12.2%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that Recall of MLP-NN (83.5%). And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that Recall of is (82.3%). So, LR performs better recall results than DL (MLP-NN), our proposed hybrid approach (LR+RF+MLP-NN).

After applying ML classifiers on Neutral Sentiments, results mention that) RF (40%) and KNN (33.3%) shows better Recall results compared to a LR (27.1%), NB (6%), and SVM (4%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that Recall of NLP-NN (46.2%) perform better recall than top two ML classifiers RF, KNN. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better accuracy (63.5%) than the top three classifiers: ML (RF, KNN), and DL (MLP-NN).

4) F1-Measure: Fig. 6 represents the performance of three different classification approaches: ML classifiers (KNN, SVM, NB, RF, LR), DL classifier (MLP-NN), and our proposed hybrid classification model approach: ML+DL (LR+RF+MLP-NN).

After applying ML classifiers on Positive Sentiments, results mention that LR (71.3%) and RF (69.8%) shows better F1-Measure results compared to a KNN (53.8%), SVM (47.2%), and NB (45%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that F1-Measure of NLP-NN (75.4%) perform better than top two ML classifiers LR, RF. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better F1-Measure results (78.8%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

After applying ML classifiers on Negative Sentiments, results mention that RF (75%), and LR (73.1%) shows better F1-Measure results compared to a KNN (54%), SVM (46.2%), and NB (21.6%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that F1-Measure of NLP-NN (79.6%) perform better than top two ML classifiers LR, RF. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better F1-Measure results (80.1%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

After applying ML classifiers on Neutral Sentiments, results mention that RF (46.8%), KNN (36.9%) and LR (36.7%) shows better F1-Measure results compared to a SVM (6.7%), and NB (10%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that F1-Measure of NLP-NN (53.1%) perform better than top two ML classifiers LR, RF. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better F1-Measure results (61.8%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

5) Area Under the Curve (AUC): Fig. 7 represents a graph of the various AUC results of three different classification approaches: ML classifiers (KNN, SVM, NB, RF, LR), DL classifier (MLP-NN), and our proposed hybrid classification model approach: ML+DL (LR+RF+MLP-NN).

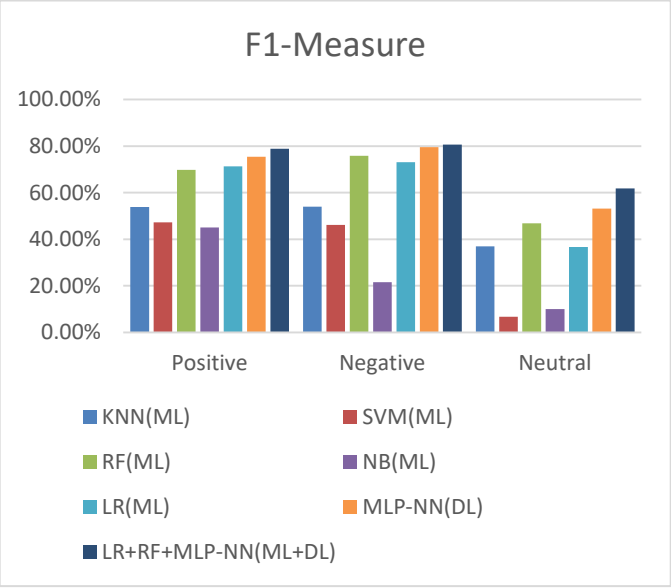

Fig. 6. F1-Measure of Ml, Dl, and Hybrid (ML+DL) Approach.

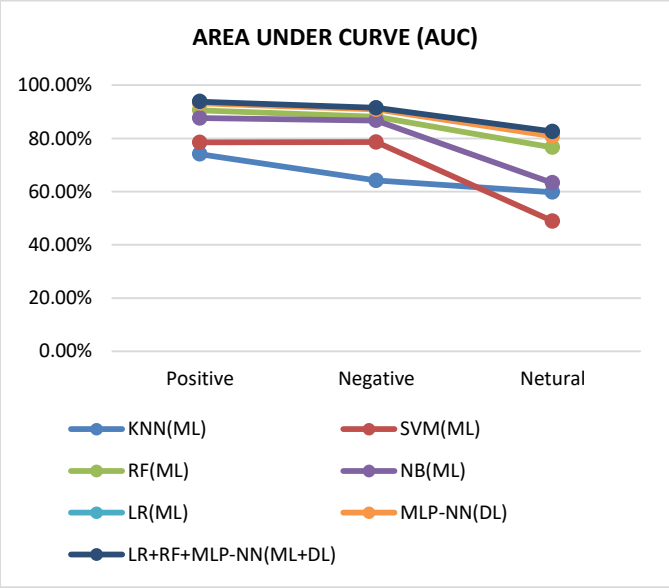

Fig. 7. AUC of Ml, Dl, and Hybrid (ML+DL) Approach.

After applying ML classifiers on Positive Sentiments, results mention that LR (93.5%) and RF (90.6%) shows better AUC results compared to a NB (87.6%), SVM (78.5%), and KNN (74.1%), and respectively. In addition, after applying DL classifier: MLP-NN, results observe that AUC of MLP-NN (93.22%) is approximate to ML classifier LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better AUC (93.8%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

After applying ML classifiers on Negative Sentiments, results mention that LR (91.1%) and RF (88.1%) shows better AUC results compared to a NB (86.7%), SVM (78.6%), and KNN (64.2%), and respectively. In addition, after applying DL classifier: MLP-NN, results observe that AUC of NLP-NN (90.9%) is approximate to ML classifier LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better AUC (91.5%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

After applying ML classifiers on Neutral Sentiments, results mention that LR (81.7%) and RF (76.6%) shows better AUC results compared to a NB (63.3%), KNN (59.8%), and SVM (48.9%), and respectively. In addition, after applying DL classifier: MLP-NN, results observe that AUC of NLP-NN (80.8%) is approximate to ML classifier LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better AUC (82.6%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

6) Ensemble classifier averaging: Fig. 8 represents the average performance of three various classification approaches: ML classifiers (KNN, SVM, NB, RF, LR), DL classifier (MLP-NN), and our proposed hybrid classification model approach: ML+DL (LR+RF+MLP-NN) utilizing various evaluation criteria.

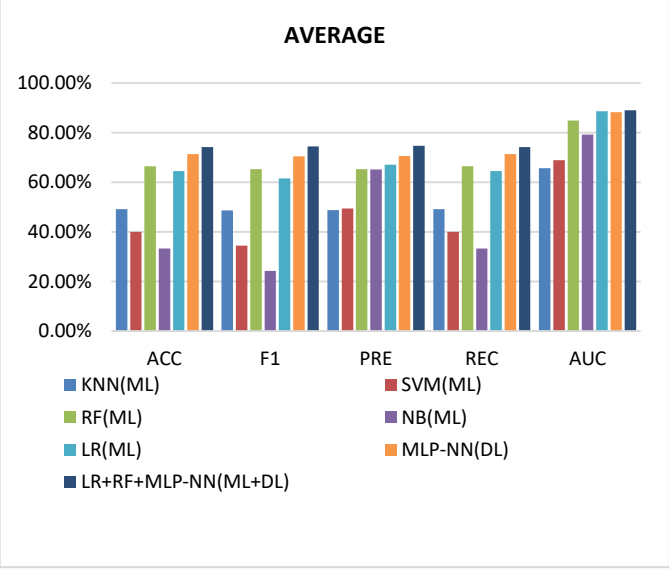

Fig. 8. Average of Ml, Dl, Hybrid (ML+DL) Approach and Evaluation Metrics.

Accuracy. After applying ML classifiers, results mention that LR (72%), and RF (70%) shows better accuracy compared to a SVM (50%), KNN (49%), and NB (45%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that NLP-NN accuracy (69%) is approximate to ML classifiers: RF, and LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better accuracy (74.2%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

Precision. After applying ML classifiers, results mention that LR (71.8%), and RF (69.6%) shows better precision results compared to a NB (62.6%), SVM (53.9%), and KNN (51.4%) respectively. In addition, after applying DL classifier: MLP-NN, results observe that precision of NLP-NN (68.2%) is approximate to ML classifiers: RF, and LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better precision results (74.9%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

Recall. After applying ML classifiers, results mention that LR (72.3%), and RF (70.3%) shows better recall results compared to a SVM (50.1%), KNN (49%), and NB (45.2%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that the recall of NLP-NN (69.1%) is approximate to ML classifiers: RF, and LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better recall results (74.2%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

F1-Measure. After applying ML classifiers, results mention that LR (71.8%), and RF (69.6%) shows better F1-Measure results compared to a KNN (47.9%), SVM (45.7%), and NB (41.8%), respectively. In addition, after applying DL classifier: MLP-NN, results observe that F1-Measure of NLP-NN (68.2%) is approximate to ML classifiers: RF, and LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better F1-Measure results (74.2%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

AUC. After applying ML classifiers, results mention that LR (88.9%), and RF (872%) shows better result of AUC compared to a NB (829%), SVM (72.8%), and KNN (70%) respectively. In addition, after applying DL classifier: MLP-NN, results observe that AUC of NLP-NN (86.1%) is approximate to ML classifiers: RF, and LR. And finally, after applying our proposed approach ML+DL (LR+RF+MLP-NN), results recognize that it performs better AUC (89.6%) than the top three classifiers: ML (LR, RF), and DL (MLP-NN).

Finally, researchers summarize our performance for a proposed hybrid (LR+RF+MLP-NN) approach results as follow:

- Positive polarity: performs higher performance results in the following evaluation criteria: ACC (89.4%), F1 (78.8%), and AUC (93.8%).

- Negative polarity: performs higher performance results in the following evaluation criteria: ACC (83%), F1 (80.7%), and AUC (91.5%).
- Neutral polarity: performs higher performance results in the following evaluation criteria: ACC (76.3%), REC (63.5%), F1 (61.8%), and AUC (82.6%).
- Average: performs higher performance results in the following evaluation criteria: ACC (74.3%), PRE (74.8%), REC (74.3%), F1 (74.5%), AUC (89.1%).

TABLE IV. COMPARISON BETWEEN STATE-OF-ARTS HYBRID MODELS AND OUR HYBRID MODEL

Study	Dataset	Hybrid Models	Accuracy
Heikal et al. [19]	ASTD	CNN + LSTM	65.05%
Al-Twairesh et al. [20]	SemEval	SF+ GE + ASEH	80.36%
Al-Azani et al. [43]	ASTD	SGD + SGD + NuSVC	85.28%
Basir et al. [44]	COVID	CNN+ BiGRU + FastText	85.4%
Saleh et al. [38]	AJGT	LR+CBOW	86.11%
Mohammed et al. [21]	Arabic tweets	LSTM+Augmented	88.05%
Our Hybrid Approach	MASR	LR+RF+MLP-NN	89.4%

In Table IV, a comparison between the performance of our model accuracy and state-of-arts hybrid models on the various Arabic datasets (SemEval, ASTD, COVID datasets, AJGT) is presented. Researchers observe the excellence of our proposed hybrid model approach compared to the previous works.

V. CONCLUSION

This paper aims to collect a simple dataset of Mobile Apps Arabic Slang Reviews (MASR) which focus on Egyptian Arabic Slang for sentiment analysis purposes. In addition, propose a hybrid supervised classification approach which combine ML, and DL approaches to automatically predict user requirements evolution to help developers update new versions. In ML approach, apply a LR which considered a statistical method, and RF which considered a decision tree method. In DL approach, apply MLP-NN which considered a linear and non-linear method. This paper utilized various evaluation metrics like: accuracy, f-measure, recall, precision, AUC, and ensemble classifier averaging. Results show that our proposed hybrid supervised classification approach achieves good performance results in the following:

- In Positive polarity, ACC (89.4%), F1 (78.8%), and AUC (93.8%).
- In Negative polarity, ACC (83%), F1 (80.7%), and AUC (91.5%).
- In Neutral polarity, ACC (76.3%), REC (63.5%), F1 (61.8%), and AUC (82.6%).
- In Average, ACC (74.3%), PRE (74.8%), REC (74.3%), F1 (74.5%), AUC (89.1%).

A limitation in this research is the size of the dataset because it focuses only on Egyptian Arabic Slang mobile reviews. However, it considered a contribution because till now no studies concentrate on it.

VI. FUTURE WORK

In future, researchers intend to accomplish various researches in various points:

1) Apply our proposed hybrid supervised approach for automatically classify Mobile Apps categories.

2) Apply our proposed hybrid supervised approach for different Mobile Apps Arabic Slang datasets in different languages.

3) Add different feature extraction methods like word embedding, and word enrichment and n-grams, also apply different tokenization, and stemming methods.

4) Propose different hybrid ML, and DL modelling approaches and compare them with our proposed approach on different Arabic Slang datasets.

5) Apply also lexicon approach in addition to MASR dataset.

6) Extract functional, and Non-Functional, and Sentimental requirements from MASR datasets using Topic Modeling approach.

***Abstract*—The goal of user experience (UX) research in human-computer interaction is to understand how humans interact with technology. This paper aimed to evaluate the interface and user experience of UbiQuitous Access Learning Portal (UQAL) and make recommendations for the system interface. UQAL Portal is an e-learning web portal that teaches a targeted group of users how to start a business or an online business using an e-learning portal. The portal will be used to search for business-related information, among other things. The User Experience Questionnaire (UEQ) is used to evaluate user experience. The interface is evaluated using a heuristic evaluation technique based on Nielsen's ten heuristics. According to the UEQ results, the average score for each aspect in 30 UQAL users is: Attractiveness aspect: 1.77; Perspicuity aspect: 2.20; Efficiency aspect: 2.30; Dependability aspect: 1.73; Stimulation aspect: 0.63; and Novelty aspect: 1.27. A comparison of the average score in the dataset product of UEQ Data Analysis Tool revealed that the Perspicuity, Efficiency, and Dependability aspects of UQAL belonged to the Excellent category. The Attractiveness and Novelty aspects could be categorized as Good, and its stimulation could be categorized as Below Average. Four evaluators participate in the heuristic evaluation, which tests all user categories in UQAL. The findings of this study can be used as a suggestion and reference for UQAL Portal improvement.**

***Keywords*—User experience questionnaire; user experience; user interface; heuristic evaluation**

I. Introduction

Because of the rapid evolution of digital technologies, new forms of human interaction and experiences are becoming possible. To achieve a positive user experience with technology, service providers must ensure a high user experience quality. Nowadays, users' demand for products is no longer limited to functional satisfaction but also includes psychological needs [1], which involve emotional, intellectual, and sensual aspects [2]. To date, user experience (UX) research has attempted to comprehend how humans interact with technologies such as computers, mobile phones, telecommunications networks, and other digital systems [3]. Similarly, user experience (UX) is a critical factor in the commercial success of digital products. It appears that the new UX movement is gaining traction among academics and industry practitioners who are looking for innovative approaches to improve the experiential qualities of technology use.

As a result, this paper aims to understand user experience better when interacting with technologies by measuring user experience while interacting with the UQAL Portal. UQAL is an abbreviation for UbiQuitous Access Learning. The UQAL Portal will bring a Digital Transformation for learners to access business-related information from the e-learning portal and for educators to supply business-related information into the e-learning portal. The B40 group in Malaysia is the target audience for the UQAL Portal. The B40 group represents the bottom 40% of income earners. The goal is to assist the B40 group in learning how to start a business or online business using the UQAL Portal.

Furthermore, the portal will be used as a platform for the B40 group to search for business-related information, among other things. UQAL is evaluated based on its user interface and user experience, and the interface is evaluated using a heuristic evaluation technique. A User Experience Questionnaire (UEQ) assesses UQAL's user experience. The evaluation of the user experience can provide feedback about the product or service and facilitate product improvements and acceptance among the targeted users.

The rest of the paper is structured as follows: Section II identifies the Experience Evaluation Methods (UXEMs) used to evaluate and measure user experience in previous papers. In Section III, the paper discusses UX evaluation methods on the UQAL Portal. Section IV discusses the findings, followed by the conclusion, which concludes and provides insight for the improvement and future direction of the UQAL Portal.

II. Background Work

A. User Experience (UX)

The International Organization for Standardization (ISO) 9241-110:2010 defines user experience as a person's perceptions and responses resulting from the use and anticipated use of products, systems, or services. Several studies have been conducted to explain the meaning and concept of user experiences with technology. User experience is used to stimulate the HCI (Human-Computer Interaction) research by focusing on the aspect of usability that goes beyond usability and its task-oriented instrumental values [4]. According to Vermeeren et al. [5], user experience examined how an individual felt about using a product, i.e., the experiential, affective, essential, and beneficial aspects. According to Melançon et al. [6], when interacting with a

product or service, the user experience was described as a fleeting, primarily evaluative feeling (good-bad), and it was about having a positive experience through a system. Lipp [7] emphasizes that user experience is subjective because it is about an individual's performance, satisfaction, feelings, and thoughts about a product or service. Despite the lack of a clear definition, the concept of user experience has emerged as an important design consideration for interactive systems [8]. According to Allam, Razak and Hussin [9], user experience is dynamic and involves multiple research areas, including HCI, product design and development, and psychology. As a result, user experience can be viewed as a phenomenon, field of study, or practice. Some work on measuring user experience and usability was carried out by [10] [11] [12] [13]. These studies assess user interaction and product usage, including satisfaction.

The user experience is dynamic because it changes over time as conditions change. As a result, user experience should be valuable after interacting with an object and before and during the interaction. While evaluating short-term experiences is important, given the dynamic changes in user goals and needs resulting from contextual factors, it is also critical to understand how (and why) experiences evolve [5]. A product's effect on a user is called the user experience. In addition, Türkyilmaz, Kantar, Bulak and Uysal [14] stated that user experience is an emotional interaction that begins with usage as a feeling. It is about how we feel and remember after using the product. The term "user experience" refers to using a device to create an experience rather than just creating a fancy interface.

Although there is no agreement in the literature on defining user experience, everyone agrees that it is a complex concept and should not be confused with usability or user interface [15]. Hellweger and Wang [15] conducted a thorough examination of the user experience concept and proposed a user experience conceptual framework. There are numerous perspectives on user experience, and it is understood in various ways by various disciplines and can be viewed from various perspectives [16]. User experience can be academically defined as any aspect of a user's interaction with a product, service, or company [17]. Nonetheless, user experience is regarded as desirable. However, what something exactly means is still up for debate, and it is a highly interdisciplinary topic [18].

A large and growing body of literature has been devoted to understanding user experience (UX) better. Due to the variety of concepts and the flexibility of adding and removing them when stating a definition, it is not easy to have a unique and general definition for user experience. User experience, in our opinion, is primarily associated with the overall design and presentation of online software solutions such as websites or apps. To date, the analysis appears to have focused on user experience in specific domains and fields. For instance, user experience evaluations in games and interactive entertainment [8], [19], [20], [21], culture [22], [23], [24], robotic [25], safety-critical domains [26], and in business and management [18] and [27].

User experience evaluations in games, and more broadly in interactive entertainment systems, had previously been performed over the last ten years [19]. HCI user experience evaluation methods are used during game development to improve user experience. To better understand the concept of user experience, HCI borrowed and explored aspects of the gaming experience such as immersion, fun, and flow [19]. Nagalingam and Ibrahim [21] conducted additional research on the user experience elements for the evaluation and design of educational games (EG). It is critical to identify the appropriate elements to model the right user experience framework for EG to assist the designer in producing an effective educational game [21].

Several studies have been conducted to investigate user experience with social robots. In 2017, Alenljung, Andreasson, Billing, Lindblom and Lowe [25] demonstrated how the user interacted with the humanoid robot Nao while conveying emotions to the robot through touch. The research objective was to gain a better scientific understanding of affective tactile interaction and see if theories and findings from emotional touch in user experience could be applied for future robotic technologies [25]. It was preliminary to conduct additional user experience studies in the Human-Robot Interaction research area.

Grundgeiger, Hurtienne, and Happel [26] recently emphasized the importance of the personal experience of consumers in security-critical domains who engage with technology such as healthcare. They summarized "interaction" concepts based on modern theories of HCI, which include personal user experience as an essential construct. They concluded that improving user experience could improve technology design, employee well-being, and modern safety management [26].

Luther, Tiberius and Brem [18] recently conducted a bibliometric analysis to identify the evolution of scientific research on user experience between 1983 and 2019. However, despite its importance for competitiveness, customer satisfaction, customer retention, and, ultimately, firm performance, the topic has so far been discussed in the HCI field rather than in business and management. As a result, businesses must adopt a successful user experience approach [18]. It is consistent with Erdos's [27] research, which found that user experience is one of the most important determining factors in the case of business software products and services. They recommended that future research concentrate on business and management-related topics.

III. Materials and Methods

The evaluation methods for user experience are another path for undergoing user experience studies. The primary goal of evaluating user experience is to support and aid in selecting the best design, ensure that development is on track, or measure and clarify whether the final product meets and exceeds the initial user experience targets [9].

There are an increasing number of methods for assessing user experience available at all stages of the development process. Several studies attempted to conduct a comprehensive review of user experience evaluation methods to understand the available methods better. Surveys on these contributions are already available [5], [28], and [29]. A study by Vermeeren et al [5] had discovered 96 user experience evaluation methods

both from academia and industry. They also discovered a need for development of UX evaluation methods, such as early-stage methods, methods for social and collaborative UX evaluation, and establishing practicability and scientific quality.

Bargas-Avila and Hornbk [28] conducted an integrated review of user experience, looking for similarities across products, experience dimensions, and methodologies (time frame restricted to 2005–2009). According to the study's findings, questionnaires (self-developed questionnaires) were the most commonly used method of assessing user experience. In addition, qualitative methods included semi-structured interviews, focus groups, open interviews, user observation, video recording analysis, and diary analysis. However, psychophysiology is rarely used to improve user experience [28]. Table I summarizes the data collection methods used by Bargas-Avila and Hornbk [28].

Maia and Furtado [29] conducted a systematic review on user experience evaluation (time frame restricted to 2010–2015). According to Maia and Furtado [29], most of the studies used questionnaires to assess the user experience rather than other tools and techniques such as interview, observation, reports, video recording, eye-tracking, etc. They reported that psychophysiological analysis was not yet used in user experience evaluation models because most studies evaluated the user experience manually. According to literature reviews, many different types of user experience evaluation methods are available in the industry and academia. However, methodological improvements in evaluating user experiences that focus on product use and their specific needs such as development phase, type of experience addressed, target users, and evaluation objective are required.

A. Respondents

Respondents were found through a WhatsApp Group announcement. Users who wish to participate in this survey have received an invitation to do so. All respondents had been informed about the survey's objectives and methods. The invitation contained a link to our survey, which was created using the online survey tool Google Forms.

B. Data Analysis

The data gathered during the evaluation process is both quantitative and qualitative. The open-ended questionnaire yields qualitative data. The UEQ provided the quantitative data. The results of the evaluation are then summarized into a table. The data was then analyzed to determine the user experience level of UQAL. The system's user experience is graded on six scales: Stimulation, Perspicuity, Efficiency, Dependability, Attraction, and Novelty. The level of user experience for each scale is calculated by processing statistical data with the UEQ Analysis Data Tool. After obtaining the score for each scale, the data is displayed using a benchmark graph to determine the quality of UQAL in comparison to other products in the data set UEQ Analysis Data Tool.

C. UQAL Portal Interface

Evaluation is a stage where the UQAL Portal's effectiveness and efficiency are perceived. The user's interface effect is measured, which concerns how simple the portal can be learned, its usability and user experience, and problems that may occur on the portal are identified. UQAL is evaluated based on its user interface and user experience. This evaluation aims to measure the user experience and user interface when interacting with the portal. A heuristic evaluation technique is used to evaluate UQAL's user interface. According to Nielsen [30], a heuristic evaluation is carried out by a group of evaluators who are given an interface. They are then asked to evaluate whether each element adheres to a set of established heuristic uses.

UQAL Portal is an e-learning web portal that teaches a targeted group of users how to start a business or an online business using an e-learning portal. The UQAL Portal can be found at https://yutp-uqal.com/. The B40 group in Malaysia is the target audience for the UQAL Portal, and the B40 group represents the bottom 40% of income earners. UQAL Portal will bring a Digital Transformation for learners to obtain business-related information from the e-learning portal and for educators to provide business-related information to the e-learning portal. The user will interact with the e-Learning portal through GUI elements such as menus, buttons, checkboxes, search fields, pagination, and notification. Fig. 1–3 depicts the UQAL interface's main menu.

TABLE I. EXAMPLES OF DATA COLLECTION METHODS

Data Collection methods	Examples
Questionnaires	SAM scale: user feedback assessed with a self-developed questionnaire; AttrakDiff; Lavie & Traktinsky; Other surveys (e.g., FSS, IMI, Emocards).
Interviews (semi-structured and open)	Interview regarding interaction experience; engagement; to understand the enchantment.
User observation (live)	In-situ observation of apps usage; observation of people experience using apps.
Video recordings	Recordings of interactions with apps; videos to capture listening experiences on the apps.
Focus groups	Group discussion to investigate preferences.
Diaries	Emotions assessed with diaries; diaries using day reconstruction & experience narration.
Probes	Participants were given a probe kit with a brief personal explanation and instruction.
Body movements	The choreography of interaction with apps was evaluated by analyzing the movements.
Psychophysiological measures	Psychophysiology (galvanic skin response, EMG, heart rate).

Fig. 1. Main page of UQAL Portal.

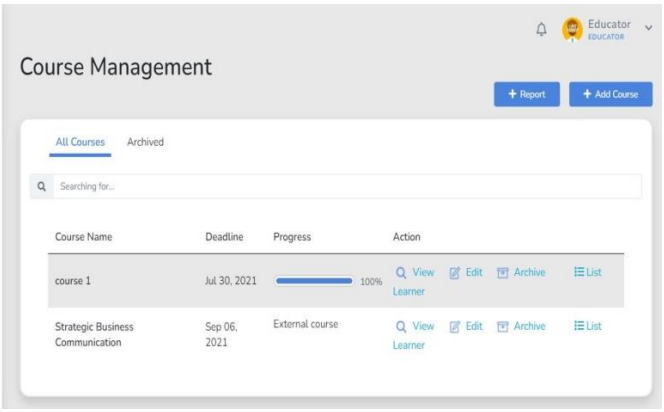

Fig. 2. Course Management Menu for Educator Interface.

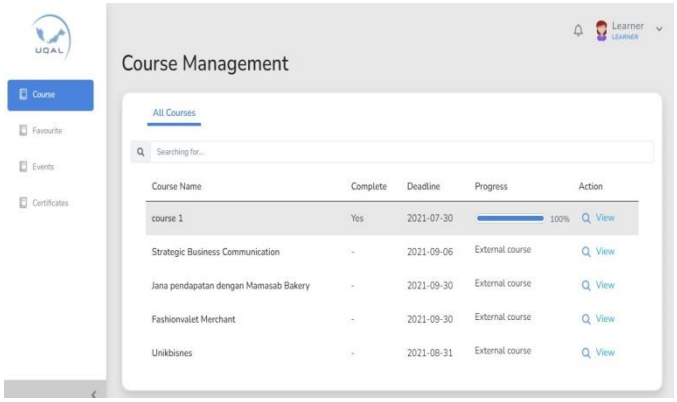

Fig. 3. Course Management Menu for Learner Interface.

D. Instruments

1) User Experience Questionnaire (UEQ): The method was chosen for this study. The questionnaire was divided into four sections. The first section asked a few questions about the user's demographic information (i.e., age, gender, race, occupation, working experiences). Users rate the usability evaluation, including the portal interface, ease of use, and learnability. These sections used a five-point Likert scale with 1 (Strongly Disagree), 2 (Disagree), 3 (Neutral), 4 (Agree), and 5 (Strongly Agree) was employed. The UEQ in the third section is used to assess the user experience of the UQAL e-learning portal. The UEQ can be accessed for free and is available at https://www.ueq-online.org/. The UEQ has seven scales and 13 items in total (as shown in Fig. 4). This study employed only the 13 items of UEQ related to the user experience to cover the user's psychological aspects such as feelings of pleasure, disappointment, and stimulation when using the portal interface. Table II shows each of these scales in detail. This section allows users to choose their own experiences and opinions while interacting with the portal. Finally, we ask the user to provide any comments or suggestions for the portal's improvement for the open-ended questions.

	1	2	3	4	5	6	7	
Boring	o	o	o	o	o	o	o	Exciting
Not interesting	o	o	o	o	o	o	o	Interesting
Difficult to use	o	o	o	o	o	o	o	Easy to use
Complicated	o	o	o	o	o	o	o	Easy
Inefficient	o	o	o	o	o	o	o	Efficient
Impractical	o	o	o	o	o	o	o	Practical
Does not Meet Expectations	o	o	o	o	o	o	o	Meets Expectations
Demotivating	o	o	o	o	o	o	o	Motivating
Cluttered	o	o	o	o	o	o	o	Organized
Inferior	o	o	o	o	o	o	o	Valuable
Unattractive	o	o	o	o	o	o	o	Attractive
Dull	o	o	o	o	o	o	o	Creative
Unpleasant	o	o	o	o	o	o	o	Pleasant

Fig. 4. User Experience Questionnaire (UEQ) Items.

TABLE II. USER EXPERIENCE QUESTIONNAIRE (UEQ) ASPECTS

Aspects	**Items**
1.Attractiveness General impression of the product. Do users like or dislike the product?	unattractive/attractive, unpleasant/pleasant
2. Perspicuity Is it easy to understand how to use the portal? Is it easy to get familiar with the portal?	difficult to learn/easy to learn, complicated/easy
3. Efficiency Is it possible to use the product fast and efficiently? Does the user interface look organized?	inefficient/efficient, impractical/practical, cluttered/organized,
4. Dependability Does the user feel in control of the interaction? Is the interaction with the product secure and predictable?	does not meet expectations/ meets expectations
5. Stimulation Is it interesting and exciting to use the portal? Does the user feel motivated to further use the portal?	boring/exciting, not interesting /interesting, demotivating/motivating, inferior/valuable
6. Novelty Is the design of the portal innovative and creative? Does the portal grab attention?	dull/creative

2) Heuristic Evaluation

a) Nielsen's ten heuristic principles are described below:

1) Visibility of system status: This system should always keep users informed of what is going on by providing appropriate feedback in a timely manner.

2) Match between system and the real world: The system should speak the user's language, using words, phrases, concepts that the user is familiar with, and adhere to real world conventions rather than system-oriented terms.

3) User control and freedom: Users frequently select system functions by accident, necessitating a marked "emergency exit" to exit the undesirable state without going through an extended dialogue.

4) Consistency and standards: Users should not guess whether various words, situations, or actions mean the same thing. Observe platform conventions.

5) Error prevention: A careful design that prevents a problem from occurring in the first place is even better than good error messages. Either eliminate error-prone conditions or check for them and provide users with a confirmation option before proceeding with the action.

6) Recognition rather than recall: Make objects, actions, and options visible to reduce the user's memory load. The user should not have to recall information from one section of the dialogue to the next. When appropriate, system instructions should be visible or easily accessible.

7) Flexibility and efficiency of use: Unseen accelerators may frequently speed up the interaction for the expert user, allowing the system to cater to both inexperienced and experienced users. Allow users to personalize frequently performed actions.

8) Aesthetic and minimalist design: Dialogues should not include irrelevant or used infrequently. Every additional unit of information in a conversation competes with the relevant information units, reducing their relative visibility.

9) Help users recognize, diagnose, and recover from errors: Error messages should be written in plain language (no codes), accurately describe the problem, and constructively suggest a solution.

10)Help and documentation: Even though it is preferable if the system can be used without documentation, assistance and documentation may be required. Any such information should be easy to find, focused on the user's task, list concrete steps to be taken, and not be too large.

b) Data Collection Procedures: The following are the data collection steps in the heuristic evaluation:

- Step 1: Establish an appropriate list of heuristics. This survey used the model based on Nielsen's 10 heuristics.
- Step 2: Identify 3 to 4 evaluators (experts). They were assuring their knowledge of the relevant industry. Experts were defined in this survey as people with several years of job experience in the software and information technology fields.
- Step 3: Briefing the evaluator/expert. They inform the evaluator about what they are expected to do and cover during their evaluation. The evaluator has explained the scope and objective of the portal inspection and the characteristics of the portal's users.
- Step 4: Evaluation phase. Evaluators must have free access to the portal to identify elements to analyze. Individual elements are examined by evaluators using heuristics. They also investigate how these fit into the overall design, meticulously documenting all issues encountered.
- Step 5: Report issues/problems. Evaluators complete the questionnaire given and report any issues and problems they discover. The evaluator's task at this stage is to assess the list of 10 Usability Heuristics for User Interface Design [30] in Table III.

TABLE III. NIELSEN'S 10 HEURISTICS

Heuristics	**Yes/No**	**Comment/ Remark**
1. Visibility of system status		
2. Match between systems and the real world		
3. User control and freedom		
4. Consistency		
5. Prevent Errors		
6. Recognition rather than recall		
7. Flexibility and efficiency of use		
8. Aesthetic and minimalist design		
9. Help users recognize, diagnose, and recover from errors.		
10. Help and Support		

The data obtained from this technique is a list of interface problems based on the evaluators' heuristic principles. The evaluation results are then compiled into a table that provides a detailed breakdown of the issues and recommendations.

IV. RESULTS AND DISCUSSION

A. Demography

Thirty users participated in the user experience survey (19 females, 11 males). Most respondents were between the ages of 18 and 35 (n = 23), followed by those between the ages of 36 and 55 (n = 6), with the remainder being over the age of 55 (n = 1). Malay (97%) and Chinese are the most common ethnic groups (3%). The majority had a bachelor's degree or were enrolled in a bachelor's degree program (70%). 7% had high school diplomas, 10% had college diplomas, and 13% had graduate degrees.

In terms of current employment status, 63% were full-time employees, 20% were students, 7% were self-employed, and 1% were full-time freelancers, unemployed, or retired. Respondents' current occupations were education and training (17%), computer and software (13%), administrator (7%), students (6%), and other fields (1%), in that order. The average working experience ranged from more than seven years (37%) to four to six years (30%), one to three years (13%), less than six months (7%), and none at all (13%).

Furthermore, approximate monthly household income for the respondent shows that 37% have more than 4500 Malaysian Ringgit, 20% have 2500–3500 Malaysian Ringgit, 10% range from 1500–2500 Malaysian Ringgit and less than 2500 Malaysian Ringgit. In addition, 7% ranges from 3500–4500 Malaysian Ringgit. The remaining respondents (17%), on the other hand, preferred not to respond. Table IV summarizes the detailed demographic information.

TABLE IV. DEMOGRAPHIC PROFILE OF RESPONDENT

Demographic Profile	Total N = 30 (%)
Age	
18– 35	23(76.7)
36–55	6(20)
>55	1(3.3)
Race	
Malay	29(96.7)
Chinese	1(3.3)
Education level	
Bachelor's degree	21(70)
Graduate degree (MS, Ph.D.)	6(13.4)
College Graduate	3(10)
High School	2(6.7)
Employment status	
Full-time employment	19(63.3)
Student	6(20)
Self-employed	2(6.7)
Working experience	
7 years or more	11(36.7)
4 to 6 years	9(30)
1 to 3 years	4(13.3)
No working experience	4(13.3)
Monthly household income	
>RM 4500	11(36.7)
RM3500–RM4500	2(6.7)
RM 2500–RM3500	6(20)
RM1500–RM2500	2(6.7)
Less than RM1500	2(6.7)

B. Usability Evaluation

This survey evaluates the portal's usability with a few items identifying general interface design and layout, ease of use, and learnability. Overall, participants gave positive feedback on usability aspects, as shown in Table V. 79.9% thought the portal interface was pleasant and easy to use (n = 24). In comparison, 83.3% thought the sequence of screens, organization of information presented, and graphical presentations were simple to understand (n = 25). As a result, 89.9% agreed that the portal was simple to use (n = 27), 86.6% agreed that it was easy to find needed information (n = 26), and 90% of respondents understood the menu (n = 26). Overall, most of the participants, 86.6%, were satisfied with the easiness of the portal (n=26). In terms of learnability, most respondents (96.6%) said that it was easy to learn how to use the portal; 89.9% said it helped them become more productive quickly. Another 93.3% found the information in the portal to be effective and helpful.

C. User Experience

Overall, the score indicates that the UQAL Portal gets a positive evaluation from users. Results from UEQ show that the overall score is in the positive range. The Likert scale data has been transformed into the UEQ Data Analysis Tool in an Excel sheet to calculate the scale means and compare the products in the benchmark data set. The measured scale means are determined by comparing them to existing values from a benchmark data set (https://www.ueq-online.org/). Comparing the results for the evaluated product with the data in the benchmark allows conclusions about the quality of the evaluated product compared to other products. Table VI shows the score of each user experience aspect.

TABLE V. MEAN AND STANDARD DEVIATION FOR EACH USABILITY ITEM

Usability Aspect	Mean and Standard Deviation, SD						
A. General Interface Design and Layout	**1**	**2**	**3**	**4**	**5**	**Mean**	**SD**
The interface of the portal is pleasant.	1	0	5	20	4	3.87	3.42
I like using the interface.	1	0	5	18	6	3.93	3.49
The sequence of screens was clear.	1	0	4	13	12	4.17	3.74
The organization of information presented was clear.	1	0	4	13	12	4.17	3.74
The graphical presentations (i.e., icons) are easy to interpret.	1	1	3	18	7	3.97	3.54
B. Ease of Use	**1**	**2**	**3**	**4**	**5**	**Mean**	**SD**
It was simple to use this portal.	0	0	3	16	11	4.27	3.79
It was easy to find information I needed.	0	0	4	15	11	4.23	3.76
It is easy to understand the functions of the menu items.	0	1	2	15	12	4.27	3.80
The information (i.e., online help, on-screen messages, and other documentation) provided in this portal is clear.	0	1	3	16	10	4.17	3.71
Whenever I make a mistake using the portal, I recover easily and quickly.	0	0	3	15	12	4.3	3.82
The portal gives error messages that clearly tell me how to fix problem.	0	1	9	16	4	3.77	3.31
Overall, I am satisfied with how easy it is to use this portal.	0	0	4	19	7	4.1	3.61
C. Learnability	**1**	**2**	**3**	**4**	**5**	**Mean**	**SD**
It was simple to use this portal.	0	0	1	16	13	4.4	3.91
I would imagine that most people would learn to use this portal very quickly.	0	0	2	18	10	4.27	3.78
I believe I became productive quickly using this portal.	0	0	3	21	6	4.1	3.61
The information provided in this portal is effective and helpful.	0	1	1	16	12	4.3	3.83
The online Help facility is useful.	0	1	3	15	11	4.2	3.74

TABLE VI. USER EXPERIENCE QUESTIONNAIRE (UEQ) RESULTS

Aspects	Average Score	Compared to Benchmark
1. Attractiveness	1.77	Good
2. Perspicuity	2.20	Excellent
3. Efficiency	2.30	Excellent
4. Dependability	1.73	Excellent
5. Stimulation	0.63	Below Average
6. Novelty	1.27	Good

The benchmark results from UEQ Data Analysis Tool revealed that perspicuity, efficiency, and dependability aspects belonged to the Excellent category, indicating that UQAL is included in the best 10% range of results, implying that 10% of the products in the dataset are better and 75% are worse. However, the stimulation aspect of UQAL could be classified as Below Average, which means that 50% of products on the dataset are better than UQAL while 25% are worse. The overall score is in the positive range, according to the evaluation of UEQ results. Minor issues on UQAL have not been shown to impact user experience significantly. Fig. 5 depicts the benchmark graph.

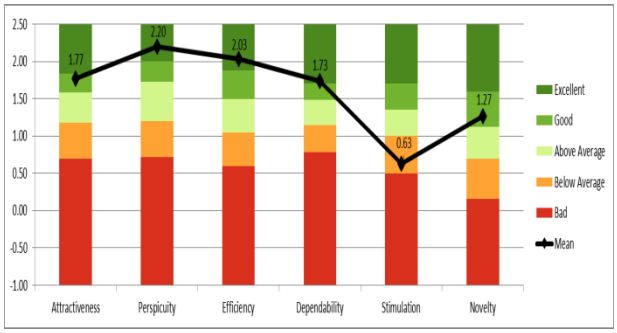

Fig. 5. UQAL's Benchmark Graph.

Another thing that this survey wanted to look into was whether UQAL should have any additional essential features. Table VII includes some comments on all the missing features mentioned.

We are looking at which aspects/features the UQAL Portal users like the least and most. According to the survey results, some respondents like how simple it is to use and understand the portal. Some respondents said they were straightforward when asked about the portal's features. For example, "I like the portal structure; it is straightforward." They commented, "This portal is simple and easy to understand." Some of the respondents commented, "User-friendly." This portal helps me find any business courses. I can easily organize and manage courses from the beginning to the end". Others commented that it is "so easy for people to understand the flow of the system because each page has different information".

Some respondents stated that the user interface design is their least favorite. They felt the portal's interface was not interesting enough to draw their attention. Some of them stated:

"The theme of the portal does not seem very interesting. Color combinations could be used to make the portal look better."

"The thing I like the least is the inconsistent type of fonts used and the size of the fonts. I found certain words or sentences do not start with a capital letter, which does not represent the professional side."

"The color of the portal. This e-learning web portal is for Malaysians who want to start a business online. The color of a website plays a vital role in attracting more B40 groups."

"The team can research which fonts are compatible for each part, especially for the Business Opportunities interface and UQAL course interface. I found certain fonts used are 'awkward', and the layout and the color of the fonts should be consistent. "

TABLE VII. USER EXPERIENCE QUESTIONNAIRE (UEQ) RESULTS

Features	Comments
1. Course/Event details	"Course introduction, course timeline, and instructors' information" "State the date when this portal updates the information of the course and event. So, the user will know the information was updated." "Can display multiple categories of data like all courses, my courses, external courses in a single screen." "Add more information of the courses." "Have a calendar to show/ list next course register." "Add description for the courses." "Have a list of courses by category."
2. Customer Service Chat/Online Chat	"Chabot or online helper to assist users when they face any issues when using the portal." "Chat feature to allow peer engagement and learners-instructor interaction." "Any online learning platform should have chat features to enable for peer engagement as well as learner-instructor interaction."
3. Information/ Content	"Give information about another interesting portal" "Can add detail grant for SME, provided from the gov-ernment" "Introduced more local corporate and business com-pany starter." "Maybe can add 'dashboard' that include information such as a graph to prove how UQAL Portal help the B40 group start the business using this portal." "Information on business events and business oppor-tunities" "Company and corporate sector involved mostly big known." "Should have "about" section which could explain to people what the portal is about."
4. User Interface Design	"Perhaps the portal should be more organized with a drop-down menu…" "No attractive colors or graphics." "Greyish button. Hope more eye-catchy." "Add more pictures or graphics to make this portal interesting." "More interesting interface maybe can add animation, the welcoming or introduction video." "It would look nicer with better images resolution."
5. Advanced Search	"Have sort and filter searching" "Allow multiple searching criteria in one screen."
6. Bilingual (BM/BI)	"Make it friendlier for example, bilingual feature for easy to understand."

D. Heuristic Evaluation Analysis

Four evaluators evaluate with backgrounds in software and information technology. Two of them have more than seven years of experience as software developers. One has over ten years of experience as an information technology administrator, and the other is a research graduate in usability. Based on the severity rating, the evaluators discussed some issues and made recommendations for improvement.

TABLE VIII. UQAL HEURISTIC EVALUATION RESULTS

Heuristic	Comments/Issues	Recommendations
1.Visibility of system status	Some courses are already marked as completed, yet in the listing, it still shows "No" under the complete column and the progress bar; I'm not sure how it works/functions (already complete, but the progress bar still shows 25%).	This portal should always keep users informed about what is going on, through appropriate feedback within reasonable time.
2. Match between systems and the real world	The portal has no elements of positive encour-agement (rewards, praise, personalization, etc.) to boost users' motivation. This type of element is essential in online learning since it requires users to learn independently.	The system should speak the user's language with words, phrases, and concepts familiar and follow real world conventions rather than system-oriented terms.
	There are no features that allow learners to interact with one another and with instructors/ lecturers/ trainers.	Any online learning platform should have chat features to enable peer engagement and learner-instructor interaction.
3. User control and freedom	When the user makes an error on a certain field, the system removes all the information that the user has filled in, even though that information is supposedly correct.	Support undo and redo.
4. Consistency	Some buttons are not suitable. For example, there is a button 'Report' I thought it was for adding a report, but it was to generate Report.	Use the standard color of buttons. Users should not have to wonder whether different words, situations, or actions mean the same thing. Follow platform conventions.
5. Prevent errors	The function is not working well for evaluation. When I try to add a new course as an educator, the system makes it compulsory to add the image of the banner. When I didn't add the image, it showed an error message. However, the page redirects me to the front page. So, I need to re-key the form again.	Properly test the portal to make sure all functionality is working. The system must be functioning well to be successful. Prevents a problem from occurring in the first place. Present users with a confirmation option before they commit to the action.
6. Recognition rather than recall	There is no error warning message when the user makes a mistake.	The system should prevent users from making mistakes. Minimize the user's memory load by making objects, actions, and options visible. The user should not have to remember information from one part of the dialogue to another.
7. Flexibility and The efficiency of use.	Advance search feature: Users do not get the benefit of a search menu there.	The search feature should add sorting and a filtering function.
	Its multi-platform, but it can't be used for the mobile version well.	Create a mobile-friendly web portal for users to access because not everyone has a laptop or tablet to access the portal.
	It would be better if you could add the calendar management for learners and educators to view the courses and events they join/conduct. For example, if I'm a learner and I click to join the event/course, then the event will be added to my calendar.	Make the calendar to be viewed monthly/weekly. So, that it easier to check which event/course that I have joined or to join.
	I'm not sure how the courses will be conducted. So that leaner can always come to this website to review back the provided material. When the course is already marked as complete, there is nowhere for me to view back what the courses are all about.	It would be better if an educator can up-load the teaching material (e.g., Power-Point slides or others material).
8. Aesthetic and minimalist design	The interface for "Course Management" (learner view) is not convenient to use. All the courses are displayed in one listing.	It would be better if you could display the listing for the courses that have already been completed in one tab and the courses not yet completed in another tab. Or you could just add the filter there to allow users to filter the listing.
	The portal theme appears to be uninteresting. This portal does not appear to employ vivid colors.	Color combinations could be used to improve the portal's aesthetic value.
	The image size used does not fit and not match the box provided.	It is possible to match all the pictures at the same size and clear.
	The dashboard for learners should be appealing and dynamic.	Choose dashboard UI elements carefully; otherwise, learners will become discouraged.
	The sidebar's use of repetitive icons appears to be confusing.	The button positioning should be con-sistent and clear (e.g., the Join button).
9. Help users recognize, diagnose, and recover from errors.	When the user makes an error on a certain field, the system totally removes all the information that the user has filled in, even though that information is supposedly correct.	Recovery from Error. Help user to recover if making an error. Error messages should be expressed in plain language (no codes), precisely indicate the problem, and constructively suggest a solution.
10. Help and support	Lack of Help to guide users.	Put Guideline to help the user. Create a help menu to make it easier for users to use the portal.
	There is no sitemap of the portal.	Create a site map to make it easier for users to navigate the portal.

The majority of problems can be found in Aesthetic and Minimalist Design principles. Two of the evaluators noticed some issues with UQAL's interface's aesthetic. The principle issues include a colorless interface, size, images resolution, icons, and buttons that should have aesthetic values according to the evaluator. The Search and Course function menus should be improved based on flexibility and efficiency of use. Some errors occur while performing certain tasks. Table VIII displays the outcome of the heuristic evaluation.

Although heuristic evaluation revealed some significant flaws in the UQAL's user interface design, it had no direct impact on the UEQ's overall score, which was positive. Previous research on heuristic evaluation has shown that it identifies more minor usability issues in an interface than other methods [31]. Regardless, the UEQ results show that the overall score is positive. Minor issues discovered during the heuristic evaluation do not appear to significantly impact user experience on UQAL.

V. Conclusion

Finally, based on the heuristic evaluation results, the evaluators discovered some issues with Nielsen's heuristic principles on UQAL's user interface design, which are commonly found in the Aesthetic and Minimalist Design principles, as well as flexibility and efficiency of use. The outcome of heuristic evaluation is a recommendation of issues and problems that must be addressed. Nonetheless, according to UEQ results, the user experience of the UQAL Portal is adequate. The sufficient average score of each aspect demonstrates this. The results of this experiment can be used as a reference for the developer to improve the UQAL Portal in the future.

Acknowledgment

We want to thank all respondents that participate in this study. The study was funded by ZG-2019-005 research grant.

Design of a Cloud-Blockchain-based Secure Internet of Things Architecture

Deepti Rani, Nasib Singh Gill, Preeti Gulia
Department of Computer Science and Applications
Maharshi Dayanand University
Rohtak, Haryana
India

***Abstract*—The growing number of Internet of Things (IoT) objects and the operational and security challenges in IoT systems are encouraging researchers to design suitable IoT architecture. Enormous data generated in the IoT environment face several kinds of security and privacy challenges. IoT system generally suffers from several issues like data storage, safety, privacy, integrity, transparency, trust, and single point of failure. IoT environment is emerging with several solutions to resolve these problems. The main objective of this paper is to design a cloud-blockchain-based secure IoT architecture that provides advanced and efficient storage and security solutions to IoT ecosystem. Blockchain technology appears to be a decent choice to resolve such kinds of problems. Blockchain technology uses a hash-based cryptographic technique for information security and integrity. Cloud computing provides advanced storage solutions with several remote services to store, compute and analyze the data. The proposed IoT architecture is based on the integration of cloud and blockchain services, which aim to provide transparent, decentralized, and trustworthy and secure storage solutions. In addition to the standard layers (perception layer, network layer, processing layer, and application layer) the proposed IoT architecture in the present paper includes a service layer, a security layer, and a parallel management and control layer, which focus on the security and management of the entire IoT infrastructure.**

Keywords*—Internet of things; cloud computing; blockchain; iot architecture; security and services

I. INTRODUCTION

Data or information security in Internet of Things (IoT) environment is a significant challenge that is getting complicated due to the exponential expansion of IoT devices, applications, and services. In the last few decades, the idea of IoT has widely extended in human life. It brings more ease, upgrades work efficiency, and promotes the growth of national economy of a country. IoT is one of the most promising technologies of the current century which has largely inter-connected the universal things (devices) using various Internet services. The interconnected IoT devices produce a large amount of data that need to be collected, aggregated, stored, and processed privately and securely [1]. But at the same time, IoT technology brings massive security risks for its data and network system.

Security and privacy are the primary requirements for the successful integration of IoT in the society. Due to the absence of proper security, the growing and extensive IoT technology is exposed to various kinds of security and privacy issues [2]. Valuable data in its original form can be captured illegally by cybercriminals from storage (cloud or media) or while communicating over the network. An advanced security system is needed to secure large amount of data generated in IoT system. Data encryption is a worthy approach that provides secure data preservation and data transmission. Blockchain technology is an innovative approach using which data can be securely preserved and transmitted on a decentralized network. Data stored in blockchain is encrypted using secure hash functions (SHA-256 and Keccak-256) that is almost impossible to tamper with [3]. Data can't be updated or deleted by third party due to immutability and integrity properties of blockchain technology. Data generated by various IoT devices can be stored and processed in network edge (device storage) or remote server itself. However, restricted capacity of IoT objects in terms of storage, computational power, and energy is a also significant challenge. Cloud computing provides scalability, management, simplicity, computation, storage and processing facilities to IoT infrastructure [4].

IoT is a large-scale information system that is generally designed using three logical layers which are the perception (sensing) layer, network layer, and application layer. Several researchers have designed many IoT architectures using these three layers for providing solutions to their respective targeted problems such as security and data processing. The present paper proposes an advanced IoT architecture that promotes the solutions for data storage, security, and management problems in IoT based smart environment.

Cloud computing provides centralized storage solutions to IoT infrastructure. It provides features like good scalability, robustness, elasticity, less cost, and power consumption that improves the performance and efficiency of IoT system. Blockchain, as discussed earlier is an innovative distributed technology that provides immutability, integrity, and security to manipulated data. Combining the blockchain technology with cloud infrastructure facilitates with more promising solutions to IoT environment [5]. Initially, the blockchain technology was designed for the security of the public digital ledger of Bitcoin cryptocurrency used for economic transactions only [6]. The Blockchain hypothesis is based on peer-to-peer network architecture in which transaction is not controlled by a single centralized entity. The transaction is stored and controlled in form of blocks in decentralized

manner and these blocks are accessible to all participants of the blockchain network in a trustworthy manner [7]. Both these technologies have brought a great revolution in communication and information in various technical fields, including IoT.

Technologies and components used in IoT systems may create critical security concerns. So, it is important to protect IoT systems in every dimension of IoT infrastructure. Efficient approaches need to be designed for the security of IoT systems. CIA triad is a widely used security model that consists of three major key components: confidentiality, integrity, and availability. These security features must be targeted while designing IoT architecture and ensuring security in every related application area [8].

The proposed architecture presented in the present paper is motivated by several kinds of issues present in the IoT ecosystem. Most of the existing IoT applications suffer from several kinds of security issues (such as privacy, integrity, and single-point of failure) as well as resource related issues (memory, storage, etc.). An ideal IoT architecture must be designed to get rid of all of these problem. The main contributions of the paper are as follows:

- The paper focus on design of an organized IoT architecture utilizing the features of blockchain technology and cloud infrastructure which provide advanced and efficient security, storage and computational solutions.
- Authors in the present paper proposed a 7-layered (perception, network, transport, processing, service, security, application and parallel management and control) Cloud and Blockchain-enabled secure IoT architecture.

Section II presents a brief survey of related literatures. Section III gives a brief description of cloud computing, blockchain technology, and integrated cloud and blockchain technologies which will be deployed to design an advanced and secure IoT architecture. Section IV presents IoT architecture consisting of a perception (sensing) layer, network/ transport layer, processing layer, service layer, security layer, and a management and control layer. The proposed IoT architecture uses edge and fog services for processing, storage, and computation at the local level. This section also presents prominent cloud and blockchain technologies in an integrated form to provide better and innovative services. Section V presents the analysis of proposed cloud-blockchain-based secure IoT architecture and provides brief discussion of improvements done by proposed IoT architectures over recently proposed existing IoT architectures. Section VI concludes the entire research work presented in the present paper.

II. Related Work

Several researchers have conducted number of researches in the area of IoT which address various aspects of designing and modeling. Several researchers have proposed different IoT architectures on the basis of different concerns related to storage, security, communication and services.

Several IoT architectures have been explored in the present paper which vary in terms of the number of layers, type of layers, and terminologies used for layers. Sethi and Sarangi in [9] presented some basic and traditional IoT architectures which include 3-layers and 5-layers IoT architectures. Three layer architecture is composed of the perception layer, the network layer and the application layer. Five-layered architecture includes two additional layers which are the processing layer and the business layer. Wu et al. proposed a five-layer IoT architecture [10]. Many authors including Gokhale et al. [11] and Muhammad et al. [12] discussed the four-layer IoT architecture. However, 3-layer IoT architecture is very common and comprises three key layers [13-15]. Initially, three-layer architecture was accepted for IoT management systems. Four-layer IoT system architecture comprises the sensing layer, the network layer, the service layer, and the application layer. In this way, many pieces of research have been conducted by various researchers to design more advanced IoT architectures and every new research targeted a specific problem to be solved. Hence, the features and behavior of IoT architecture depend on the targeted problems.

In recent years, some architectures have been designed using several advanced technologies. Cloud computing provides cetral data processing facility. Cloud is a part of the middle layer that lies below to the application layer and above to the perception and the network layer [16]. IoT architecture proposed by Hassan and Eassa [4] was dedicated to smart home systems that was designed using cloud computing, context-awareness and some other building blocks.

In terms of IoT, data is significant digital asset that need to be stored with efficient and reliable security solutions. Some of the most recent IoT architectures focused on decentralized blockchain technology in order to provide security, immutablitity and trust to the data generated by IoT system. Many researchers have discussed about decentralized blockchain approach [17]. Zhou et al. in [18] proposed a blockchain-based secure IoT system that facilitates homomorphic computation and system security. Ullah et al. also discussed blockchain-based approach for providing security to IoT.

III. Cloud Computing and Blockchain

The exponential growth of IoT technology creates massive and heterogeneous network traffic. Along with the information this technology generates lots of security issues. An ideal IoT architecture can efficiently deal with such affairs. It must be able to secure the entire IoT infrastructure throughout its layers and able to manage and control all the activities. The proposed framework utilizes cloud computing and blockchain to promote information security.

A. Cloud Computing

Cloud computing is the latest Internet-based technology that provides on-demand availability of resources such as data storage and computing power without direct management by the user. IoT data, services and incidents can be remotely stored, computed and processed over the Internet using cloud services and can be accessed whenever required. Cloud

computing provides many services such as Platform as a service (PaaS), Infrastructure as a service (IaaS), and Software as a Service (SaaS) with affordable cost, scalability, faster speed, high flexibility, reduced complexity, and low risk [19], [20].

1) IaaS: It facilitates on-demand fundamental computing, networking and storage resources to consumers over the Internet on the basis of their request. It is composed of physical and virtual building blocks that provide the facility of execution of workloads and applications without worrying about storage and computation efficiency with little expenses.

2) PaaS: In this cloud computing system, users are facilitated with hardware, software and infrastructure services for developing, executing and managing applications without any expenditure and complexity. The users need to pay only for some resources they utilize. Cloud service providers like Microsoft Azure, Amazon Web Services (AWS), IBM, Google Cloud offer PaaS services.

3) SaaS: Cloud computing provides on–demand software services to the users without direct installing on the system. The users can remotely access these services over the Internet without complex hardware and software management.

B. Blockchain

Initially, blockchain technology was particularly introduced and adopted for Bitcoin cryptocurrency [6]. But in recent years, it is widely deployed in numerous application areas to keep digital records in decentralized and secure manner. It is a good choice for digital forensics to preserve digital evidences with high security, integrity, authenticity and confidentiality. It is a decentralized ledger technology that is anticipated on the peer-to-peer network [21].

A blockchain is a group of interconnected blocks used to store transactional data or events that are managed by all the participants without requiring a central authority manager. It stores event information in such a way that is virtually impossible to add, modify, or delete by unauthorized users. It allows all participating (authorized) users to generate and validate transactions in a peer-to-peer manner. Cryptography [22] and consensus [23] approaches are most significant components of blockchain technology.

Cryptography ensures the security and privacy of data and participants. Cryptographic hash functions are the most widely used techniques adopted by blockchain technology. The term 'Blockchain' is composed of block and chain where a chain is divided into many blocks. The initial block (genesis block) has no parent block and its value is set to zero. The consensus approach provides trust in an untrustworthy environment. It verifies the integrity and trust of the transactions. Being a decentralized technology, each block (node) in the blockchain network stores a copy of the ledger to protect data from a single point of failure.

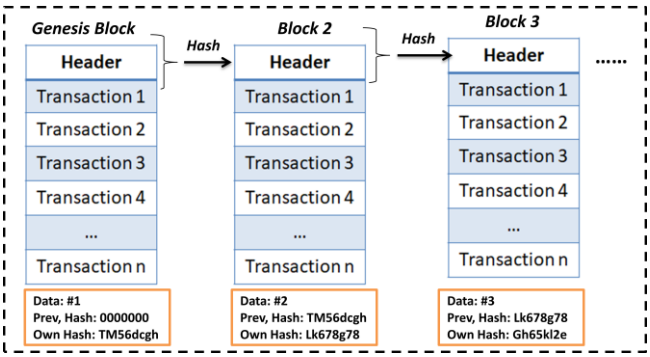

Fig. 1. Linked Blocks.

Fig. 1 shows how blocks are linked and arranged where only the first block has no parent (previous) block to it, hence its previous hash is automatically set to 0 and own hash value is generated for block 1. The hash value of block 1 is passed to block 2 and that value becomes its previous hash then the own hash value of block 2 is generated. The ledger in the blockchain contains a certain number of blocks whereas the first part contains a fact that needs to be stored in a database (e.g., network traffic logs, a record, etc.). The second part contains the header information. It includes the transaction hash, the hash of the previous hash, and the timestamp. This kind of storage makes a sequential chain of blocks [24]. When a new transaction or record needs to be added to a blockchain, first it will be added to a new block. The records added to the blocks in a blockchain can be verified individually using a hash function. Hash functions can ensure data integrity inside blockchain networks [25].

1) Selection of hash functions: A lightweight hash function must be used for block mining. The algorithm used for hashing must serve security using cryptography. The function should also fulfill certain conditions. The output size of a lightweight hash algorithm is 256 bits. If this size is reduced, the security strength also get reduced. The hash algorithms designed for IoT devices need to be designed specifically. These devices do not have sufficient memory of their own to calculate the area for implementation. So some microchips can be embedded in IoT for using cryptographic hash (like SHA-1 and SHA-2) [26].

2) Block structure: Fig. 2 presents the Structure of the Hash Chain or Block. A block structure is composed of a header and the body. The header consists of various fields like Version number, a timestamp, block size, and related transactions [27].

Every transaction generates a hash value to generate a unique Merkle root. Here, the cryptographic nonce is used for proof of the transaction in an encrypted manner i.e. called 'proof-of-work' or 'proof-of-state'. Miner identifies a nonce that generates hash values according to the set value. Difficulty targets the time of block creation. Each block is generated by a distinct hash value. A Merkle tree is a type of binary tree that is formed of hash pointers. It is constructed from leaf nodes toward the head or root node.

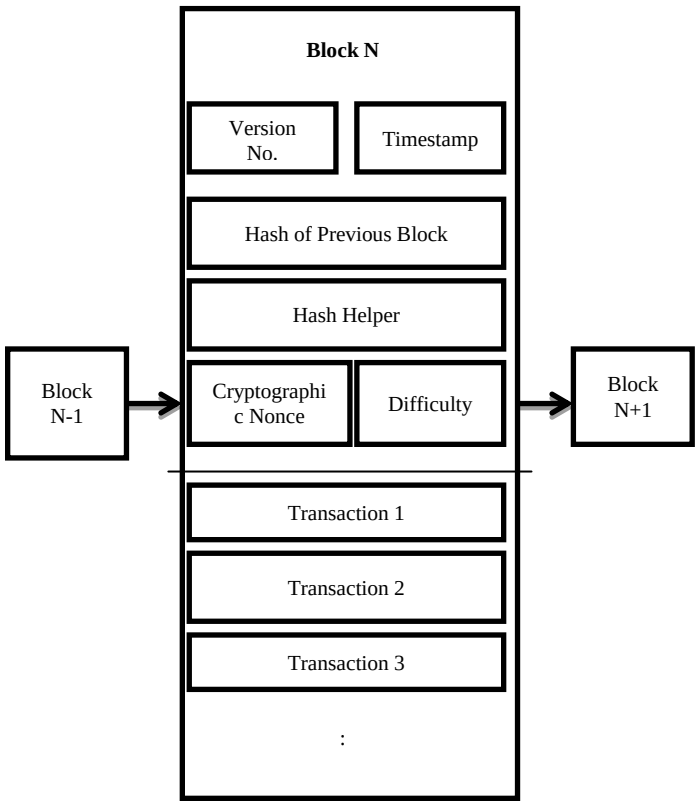

Fig. 2. Blockchain Block Structure [11].

C. Integrated Cloud and Blockchain-Based Internet of Things (BCoT)

The integration of cloud computing in IoT constructs a Cloud of Things (CoT) environment [28]. Cloud computing offers many opportunities in various technical areas including IoT. Cloud computing contributes to making IoT services flexible, scalable, and cost-effective. These services reshape the IoT environment and improve system performance by providing flexibility and robustness. However, the traditional cloud model is based on centralized communication [29]. IoT devices are connected, monitored, and managed by a central server in the cloud. If the centralized system is attacked, it may lead to the destruction of the whole system. An IoT architecture that adopts cloud computing needs a more advanced solution to make the infrastructure decentralized or distributed. It becomes difficult to scale the widespread centralized IoT infrastructure and its communication network requires many communication channels. Several concerns arise in the case of big communication networks like the requirement of a trusted third party (a central cloud server), high communication latency, and increased cost.

To achieve a legitimate solution, a decentralized ecosystem approach needs to be deployed in computing. Blockchain technology is based on peer-to-peer network architecture. The blockchain is a decentralization-based technology and it doesn't depend on the central point of control for transaction management. It also reduces the risk of single-point failure occurring due to disruption of central authority [30]. Each node can be verified independently and the architecture built using blockchain technology ensures secure and robust operations [31]. Integration of blockchain and cloud computing in combined form provides several significant benefits [32]. The blockchain-based architecture uses a distributed storage and computing approach using virtual storage nodes. Blockchain uses a virtual decentralized storage system without using a central authority. Blockchain behaves as a layer among various cloud servers and end-users. Using only cloud services may lead to high-security issues because the centralized server is only responsible for the security and privacy of the entire communication network. Blockchain-as-a-service (BaaS) follows peer-to-peer communication that eliminates the requirement of a trusted third party. Adoption of blockchain technology integrating with cloud computing provides major benefits discussed below:

- Decentralization: It can solve the bottleneck problems occurring in centralized structures, such as single points of failure [33] as well as it also reduces the communication delay and power consumption in IoT devices. It also resolves traffic load balancing issues by establishing short routes [34].
- Enhanced Security and Privacy: For data processing, the Cloud of Things (CoT) need to depend on a third party i.e., a cloud service provider that raises privacy issue. Blockchain-based cloud of Things (BCoT) provides a trustworthy access control that enables only authorized users to access all the services automatically.
- Integrity: Blockchain resolves the problem of data integrity, management and control, and synchronization in distributed databases.
- Quality of Service (QoS): Cloud computing alone is unable to handle Quality of Service for many applications like reliability, real-time, and security. Edge computing is an alternative to cloud computing that can overcome these problems. But it has less scalability, and it is a costly solution. Integrated blockchain with cloud in IoT (BCoT) also resolves this problem [35].
- Immutability: Blockchain provides immutability due to the uniqueness of blocks with unique hash values.
- Scalability: Cloud provides a better storage facility. Integrating blockchain in IoT with the cloud provides better system scalability due to the consensus mechanism.
- Fault tolerance: Replication and redundancy are basic concepts behind fault tolerance which are handled in cloud computing [36].
- Cost optimization: Cloud system provides robust integration of massive data. It also provides distributed resource facility. It improves operational efficiency and reduces cost.
- Strong Authentication: Due to strong encryption and key concepts, a Blockchain-based system provides better authentication.

- Consensus: Consensus is used to establish trust. Consensus may differ in scalability, fault-tolerance, power consumption, etc. [37].

IV. Proposed IoT Architecture

So far, there is no generalized architecture of IoT that has been adopted globally and that can provide various advantages such as efficient storage, decentralized security, and proper data and event management and control altogether in a single IoT architecture. Different researchers have proposed different IoT architectures consisting of different numbers of layers. With the origination of IoT, initially, very simple architectures were proposed that describe the basic scheme of IoT. For many years, three layers architecture consisting of the perception (physical) layer, network layer, and application layer has been widely used. However, this architecture does not provide adequate information about IoT security. It is suitable just for development in the initial stage [10]. It was not sufficient for IoT development; hence a better model was required that can explain the features and inferences of IoT more appropriately.

A. IoT Functional Building Blocks

An ideal IoT framework must consists of all standard components (like sensors, actuators, devices, communication protocols, network and device controllers, etc). The model presented here is composed of seven layers and all the standardized modules (blocks) which are mandatory for an ideal IoT model. IoT system architecture consists of various functional building blocks to assist different utilities viz. sensing, actuation, identification, communication, and management [38], [39].

- Connected Objects (Heterogeneous Things): Internet-connected devices or things are the main components of an IoT system that include sensors, actuators, monitoring devices, Bluetooth Low Energy (BLE) devices, and Radio Frequency Identifiers (RFID). IoT devices are end nodes that can communicate with other connected nodes (devices and applications). These nodes can send and receive data, process the data locally, or get it processed by centralized servers or cloud-based back-ends. All connected nodes generate a certain amount of data in any form that is processed by a data analyzer to generate useful information.
- Communication: This block carries out communication between connected devices and remote servers. It contains components like communication protocols, network enabling devices, etc.
- Processes: Processes are the technologies or functions which are responsible for information processing. The main processes of IoT systems are communication, accumulation, and analysis.
- Services: IoT system performs several types of functions like device modeling, device control, device discovery, data analysis, data control, and data publishing. The service module includes various service-providing technologies such as cloud/fog/edge computing and blockchain technology.
- Management: The management layer contains various functions to govern or monitor activities and components of the entire IoT system.
- Security and Privacy: The security layer provides various functional approaches to secure IoT systems such as authentication, authorization, access control, integrity, privacy, and security.
- Application: The application layer works on the applications of IoT architecture. It functions as an interface for IoT systems and provides the required elements to monitor and control IoT systems. It also allows users to visualize and analyze the present status of the IoT system.

B. Layers of Proposed IoT Architecture

The proposed IoT framework also highlights the concept of the flow of data (information) over a network through an IoT infrastructure. The IoT architecture presented in this paper pays attention to the flow of information through six standard layers that is managed and controlled using a parallel layer. A standard architecture of an IoT system has been depicted in this paper. Fig. 3 presents the proposed IoT architecture enabled with integrated cloud computing and blockchain technology.

1) Perception layer: The perception layer also known as the sensing layer is a physical layer. This layer encompasses many types of sensors. The general idea behind this layer is to collect real-time data from heterogeneous sources such as connected physical and digital devices, controllers, and applications [10]. Sensors are the most important tools which contribute to sensing and collecting essential data from related sources. The sensor senses the presence of a physical thing or a quantity and collects value on a physical parameter e.g., temperature, pulse rate, etc. The sensor returns output in form of signals readable by humans. Transducers are the tools that convert signals from one form to another form. This layer is also known as the physical layer because it can collect data and values directly from devices. The components (Things) of this layer represent the front end of IoT. The ‘things’ are the uniquely identifiable devices carrying a unique IP address that makes them easily identifiable over the network. The perception layer contains various devices such as RFID tags and readers, GPS, cameras, etc. with important sensing technologies.

a) Controller: Microcontrollers are most widely used in IoT technology. A microcontroller operates at the physical/ abstraction layer running the selected operating system/real-time operation system, which provides operating facilities to IoT devices. A microcontroller is a single integrated chip (IC) embedded with a CPU, RAM, ROM memory, and peripherals. It is like a small computer itself. Many things are embedded in a single chip, and it provides lower performance than a microprocessor. But it is a much better choice for smart IoT devices, and its computing power is also sufficient for all IoT applications.

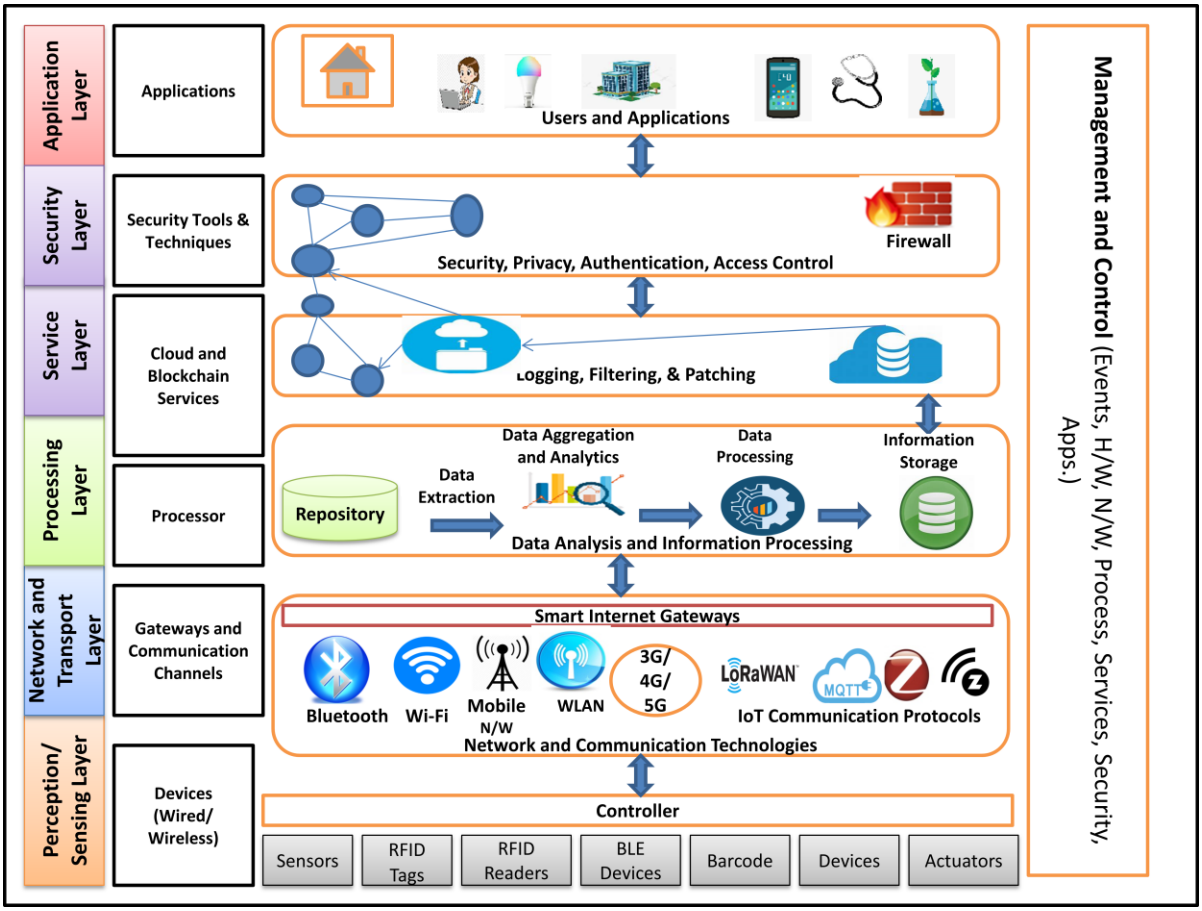

Fig. 3. Blockchain-Enabled Secure IoT Architecture.

2) Network and transport layer: The transport layer receives data packets from the perception layer and transmits them to further layers using various network technologies viz. Bluetooth, Wi-Fi, wireless LAN, and various IoT communication protocols (HTTP, Zigbee, MQTT, Z-Wave, 6LoWPAN, LoRaWAN, etc.) [40]. This layer performs data management from storage to processing state of data leading to reliable data transportation [41].

a) Smart Gateway: It is not possible to directly connect many sensor networks and IoT. IoT and sensor networks consist of sink nodes and base stations. The role of the gateway is to collect the data from base stations and the sink nodes and generate a multi-hop communication structure. In this structure, multiple nodes develop and spread more widely. More heterogeneous data development requires more processing and comprehensive data analysis from the gateway. This structure also customizes the security according to the requirements of IoT and WSN. Sink nodes can efficiently handle the sensor nodes. Here, the gateway handles the heterogeneous data collected from various kinds of devices and networks.

3) Processing layer: In IoT systems, data is captured from devices and stored in datasets, and processed for further requirements. The processing layer is the brain of the IoT system that contributes to the analysis of event data and information processing. Events captured by different sensor devices are stored in datasets. An enormous amount of raw data is extracted from the data repository that is to be analyzed and processed. The processing layer operates on a real-time system and it is responsible for data security through encryption and decryption approaches.

The information gathered from smart IoT devices or end nodes is sent to the cloud [42]. The information is then processed through any processing technique (which could be AI/ Machine learning) for providing data to the user. A certain level of intelligence is added to the devices which makes the IoT system smart. Devices like sensors and actuators are added to the system which collects information from IoT devices and sends it to the cloud through a communication mechanism (Bluetooth, WiFi, Zigbee, etc.) [43].

4) Service layer: The service layer provides a rich set of functions for communication, processing, and storing. This layer is responsible for managing IoT services. Cloud and edge [44] are important IoT services. These services are required to enable IoT systems to meet the security, scalability, and speed requirements [45].

a) Cloud Computing: Technically, the cloud is not a mandatory part of an IoT system. Data storage and data processing take place remotely in the cloud rather than in the system itself. Most of the users store their data on Google

Drive rather than on personal computers. Google Drive uses Google cloud services. Cloud computing makes the Internet of Things more successful by enabling users to perform computing using the services provided over the Internet [46]. A large amount of data is generated by rapidly growing IoT technology that arises the problem of storing, processing, and accessing the data. The integration of cloud computing into the Internet of Things gives an innovative solution. Uploading and storing of sensory data streams take place on the cloud instead of the local device storage.

b) Edge Computing: In IoT edge, devices and sensors communicate real-time data to a network. Pairing the IoT with edge computing makes data processing much faster. In the absence of cloud computing, edge networks and edge computing approaches can control IoT system units individually. The combination of edge and the cloud provides much better development for IoT. Edge computing also reduces the load of data by aggregating it before uploading it to the cloud. Azure is a widely used IoT edge [47]. It allows for storing, processing, and analyzing large volumes of real-time data locally at the network edge. It saves time and resources to send all data to the cloud. Sensitive information is processed and packaged into several packages and sent securely to the cloud.

c) Fog Computing; Fog computing can be used as an alternative to edge computing. If gateways are not able to handle interoperability and trans-coding, this can be attained through fog computing. A fog network is established between the cloud and gateway network. Fog provides better and refined applications and services by extending conventional cloud computing [47]. Fog computing provides a virtual platform that provides storage, computation, and network services between IoT end nodes and the cloud [48]. Fog can provide better quality functioning to mobile nodes by positioning the proxies and access points according to nodes. Fog provides better communication than gateways. It can also include virtual sensor nodes and virtual sensor networks. By co-locating with the smart gateway, it provides low latency communication, temporary storage, better security, more privacy, and easy preprocessing of smart tasks like facilities [49].

d) Blockchain Services; Blockchain technology can be utilized to store digital information in a public database. Some widely known industries like Amazon and Microsoft Azure offer blockchain services i.e. Blockchain as a service (BaaS). A Group of digital information is stored in form of blocks in a hierarchical form. A unique encrypted code is assigned to each block that distinguishes them from each other. These blocks are generally designed using a hash mechanism combined with special programming techniques [50]. It provides improved security by removing human involvement. It uses Asymmetric key cryptography for transactions. Block of keys (public and private keys) are used for entire transactions. Signatures are validated using a private key and a public key verifies the signatures generated by a private key. The decentralization of blockchain makes it harder to tamper with the stored results. However, blockchain services are utilized only to store transactions. The transactions are verified, hashed, and stored in blocks in form of digital signatures.

5) Security layer: Security is the major requirement of IoT architecture. The IoT security layer takes responsibility for managing the security of various components of IoT across the entire infrastructure. The security layer is essential for the security of all the layers of IoT architecture. It makes the information secure before communicating between external and internal users. This layer collects the processed data from the processing layer and encrypts it before sending it over the network using a strong encryption algorithm or a combination of selected encryption algorithms. The legitimate receiver receives the encrypted information that could not be recognized by the illegitimate user [51]. However, securing only the information is not sufficient to secure an IoT infrastructure. It is required to follow all security measures to protect the IoT environment. Authentication and access control mechanisms are used to manage and improve the security system. Blockchain provides security solutions for storage as well as communication.

a) Device Security: Smart devices around the world can communicate with the services like servers or the cloud using Ethernet or Wi-Fi. But these devices are not well-equipped to manage the security concerns of Internet connectivity. The devices must be activated by security features. Security features embedded with hardware and firmware enable devices to handle security, authentication, encryption, proxies, caching, connection loss, timestamps, etc. Device security can be achieved using the following methods:

- Trusted platform module: IoT enabled chips could be embedded with cryptographic keys for the security of end nodes. Security chips containing the security protocols that can be deployed on the sensor devices and these protocols are called to recognize the security operations. Security operations include mutual authentication, mutual signature verification, etc. The security chips may be connected to the sensors using an SD card [52].
- A secure boot process can prevent unauthorized code from the device.
- Security patches must be updated regularly to protect from malware and threats.

b) Network/Communication Security: A communication network is a medium over which data is transmitted and received. Unsecure communication channels might be liable to serious security risks. The communication layer must be equipped with innovative security solutions. Data communication over the network should be encrypted for a secure connection. Data encryption protects communicating data from unauthorized access and information interception. IoT-centric messaging protocols (AMQP, MQTT) can use Transport Layer Security (TLS) cryptographic protocol for end-to-end data protection. However, firewall also works as an obstacle between a secure and insecure network. A firewall is like a physical security fence that monitors the network and

attempts to block certain types of incoming suspected network traffic to prevent attacks on a private network. It does this by filtering both in and out network traffic. Blockchain is a smart security mechanism that provides end-to-end security to entire IoT architecture including cloud.

c) Service Layer Security: Modern IoT systems adopt cloud-based service solutions, which are vulnerable to privacy violations, and failure on a single point, Denial-of-service attacks [53]. Blockchain is an advanced technology that employs a cryptography approach to guarantee the security of distributed ledgers. It supports many advanced technologies such as hashing, elliptic-curve, and distributed consensus approach. Blockchain combined with services provides a promising solution. Cloud is a central system that can be exploited by attackers. Blockchain provides independent and distributed services utilizing public-key cryptography algorithms. Blockchain-based IoT system also facilitates access control.

d) Application layer Security: The application layer is the most sensitive and wider attack surface. Applications are directly exposed to users. The users could be authenticated or malicious actors. The security of the application layer depends on the type of application and the purpose of the application. Security needs to be customized to the unique situation [54]. Trade-offs accompanying strict security measures might be effective in preventing attacks. Application layer security also relies on the selection of communication protocols such as (HTTP, MQTT, CoAP, etc.) used with the system. Each protocol has its strategy to conduct user authentication. So it is important to be familiar with the pattern of each protocol for security improvements. Message Queuing Transport Protocol (MQTT) is the most widely used Client Server publish/subscribe messaging transport protocol. It is a simple, ideal, and above all lightweight messaging protocol used in end-to-end communication. MQTT can be used for telemetry to receive data from sensors and actuators and can command that remotely using the MQTT client library [55]. It supports various authentication mechanisms and Secure Socket Layer (SSL)/Transport Layer Security (TLS) based encryption for transport protection [56]. Application firewalls can be used to guard the application layer. However, firewalls must build and configure considering the specificity of applications. A highly secure application layer can protect other layers too from security breaches because most of the breaches enter through the application layer. It is important to consider security in the designing of protocols [57].

6) Application layer: The application layer is the top layer of IoT architecture. This layer directly interacts with outside users and delivers application-specific services to the users. All the communication from user to system passes through the application layer [58].

a) Authentication: The security mechanism is integrated with the application layer. A user who wants to access an IoT system first needs to pass through the authentication process. Using an identity identification mechanism, the unauthorized user is prevented to access the system.

b) Risk Assessment: The integration of effective security mechanisms in IoT provides an improved security structure.

c) Intrusion Detection: Several application-specific intrusion detection techniques are used with IoT to find security solutions. All the incoming and outgoing events are monitored and their logs are stored in databases which are analyzed for threat detection. An alarm is triggered on the occurrence of suspicious activity.

7) Management and control layer: IoT is an ecosystem where several heterogeneous devices (things) are connected using the Internet carrying distinct missions and functionalities. IoT management has been a challenging task for researchers [59]. In the network, the devices are connected and recognized with the help of their unique IP addresses. IoT device management is like ant colony management. This is a parallel layer that aims to provision, configuration, administration, monitor, and diagnostics of various assets utilized on IoT platforms. It also plays an important role to detect various challenges faced by connected devices.

a) Device Management and Control (DMC): IoT devices can be managed using various tools and techniques designed for IoT device management. IoT device management is used to maintain the security, connectivity, and efficiency of connected smart devices. Management and control Fundamental requirements of IoT device management are:

- Provisioning and Authentication: Provisioning is the process of registering an IoT device to ensure its reliability of an IoT device and authentication is the process through which only devices with valid credentials (certificate/key) are registered. It is necessary to protect the IoT system from malicious attacks.
- Configuration and Control: This is the process of installing a new device using some settings to enable it for working. But only installation does not ensure its performance, functionality, and security from threats. So while configuring the control settings must be fine-tuned for device maintenance and management.
- Monitoring and Diagnostics: To solve very issues, it is necessary to identify them first. A constant monitoring system provides the continuous logging of a device.
- Updates and Maintenance: The software is required to be updated frequently from the moment of installation for the flawless functionality of a device. Devices can be updated and maintained manually as well as remotely.

b) Network Management and Control (NMC): Network management is the process of operating, monitoring, and controlling an entire network to optimize its efficiency [60]. NMC is a diversified authority that provides various network management tools, techniques, protocols, and processes to the network administrator. Network management and control emphasize on management, monitoring, and control of various network components responsible for device connectivity and data communication. Several types of networks enabling

devices (Bluetooth, router, gateways, switches, cables, etc), communicating protocols, technologies (Wi-Fi, 3G/4G, etc.), and services (Internet) are used for connectivity and communication. Network management and monitoring are developed every year and are launched in periodic seasons. NMC monitors and analyzes the network traffic that might contain normal as well as anomalous traffic patterns. Based on the nature of the traffic patterns, it is routed and controlled.

c) Data/Information management: Data management is the process to aggregate and analyzing overall collected valid data and refining it into information [61]. Large volumes of data are produced by different IoT devices and applications [62]. A perfect data management framework is needed that can efficiently collect, manage, and distribute data and must be compatible with existing software and hardware. Data collected from IoT devices are used for analytical purposes. IoT data is processed, managed, and analyzed locally using edge computing and at a centralized level using cloud computing.

d) Security and event management: End-to-end security management is essential for ensuring the privacy and security of IoT devices, services, information, and applications. It protects IoT systems from various attacks. Data, logs, and event monitoring and analysis make IoT systems enable them to protect themselves from various threats and vulnerabilities. But it is difficult to prevent all security risks so an efficient security event management process is required that could ensure rapid recovery. Real-time insight tools and audit trails provide facilities like monitoring, analytics, and log management which can be utilized to get the root cause of an event. This information can be used in digital forensic investigations as evidence.

V. Comparative Analysis and Discussion

Most of the well-known existing IoT architectures generally composed of three or four layers. Traditional IoT architectures do not focus on the storage efficiency and security properties altogether. IoT architecture proposed in the present paper collectively focused on these necessary properties in order to design an efficient IoT architecture. Integrating cloud computing and blockchain technology into IoT ecosystem can provide endless solutions to various kinds of security and storage issues. Table I briefly presents comparative analysis of proposed cloud-blockchain-based secure IoT architectures with some recently proposed advanced IoT architectures.

Quereshi et al. in [63] proposed a cloud-based IoT architecture to overcome the problems of storage and resources. Das et al. in [64] proposed a smart IoT architecture integrating cloud computing with IoT mechanisms. The approaches proposed in [63] and [64] resolve storage and resource related problems. But the centralized storage and access facilies provided by cloud computing may create data security, integrity, and privacy issues. The data stored on cloud platform can be easily compromised by unauthorized users. Author in [65] presented a white paper with his research work that consists of an IoT architecture. The proposed architecture focused on connectivity, data management and application analytics. Qiu et al. in [66] proposed an IoT architecture dynamic blockchain technology. This architecture facilitates decentralized storage with trust, transparency and security. Hou et al. in [67] proposed an IoT architecture using the Blockchain technology. This architecture provides good performance in terms of security, integrity, authentication, reliability and trust. However, storage and scalability still remain significant issues. Which can be resolved by storing the data on cloud platform integrating with blockchain technology. Sharma et al. in [68] focused on advantages of blockchain technology while designing the IoT architecture.

TABLE I. Comaparative Analysis of Proposed Cloud-Blockchain-Based Secure IoT Architecture with Existing IoT Architectures

Literatures	Research Gap	Improvements by proposed Architecture
Qureshi et al. [63]	Security and integrity issues due to centralized storage	Integration with Blockchain technology provides better security and integrity.
Das et al. [64]	Data protection, integrity, security issues	Integrating with Blockchain technology resolves security and integrity issues.
A. Hakim [65]	Not focused on security and resource problems	Focused on security, integrity and storage solutions
Qiu et al. [66]	Focused on bitcoin; Storage issue	Provides advantages of cloud and blockchain technologies and it is not application-specific
Hou et al. [67]	Lack of scalability	Cloud computing can overcome the scalability issue.
Sharmaet al. [68]	Focused only on advantages of blockchain	Proposed architecture consideres advantages as well as disadvantages of cloud and blockchain

IoT architecture proposed in present paper considers the advantages as well as disadvantages of cloud computing and blockchain technology. There are several disadvantages of both of these technologies beside their advantages that must be fixed while implementing them into IoT ecosystem.

VI. Conclusion and Future Scope

The paper presents a design of integrated cloud and blockchain-based secure IoT architecture to resolve various kinds of data security and storage challenges. The proposed cloud-blockchain-based secure IoT architecture is composed of seven layers. In addition to various layers (perception layer, network layer, processing layer, and application layer) which are very common in existing IoT architectures and generally included in the design of every IoT architecture, the proposed IoT architecture includes three additional layers namely the service layer, the security layer, and the management and control layer. Blockchain technology provides end-to-end security solutions with trust, integrity, reliablility and reduces many types of challenges in IoT infrastructure. The service layer is the key layer of IoT architecture that uses integrated features of cloud computing and blockchain. This approach provides decentralized or distributed services in an IoT environment that overcomes various challenges occuring due to centralized communication. It prevents single points of failure, high communication costs, and the need for a central agent. It also provides several security benefits by using advanced cryptographic mechanisms like hashing to encrypt

data and events in an IoT environment. The management and control layer placed in parallel to the entire architecture contributes to monitoring, managing, and controlling various activities and components throughout the IoT system. A secure and well-managed IoT architecture is the basic requirement of successful IoT technology. It is highly needed for realizing the dream of smart cities. Therefore, the proposed IoT architecture can be of greatly helpful for researchers as well as can be used in industries and other private and government sectors for building smart infrastructures. In future, the proposed IoT architecture can be deployed for developing different applications in IoT infrastructure with high security and efficiency.

***Abstract*—The accurate analysis of medical data is dependent on early disease detection and the value of accuracy is reduced when the medical data quality is poor. However, existing techniques have lower efficiency in handling heterogeneous medical data and the complexity of the features was not enhanced using an optimal feature selection model. The present research work has used the machine learning algorithm effectively for chronic disease prediction such as heart disease, cancer, diabetes, stroke, and arthritis for the frequent communities. The detailed information about the attributes is required to be known as it is significant in analyzing the medical data. The process of selecting the attributes plays an important role in decision-making for medical disease analysis. This research proposes Binary Moth-Flame Optimization (B-MFO) for effective feature selection to achieve higher performance in small and medium datasets. Additionally, the Whale Optimization Algorithm (WOA) is used that showed better performances for LSTM that suited well for the process of classification to predict the time series. The present research work utilizes Spark Streaming layers for data streaming to diagnose using Long Short Term Memory (LSTM) with whale optimization approach which is from the heterogeneous medical data. The proposed B-MFO-WOA method results showed that the proposed method obtained 97.45% accuracy better compared to the existing Modified adaptive neuro-fuzzy inference system of 95.91% of accuracy and B-MFO of 92.43 % accuracy for the models.**

Keywords*—Binary moth-flame optimization; complexity of the features; medical data; long short term memory; spark streaming layers; whale optimization algorithm

I. INTRODUCTION

The healthcare business uses huge data of medical treatment and recordings of every patient. The medical information is recorded and printed with various versions that are converted to digital versions efficiently [1]. Due to the extreme volume of patient details, it is possible for enhancing the quality of health care effectively for saving expenses. All the information present could be used in the multi-health care discipline such that health care illness and surveillance are preventative for management [2]. The Big Data (BD) tools are combined with the machine learning and data mining techniques that showed challenges in areas such as health care, education, transportation, and social media with other networks. The machine learning techniques were used that encompassed the phrase that referred to the large datasets. The regular utilization is progressively performed with little that indicates the basic intricacy and lay the first stone with subsequent ethical and misunderstandings of possible ways [3].

The BD movement is applied to unlock endeavor of large dataset values for making the decision, improving the outcomes, efficiency, and data owners have shown the deliverables. The goals are required to be accomplished, that is, collected, stored, access, managing data with various forms turns the volume with the simple steps [4–7]. Intelligence is applied on data points of high information to improve efficiency. Digital equipment usage increases for model and amount of data increases with unparalleled rate [8–10]. The deep knowledge discovery is computed in big healthcare data which has achieved the best results. However, the selection of the optimum subset of relevant and effective features is used for constructing an accurate model. Thus, the selection of features from a vector of one or zero is used for constructing an accurate model. Apache Spark was deployed in the cloud as it focused to apply on the ML models.

The contribution of the research work is as follows:

- The use of the Whale Optimization Algorithm (WOA) showed better performances for LSTM that suited well for the process of classification to predict the time series and solve optimization problems. To compute simulation of prey search, and prey encircling, humpback whales of bubble-net foraging are mimicked.
- Transfer functions such as U-shaped, V-shaped and S-shaped were applied to convert the continuous value to binary values for the feature selection process using the B-MFO technique.

The organization of the research paper is shown as follows: Section II is the literature review of the existing models and Section III illustrates the proposed method. Section IV shows results and a discussion of the proposed method. The conclusion and future work of the proposed research is given in Section V.

II. Literature Review

Nadimi-Shahraki et al. [11] developed a feature selection technique of B-MFO for the HER medical dataset. The developed model reduced the algorithm performances and therefore, the present research used a binary moth-flame optimization (B-MFO) for the selection of effective features based on the large medical datasets. The features such as S-shaped, U-shaped, and V-shaped transfer functions were used which converted continuous to binary values. The B-MFO technique was applied to use a U-shaped transfer function for feature selection to improve performance in a large dataset. While considering the other datasets (Pima and Lymphography), the suggested B-MFO achieved less accuracy when compared with existing Binary Particle Swarm Optimization (BPSO) method.

Li et al. [12] utilized an optimization approach for reinforcement learning on the Electronic Health Records (EHR) for the treatment. Reinforcement learning provided an efficient path for providing a decision sequentially. The developed model used reinforcement learning for optimizing the treatment for analyzing the diseases, diabetes, and sepsis, and showed complications. The EHRs data was modeled in an environment that obtained a probability that was used for the RL process. The agents were explored better as the basic model was cooperative for multi-agent reinforcement based on the value decomposition. However, the recommended model was additionally required to be extended through the decomposition model and thus the results obtained were better than the existing benchmark models.

Sousa et al. [13] applied the decision-making technique for big data analysis in healthcare organizations and People management. The decision-making process is based on healthcare on big data analysis to support healthcare decisions and applied some techniques to increase efficiency. The suggested model has the limitation of irrelevant feature selection that degrades the performance of the classification accuracy and showed diversity in terms of performance.

Chelladurai and Pandian [14] developed the blockchain based EHR model for an automation system for healthcare. The model could access the health data from one provider to another which remained a challenge when they accessed the health records. The fragmented model launched with the health models was immutable with the patient log by using the modified Merkle tree data to secure the storage. The health records were updated by exchanging information among distinct providers. Even though, the viewership contracts were developed on peer-to-peer blockchain networks and blockchain using Merkle tree generation and hashing that required an extension to ensure the integrity of the content.

Vidhya and Shanmugalakshmi [15] developed a Modified adaptive neuro-fuzzy inference system (M-ANFIS) to analyze the multi-disease using the Big Data (BD) from health care. The health care domain obtained an influence based on the BD that affects the data sources as they are concerned with healthcare organization as it is famous with the volume, complexity, high dynamism, and heterogeneity. The BD analytical techniques utilize the functions, tools, and platforms for realizing it among distinct domains that were affected by various health organizations. The healthcare applications show possible propitious research directions. The multiple diseases were analyzed by using Modified Adaptive Neuro-Fuzzy Inference System (M-ANFIS). Yet, the increasing of sources like audio, video, image, GPS, and medical sensors are having prioritization and designation for the level of patients at the emergency.

Ahmad et al. [16] developed a hybrid ML model for the prediction of mortality in paralytic ileus patients based on EHR. Various machine learning techniques were used including Support Vector Machine with Radial Basis Function (SVM-RBF) for the classification to find the highest rank order among the extracted features. Yet, the developed model required robust models for improving the accuracy of the model to improve the model's feasibility.

Shi [17] developed a novel hybrid deep learning model architecture for the prediction of acute kidney injury based on the patient's record data that included Ultrasound kidney images. The developed model used Convolutional neural networks (CNN) that has Resnet and VGG was made as a hybrid model. The feature maps were concatenated with both types of models for creating the input. However, the suggested model required a continuous optimized approach using the larger clinical database for the paired datasets.

From the literature works, the major problems with big data analytics are the size of the data sets and the complexity with validating long-term predictions for medical diagnostics and treatment. Both the amount of data used in healthcare organizations and the number of data sources are expanding. Healthcare facilities face issues including inconsistent and inaccuracy in patient data as a result of the high speed and growing size of big data. It also has trouble in organizing the data after extracting and integrating them, and more attention is needed to increase accuracy and reduce errors in clinical judgments and other medical tools Therefore, this paper proposed a Binary Moth-Flame with Whale Optimization technique to deal with such issues and the difficulties of implementing big data analytics for the enhancement of healthcare services.

III. Proposed Method

The proposed approach is developed by accumulating enormous amounts of data related to patient care over time in order to comprehend and predict diseases that demands an aggregated approach. While the structured and unstructured data originating from large data sets are collected from clinical and nonclinical modalities to gain information about the disease states. As a result, this study attempts to assess the value of predictive analytics in the health care system by examining the accuracy and other metrics in the provision of medical care.

The block diagram of the proposed Modified feature selection optimization approach is shown in Fig. 1. The block diagram consists of a health care data block which is undergone the process of pre-processing. The pre-processed data is undergone for the feature selection of the data and obtained the outputs. Initially, the collected data that consisted of laboratory reports, imaging reports, medication reports,

medication, caregiver notes, and mortality for both out and in the hospital, etc. are applied for the Spark Streaming layers. The main aim of using the spark streaming layers is to improve the diagnosis of the disease based on the data streaming. However, the spark streaming model required effective features for the model construction. Therefore, an optimum model was used for selecting the relevant subsets that were required for the model, and thus it helps to process further diagnosing the disease using the data streaming layers. The proposed B-MFO-WOA algorithm is generated by developing an initial solution. The image data is pre-processed and the parameters are optimally selected by using the Whale optimization algorithm. For finding the best solution during the exploration and exploitation phase, the B-MFO algorithm is used for the selection of subset features. The three transfer functions such as S, V, and U are integrated for solving the optimization problem. The S, V and U transfer functions select the best values based on the generation of slopes and the saturation. These integrated functions are required for improving the B-MFO algorithm performances. The transfer functions such as S and V helps to convert the continuous variables to a binary value of 0 and 1. The U-shaped transfer function maps the velocity function that is continuously generated with the probability values and updates the particle positions. The integration of all these three transfer functions into the B-MFO algorithm showed an improvement in the performance of searching it on the binary searching space. The search space values are having the probability value for uploading the particle position. Once finding the best features, they are fed to the LSTM classifier that uses a softmax layer and obtains an output as a final label to predict the named data labels. The score for the label is named based on the weighted average for the probability prediction when the classifier is applied to the data. The probability of tagging is done for the labels as 1 and the weight parameter is either set as 0 or 1 for knowing the relative importance of the classifier compared with others. Thus, the health care diagnosis is performed for the data.

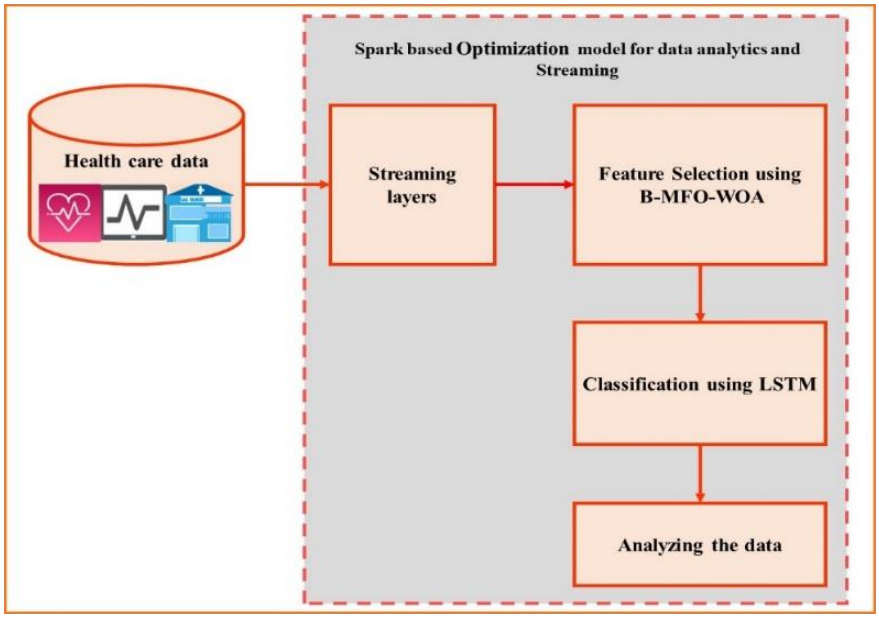

Fig. 1. The B-MFO-WOA and LSTM Model for Medical Data Analysis.

A. Dataset Collection

The health data of the patients are recorded with EHR provides the services for health care in the medical center. The medical centers are registered in detail regarding the patients. The network administrators are registered with the medical centers for participation. The EHR identifies and generates each of the data that is stored in the medical centers. The data is associated total 40,000 number of patients who have stayed in the care units. The units range from the years 2001 and 2012 acquired by Beth Israel Deaconess Medical Center [18]. Initially, the collected data that consisted of laboratory reports, imaging reports, medication reports etc., which are the medical data present in the dataset are applied for the Spark Streaming layers.

B. Feature Selection using B-MFO-WOA

The main aim of using the spark streaming layers is to improve the further diagnosis of the disease based on the data streaming. The stream layers contain polyline, polygon, and point-based features and unlike other feature layers with the services, the data sources have made explicit calls to the data and response for broadcasting the data. In most cases, the features at the irregular intervals are broadcasted and the present research work uses Spark Streaming layers for data streaming to diagnose further.

1) Problem of Feature Selection: The feature process is to select the optimal subset of features to increase the efficiency and relevant features of the model. Accurate data model is constructed and formulated using a feature selection process with a vector having 1 or 0 subsets of features based on the transfer function. It obtains the probability values that change the vector elements that is represented as 0 which can be non-selected and 1 is the selected ones. The feature vector length is the same as the dimensions of the dataset which is used for determining the fitness function which evaluates the subset of

features. This technique reduces the number of features and increases the accuracy of the model. The objective is represented as a fitness function as the CE has shown the error in the classification. N_{sf} and N_{tf} are known as the selected features that are present as a total in the feature dataset. The classification quality significance is given using η and λ (1 − η), as shown in the (1):

$$Fitness = \eta \cdot CE + \lambda \frac{N_{sf}}{N_{tf}} \quad (1)$$

Therefore, the present research uses WOA and B-MFO algorithms for the selection of features.

2) WOA: The WOA uses the exploitation phase for bubble net attacking to perform modeling the bubble net behavior that is having humpback. The two kinds of approaches are designed as follows:

The Shrinking encircling mechanism is performed that achieves the behavior by decreasing the value. The proposed model uses the value to achieve by decreasing a value that represents the fluctuation range when it is decreased. The bubble-net method uses humpback whales to randomly search for prey. Next, in the exploration phase where the prey search is based on the variation in the vector which is used for prey search called exploration. The humpback whales randomly search their positions as per each of their positions. The mutation and evolutionary operations have been included in WOA for formulating and reproducing the behavior of humpback whales that were decided for minimizing the internal parameters and heuristics. This was implemented by the basic WOA version algorithm.

Automatic disease detection is performed using the fitness function for achieving a better classification measure which maximizes the accuracy. The positions for the current solution are updated. The prey is encircled with the phase that performs the process of whale hunting which has started encircled prey position. The whale's best position is found and is considered to be the finest whale. The best whale is towards the other whale which moves once the position is updated. The best solution is determined based on the distances among y^{th} whale where the prey shows the best solution. The distance among the y^{th} whale and the prey calculate the best solution which is ranging between [-1, 1].

3) B-MFO: For finding the best solution during the exploration and exploitation phase, the B-MFO algorithm is used for the optimization of subset features. The three transfer functions such as S, V, and U are integrated for solving the optimization problem. The transfer function of V and S shaped techniques are used in the present research work to convert the MFO function into a binary function. These transfer function names were adapted with the multiple alterable parameters which solved the problem of feature selection. Each of the categories has four versions for transferring the functions and twelve versions had introduced 3 categories for the transfer functions. The datasets such as heart disease, cancer, diabetes, stroke, and arthritis are evaluated for the frequent communities. Additionally, the B-MFO is compared with the best results which are known for its binary metaheuristic optimization approach.

4) B-MFO Variants: The transfer function of S-shaped in B-MFO: The S-shaped or sigmoid function is the transfer function used is named as S_2[100]. The model is introduced originally to develop the binary PSO (BPSO).

$$TF_s(v_i^d(t+1) = \frac{1}{\left(1+exp^{-v_i^d(t)}\right)} \quad (2)$$

From (2), $v_i^d(t)$ is the i^{th} search agent's that is operating at a velocity having the dimension d at the t^{th} iteration. The TFs are converting the probability value of velocity to its next position represented as $x_i^d(t+1)$. The expression is obtained based on the velocity probability value. Here, r is a random value which is ranging from 0 and 1 in (3).

$$x_i^d(t+1) = \begin{cases} 0 & if\ r < TF_s\ (v_i^d(t+1)) \\ 1 & If\ r \geq TF_s(v_i^d(t+1)) \end{cases} \quad (3)$$

From the above expressions, the positions of the search agents are computed based on the current and previous positions. The binary metaheuristic algorithm called BPSO and BGSA is used for transferring the functions. It is used for calculating the probability value that can change the position. The applied transfer function updates the position for each search agent that calculates the probability value. Each of the variants is S-shaped transfer function that showed a slope having S-transfer function. Probability value changes to a positive value as increases in the transfer function. A higher probability function is achieved using S-shaped functions. The S4 provides the lowest value which has affected the position and updates the search agents to find the optimum solution.

C. The Transfer Function of V-Shaped in B-MFO

The V-shaped function is a hyperbolic function that is named with V2 for developing BGSA that has the position to update which is shown in (4).

$$TF_v\left(v_i^d(t+1)\right) = \left|tanh(v_i^d(t))\right| \quad (4)$$

Where t is iteration, d is dimension, velocity of i^{th} search agent is denoted as $v_i^d(t)$. S-shaped function differs from the V-shaped function. The new rules of the updated function are given in (5).

$$x_i^d(t+1) = \begin{cases} -(x_i^d(t) & If\ r < TF_v(v_i^d(t+1)) \\ x_i^d(t) & If\ \ r \geq TF_v(v_i^d(t+1) \end{cases} \quad (5)$$

From the above Equations $x_i^d(t)$ has i^{th} search agent having the position and $-x_i^d(t)$ is the complement value of $x_i^d(t)$. The random value range of 0 and 1 is denoted as r. In case the velocity is low then TF_v encourages the search agents for staying in the positions else the velocity is high. Also, $x_i^d(t)$ has three variants having V-shaped function which is represented as V_1 , V_3 and V_4 are introduced. The higher probability is provided by V_1 than V_2, V_3, and V_4 for the same velocity that affects search agent update and finds an optimum solution.

D. The Transfer Function of U-Shaped in B-MFP

The α and β are two control parameters in the Transfer function of U-shaped that define the slope of U-shaped function width. The U-shaped function is given in (6) and (7).

$$TF_u\left(v_i^d(t+1)\right) = \alpha\left|\left(v_i^d(t)\right)^\beta\right| \quad (6)$$

$\alpha = 1, \beta = 1.5,2,3,4$

$$x_i^d(t+1) = \begin{cases} -(x_i^d(t) & If\ r < TF_u(v_i^d(t+1)) \\ x_i^d(t) & If\ \ r \geq TF_u(v_i^d(t+1) \end{cases} \quad (7)$$

Where t is iteration, d is a dimension, velocity of i^{th} search agent is $v_i^d(t)$ and r of the uniform random number is in the range of 0 and 1. The transfer function of the U-shaped is applied with two conditions. The lower and upper bounds are limited by 1 in (8) and (9).

$$lim_{v_i \to \infty}\, U(v_i^d(t) = 1 \quad (8)$$

$$lim_{v_i \to -\infty}\, U(v_i^d(t) = 1 \quad (9)$$

The variants obtained from the U-Shaped Transfer function is named as U_1, U_2, U_3 and U_4 which were used with the control parameters. The initial iterations were explored for the whole search space of important step that was explored with exploitation with the final iterations. The exploitation step is important for finding a better solution.

The random value for the search space is generated as indicated in (10):

$$E(u) = (e_1, e_2, \ldots e_h) \quad (10)$$

From the above equation (7), E is known as the whales' original population, the interconnected layers with the numbers are represented as h for the process of optimization.

E. B-MFO-WOA

Begin
The population of whales are initialized
Each search agent's fitness function is evaluated
X_{best} = searches for the best search agent
while ($t < maximum\ number\ of\ iterations$)
for each of the search agents:
The positions are Updated as $\alpha, A, C, l\ and\ p$
$if(p < 0.5)$:
$if(|A| < 1)$:
The current agent is updated
else:
The random population of moth is initialized and the objective function is calculated
The set of flames from the same moth is created
The positions of the moths are updated
The flame size has to be changed
End
Return with the best solution

F. Classification

The obtained features are now fed for the LSTM to exhibit the performances. Apache Spark was deployed in the cloud as it focused to apply on the Deep learning LSTM model. The prediction is performed for the higher rate of diagnosis which determines the global best function. The hyperparameters are randomly selected and are passed for the LSTM training. At each iteration, the calculation of parameters is performed. The iteration is stopped when the fitness function is matched The output from the LSTM cell is denoted as h_t, c_t is the memory cell value, LSTM cell output from the previous moment is represented as h_{t-1}. The input data for the LSTM cell is represented as x_t operating at the time t. The process of calculating the LSTM unit is explained in the following steps:

LSTM unit calculation process is explained in steps.

$\widetilde{c_t}$ is known as the candidate memory which is calculated and the bias is represented as b_c. The weight matrix is represented as W_c which is as shown in (11).

$$\widetilde{c_t} = tanh(W_c.[h_{t-1}, x_t] + b_c) \quad (11)$$

The input gate i_t is the current input data that updates the memory cell's state value and controls the input gate. The bias is represented as b_i and the weight matrix is represented as W_i, The sigmoid function is denoted as σ which is shown in (12).

$$i_t = \sigma(W_i.[h_{t-1}, x_t] + b_i) \quad (12)$$

f_t is the forget gate which calculates the memory state value obtained based on the historic data that updates and controls the forget gate. The bias is represented as b_f and the weight matrix is represented as W_f, as given in (13).

$$f_t = \sigma(W_i.[h_{t-1}, x_t] + b_f) \quad (13)$$

The current moment memory cell c_t is evaluated and the value for the last LSTM unit is denoted as c_{t-1}, as given in (14).

$$c_t = f_t * c_{t-1} + i_t * \widetilde{c_t} \quad (14)$$

Where '*' denotes the dot product. Input and forget gate control updates the memory cell based on the state value for the last cell and the candidate value.

Where, o_t is known as the output gate which calculates the memory cell state value as the output is controlled by the output gate as shown in (15).. The bias b_0 and the weight matrix is denoted as W_0.

$$o_t = \sigma(W_0.[h_{t-1}, x_t] + b_0) \quad (15)$$

The output h_t for the LSTM cell is calculated as shown in (16).

$$h_t = o_t * tanh(c_t) \quad (16)$$

LSTM model update, reset, read and keep long time information easily based on memory cell and control gates. The classifier uses a softmax layer for obtaining an output at the final labels for detecting the named data labels. The score for the label is named based on the weighted average for the probability prediction of disease when the classifier is applied

to the data. The probability of tagging is done for the labels as 1 and the weight parameter is either set as 0 for non-diseased labels or 1 for the diseased labels that knew the relative importance of the classifier when compared with others.

IV. Results and Discussion

The proposed model is operating with Python API libraries that are interfaced with the Local Server running in Windows PC 10 pro, 16 GB NVIDIA Geo-force GPU with i9 CPU operating at 2.5GHz.

A. Performance Metrics and Evaluation

The proposed method results are evaluated in terms of performance metrics for the optimized LSTM based model with the Whale Optimizing approach. Indication must be used to guide the use of diagnostic tests in health care settings. Unfortunately, many order tests without taking into account the supporting data. Therefore, in this research, Sensitivity and specificity are crucial test accuracy indicators that enable medical professionals to decide whether a diagnostic tool is appropriate. Healthcare professionals should use diagnostic tests with the appropriate level of assurance in the accuracy, specificity, sensitivity, Area Under Curve (AUC) and Receiver Operating Characteristics (ROC). The mathematical expression for the performances is given in (17–21):

$$Accuracy = \frac{TP+TN}{TP+FP+TN+FN} \times 100 \quad (17)$$

$$Sensitivity\ or\ Recall = \frac{TP}{TP+FN} \times 100 \quad (18)$$

$$Specificity = \frac{TN}{TN+FP} \times 100 \quad (19)$$

$$AUC = y = f(x) \times 100 \quad (20)$$

where $x = a$ and $y = b$

$$ROC = TPR = \frac{TP}{TP+FN} \times 100 \quad (21)$$

From the above Eq. (17-21), TP is known as True Positive, TN is True Negative, TP is True Positive, TN is True Negative. Table I shows the analysis of different algorithms having data size with 5 GB with feature selection.

TABLE I. The Different Algorithms Having Data Size with 5 GB with Feature Selection

Algorithms	Accuracy (%)	Sensitivity (%)	Specificity (%)	AUC (%)	ROC (%)
CNN	86	85.25	83.11	84.1	82.23
DNN	90	86.24	84.45	87.45	83.12
LSTM	92	90.8	89.21	91.21	88.24
LSTM based Co-learning model	95.4	92.24	91.21	93.45	91.00
Proposed method (B-MFO-WOA)	99.21	95.45	93.48	95.78	96.87

The health analysis was performed on the patients classified as healthy and unhealthy patients. The results inferred that the percentage for each of the patients is analyzed with respect to the healthy patients with the highest percentage. The existing algorithms used for results analysis are Convolution Neural Network (CNN), Deep Neural Network (DNN), Long Short Term Memory (LSTM), LSTM based Co-learning model. The large training data was needed but failed to encode the position and orientation of the object by using the CNN model. The DNN model was hardware-dependent and showed unexplained behavior in the network when the data were fed. Similarly, the LSTMs showed complexity in the model due to large data set training that needed memory to train. Thus, the existing models showed lower values of performance when compared to the proposed method. Table II shows the evaluation of different clusters that are obtained for different diseases. The present research depicts the number of patients with a particular disease carried out with distinct clusters, patients with various diseases. The existing models such as DNN, CNN, LSTM, LSTM based Co-learning model were used for the evaluation of results in terms of accuracy, sensitivity, specificity, AUC, and ROC. The CNN model obtained 84% of accuracy CNN, 82.95% of sensitivity 81.11% of specificity, AUC of 79.25%, and ROC of 83.02%. The DNN model obtained 87% of accuracy, a sensitivity of 84.24%, specificity of 82.45 %, AUC of 80.65%, and ROC of 84.45%. Also, LSTM model obtained 90% of accuracy, 88.8% of sensitivity, 86.21% of specificity, 86.24% of AUC, and ROC of 88.21%. The existing LSTM based Co-learning model obtained 93.4%, 91.04% of sensitivity, 90.11 % of specificity, AUC of 91.78%, and ROC of 90.99%. The proposed method obtained better accuracy of 95.24%, sensitivity of 92.45%, specificity of 90.4%, AUC of 93.45%, 93.25% of ROC. Fig. 2 illustrates the results obtained for the proposed method with feature selection algorithms.

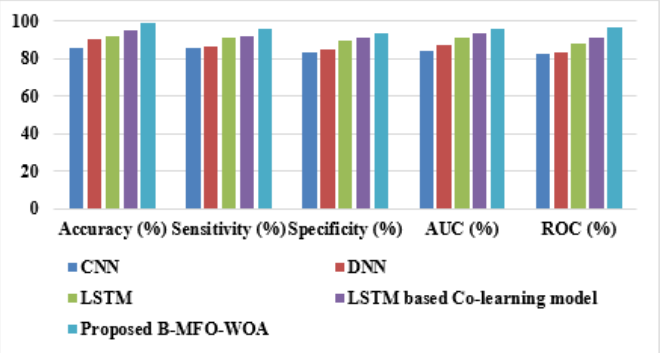

Fig. 2. Results Obtained for the Proposed Method with Feature Selection Algorithm.

TABLE II. Different Algorithms Evaluating Performances for Distinct Data Size with 5 GB Without Feature Selection

Algorithms	Accuracy (%)	Sensitivity (%)	Specificity (%)	AUC (%)	ROC (%)
CNN	84	82.95	81.11	79.25	83.02
DNN	87	84.24	82.45	80.65	84.45
LSTM	90	88.8	86.21	86.24	88.21
LSTM based Co-learning model	93.4	91.04	90.11	91.78	90.99
Proposed method	95.24	92.45	90.4	93.45	93.25

The existing algorithms used for results analysis are Convolution Neural Network (CNN), Deep Neural Network (DNN), Long Short-Term Memory (LSTM), LSTM based Co-learning model. Table III shows the evaluation of performance metrics for different algorithms having greater than 5 GB data size with feature selection algorithm. From the Table III, it clearly shows that the feature selection algorithm with more than 5 GB data size obtained Accuracy of 88%, Sensitivity of 86.25%, specificity of 90.12%, ROC of 82.02%, AUC of 79.25%. The DNN model obtained 92% of accuracy, 89.24% of sensitivity, 91.45% of specificity, AUC of 80.65%, 83.45% of ROC, LSTM of 93%, 92.8% of Sensitivity, AUC of 86.24%, ROC of 87.21. The LSTM based Co-learning model obtained accuracy of 98.6%, sensitivity of 98.21%, specificity of 97.21%, AUC of 91.75%, and ROC of 90.99%. The proposed method obtained 99.32% of accuracy, sensitivity of 98.98%, specificity of 98.78%, AUC of 95%, ROC of 92.56%.

TABLE III. EVALUATION OF PERFORMANCE METRICS FOR DIFFERENT ALGORITHMS HAVING GREATER THAN 5 GB DATA SIZE WITH FEATURE SELECTION ALGORITHM

Algorithms	Accuracy (%)	Sensitivity (%)	Specificity (%)	AUC (%)	ROC (%)
CNN	88	86.25	90.12	79.25	82.02
DNN	92	89.24	91.45	80.65	83.45
LSTM	93	92.8	92.8	86.24	87.21
LSTM based Co-learning model	98.6	98.21	97.21	91.78	90.99
Proposed method	99.32	98.98	98.78	95	92.56

Table III show the results obtained by the proposed method that is evaluated using existing algorithms, such as CNN, DNN, LSTM, and LSTM based co-learning model when the data was greater without feature selection and feature selection algorithm. The existing LSTM based Co-learning model obtained 98.6% of accuracy, sensitivity of 98.21%, specificity of 97.21%, AUC of 91.78 %, and ROC of 90.99%. Similarly, the proposed method obtained 99.32 % of accuracy, 98.98 % of Sensitivity, specificity of 98.78%, AUC of 95%, and ROC of 92.56%.

TABLE IV. PERFORMANCE METRICS OBTAINED BY DISTINCT ALGORITHM HAVING DATA SIZE GREATER THAN 5 GB WITHOUT FEATURE SELECTION ALGORITHM

Algorithms	Accuracy (%)	Sensitivity (%)	Specificity (%)	AUC (%)	ROC (%)
CNN	87	86.14	85.45	85.42	85.24
DNN	91	89.16	88.98	84.57	88.45
LSTM	92	91.23	93.11	86.21	92.21
LSTM based Co-learning model	97.21	94.47	95.211	93.7	96.09
Proposed method	97.45	95.02	96.78	96.87	95.4

Table IV shows the results obtained for different algorithms that are having 5GB greater size without feature selection algorithm. The accuracy of the proposed model without feature selection was obtained as 97.45%, sensitivity of 95.02%, specificity of 96.78%, AUC of 96.87%, and ROC of 95.4%. Fig. 3 illustrates the comparison of results for the proposed method without using the feature selection algorithm.

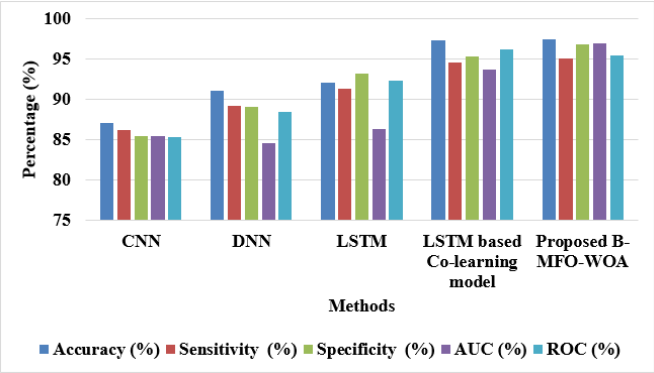

Fig. 3. Comparison of Results for the Proposed Method without using the Feature Selection Algorithm.

B. Comparative Analysis

Table V shows the comparative analysis of the proposed method and existing models evaluated in terms of accuracy, specificity, and sensitivity. The existing B-MFO model needed U-shaped transfer functions for the selection of effective features to overcome the problem of large scale optimization that resulted in Accuracy of 92.43%, Specificity of 92.43%, and sensitivity of 83.51%. Similarly, the Modified adaptive neuro-fuzzy inference system obtained an accuracy of 95.91%, specificity of 98%, and sensitivity of 97.9%. The classification was performed using an SVM-RBF that applied data to the outputs where the classification limited the results for a few of the data values thus obtained an accuracy of 81.30%, sensitivity of 35.59%, and specificity of 91%. The developed CNN model was overloaded with the historic data as it was continuous for data streaming and it was challenging to store, process, and analyse obtained an accuracy of 90% and Sensitivity of 90%. However, the model was required to be extended through the value decomposition model and thus the results obtained were better than the existing benchmark models.

TABLE V. COMPARATIVE ANALYSIS

Method	Dataset	Accuracy (%)	Specificity (%)	Sensitivity (%)
B-MFO [11]	EHR from Beth Israel Deaconess Medical Centre	92.43	96.85	83.51
Modified adaptive neuro-fuzzy inference system [12]		95.91	98	97.9
SVM-RBF [16]		81.30	35.59	91
Convolutional neural networks [17]		90	90	-
Proposed method		97.45	96.78	95.02

V. CONCLUSION

The proposed method showed better performances when operated with B-MFO for the selection of effective features

which were evaluated for large and small medical datasets. The three transfer functions such as S, V, and U-shaped transfer functions are used for the conversion of MFO from the values of continuous to binary values. The WOA is used as an appropriate algorithm to select constrained and unconstrained problems for overcoming the practical applications based on the structural reformation. The combination of the B-MFO-WOA is iteratively executed and is compared with various solutions till an optimum or satisfactory solution is found. The WOA showed better performances for LSTM that suited well for the process of classification to predict the time series. The given time is lagged for an unknown duration of the model as it is based on a deep learning model. The developed model co-learns the best soft labels and deep neural networks based on the training procedure. The Whale optimization approach has the ability for improving the population quality and improves the speed of the algorithm for disease presence prediction. The simulation results showed that the proposed method achieved the objectives by attaining 97.45% accuracy which is better when compared to the existing Modified adaptive neuro-fuzzy inference system of 95.91% of accuracy and B-MFO attained the accuracy of 92.43 %. However, the model showed the complexity in the model due to more features included in a given predictive model which will be analyzed in the future work.

Implementation of a Mobile Application based on the Convolutional Neural Network for the Diagnosis of Pneumonia

Jazmin Flores-Rodriguez, Michael Cabanillas-Carbonell
Facultad de Ingeniería, Universidad Privada del Norte
Lima, Perú

***Abstract*—Pneumonia is the main cause of infant mortality in Peru, which has led to plansfig, such as vaccination campaigns, greater economic investment in health, and the strengthening of specialized medical personnel, however, mortality rates remain high. In this sense, the implementation of new computer technologies such as Deep Learning through the use of the artificial neural network is proposed. The objective of this project was to determine the influence of a mobile application based on a Convolutional Neural Network for the diagnosis of Pneumonia, the project consists of the analysis of images of Chest X-rays with Pneumonia and Normal by means of an application developed called "Diagnost". The study was carried out considering a control group and a study group formed by 33 medical staff members who used the application. The analysis of the data obtained was made based on the study of 3 indicators, detection time, result in accuracy, and reduction of medical assistance. According to the results, it was concluded that the mobile application based on the convolutional neural network allows the early detection of Pneumonia and allows the reduction of medical assistance, however, it is still necessary to continue working on the accuracy of the diagnosis.**

Keywords*—Pneumonia; convolutional neural network; deep learning; chest x-rays

I. Introduction

Respiratory infections contribute to high mortality rates worldwide, accounting for more than 4.5 million deaths per year, especially in low- and middle-income countries [1]. These infections cause upper respiratory tract diseases such as rhinitis, sinusitis, pharyngitis, and lower respiratory tract diseases such as bronchitis and pneumonia [2].

The world health organization (WHO) states that Pneumonia is the leading cause of infant mortality in children under 5 years of age worldwide [3], where 2.4 million of these occurred in the first month of life, as well as 1.5 million deaths at the age of 1 to 11 months of life, and 1.3 million at the age of 1 to 4 years [4]. Community-acquired pneumonia is an acute inflammation of the lung parenchyma from microorganisms and is demonstrated by radiological changes in patients and systemic infections, where pneumococcus is probably the most frequent germ. The cause of pneumonia can be fungal, bacterial, or viral, where pneumonia caused by bacteria can be easily treated with antibiotics, but only one-third of children with pneumonia receive the correct medication [5]. According to different studies on the increase of pneumonia in the seasons [6], [7], [8] it has been proved that the belief that low temperatures in winter are the major cause of pneumonia is false; most of the origins of this disease do not depend on seasonal causes.

In Peru in 2021, 1153 cases of pneumonia and 12 deaths from the same cause were reported in children under 5 years of age; so far in the current year 2022, 2149 cases of pneumonia and 21 deaths from the same cause have been reported in the same age range [9], [10]. According to Peru, pneumonia is one of the main causes of death, especially in the pediatric population, highlighting that the method of prevention is timely diagnosis and adequate treatment to help reduce its fatal consequences [11], [12].

The Ministry of Health has carried out contingency plans such as mass vaccination campaigns against pneumonia and influenza, greater economic investment in health, and the reinforcement of specialized medical personnel; however, mortality rates are still high, making it essential to implement new techniques that contribute to the early diagnosis of pneumonia.

Therefore, the aim of this research is to determine the influence of Convolutional Neural Network-based mobile applications on Pneumonia diagnosis. Focusing on early detection of pneumonia, the accuracy of detection, and reduction of medical assistance is in order to contribute to the reduction of pneumonia cases, focusing on early detection by making use of a deep learning technology tool provided to physicians by reducing the demand for these in the detection of pneumonia.

The research is organized as follows. Section II contains a bibliographic study of previous research and its results obtained. Section III details the concepts related to the convolutional neural network for the diagnosis of pneumonia. Section IV formulates the methodology to be used and the type of research. Section V is the case study, where the development and training of the convolutional neural network are described, as well as the development of the application. Section VI is the results phase, showing the descriptive analysis and inferential results. In Section VII, the discussions, analysis, and interpretation of the results are developed. Finally, in Section VIII, conclusions are drawn to enhance the proposed objective.

II. Bibliographic Study

According to [13], a fast and reliable detection method is required to prevent the spread of infections. In recent years, great expectations have been raised from the community of healthcare professionals and patients regarding the use of smart technology to provide innovative solutions for the treatment of diseases this due to the great potential of the technology [14].

In [15] it is stated that regularly the users are not informed about the treatments or the symptoms related to the disease and in case of small problems the user has to go personally for a check-up and which is more time-consuming.

In [16], investigated the case of severe retinopathy of prematurity leading to newborn limitations or blindness, and the need for accuracy and interpretation in deep learning for medical care of these cases, in that study, was used as study material data of premature infants between the years 2011-2014, with the registration of 5000 patients showing 102 variables, where it was necessary to group the records by variants, thus the sample size of 385 patients was determined, and a simple model was built to predict patients with severe retinopathy, the objective of the research is to provide physicians with an interpretable machine learning model. The research that was done allowed us to know that the construction of a deep learning model requires a considerable amount of data and that this model can be an ally to our physicians and that it is easy to understand [17].

The research article [18] on the classification of X-ray chest images using a Convolutional Neural Network aimed to classify chest images previously captured by the cameras of a system, so the convolutional neural network was built, since it has a high performance, being used in problems of classification of images, signals or medical images. For the classification of these images are used large networks previously trained, this network with a real-time application allows the classification to occur in less time. During the training of the network to identify anomalies of the images it is required to classify the data in subsets and increase the data. Likewise, for the present research, the convolutional neural network and the classification of X-ray images will be used.

The research article [19], proposed a method for the classification of pathologies in chest X-ray images based on deep learning or deep learning, for this purpose it makes use of a large number of X-ray images, and from the images, a classification was made between the pathology of pulmonary nodules and cardiomegaly, from that it was concluded that the results obtained showed an improvement for the detection of nodules and cardiomegaly compared to existing methods. In comparison to the present investigation, the use of a deep learning model was made for the classification of X-ray images for pneumonia disease.

In [20] proposed a method for diagnosis based on an imaging study of patients with pneumonia by means of deep learning techniques, in order to achieve a distinction between patients with pneumonia and healthy patients, as well as to differentiate viral between and bacterial pneumonia. The model achieved acceptable results, but with certain limitations in the classification of viral and bacterial pneumonia.

The article [21] proposed a new architecture based on ResNet 50 with some adjustments, for the analysis of medical images of the chest to highlight examples infected with pneumonia. The aim of the research was to highlight the use of machine learning to create a model with accuracy that correctly answers the questions posed to it in the shortest time. The image classification obtained an accuracy of 97.56%. Likewise, in the present research, use was made of the deep neural network trained CVPR 2015 or ResNet152, from this network the weights and parameters necessary for the training of the convolutional network are obtained.

III. Concepts Related to Convolutional Neural Network for Pneumonia Piagnosis

A. Convolutional Neural Network

1) Machine learning: Machine learning is a type of artificial intelligence technique where computers learn to do something without being programmed to do it. The program learns and associates combinations of distinctive features, resulting in a learning process also known as "building a model".

2) Deep learning: Este permite el proceso de Machine Learning por medio del uso de la red neuronal artificial , la cual se realiza por medio de niveles, siendo el primer nivel bastante simple enviando esta información al siguiente nivel, aquí es donde la información sencilla es combinada volviendola más compleja al seguir enviando la información obtenida de forma sucesiva a más niveles.

3) Artificial neural networks: Artificial neural networks are an imitation of the behavior of our neurons in the brain. Our brain has a huge number of neurons connected to each other, forming a neural network, these neurons have three main parts: the dendrites, the body, and the axon. Where the dendrites are in charge of transporting the electronic pulses to the body of the neuron, the body recognizes and works on the signals that arrive and the axon is a single nerve fiber in charge of communicating the body of a neuron with the others. The synapse originates with the contact between the oxon and the dendrite of another neuron [22].

4) Neural network model: A neural network is the joint use of many single neurons, this neural network is made up of hundreds or even thousands of neurons, this is where the concept of layer appears, which is the grouping of all neurons in several sets within the neural network (Fig. 1), where each layer has its own weight matrices, its bias vectors and their respective outputs [22]. Furthermore, the inputs of the subsequent layers are the outputs of the lower layers.

5) Red convolutional: He mentions that a convolutional network is a kind of multilayer network that consists of different alternating convolutional and subsampling layers, finally, it has a sequence of layers that are completely connected like a multilayer perceptron network. In addition, the input of a convolutional network is usually an image of m x m x r, where m is the height as the width of an image and r is the number of channels and it works with grayscale where r=1. Convolutional layers have k filters or Kernels.

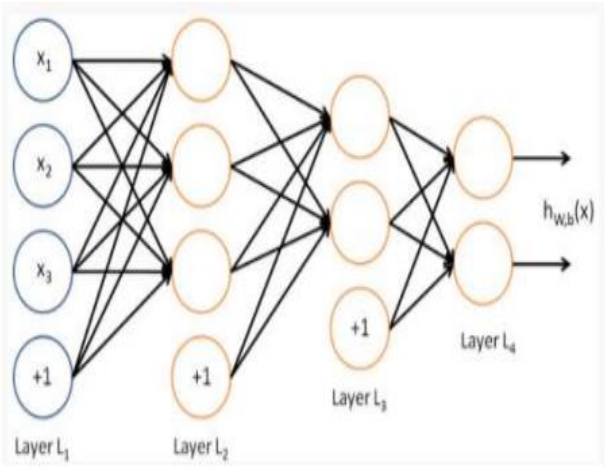

Fig. 1. Multi-layer Neural Network [22].

Layers of a convolutional network:

a) Input layers: The input layer of a convolutional network is an image.

b) Convolutional layer: In this layer, the reduction of the number of possible connections between the neurons of the hidden layer and elements of the input image is carried out, which consists of reducing the computational load of the system. This layer allows extracting useful features from the images to help with their analysis [22]. The convolution is an operation of products and sums between the input image and the Kernel filter, this generates a feature map, where the advantage is that the filter used serves to extract the same feature in any part of the image.

c) Pooling or subsampling layer: In this layer, we use the characteristics of the images obtained in the convolution layer to classify them. The objective of this layer is to support the image characteristics obtained and locate the predominant features of the image. This layer has two types of pooling, pooling or overage-pooling, and max-pooling. In the overage-pooling the elements of the submatrix are selected and their average is calculated and the result is stored in the first position of a matrix which is the output, on the contrary, in a max-pooling, the element with value is searched and this goes to the first position of the output matrix (Fig. 2).

d) Full-Connected Layer: This is the last layer of a convolutional neural network, where we try to classify to determine to which class each input image belongs. In this layer, each neuron is connected with each and every one of the elements of the matrix of the previous layer.

e) Pre-Training. The training of a convolutional neural network is important for the transfer of learning, so it is essential to use pre-trained networks with different applications. These pre-trained models are successfully applied, and the use of these pre-trained networks can be to make small adjustments or function as a feature extractor to achieve a better performance of the data to be processed. Pre-training means initializing the networks with previously trained parameters, instead of setting parameters randomly [23].

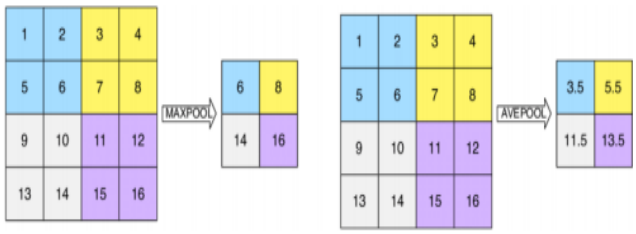

Fig. 2. Differences in Max-pooling and Overage-pooling Operation [22].

6) Respiratory diseases: According to [24], most diseases of the respiratory system fall into one of three categories: obstructive pulmonary diseases, restrictive disorders, and pulmonary diseases.

Within the category of obstructive pulmonary diseases, we have all disorders of the respiratory tract such as asthma, bronchiolitis, etc. Restrictive disorders, also known as parenchymal diseases, include anomalies of the chest wall, as well as neuromuscular diseases. Also [24] states that studies of patients with respiratory diseases begin with a complete anamnesis, this anamnesis should focus on the factors that trigger dyspnea such as cough, which are the cardinal symptoms of respiratory disease.

IV. Methodology

A. Type of Research

The present research is of the applied type since the knowledge acquired by practice is applied in most cases for the benefit of society [25]. The research design is experimental because one or more study variables are manipulated in order to observe the effect of one variable (independent) on another variable (dependent). This is done in order to discover the cause of a particular situation or event [26]. In addition, the type of research is pure experimental type, this type of research meets the requirements to achieve internal validity and control because it has comparison groups. Within this type of research, pretests and posttests can be used to study the evolution before and after the experimental treatment [27].

The independent variable for the research was "Convolutional Neural Network based mobile application", while the dependent variable was "Diagnosis of Pneumonia".

B. Population and Sample

The target population of this research project is the 80 users and/or medical personnel of the hospitals and clinics that will use the mobile application.

The statistical formula (1) was used to determine the sample size.

$$\boldsymbol{n} = \frac{N * Z_{\alpha}^{2} * p * q}{e^{2} * (N-1) + Z_{\alpha}^{2} * p * q} \quad (1)$$

The research population considered a population of 80 members of the hospital's medical staff who will use the mobile application, with a confidence level of 95% and a margin of error of 5%. A 50% probability was considered that the event studied would occur and a 50% probability that the event would not occur. The Table I is the detail of the results of the sample:

TABLE I. SAMPLE VALUES

Nomenclature	Parameter	Value
Population or Universe Size	N	80
The statistical parameter that depends on the Confidence Level (CN)	Z	1.960
(1 - *p*) = Probability that the studied event does not occur.	p	50.00%
(1 – *p*) = Probabilidad de que no ocurra el evento estudiado	q	50.00%
Maximum accepted estimation error	e	3.00%

The sample under study for this research project consisted of 67 members of the hospital's medical staff who will use the mobile application. This was randomly divided between the experimental group (RG1) and the control group (RG2), with 33 members in each group.

C. Indicators

For this research, three indicators were taken into account: "Detection time" (early detection is evaluated); "Outcome" (detection accuracy is evaluated); and "Time to care" (reduction of medical assistance is evaluated).

D. Techniques and Instruments for Data Collection and Analysis

In order to collect data on the variables, it was necessary to collect data by means of detailed procedures using techniques and instruments.

1) Techniques: For the present research study, the technique of observation and data collection was used. Where observation was used to review the evaluation of the influence of the dependent variable on the independent variable.

2) Instruments: Data collection was carried out through the Quantitative Observation Sheet instrument, and then a statistical analysis of the data collected was performed.

3) Procedure: The next step consisted of analyzing the indicators, frequency tables and formulas, through calculations in SPSS software.

E. Methodology for Development

A comparison of agile methodologies was made in Table II in order to choose the one that best suited the proposed project.

For this research, the agile methodology called Scrum was chosen since it will have a short duration and it allows us to have a broad and interactive control of the processes. Scrum is a reference framework within the Agile software development methodology that allows for the creation of complex software and delivers it in a simpler way compared to the waterfall methodology. Scrum proposes short iterative cycles that last about a week or even a month, this period of work is known as iteration or sprint [28].

The framework allows for increased productivity and creativity during the project, enhances team engagement, and enables collaborative task completion [29], as well as understanding the customer's needs as a team to collaborate and deliver maximum value during each iteration.

TABLE II. COMPARISON OF AGILE METHODOLOGIES

Methodologies	Characteristics	Roles	Advantages
RUP	They present reiterative development.	Analysts, Developers, Managers, Stakeholders, specialists, and reviewers.	Extensive documentation, software quality checking, configuration, and change control.
SCRUM	They are used in environments based on agile software development.	Product Owner Scrum Master Developer Teams.	Advantages such as higher project productivity, transparency in the development of processes, and greater control
XP	Continuous, repeated, and automated unit testing.	Programmer, tester, client, follow-up, coach, consultant, and manager.	Communication, simplicity, feedback, decreased trace errors, and high-quality minimum time.

V. CASE STUDY

A. Solution Development

The research developed was technically feasible, since everything necessary for the development of the mobile application and the training of the convolutional neural network is accessible. Tables III and IV below detail the technical aspects considered for the development of the research.

1) User equipment: Regarding the requirements of the mobile equipment on the users' side, the following characteristics specified in Table III were recommended.

TABLE III. CHARACTERISTICS OF MOBILE EQUIPMENT

Characteristics	Optimo
Display	5.1
Battery	300 mAh
Memory	4 GB RAM, 32 GB ROM
Processor	Qualcomm dual core 2.15 GHz+ dual core 1.593 GHz
Operating System	S0 Android 6.0.1
Keyboard	Touch screen with on-screen keyboard
Web	2G/3G/4G/LTE capable

2) Software platforms: During the development of the project, the list of necessary software was divided in Table IV shows the necessary software to be used for the development of the mobile application.

3) Development: For the development of each Sprint, reviews, and deliverables were planned to validate the progress obtained at the end of the Sprints. The estimated speed of the Sprint was 14 days.

a) Sprint N°1: In this phase, the data processing was developed which consisted of Thorax X-Ray images, these were divided into two groups: Training and Test stored in Drive. Likewise, the construction of the neural network and its training were carried out.

TABLE IV. LIST OF SOFTWARE REQUIRED FOR THE DEVELOPMENT OF THE MOBILE APPLICATION

Topic	*Description*
Smartphone (emulator)	Samsung S7
Mobile Operating System	Android 8.0.0
Data storage	SharedPreferences
Programming	Android
Development environment	Android Studio
Play Store	Online store service that allows the distribution of apps
Portátil Asus	Windows 10, intel core i5, eighth generation, Ram 16 GB, hard disk of 1tb.
Operating System	Microsoft Windows 10
Programming	Python
Libraries	Tensorflow, numpy, keras, python, json, panda, matplolib, gdown, sklearn.
Development environment	Google Colab, Keras, Python, Miniconda, Tensor Flow
Dataset	Mendeley Repository
Server	Centos 7, Google Cloud Platform
Pre-trained model	DenseNet
Postman	Perform Get and Post requests
Deep learning technology	Deep learning course on the Udemy platform
Google Drive	Dataset storage and model colab
Google Books	Purchase of books for this research

In Fig. 3, the project folders were defined and the folders of X-ray images of the thorax with Pneumonia and Normal were read.

```
# Definir el Folder principal del proyecto
project_folder = "/content/drive/MyDrive/deep-learning-2/rayosX-tesis-2021"

# Libreria glob: para leer el contenido de cada carpeta
files_train_neumonia = glob.glob(project_folder+"/dataset/train/neumonia/*.jpg")
files_test_neumonia = glob.glob(project_folder+"/dataset/test/neumonia/*.jpg")
files_train_normal = glob.glob(project_folder+"/dataset/train/normal/*.jpg")
files_test_normal = glob.glob(project_folder+"/dataset/test/normal/*.jpg")

# Obteniendo imágenes al azar de cada folder, usamos la libreria image de Keras
# Cargamos las imagenes dentro de la variable: image_...
file_train_neumonia = files_train_neumonia[randrange(len(files_train_neumonia))]
image_train_neumonia = image.load_img(file_train_neumonia)

file_test_neumonia = files_test_neumonia[randrange(len(files_test_neumonia))]
image_test_neumonia = image.load_img(file_test_neumonia)

file_train_normal = files_train_normal[randrange(len(files_train_normal))]
image_train_normal = image.load_img(file_train_normal)
```

Fig. 3. Assigning Image Folders to Variables.

Fig. 4 shows the dimensioning of the established images and Fig. 5 shows the data augmentation using the ImageDataGenerator libraries of Keras:

```
from keras.preprocessing.image import ImageDataGenerator

# Dimensión de las imgs a procesar
img_width = 224
img_height = 224
batch_size = 40
```

Fig. 4. Size the Images to 224 x 224.

```
# Data Augmentation and Normalization (Aumentamos lacantidad de imagenes y las normalizamos dividiendo entre 255)
datagen_train = ImageDataGenerator(rescale=1.0/255.0,      # Normalizar los valores al rango [0-1]
                                   horizontal_flip=True,   # Giro horizontal
                                   rotation_range=15,      # Giro aleatorio (clockwise) entre 0 y 15 grados
                                   width_shift_range=0.15, # Mover la img horizontelmente 15%
                                   height_shift_range=0.15, # Mover la img verticalmente 15%
                                   zoom_range=0.2)         # Zoom in / Zoom out aleatorio de 20% => 80% - 120%
```

Fig. 5. Command for Data Augmentation and Normalization.

Fig. 6 shows the data results of the data augmentation, it can be seen that the generated images change their position within the data augmentation process.

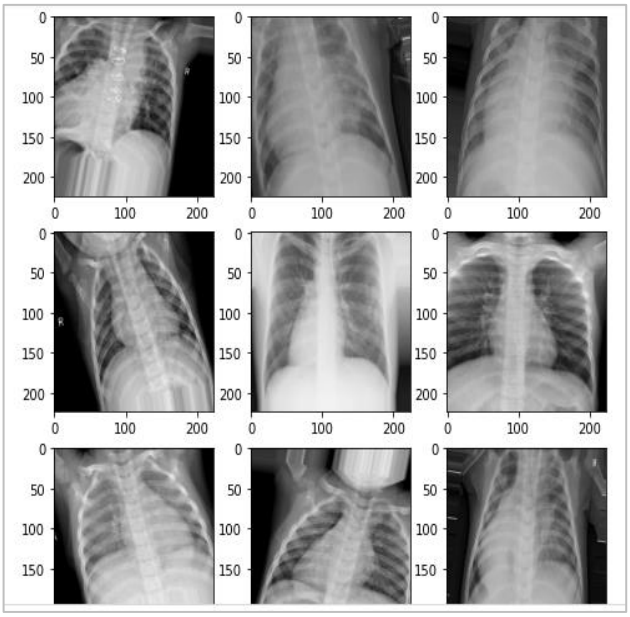

Fig. 6. Data Enhancement Process.

The use of the trained DenseNet neural network can be seen in Fig. 7.

The architecture of the new classifier using the pretrained DenseNet model is shown in Fig. 8.

Finally, the training of the convolutional Neural Network is shown in Fig. 9.

c) Sprint N°3: For this phase, the Login interface of the application was developed as shown in Fig. 10(a); the main menu of the application was created as shown in Fig. 10(b); and requests were made from the application as shown in Fig. 10(d).

VI. Results

A. Descriptive Analysis Experiment Group

Fig. 13 shows the comparison of means in post and pre groups of experiments for Indicator N° 1 Detection time:

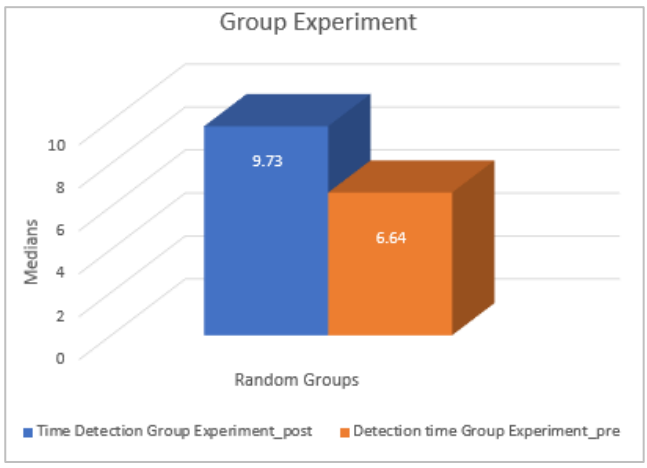

Fig. 13. Experiment Group Post and Pre Detection Time.

Fig. 14 shows the comparison of means in groups of post and pre-experiment groups for Indicator N° 2 Result.

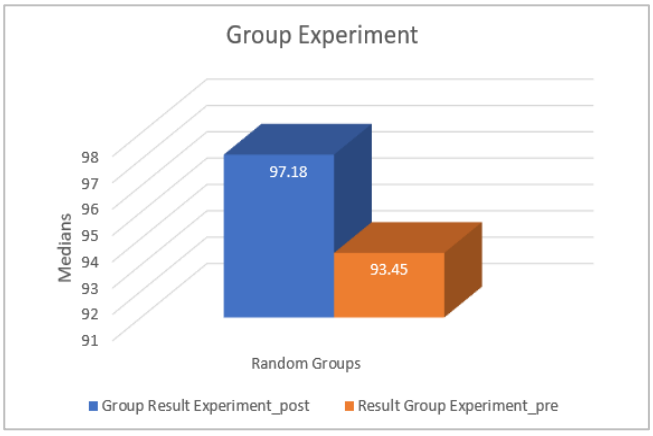

Fig. 14. Group Experiment Post and Pre Result.

Fig. 15 shows the comparison of Means in Groups of Experiment post and pre of Indicator N° 3 Attention Time:

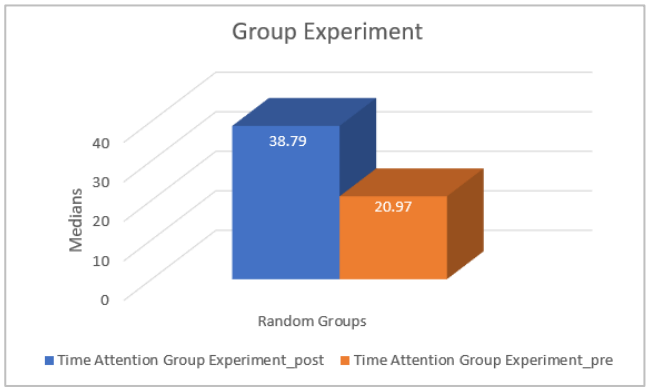

Fig. 15. Experiment Group Pre and Post-Time of Attention.

B. Inferential Results

1) Normality test: We proceeded to perform the normality test assisted by the SPSS software for the indicators of Detection Time, Result, and Attention Time through the Shapiro Wilks method, due to the fact that our sample size is less than 50.

Where:

Sig.<0.05 Adopts a non-normal distribution.

Sig.>= 0.05 Normal distribution.

Sig. P: Value or critical level of the contrast.

a) Indicador N°1: Para el Indicador se obtuvieron los siguientes resultados:

TABLE V. Normality Test Detection Time Indicator

	Kolmogorov-Smirnov			***Shapiro-Wilk***		
	Statistician	gl	Sig.	Statistician	gl	Sig.
Control Group	.299	33	<.001	.756	33	<.001
Experiment Group	.263	33	<.001	.872	33	.001

Table V indicates that the significance of the Control group is 0.001 and the significance of the Experiment group is 0.001, in both values are less than 0.05, then it is stated that the data have a normal distribution.

b) Indicator N°2: The following results were obtained for this indicator:

TABLE VI. Normality Test Indicator Result

	Kolmogorov-Smirnov			***Shapiro-Wilk***		
	Statistician	gl	Sig.	Statistician	gl	Sig.
Control Group	.329	33	<.001	.502	33	<.001
Group Experiment	.446	33	<.001	.404	33	<.001

Table VI indicates that the significance of the Control group is 0.001 and the significance of the Experiment group is 0.001, both values are less than 0.05, so the data are said to have a normal distribution.

c) Indicator N°3: The following results were obtained for this indicator:

TABLE VII. Normality Test Attention Time Indicator

	Kolmogorov-Smirnov			***Shapiro-Wilk***		
	Statistician	gl	Sig.	Statistician	gl	Sig.
Attention Time Control Group	.329	33	<.001	.502	33	<.001
Attention Time Experiment Group	.446	33	<.001	.404	33	<.001

The significance level for the control and experimental groups shown in Table VII is 0.001, both values are less than 0.05, so the data have a normal distribution.

2) Hypothesis Testing

a) Indicador N°1: H0, the Convolutional Neural Network-based mobile application does not allow early detection of Pneumonia in 2021. H1, The Convolutional Neural Network-based mobile application enables early detection of Pneumonia in 2021.

For the hypothesis test, the nonparametric Wilcoxon test was performed, where a significance level of 0.01 was obtained, which is less than 0.05, the limit value to see if the research is accepted.

In this case, by obtaining a p-value greater than 0.01, the alternative hypothesis (H1) is accepted and the null hypothesis (H0) is rejected.

b) Indicator N°. 2: H0, the Convolutional Neural Network-based mobile application does not allow accurate detection of Pneumonia in 2021. H1, the Convolutional Neural Network-based mobile application allows the accurate detection of Pneumonia in 2021.

For the hypothesis test, the nonparametric Wilcoxon test was performed, where a significance level of 0.340 was obtained, which is greater than 0.05, the limit value to see if the research is accepted.

In this case, by obtaining a p-value greater than 0.05, the null hypothesis (H0) is accepted and the alternative hypothesis (H1) is rejected.

c) Indicator N°3: H0, the mobile application based on the Convolutional Neural Network does not allow the reduction of medical assistance when diagnosing Pneumonia in 2021. H1, the mobile application based on the Convolutional Neural Network allows the reduction of medical assistance when diagnosing Pneumonia in 2021.

For the hypothesis test, the nonparametric Wilcoxon test was performed, where a significance level of 0.01 was obtained, which is less than 0.05, the limit value to see if the research is accepted.

In this case, by obtaining a p-value of 0.01, the alternative hypothesis (H1) is accepted and the null hypothesis (H0) is rejected.

VII. Discussion

From the results obtained in the present research work, it is observed in the descriptive analysis in the Detection Time indicator, Fig. 16 shows a deviation of 2.24 in the Control group and in the Experiment group (Fig. 17), a deviation of 1.78 is observed. Likewise, as observed in the hypothesis test, it has a significance level equal to 0.01, which is less than 0.05; determining that a mobile application based on the convolutional neural network allows the early detection of pneumonia in the year 2021. According to the research [30] for the diagnosis and treatment of pneumonia in pigs, it is verified that its expert system supports in some way reducing the time in which a pig is treated and that it is treated efficiently, in order to avoid aggravation and death, with the help of the knowledge provided by the specialist and thus develop an expert system that helps in making decisions to treat the disease in time.

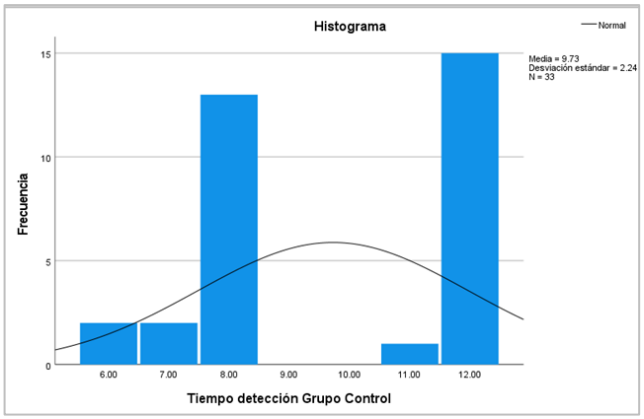

Fig. 16. Histogram of Control Group Indicator Time of Detection Indicator.

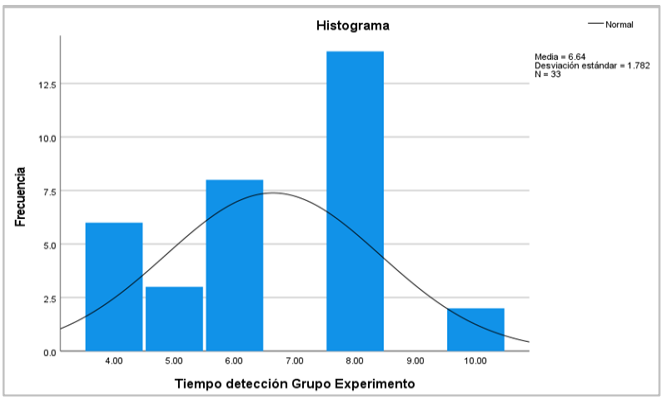

Fig. 17. Histogram of Experiment Group Indicator Detection Time.

Likewise, in the descriptive analysis in the Result indicator, in Fig. 18, a deviation of 4.10 is observed in the Control group, and in the Experiment group (Fig. 19), a deviation of 14.93 is observed. Likewise, as observed in the hypothesis test, s has a significance level equal to 0.340, which is greater than 0.05; determining that a mobile application based on the convolutional neural network does not allow the accurate detection of Pneumonia in the year 2021.

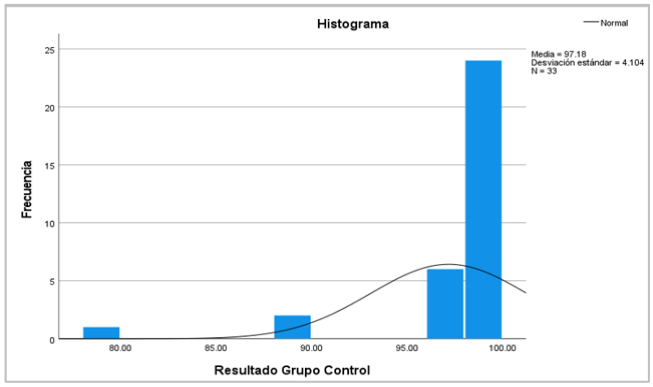

Fig. 18. Histogram of Control Group Indicator Result.

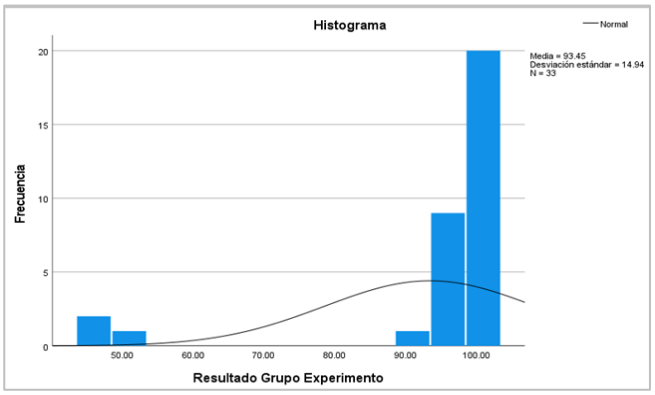

Fig. 19. Histogram of Experiment Group Indicator Result.

In addition, the descriptive analysis in the Attention Time indicator, in Fig. 20, shows a deviation of 12.38 in the Control group, and in the Experiment group (Fig. 21), a deviation of 9.16 is observed. Likewise, as observed in the hypothesis test s has a significance level equal to 0.01, which is less than 0.05; determining that a mobile application based on the convolutional neural network allows the reduction of medical assistance when making the diagnosis of Pneumonia, in the year 2021.

VIII. Conclusion

Convolutional network-based X-ray image classification has been widely used for different applications and predictions. In the present research work, we proposed the training of a Convolutional Neural Network for the Diagnosis of Pneumonia through the analysis of chest X-ray images implemented in a mobile application, in order to provide a technological tool to medical personnel, contributing to the early diagnosis of pneumonia.

From the results obtained, it was concluded that it was possible to prove that a mobile application based on the convolutional neural network allows the early detection of pneumonia and also allows the reduction of medical assistance when making the diagnosis. Although favorable results were achieved, it was also determined that there is still work to be done on the accuracy, since according to the studies for indicator 2, the mobile application based on the convolutional neural network does not allow the accurate detection of pneumonia, so for future research, it is proposed to improve the model to achieve greater accuracy.

***Abstract*—This paper compares different initialization methods and investigates their performance and effects on estimating kinetic parameters' value in models of biological systems. Estimating parameters values is difficult and time-consuming process due to their highly nonlinear and huge number of kinetic parameters involved. Global optimization method based on an enhanced scatter search (ESS) algorithm is a suitable choice to address this issue. However, despite its resounding success, the performance of ESS may decrease in solving high dimension problem. In this work, several choices of initialization methods are compared and experimental results indicated that the algorithm is sensitive to the initial value of kinetic parameters. Statistical results revealed that uniformly distributed random number generator (RNG) and controlled randomization (CR) that being used in ESS may lead to poor algorithm performance. In addition, the different initialization methods also influenced model accuracy. Our proposed methodology shows that initialization based on opposition-based learning scheme have shown 10% better accuracy in term of cost function.**

***Keywords*—Metaheuristic; opposition-based learning; kinetic parameters; initialization method; metabolic engineering**

I. Introduction

Kinetic models of living cells have drawn the attention of both practitioners and researchers in recent years [1]. Their applications are important in metabolic and bioprocess engineering as they facilitate scholars to better understand, accurately predict and consistently improve the desired products in systems biology [2,3]. The models are formulated by means of ordinary differential equations (ODEs) to mimic various functional behaviours such as glycolysis reactions via metabolic pathway and phosphorylationin signal transduction of human cells. Due to the highly nonlinear biological systems, building such model is considered both challenges and time-consuming [4].

One important aspect of model building is parameter estimation, which consists of finding the best possible value of kinetic parameters that produce best fit model to the experimental data. The goodness of fit can be measured by minimizing distance value in the simulated model and experimental data. Thus, searching best parameter values in kinetic model can be depicted as a nonlinear optimization problem [5] and this class of problem is difficult to be solved. In this view, various optimization algorithms have been proposed in parameter estimation and their findings revealed that local optimization often fails to obtain snear-optimal solution [6]. Although improvements such as iterated local search have been proposed, they still consume high computational cost. Consequently, global optimization which is based on metaheuristic is an ideal option to address this issue. Global methods are quite capable in parameter estimation problem as they are more likely to reach the global minimum compared to local methods.

Enhanced scatter search (ESS) is one of the metaheuristic algorithm which have recently shown to yield promising outcomes in biological problems [7,8]. The algorithm benefits from global exploration and local exploitation using various choices of local search. The balanced tradeoff between global and local methods in ESS has shown promising results in solving optimization problems. However, when dealing with high dimension problem involving hundreds of kinetic parameters, performance of most global methods including ESS are deteriorate. One of the most neglected mechanisms in global methods is the way they generate the initial solution which were commonly derived using random number generator (RNG). The initialization methods may influence the efficiency and performance of the optimization algorithm in terms of its probability in finding the global minima, convergence's rate and variance of statistical results [9]. To date, only a few works have been done for comparing initialization methods in optimization. So far, no comparative study with regard to initialization method has been done in large-scale parameter estimation problem, particularly in the biological domain. The limitation of existing work in the field of global optimization is they only rely on RNG for initialization and only focus on search operator or the way new solution are produced. The high complexity of the problem such as in biological domain or healthcare is challenging and applying optimization method must properly select the best initialization because it will influence the

output. Hence, this issue motivates this research to further investigate the effect of different initialization method.

This paper compares and investigates the effects of several initialization methods (also known as diversification generation method in ESS algorithm) from the context of parameter estimation in systems biology models. The evolutionary algorithm based on ESS is utilized in this study due to its efficiency and reliability in parameter estimation problem [7]. The paper is organized as follows: Section II explicates the problem statement in parameter estimations; Section III delineates ESS algorithm; Section IV introduces several initialization methods; Section V compares the methods and presents the discussion of their results and Section VI presents the conclusion of this study.

II. Problem Background

In a nonlinear kinetic model of biological systems, the parameter estimation problem deals with finding an unknown value of kinetic parameters to minimize a distance (objective or cost function) between simulated model and real data. The value of cost function determines the goodness of fit of the model. The observables, which are referred to as the output state variable, are experimentally measured. The cost function of this problem, which is also known as weighted nonlinear least squares J is defined as:

$$J = \sum_{exp=1}^{n_{exp}} \sum_{obs=1}^{n_{exp}^{obs}} \sum_{s=1}^{n_s^{exp,obs}} (ym_s^{exp,obs} - y_s^{exp,obs}(\boldsymbol{p}))^T W (ym_s^{exp,obs} - y_s^{exp,obs}(\boldsymbol{p})) \quad (1)$$

where n_{exp} is the number of experiments, n_{exp}^{obs} is the number of observables per experiment and $n_s^{exp,obs}$ is the number of samples per observable in each experiment. Time series experimental data is denoted as $ym_s^{exp,obs}$ and predicted model is denoted as $y_s^{exp,obs}(\boldsymbol{p})$. The kinetic parameters vector to be estimated is $\boldsymbol{p}$. The time span for observables is denoted as T and finally W represents the weight matrix to balance the contributions of the observables. Minimization of the above cost function is subject to the following constraints:

$$\dot{x} = f(x, \boldsymbol{p}, t) \quad (2)$$

$$x(t_0) = x_0 \quad (3)$$

$$y = g(x, \boldsymbol{p}, t) \quad (4)$$

$$\boldsymbol{p}^{lb} \leq \boldsymbol{p} \leq \boldsymbol{p}^{ub} \quad (5)$$

where derivative of $\dot{x}$ is the function f of ODEs model that describes the dynamics of biological systems, x_0 is the initial condition at time t_0, g is the observable functions and $\boldsymbol{p}^{lb}$ and $\boldsymbol{p}^{ub}$ are the lower bound and upper bound of the kinetic parameter vector $\boldsymbol{p}$ respectively. This nonlinear and multimodal problem consists of many local minima. Thus, the process of finding the global minima is both challenging and time-consuming.

III. Enhanced Scatter Search (ESS) Algorithm

An enhanced scatter search (ESS) is a metaheuristic that belongs to the family of evolutionary algorithms. This algorithm is similar with genetic algorithm (GA) with regards to maintaining and updating their population members and evaluating their cost function in an iterative cycle. However, unlike GA, ESS does not use crossover and mutation as their evolutionary operators. Instead, it uses the combination among members in a reference set (*RefSet*). In this study, four phases of ESS algorithm are used, namely: 1) initialization method, 2) *RefSet* update method, 3) *RefSet* member generation and combination method, and 4) hybrid of the local search method. More advance designs and their mechanism can be found in [10,11].

This algorithm starts with randomly generating m population of diverse vectors by means of initialization (diversification generation) method. The m size is ten times the problem size to ensure that the large initial solutions in the search space are widely sampled, thus increasing the chances of avoiding local minima. Although uniformly distributed random number is a popular method usually utilized to generate initial solutions in various optimization algorithms, there are other strategies that may provide better initial solutions. Therefore, we compared and investigate four different initialization methods which will be briefly discussed in Section IV.

After the diverse vectors are generated, each vector is evaluated and half of the *RefSet* members $b/2$ (b is the *RefSet* size) is formed. The diversification method produces high quality initial *RefSet* member. The remaining *RefSet* members are choosen from the *RefSet* by random cycle to complete a *RefSet*. Then, the subset generation produces pairs of members in *RefSet*. Let us consider members of a *RefSet*, x^i, to be combined with the rest of members in *RefSet*, $x^j, \forall i, j \in [1,2,..b], i \neq j$. The pairs of the combination ($combi_1$ and $combi_2$) are defined as follows:

$$combi_1 = x^i - m(1 + \gamma \cdot \delta) \quad (6)$$

$$combi_2 = x^i + m(1 - \gamma \cdot \delta) \quad (7)$$

where

$$m = \frac{x^j - x^i}{2} \quad (8)$$

$$\gamma = \begin{cases} 1 \; if \; i < j \\ -1 \; if \; j < i \end{cases} \quad (9)$$

and

$$\delta = \frac{|j-i|-1}{b-2} \quad (10)$$

Every pair of combination ($combi_1$ and $combi_2$) in the *RefSet* members is used to create new hyper-rectangles which are defined by their relative positions and distance and thus, resulting in a new solution within them. The hyper-rectangles based combination methods are applied and are defined in the following equation:

$$x^{new} = combi_1 + R \cdot (combi_2 - combi_1) \quad (11)$$

where x^{new} is new solution generated and R is the random number, $R \sim U([0,1])$. This combination strategy is similar to the mutation operator in differential evolution (DE) [12,13], which is effective in updating population members. In ESS,

the vectors of combination ($combi_1$ and $combi_2$) are systematically generated. They are not randomly generated, as practiced in DE. Using this combination strategy, every *RefSet* member generates a hyper-rectangle among the rest of *RefSet* member. The new number of solution produces $b-1$ solution for each *RefSet* member. After this strategy is implemented, a new solution (offspring) is generated with different distance and direction around their *RefSet* members (parents). In this case, if the offsprings have better (lesser) fitness value compared to their parents, the current solutions will be replaced. Otherwise, the same *RefSet* members will be used for the next iteration. In order to accelerate convergence, gradient local search is performed using Sequential Quadratic Programming (SQP). The algorithm is applied using *fmincon* solver in MATLAB. This solver minimizes the cost function using the results obtained in ESS using different vectors. If the solution obtained by *fmincon* outperforms the solution generated by ESS, the solution from *fmincon* will replace the current solution and it will in turn be added to *RefSet* members for further update. Otherwise, the solution from *fmincon* will be discarded. This process is repeated until the stopping criteria are met.

IV. Initialization Methods

We implement five initialization methods in the ESS algorithm in order to compare and investigate their effects on parameter estimation. The methods are random number generator (RNG), controlled randomization (CR), opposition-based learning (OBL), quasi-opposition learning (QOBL) and chaotic (Tent) map.

A. Random Number Generator (RNG)

The most commonly used initialization method in optimization algorithms is random number generator (RNG). RNG is defined as below: Let $X_i(x_{i,1}, x_{i,2}, \dots, x_{i,D})$ be the ith member of the population, each $x_{i,j}$ is generated between lower and upper bound (lb_i,ub_j). In summary, it generates uniformly distributed random numbers as in the following equation:

$$x_{i,j} = ub_j + R \cdot (lb_j - ub_j), j = 1, \dots, D \quad (12)$$

where R is the random numbers between 0 and 1. The vector of $X_{i,j}$ contains a list of random initial population generated between lower bound and upper bound $[lb, ub]$ for each of the variable.

B. Controlled Randomization (CR)

Unlike RNG, controlled randomization (CR) strategy generates the first five populations ($n = 5$) of equal size for each vector as in the following equation [14]:

$$x_{i,j} = \frac{R \cdot (npar) + i - 1}{n} \quad (13)$$

where $x_{i,j}$ is the vector of candidate solutions, R is the random numbers in the between 0 and1, and $npar$ is the number of kinetic parameters. After the first five vectors are generated, the remaining vectors are generated randomly and all initial solutions are put in the boundaries:

$$x_{new} = x_i \cdot (ub - lb) + lb \quad (14)$$

where lb and ub are lower and upper bounds, respectively. This strategy generates a set of diverse vectors which contain equal sizes of range in the first five vectors and other random vectors lie in sixth vector to m diverse vectors. It should be noted that ESS algorithm used CR strategy as its default initialization method [11].

C. Opposition-based Learning (OBL)

Opposition-based learning (OBL) is introduced in the field of computational intelligence [15]. This scheme is subsequently applied in optimization areas [16]. The basic idea of OBL is to generate a set of opposite numbers from first initial solutions generated by RNG, as follows: Let $x \in [lb, ub]$ is a random value. The opposition value of x is defined by:

$$\breve{x} = lb + ub - x \quad (15)$$

Based on Eq. (15), the opposite point for optimization in dimension space *D* is defined as follows:

Let $X_i(x_{i,1}, x_{i,2}, \dots, x_{i,D})$ be the i th member of the population and each member $x_{i,j}$ be bounded by (lb_i,ub_j) and $x_i \in [lb_i, ub_i], \forall i \in \{1,2,..D\}$. Thus, the opposite value of $\breve{X}_\iota = (\breve{x}_{i,1}, \breve{x}_{i,2}, .., \breve{x}_D)$ is defined as:

$$\breve{x}_{i,j} = lb_i +, ub_i - x_{i,j}, j = 1, \dots, D \quad (16)$$

Both X and $\breve{X}$ is merged. Now, let us assume $F(x)$ is the cost function in minimization problem. If cost function value of $f(\breve{x})$ is smaller than $f(x)$, $f(\breve{x}) < f(x)$, point X can be replaced with $\breve{X}$. Otherwise, point X will stay in the current population. All the population members will be evaluated and the initial population with fittest members among X and $\breve{X}$ is formed.

D. Quasi Opposition-based Learning (QOBL)

Another family of OBL is quasi-opposition learning (QOBL) which modified version of OBL that increases population uniformity [17]. Considering the opposite point in equation 16, the middle point $m_j = \{m_1, m_2, .., m_D\}$ is calculated as follows:

$$m_j = \frac{lb_j + ub_j}{2}, \forall j \in \{1,2,..D\}. \quad (17)$$

Then, quasi-opposite point $\breve{X}^Q = (x_1^Q, x_2^Q, .. x_n^Q)$ is selected randomly within the range of opposite points of $\breve{X}$ and middle point m:

$$\breve{x}_i^Q = \begin{cases} R \cdot (mj, \breve{x}_{i,j}) \; if \, x_{i,j} \le m_j \\ R \cdot (\breve{x}_{i,j}, mj) \; if \, x_{i,j} > m_j \end{cases} \quad (18)$$

where R is a random value drawn uniformly in the range of lower bound and upper bound. Like OBL, $\breve{X}^Q$ and X are merged and the best solution is chosen, that is, the fitness of the cost function.

E. Chaotic Map

Another alternative of uniformly distributed random numbers for diversification generation is chaotic map. This approach is based on the deterministic and chaotic systems and it is not necessarily random. In this paper, we investigate

one family of the chaotic map, which is Tent map [18] which is defined as:

$$x_{i,j}^{(k+1)} = \begin{cases} \frac{x_{i,j}^{(k)}}{0.7} x_{i,j} < 0.7 \\ \frac{10}{3}\left(1 - x_{i,j}^{(k)}\right) x_{i,j} \geq 0.7 \end{cases} \quad (19)$$

where $x_{i,j}^{(k+1)}$ is j th variable of i th individual in k th iteration. $x_{i,j}^{(k)}$ is the initial variable that is generated randomly using RNG. In this strategy, solutions which are generated from Tent map are not predictable and are highly sensitive to initial variables.

V. Result and Discussion

A large-scale model is used to test the different initialization methods in ESS algorithm. The model involves dynamic processes that reproduce the response to a pulse in extracellular glucose concentrations of central carbon metabolism (CCM) in *E. coli*. This model consists of 18 metabolites: 17 internal metabolites in cytosol and 1 extracellular metabolite (*glucose*) in extracellular compartment.

These metabolites consists of PEP, G6P, PYR, F6P, G1P, 6PG, FDP, GAP, CPEP, CG6P, CPYR, CF6P,GLCex, CG1P, CPG, CFDP, CGAP and Glucose. The model also contains 48 reactions coupled with 166 kinetic parameters. The mathematical formulation and description of this model can be found in [19]. Table I summarizes the characteristics of CCM E. coli model.

TABLE I. Characteristics of the Central Carbon Metabolism (CCM) in E.coli

Number of kinetic parameters	Dynamic metabolites	Observed metabolites	Noise level	Lower value	Upper value
116	18	9	Real	$0.1 \times p_{ori}$	$10 \times p_{ori}$

Note: For fair comparison, lower and upper bound are set as a function of p_{ori}, where p_{ori} is a set of kinetic parameters obtained from original publication. In this data, only observed metabolities are measured.

In order to obtain statistically significant result, we ran each initialization method discussed in Section IV, 20 times and reported the best, mean, and worst results; as well as average function evaluations, CPU time and standard deviation. Function evaluation for each run was limited to 100,000 (the stopping criteria) to let the algorithm obtain the best parameter values. The RefSet size used was 36, which is the recommended size in this problem. With the high number of function evaluations and hundreds of parameters, the minimization process is expected to consume very lengthy CPU time. To surmount this drawback, Parallel Computing Toolbox in MATLAB has been used and it expedited the computation by assigning each run to eight different processors (logical cores) simultaneously. In this strategy, eight computations for each method was run independently using parfor loop which is available from the abovementioned toolbox. It should be noted that a single run takes approximately 11 hours, so 20 runs take approximately 220 hour. Using the parallel strategy, 20 runs only take approximately 33 hour, which reduced 72.6% of CPU time needed. All methods were experimented on i7 CPU with 16GB RAM which implemented in MATLAB 2015.

Table II shows that the best (minimum) cost function was obtained from QOBL method with $J = 210.0511$. The second best value is 229.1855, which was obtained from CR. Only RNG, OBL and TENT produced cost function values which were slightly higher than the published benchmark value, 233.90. The results revealed that QOBL is the best method in finding global minimum. However, although QOBL presented the minimum value, its average standard deviation was relatively higher than RNG, OBL and TENT. RNG is the most consistent method followed by OBL, having 4.5955 and 4.7331 standard deviation each, respectively. In terms of search effort, RNG produced the lowest average of function evaluations (1.2327e+05) and also its CPU time is also the lowest with 3.8191e+04 seconds. It should be observed that QOBL is the best initialization method if we consider its ability in minimizing the cost function in large-scale parameter estimation problem.

TABLE II. Experimental Results Obtained from the 20 Runs Conducted using different Initialization Methods

Initialization method	Best value	Worst value	Mean value	Standard deviation	Function evaluation	CPU time (s)
RNG	234.6651	252.0459	245.7053	4.5955	1.2327e+05	3.8191e+04
CR (rerun)	229.1855	270.0339	245.5427	10.0586	1.2421e+05	4.3142e+04
OBL	234.5223	250.9120	243.9961	4.7331	1.2546e+05	4.1942e+04
QOBL	210.0511	255.0070	241.4211	9.3596	1.2830e+05	4.2574e+04
TENT	234.2876	259.8841	246.2248	6.4994	1.2533e+05	4.0755e+04

Note: The best (minimum) value of cost function (weighted nonlinear least square) is shown in shaded cell. CR (rerun) indicates our own experimental result (in case when comparing with publish result in the next subsection).

Additional information to compare the different initialization methods is given in Fig. 1 and Fig. 2. The figures depicts the best curves (with minimum cost function *J*) among the 20 runs obtained from RNG, CR, OBL, QOBL and Tent methods. The curves show that all methods are able to minimize the cost function at a similar rate in terms of function evaluations and CPU time. Note that we have set the same initial guess as the initial value for all methods. This gives fairer comparison and assumes that the search space is feasible. In Fig. 1, starting from the first fractions of 1,000 function evaluations, QOBL has better speed and found acceptable cost function value when it reached approximately 25,000 function evaluations. Meanwhile, CR has the slowest speed until it reached around 40,000 evaluations. All methods continued to progress they reached the final evaluations. In this case, QOBL found the best value of 210.051 at 123,979 function evaluations. At the end of the evaluations, all solutions were able to achieve equivalent solutions in terms of quality, although, the best (minimum) value was obtained by QOBL while the worst (maximum) value obtained by RNG. In

Fig. 2, default initialization method based on CR has obtained slow convergene rate compared to others. It can be noticed where CR obtained acceptable value of cost function when CPU time reached nearly 8 hours, while QOBL reached the acceptable value at nearly 1.3 hours. The results revealed that RNG which is mostly used initialization method and CR as default initialization method in ESS have obtained poor result. Meanwhile, initialization method based on QOBL is a better alternative which was not only able to speed up convergence, but also obtain optimal solution.

To evaluate the quality of the parameter estimates, we compared the best result (QOBL) with a published benchmark result [20]. One thing to note is benchmark result used conventional CR as their initialization methods for the ESS. Table III shows that our study produced the best cost function, J = 210.05 compared to the benchmark's J = 233.90. However, our work obtained a bigger number of function evaluations compared to CR, with a difference of 33,251 evaluations. In terms of CPU time, the benchmark also produced shorter time of approximately 3 hours for a single run. Due to different stopping criteria used (the benchmark study uses CPU time) and different hardware specifications, comparing QOBL and CR in terms of CPU time seems unfair. It should be noted that in terms of efficiency in finding global minimum, method used in this study produced better results compared to CR.

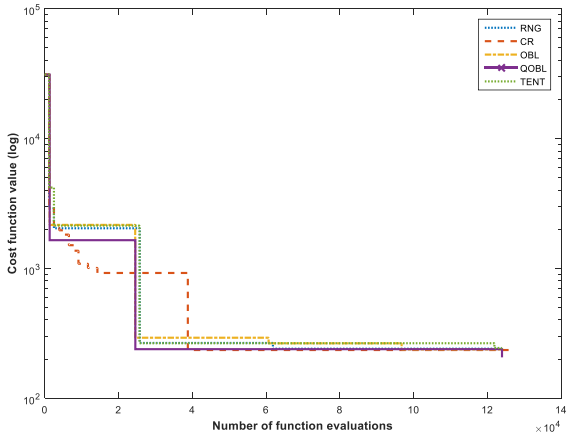

Fig. 1. Convergence of the Five Initialization Methods in Scatter Search.

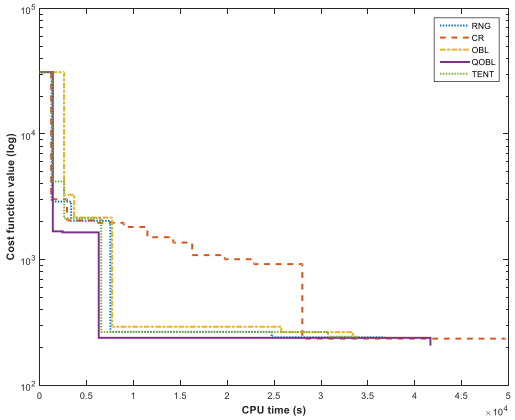

Fig. 2. Slow Convergence of the Five Initialization Methods in Scatter Search.

TABLE III. COMPARISON OF QOBL METHOD WITH PUBLISHED BENCHMARK IN SCATTER SEARCH

Initialization Methods	Best cost function J	Number of function evaluations	CPU Time (seconds)	ΣNRMSE
QOBL	210.05	12.3979e+04	4.1671e+04	2.3773
CR [20]	233.90	9.0728e+04	1.0800e+04	2.4921

Note: The best values are shown in shaded cell.

The decision variables (kinetic parameters) obtained from QOBL may provide the optimal model prediction since it produced the lowest cost function J and may produce best fit to experimental data. The goodness of fit can be measured by calculating root-mean-square-error ($RMSE$) for all metabolites. $RMSE$ is used to measure prediction error which is the different between experimental data and predicted model. The following equation defines $RMSE$,

$$RMSE = \sqrt{\frac{\sum_{exp=1}^{n_{exp}} \sum_{s=1}^{n_s^{exp,obs}} (ym_s^{exp,obs} - y_s^{exp,obs}(\boldsymbol{p}))^2}{n_{\epsilon xp} \cdot n_s^{exp,obs}}} \quad (20)$$

with the same notation defined in Eq. (1). In this case, normalized RMSE is used to cater for different magnitudes of observables. Each RMSE is divided by the range of value of observables as defined as,

$$NRMSE = \frac{RMSE}{\max(ym^{exp,obs}) - \min(ym^{exp,obs})} \quad (21)$$

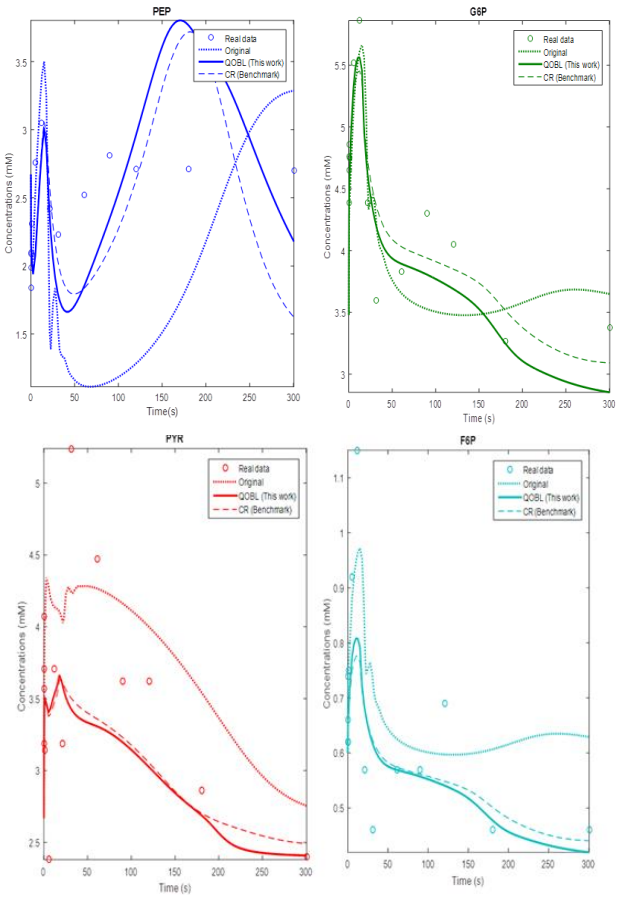

Fig. 3. Model Prediction over Experimental Data.

Thus, $\Sigma NRMSE$ is the sum of all $NRMSE$ for all observables. Table II shows our $\Sigma NRMSE$ is lower than the benchmark, means that it has better fit compared to the parameters obtained in the benchmark.

To measure the goodness of fit from parameter estimates with QOBL, we plot the model prediction over experimental data as shown in Fig. 3. For the sake of brevity, we plot only four out of nine metabolites. We chose metabolites which have very high nonlinear biological system, namely, PEP, G6P, PYR and F6P. The figure shows dynamic concentration change of extracellular glucose that responded to a pulse in central carbon metabolism. To compare the goodness of fit with other parameters, we also plot another fit based on parameters value from original published results and benchmark results. It should be observed that kinetic parameters retrieved from initialization methods based on QOBL represent a good fit between experimental data and predicted model.

VI. Conclusion

This paper studies different initialization methods and investigated their performance and effects on solving large-scale parameter estimation problem. We compared five initialization methods which are based on stochastic and randomization methods and implement them in ESS algorithm. Experimental results revealed that the choice of initialization (diversification generation) methods influenced the performance of the algorithm. The quality of solution, speed of convergence and statistical results were obtained with different characteristics derived from different initialization methods. Our statistical analyses revealed that the most popular initialization method, random number generator (RNG) performs poorly and there are significant better alternatives to this method, which have comparable computational requirements. In addition, the accuracy of model prediction also depends on the choice of initialization methods. Further investigation is needed to discover whether the same findings can be produced when different models and problems associated with parameter estimation are used. More intensive studies also need to be conducted on why some methods are generated more consistent performance in terms of statistical analysis and value of kinetic parameters in biological systems.

***Abstract*—In this digital era, protecting an organisation's sensitive information system assets against cyberattacks is challenging. Globally, organisations spend heavily on information security (InfoSec) technological countermeasures. Public and private sectors often fail to secure their information assets because they depend primarily on technical solutions. Human components create the bulk of cybersecurity incidents directly or indirectly, causing many organisational information security breaches. Employees' information security awareness (ISA) is crucial to preventing poor information security behaviours. Until recently, there was little combined information on how to improve ISA and how investigated factors influencing employees' ISA levels were. This paper proposed a comprehensive theoretical model based on the Protection Motivation Theory, the Theory of Planned Behaviour, the General Deterrence Theory, and Facilitating Conditions for assessing public sector employees' ISA intentions for information security behaviour. Using a survey and the structural equation modelling (SEM) method, this research reveals that the utilised factors are positively associated with actual information security behaviour adoption, except for perceived sanction certainty. The findings suggest that the three theories and facilitating conditions provide the most influential theoretical framework for explaining public sector employees' information security adoption behaviour. These findings support previous empirical research on why employees' information on security behaviours vary. Consistent with earlier research, these psychological factors are just as critical as facilitating conditions in ensuring more significant behavioural intention to engage in ISA activities, ensuring information security behaviour. The study recommends that public-sector organisations invest in their employees' applied information security training.**

Keywords*—Information security awareness; behaviour strategies; self-administered questionnaire; structural equation modelling (SEM)

I. Introduction

Securing information system assets has become a primary issue for organisations in today's digital environment to protect them from criminal assaults. In recent years, both cybercrime and data breaches have expanded considerably. By 2021, cyber-crime is predicted to cost more than $6 trillion, up from $3 trillion in 2015, according to the Cybersecurity Business Report [1]. As a result, organisations are constantly struggling to protect the security of their information assets, which causes them to spend heavily on technical countermeasures [2]. However, concentrating just on the technological areas of information security is insufficient since information security is multidisciplinary, with the human factor playing a significant role. The exploitation of human factors is responsible for a considerable percentage of organisational information security incidents [1]. In other respects, human error is directly or indirectly primarily the result of security breaches, including both intentional and unintentional negative behaviour [3]. According to ENISA [4], about 77% of data breaches occur due to human vulnerability. Additionally, it has been previously shown that over half of all information security breaches are caused by staff's insufficient compliance with information security policies [5].

In consideration of this context, staff members' information security awareness (ISA) has a significant influence on their information security behaviours and their compliance with security policies [6], [7]. Previous research has asserted that a lack of staff ISA as defined by information security policies (ISP) and procedures is the main reason for sensitive information misbehaviour [3]. Additionally, ISA has been a critical concern in research and practice [8] because humans are often identified as a weak link in efforts to protect systems and networks [9]. For this reason, among others, the most recent Cyber Security Breaches Survey 2019 demonstrates that cyber security is a top priority for senior management in the workplace [10].

Even though research and practice prioritise employees' information security awareness, most employees are unaware of information security risks and challenges [6]. For instance, about 90% of cybersecurity experts reported that the organisations for which they work feel exposed to insider threats [3]. According to Jaeger [11], research on ISA is still in its infancy, with numerous new areas to be explored. Even though many studies have been done on ISA, there is still no complete picture of the concept of ISA and how it fits into other constructs [11]. Other studies support this, suggesting that ISA campaigns and education fail to influence employees' behaviour for various reasons [12], [13].

*Corresponding Author.

It has been revealed that organisations fail with their ISA campaigns because they do not appropriately employ the factors impacting personnel's ISA levels while producing the content and developing material for the ISA campaigns [13], [1]. Most importantly, it was found that there were no good ways to make exciting and valuable materials for improving ISA. As a result, several behavioural factors, such as communication channels [14, 15], were not considered when ISA campaigns or initiatives were made to keep improving ISA levels [13].

Our assessment [67] of the relevant literature revealed that most research that relied on constructing models for ISA focused only on behavioural intentions or actual behaviour. Therefore, concentrating on both aspects is crucial and needs additional research [47], [51]. In ISA-related research, facilitating conditions factors have been mostly neglected; this issue also needs thorough investigation. This research implemented its developed model by concentrating on behavioural intention and actual behaviour and two facilitating conditions: organisational support and communication channels to fill these gaps. Incorporating these factors and verifying that they can enhance ISA by employing a combination of control, motivation, prediction, deterrence, and technical-related factors—which aid in managing human thought from a broad perspective to achieve optimal behavioural security practices—will enhance the current understanding.

This study, however, is a continuation of our prior research [16], which seeks to improve ISA among public-sector organisation staff by merging motivational, control/prediction, and deterrence variables into employees' behaviour to promote security awareness and reduce breaches. This study looks at the development and evaluation of a conceptual framework based on factors from the literature on information security from previous international studies. According to the model's constructs, the mediator variable is ISA's behavioural intention, and the dependent variable is InfoSec's actual behaviour. In contrast, the independent variables are a set of ten variables that have never been investigated together in the InfoSec literature. The theoretical background and conceptual model are described in Section II, followed by the methodology and results in Sections III and IV, respectively. Section V discusses the comparative evaluation of the study model. Finally, in Section VI, the conclusion is provided, along with limitations and suggestions for future studies.

II. Theoretical Background and Conceptual Model

This study highlights a new perspective relying on protection motivation theory (PMT), theory of planned behaviour (TPB), and general deterrence theory (GDT), as well as the facilitating conditions to enhance employees' ISA intentions. The different perspectives of these theories and the facilitating conditions show the whole chain of the InfoSec behaviour adoption process. Thus, it helps organisations reduce information security breaches by changing employees' behaviour to match information security policies and rules [7, 15, 17–22]. An assessment of theories utilised in related work revealed that the theories of TPB, PMT, and GDT are most often used [23]; [24]. TBP is one of the most influential theories describing human behaviour in different fields, such as organisational behaviour, public relations, healthcare, or advertising [11]. PMT is one of the most effective models for predicting a person's motivation and intention to take preventative measures [25]. GDT provides a practical focal point for describing misbehaviour [15]. The security education, training, and awareness (SETA) initiatives are the methods through which organisations raise information security awareness, educate staff on the necessity of ISA, and train end-users to take on information security activities [26]. Furthermore, facilitating conditions help employees accomplish their duties and responsibilities more quickly and effortlessly [22]. Fig. 1 presents the study model and utilised factors in a concise form.

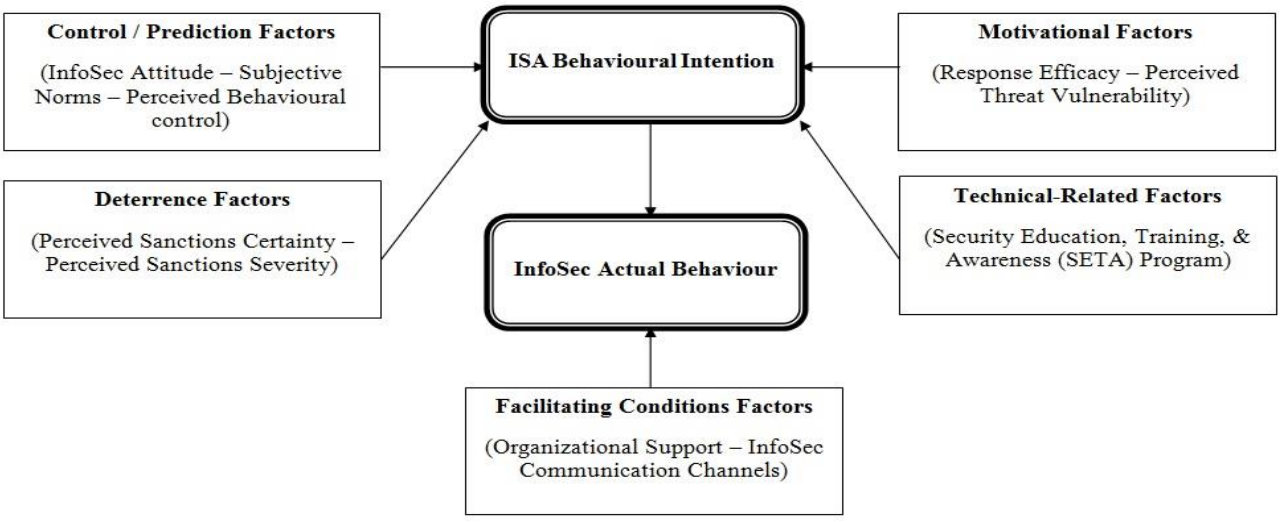

Fig. 1. Research Model.

A. Control and Prediction Factors

Many previous studies extracted prediction and control factors from TPB theory, and its constructs were employed in the field of information technology, proving their effectiveness by controlling employees' beliefs [3], [18], [27], [28]. According to Ong and Chong [29], some researchers have benefited from more helpful and practical recommendations due to citing TPB. Additionally, some studies [30-33] have applied the TPB to predict ISP compliance, information security awareness, and knowledge sharing from an individual's behavioural perspective, making the TPB more applicable to describing how employees participate in ISA activities. Hence, avoiding and mitigating information security breaches. Commonly, human interactions influence a person's beliefs and emotions, thoughts, feelings, behaviours, and actions. TPB contends that attitudes, subjective norms, and perceived behavioural control all impact intentions, which are the foundation of motivation to do behaviour [34]. Several studies have explored the association between attitude and intention [18], [28]. Attitude determines intention, according to TPB [34]. The study intends to utilise InfoSec attitude to represent an individual's acceptance or rejection of an idea. Thus, the employee's positive InfoSec attitude towards ISA reflects his/her intention. Conversely, negative InfoSec attitudes will reduce his/her intention. Consequently, an employee who positively believes in ISA is willing to engage in ISA activities and vice versa. Thus, it is hypothesised that:

H1: Employees' InfoSec attitudes toward ISA have a positive impact on their intention to participate in ISA activities.

Subjective norms are the perceived societal constraints exerted on a person to engage in or abstain from a specific behaviour [32]. Under this social pressure, a person acquires a set of norms, values, beliefs, and motives from significant individuals such as executives, managers, and co-workers [35]. When vital individuals exercise positive pressure on the employee in the context of ISA, this positively impacts the employee's intentions [33]. Thus, it is hypothesised that:

H2: Subjective norms towards ISA engagement positively affect employees' behavioural intentions.

Perceived behavioural control is a critical component of TPB [3], which refers to an individual's sense of how easy or difficult a task or action is to accomplish. Research in the information security arena has shown that perceived behavioural control has a significant effect on behavioural intentions [15], [28], [33]. In the current study, perceived behavioural control refers to the perception that adopting information security awareness is not difficult and has a positive impact. Thus, it is hypothesised that:

H3: Perceived behavioural control towards ISA has a positive impact on the behavioural intentions of employees.

B. Motivational Factors

According to the relevant literature, the PMT model is considered one of the best theories for predicting and motivating a person's intention to take preventive steps [17], [36]. The PMT theory was developed by Rogers [37] to understand fear appeals and predict suitable responses for personal protection when faced with a threat. When a person learns about potential threats, he or she becomes more aware of the risks to which he or she may be exposed. Threat appraisal and a coping appraisal are two primary constructs in PMT. The act of determining the intensity and sensitivity of danger is referred to as threat appraisal. While evaluating the success of protective measures and the perceived self-efficacy of the person under threat is referred to as coping appraisal. Empirical studies [2], [7], [14], [38] have shown the efficacy of PMT in implementing adherence and compliance to security standards and policies among an organisation's employees. Because these were the components found to have a positive influence in the literature related to the topic, this study used one factor from threat appraisal constructs: perceived vulnerability, and one from coping appraisal constructs: response efficacy. The perceived vulnerability relates to a person's appraisal of a potentially harmful circumstance and whether or not he or she is at risk [17]. Employees who perceive a high level of vulnerability in their organisation's information systems are more likely to take preventative measures. According to previous study findings [38], employees' perceived vulnerability in a cyber-attack incident encourages them to engage in preventive measures. As a result, it stands to reason that people who believe they are not vulnerable to security risks lack appropriate security knowledge and often fail to comply with workplace security policies. On the other hand, people who believe they are more exposed to security risks are more likely to engage in ISA activities and participate in preventative activities [39]. Thus, it is hypothesised that:

H4: Perceived vulnerability toward ISA has a positive impact on the behavioural intentions of employees.

Response efficacy relates to an individual's belief that adopting or implementing a certain preventative measure is the best method to reduce security risks [40]. When a person is persuaded of the utility of a risk-reduction mechanism, he or she will almost certainly adopt risk-reduction behaviour. However, if the person is not persuaded, he or she will not adopt it [17], [36], [41]. As a result, if employees think ISA gives them enough information and awareness to keep information security breaches and risks from happening, they are more likely to be motivated to participate in ISA activities. Thus, it is hypothesised that:

H5: Response efficacy towards ISA has a positive impact on the behavioural intentions of employees.

C. Deterrence Factors

The earliest version of the deterrence theory was created by the philosophers Cesare Beccaria and Jeremy Bentham, based on the assumption that individuals seek to maximise pleasant outcomes, such as rewards, and avoid painful ones, such as penalties [42]. GDT has been chiefly used in criminology to minimise deviant behaviour in people. In recent decades, it has been successfully and efficiently used for information technology as well as preventative information security [15], [19], [20], [27], [43]. In GDT, the deterrence model is built on three core constructs: certainty of sanctions, the severity of sanctions, and celerity of sanctions. Such determinants impact people's attitudes toward preventing activities that are regarded as undesirable in society. The constructs' of GDT: perceived

certainty of sanctions and perceived severity of sanctions are included in the study model due to their positive influence in the relevant literature [20], [43]. Perceived certainty of sanctions refers to a person's belief that the authorities are likely to detect delinquent behaviour. In contrast, the perceived severity of sanctions refers to the person's belief that s/he would be punished seriously if deviant behaviour is proven [3], [45]. When employees who break information security policies understand the consequences of their actions, they are more likely to participate in ISA activities and thus change their behaviour. Thus, it is hypothesised that:

H6: Perceived certainty of sanctions towards ISA has a positive impact on the behavioural intentions of employees.

H7: Perceived severity of sanctions towards ISA has a positive impact on the behavioural intentions of employees.

D. Technical-related Factors

Previous research has looked at the role of technical-related factors in improving ISA among users. Studies have a wide variety of interests in awareness-related variables that may not be within the vast area of education, training, and awareness. For example, the integrated model of Ramalingam et al. [46] used "Threat Awareness", "Password Awareness", and "Content Awareness"; Hanus and Wu [40] used "Threat Awareness" and "Countermeasure Awareness". Furthermore, Han [47] used "Security Technology Awareness"; Mamonov and Benbunan-Fich [48] used "Threat Awareness"; Khan and AlShare [49] used "information security policy scope". Moreover, Koohang et al. [50] used "Security Issues Awareness" and "Security Policy Awareness"; and Hwang et al. [51] used two separate constructs: "Security Policy" and "Security Education". According to Yaokumah et al. [52], security education benefits employees by improving their awareness of the organization's security environment, policies, and regulations. Effective training programmes may teach employees how to make secure information security choices. Staff security awareness programs may aid in the improvement of their security behaviour. Security education, training, and awareness (SETA) programs are educational and training programs designed to increase employees' knowledge of information security. These programs foster continued interest in rules and guidelines, risks, and the skills required to perform information systems security activities [21]. Consequently, rather than using the limited constructs of security awareness, the study prefers to use SETA as a construct with its complete and comprehensive concept of education, training, and awareness as compared to the limited constructs of security awareness. Employees may think they have the requisite knowledge and abilities to handle security issues in the workplace if they perceive SETA as effective. It stands to reason that employees with sufficient training are better equipped with skills and knowledge regarding security regulations and countermeasures. As a result, their behaviour will improve in order to comply with security policies. Hence, it is hypothesised that:

H8: SETA programs have a positive impact on the behavioural intentions of employees.

E. Behavioural Intention

One of the most significant constructs in TPB is the intention, which refers to the state of mind of a person in which the planning and forethought are to achieve a particular behaviour [3], [33]. According to the relevant studies, an individual's desire to achieve a goal that satisfies him or her yields an intention to participate in behaviour that encourages that goal. Bélanger et al. [14] and Thompson et al. [39] demonstrated that early conformity behavioural intention significantly predicts early conformity actual behaviour. In an attempt to predict the first adoption of information security behaviours, Ofori et al. [19] and Shropshire et al. [53] demonstrated a significant correlation between intention and actual behaviour. Although positive behavioural intentions toward a specific behaviour may ensure that the actual behaviour is achieved [51], intention alone may not adequately determine actual behaviour if explanatory power is not obtained by investigating both. Thus, it is hypothesised that:

H9: Employees' behavioural intentions towards ISA positively affect their adoption of InfoSec actual behaviour.

F. Facilitating Conditions Factors

External factors termed "facilitating conditions" (FC) are external factors outside the original theories. FCs are influential determinants that, along with other factors, promote a particular behaviour and are used to promote behavioural intention or actual behaviour to adopt technology [66]. These factors are included in the study's model to make an action easy to do. The study's model contains two constructs of facilitating conditions: organisational support [33] and InfoSec communication channels to promote employees' behaviour according to information security regulations. Organisational support indicates to employees; global beliefs about how an institution recognises and appreciates the employees' contributions and cares for their well-being. As Ofori et al. [19]; Khan and AlShare [49]; and Safa et al. [22] point out, organisations that show a commitment to their employees' well-being are better capable of protecting their assets through knowledge sharing and collaboration. Thus, it is hypothesised that:

H10: Organizational support towards employees facilitates their InfoSec's actual behaviour in accordance with information security policies.

Employee perception of the value of information and an organization's information security communication all contribute to the improvement of ISA through increasing knowledge of the importance of information security [1]. Moreover, employee communication channels regarding information security may reduce ambiguity and increase the frequency and usefulness of cross-functional communication, hence improving an individual's behaviour formation efficiency. Without formal communication channels, attitudes that violate safety norms would spread rapidly and prevent adopting correct ones [15]. According to Bélanger et al. [14], institutions may increase employee knowledge and awareness through targeted communications about the new need and justification for the recommended measures and security-related training. In terms of communication channels, this study asserts that effective communication amongst staff about

all information security concerns and issues may help reduce human vulnerabilities associated with having adequate expertise to comply with applicable laws and regulations. Thus, good communication can help employees learn new skills, make better decisions, report incidents, and clear up misconceptions about information security [13]. Hence, it is hypothesised that:

H11: InfoSec communication channels positively affect employees' InfoSec actual behaviour.

III. Methodology

This study aims to demonstrate how public organisations can manage the human component and increase their ISA by examining factors such as prediction, control, motivation, deterrence, technical-related, and facilitating conditions for the adoption of InfoSec behaviour and reducing the risk of information security breaches. The success factors were designed to maximise employees' ISA by relying on constructs from TPB, PMT, and GDT, as well as three external factors. Hence, this study methodology adheres to a positivist philosophy, which involves identifying essential relationships relating to the phenomenon (in this instance, the adoption of InfoSec behaviour); it also adheres to a quantitative approach, which is implemented via the distribution of a questionnaire. Expert feedback was used to develop the research model. Quantitative approaches were also used to enhance the model. Because the research is aimed at public sector units' employees, data was gathered from public government organisations in the Sultanate of Oman. A questionnaire with a 5-point Likert scale was used to gather data.

A. Instrument Development and Data Collection

After consulting questions from relevant past research, the questions in the present study's questionnaire were constructed to correspond to the framework and constructs. The questionnaire was divided into two sections: the first included six questions on the participants' demographics, and the second included questions about the proposed model's variables, for a total of 71 questions. In the final form of the questionnaire, each component was addressed with different questions with various options ranging from strongly disagree to strongly agreed (Using a Likert scale of 5-points). Before distribution, a pilot study with 100 respondents was conducted to ensure the reliability of the questionnaire's items [16] and to determine whether the questionnaire's questions were appropriate, intelligible, and subject to a single interpretation. The current study's data collection started in the first week of January 2022 and was finished by the end of February 2022 (Over approximately seven weeks). After describing the purpose of the study to the participants, we asked them to answer the questionnaire based on their knowledge and experience. Their consent was necessary for the researchers. They were given the questionnaire after confirming their consent to participate in this research. Participants were informed that their responses would be used exclusively for statistical and scholarly reasons and would be kept private. The study used stratified random sampling, which divides a target population into smaller subgroups called "strata". Random samples are drawn from these groups based on how much of the target population they make up.

B. Participants' Demographic Characteristics

The Sultanate of Oman's public sector employs 170,104 employees [54], making it one of the major sectors in the country. According to Krejcie and Morgan's equation [55], a sample of at least 384 participants is necessary for this study's intended population. Employees in the public sector were given 480 questionnaires, of which 415 were returned. The overall response rate was 86%, with 24 outliers. An overall response rate of 81% was obtained from the 391 validated responses. The remaining responses were discarded due to their repetitive answers or incompleteness. As shown in Table I, males comprised 248 (63.4%) of the total participants. The group over 40 years had the highest frequency of respondents' age, with 119 (30.4%), followed by 31—35 years of age, with 112 (28.6%). A bachelor's degree was the most often mentioned qualification among respondents (174; 44.5%). The most frequently occurring occupation among respondents (163; 34.8%) was "Employee", followed by "Technician" (70; 17.9%). The group with more than ten years of experience had the highest frequency of responders with more than ten years of experience (208; 53.2%). Most respondents belonged to educational or service-related institutions, with 128 (32.7%) and 101 (25.78%), respectively.

TABLE I. Demographic Characteristics

Variables		Frequency	%
Gender	Male	248	63.4
	Female	143	36.6
Age (years)	25 or Less	20	5.1
	26 – 30	33	8.4
	31 – 35	112	28.6
	36 - 40	107	27.4
	Above 40	119	30.4
Education	Diploma	52	13.3
	High Diploma	82	21
	Bachelor	174	44.5
	Master	71	18.2
	Doctorate	12	3.1
Employment Situation	Employee	136	34.8
	Specialist	53	13.6
	Technician	70	17.9
	Chief-Employee	47	12
	Manager	30	7.7
	Other	55	14.1
Experiences	1 - 2	26	6.6
	3 - 5	48	12.3
	6 - 10	109	27.9
	Above 10	208	53.2
Organization	Education	128	32.7
	Health	75	19.2
	Service	101	25.8
	Other	87	22.3

IV. RESULTS

A structured questionnaire adapted from prior studies was used to address the proposed conceptual model, which was then translated from English into Arabic and distributed to the target population. It was because the language of the survey had changed from one language to another that both exploratory factor analysis (EFA) and confirmatory factor analysis (CFA) were used. SEM with AMOS version 24 was also used to see if the research hypotheses were accepted or rejected. Both measurement (MM) and structural (SM) models were developed in the study to model talent variables. They are two essential components used in the SEM to verify the study model's validity and reliability. The measurement model examines the relationship between latent constructs and their items to see if these indicators accurately measure the relevant talent construct. This step must be done before fitting the MM to the data to check the reliability and validity of the factor's items. In contrast, the structural model examines the relationships between one latent construct and other latent constructs [56].

A. Measurement Model Testing

SEM is a suitable approach for assessing data and estimating associations between constructs by accepting or rejecting formulated hypotheses to investigate the relationships between constructs in the study's model. SEM has many advantages, like isolating errors and estimating regression between latent constructs. Skewness and kurtosis tests were used to test the data distribution's normal state (normality); the study followed Hair et al. [57]'s recommendations and utilised a critical cut-off value of ±2.58. The results indicated that the skewness and kurtosis values for each model's variables were within the specified limits, indicating that the distribution is normal. For determining the suitability of factor analysis, Bartlett's test of sphericity (significant at $p<0.001$) and the Kaiser-Mayer-Olkin test (KMO) (values ranging between 0 and 1) were conducted. [58]. The KMO test score was 0.919, with a minimum suggested score of 0.50 and values greater than 0.9 were deemed excellent. The Chi-square statistic was significant (14100.952). The results of the KMO and Bartlett's tests are shown in Table II.

In line with relevant existing literature, the model for this study was constructed by incorporating the most successful parameters from three psychological theories and three external factors. Consequently, confirmatory factor analysis (CFA) is an important second step in evaluating whether the measured determinants align with our interpretation of the proposed model [59]. Furthermore, to develop the best potential measurement model, every item or latent variable that was not a good match (not fit) must be excluded [56]. The most frequent model-fit measures, according to Bollen [60], are the chi-square test (χ^2), comparative fix index (CFI), incremental fix index (IFI), Tucker-Lewis index (TLI), and root mean square error of approximation (RMSEA). Hence, in this study, these measures and the p-value were utilized as a goodness of fit indices to analyze the exogenous and endogenous variables. As a finding, χ^2 = (2558.954), degrees of freedom = (1346), ratio-χ^2/df = (1.901) less than 5, CFI = (.910), IFI = (.911), TLI = (.901), and RMSEA = (.048) less than 0.080, indicating that the measurement model was a good match (fit) with the data gathered [57]. Furthermore, the Root Mean Square Residual (RMR) = (0.037), less than 0.10. According to Table III, all model-fit indices surpassed the indicated acceptable thresholds.

The study used CFA to calculate the factor loading of the measurement variables to estimate the convergent viability. According to Hair et al. [57], if the loading factor of the indicators is more than 0.50 and the sample size is 300 or above, the loading factor shows an acceptable level of convergent validity. As a result, we removed indicators from the study's model with a factor loading of less than 0.50. Due to lower factor loadings (less than 0.50) or cross-loadings, the indicators SN1, SN5, and SN6 in subjective norms, PBC1 in perceived behavioural control, PV5 in perceived threat vulnerability, RE1, RE2 in response efficacy, PCOS1 in perceived sanctions certainty, PSOS1, PSOS2, and PSOS3 in perceived sanctions severity, SETA2 and SETA7 in security education, training, and awareness, BI7 in behavioural intention, OS1 in organisational support, and COM5 in InfoSec communication channels were eliminated from the proposed model. Internal consistency in the measuring of model variables is provided through reliability measurement. A questionnaire's reliability (Cronbach's alpha) is thought to be accepted when it is more than 0.6 [61], and when it is above 0.7, it is indicated to be composite reliability [56]. The two kinds of reliability testing were used in this analysis. Cronbach's alpha scores vary from 0.807 to 0.908, while composite reliability scores range from 0.814 to 0.901. As a result, the reliability and composite reliability values for the entire model's variables were more than 0.7. Table IV provides an overview of the statistical measurements.

TABLE IV. THE VARIABLES, MEASURES, AND THEIR DESCRIPTIVE STATISTICS

Variables	Items	Measures	Factor Loading	AVE	Alpha	CR
InfoSec Attitude	ATT1	Information security awareness is necessary.	0.773	0.514	0.870	0.862
	ATT2	Information security awareness is beneficial.	0.877			
	ATT3	Practicing information security awareness activities is useful.	0.754			
	ATT4	I believe that information security awareness is a useful behavioural tool to safeguard the organization's information assets.	0.633			
	ATT5	My information security awareness has a positive effect on mitigating the risk of information security breaches.	0.624			
	ATT6	Information security awareness is a wise approach that decreases the risk of information security incidents.	0.624			
Subjective Norms	SN2	My colleagues think that I should have information security awareness to protect organizational information assets.	0.685	0.545	0.864	0.781
	SN3	My friends in my office encourage me to understand information security policies.	0.699			
	SN4	The head of the department thinks that information security awareness is a value culture	0.822			
Perceived Behavioural Control	PBC2	I have the necessary awareness about information security to share with the other employees.	0.766	0.636	0.873	0.875
	PBC3	I have the ability to adopt information security awareness to mitigate the risk of information security breaches.	0.804			
	PBC4	Information security awareness adoption is an easy and enjoyable task for me.	0.803			
	PBC5	I have enough knowledge to behave safely in terms of information security.	0.817			
Response Efficacy	RE3	At my work, efforts to ensure the safety of my confidential information are effective.	0.668	0.661	0.858	0.852
	RE4	The preventative measures available to me to stop people from gaining access to my organization’s information are adequate.	0.880			
	RE5	The preventative measures available to me to prevent people from damaging my information system at work are adequate.	0.873			
Perceived Threat Vulnerability	PV1	I know my organization could be vulnerable to security breaches if I don’t adhere to its information security policy.	0.755	0.524	0.812	0.814
	PV2	I could fall victim to a malicious attack if I fail to comply with my organization’s information security policy.	0.727			
	PV3	I believe that trying to protect my organization’s information will reduce illegal access to it.	0.673			
	PV4	My organization’s data and resources may be compromised if I don’t pay adequate attention to guidelines.	0.737			
Behavioural Intention	BI1	I am willing to practice my information security awareness because of its potential to reduce the risks.	0.674	0.501	0.872	0.857
	BI2	I will share my information security awareness with my colleagues to comply with security policies.	0.734			
	BI3	I intend to help my colleagues to increase their awareness of information security	0.776			
	BI4	I intend to collaborate with other staff to decrease insider threats in my organization.	0.699			
	BI5	I will inform the other staff about new methods and software that can reduce the risk of information security.	0.686			
	BI6	I will share the report on information security incidents with others, in order to reduce the risk.	0.665			
InfoSec Actual Behaviour	AB1	I frequently practice my experience about information security with my colleagues.	0.663	0.505	0.908	0.901
	AB2	I practice my information security knowledge with my colleagues.	0.653			
	AB3	I frequently share my expertise from my information security training with my colleagues.	0.680			
	AB4	I frequently talk with others about information security incidents and their solutions in our meetings.	0.709			
	AB5	I avoid mistakes in the domain of information security.	0.783			

	AB6	I always mitigate information security threats.	0.785			
	AB7	I think about the consequences of my behaviour before any action.	0.666			
	AB8	I am careful about my behaviour in the domain of information security.	0.642			
	AB9	I frequently assess my information security behaviour to improve it.	0.750			
Perceived Certainty of Sanctions	PCOS2	I believe that if I violate the confidentiality of information, the management will realise it.	0.769	0.640	0.866	0.875
	PCOS3	If I violated the organization's security policies, I would probably be caught.	0.624			
	PCOS4	I believe that if I transfer organisational information outside, the organisation will find out about my violation.	0.907			
	PCOS5	I believe that if I sell organisational information, my organisation will discover it.	0.870			
Perceived Severity of Sanctions	PSOS4	I deserve punishment if I violate the confidentiality of organisational information.	0.782	0.605	0.807	0.820
	PSOS5	I think punishment will be high if I sell or transfer organisational information outside.	0.854			
	PSOS6	I think receiving sanctions because of my information security misconduct will negatively influence my career development.	0.688			
Organizational Support	OS2	The organisation cares about my information security awareness level.	0.839	0.654	0.863	0.883
	OS3	The management appreciates employees for their information security awareness.	0.805			
	OS4	The management awards employees for their compliance with information security policies.	0.766			
	OS5	The management encourages employees to participate in information security awareness engagement.	0.824			
InfoSec Communication Channels	COM1	We have communication channels established for employees to report information security suspected improprieties.	0.755	0.669	0.875	0.889
	COM2	The management communicates employees' security duties and control responsibilities in an effective manner.	0.922			
	COM3	Communication flows across the organisation adequately (e.g., from department to department) to enable employees to discharge their responsibilities securely and efficiently.	0.753			
	COM4	I feel as though I am a part of the information security decision-making process within my organization.	0.727			
Security Education, Training and Awareness	SETA1	My organization gives employees training to help them become more aware of information system security issues.	0.610	0.568	0.866	0.866
	SETA3	SETA increases my knowledge of security issues.	0.752			
	SETA4	SETA motivates the learners to integrate the security knowledge taught.	0.855			
	SETA5	My organisation provides employees with appropriate security education before giving them authorised access to the institution's network.	0.844			
	SETA6	My organization utilizes various communication methods in order to improve the information security awareness of employees.	0.679

Note: PV = Perceived Threat Vulnerability, PBC = Perceived Behavioural Control, OS = Organizational Support, PCOS = Perceived Certainty of Sanctions, COM = InfoSec Communication Channels, SETA = Security Education, Training and Awareness, ATT = InfoSec Attitude, SN = Subjective Norms, AB = InfoSec Actual Behaviour, PSOS = Perceived Severity of Sanctions, RE = Response Efficacy, BI = Behavioural Intention.

Discriminant validity is realized when a construct is remarkably different from the other constructs since there is no association between constructs that do not relate to each other [57]. The square root of the AVE was more significant than the correlations between the construct and the other model's constructs, which varied between 0.017 and 0.778 for the given model. Moreover, the maximum shared squared variance (MSV) was smaller than the AVE. Thus, the discriminant validity verification supported all of the model's constructs. Table V displays the matrices of correlation between various latent variables.

B. Structural Model Testing

In this study, the same set of fit indices is used to analyse the structural model. As indicated in Table III, all fit indices were within the acceptable ranges: χ^2 = (3378.335), degrees of freedom= (1393), ratio-χ^2/df= (2.425), RMSEA = (.060), with the exception of CFI = (.853), IFI = (.854), and TLI = (.850). However, another method of evaluating the values derived from the CFI, IFI, and TLI indices should be considered. According to Bentler and Bonett [62] and Sharma et al. [63], the TLI cut-off point is continually shifting. Since there is no globally approved measuring standard, a TLI value between 0.80 and 0.90 may be considered a moderate or acceptable fit. Bentler [64] believed that CFI indicates a good fit when it equals or surpasses 0.90, while values larger than 0.80 and reaching 0.90 suggest a generally adequate fit, and Bollen [60] made the same suggestion for IFI index values. Moreover, Schumacher and Lomax [65] state that if the IFI, CFI, and ITL values are greater than 0.90, they are considered excellent fits, but they may also be considered moderate if the values are between 0.85 and 0.90. As a result of the above, we believe that the model is both appropriate and a good match for the data, as the parsimonious index provides the most accurate measurement (RMSEA= .060).

TABLE VI. STRUCTURAL MODEL CAUSAL PATHS

Paths	Standardized estimate (β)	P-value	Result
ATT → BI	0.138	0.009	Supported
SN → BI	0.146	0.020	Supported
PBC → BI	0.300	0.000	Supported
PV → BI	0.311	0.000	Supported
RE → BI	0.148	0.045	Supported
PCOS → BI	-0.107	0.106	Rejected
PSOS → BI	0.276	0.000	Supported
SETA → BI	0.139	0.000	Supported
BI → AB	0.582	0.000	Supported
OS → AB	0.262	0.001	Supported
COM → AB	0.187	0.015	Supported

Note: ATT = InfoSec Attitude, SN = Subjective Norms, PBC = Perceived Behavioural Control, RE = Response Efficacy, PV = Perceived Threat Vulnerability, PCOS = Perceived Certainty of Sanctions, PSOS = Perceived Severity of Sanctions, SETA = Security Education, Training and Awareness, BI = Behavioural Intention, OS = Organizational Support, COM = InfoSec Communication Channels, AB = InfoSec Actual Behaviour.

The findings of the causal paths are shown in Table VI. Employees' ISA behavioural intention was significantly influenced by InfoSec attitude (β=0.137, p=0.009), subjective norms (β=0.107, p=0.048), perceived behavioural control (β=0.296, p=0.000), response efficacy (β=0.148, p=0.018), perceived threat vulnerability (β=0.297, p=0.000), perceived sanctions severity (β=0.274, p=0.000), and security education, training, and awareness (β=0.139, p=0.000). On the other hand, the impact of perceived sanctions certainty on employees' ISA behavioural intentions was insignificant. As a result, H6 is rejected. Finally, the results demonstrated that ISA behavioural intention (β=0.584, p=0.000), InfoSec communication channels (β=0.188, p=0.015), and organizational support (β=0.262, p=0.001) all had a significant impact on InfoSec actual behaviour adoption.

V. COMPARATIVE EVALUATION OF THE STUDY MODEL

The study's significance derives from the inclusion of control, prediction, motivation, and deterrence approaches, all resulting from three main theories: TPB, PMT, and GDT. This study investigated whether the TPB affected intentions in information security behaviour adoption among public organisation employees and revealed that the TPB has a good to excellent effect, supporting results of previous studies [3], [18], [27], [28] and contradicting the findings of Rajab and Eydgahi's [2] study. The presented factors encourage institutions' employees to engage in ISA activities and, consequently, InfoSec behaviour adoption. The results of the InfoSec attitude analysis indicated that employees who expect advantages from ISA activities are more likely to adopt InfoSec behaviours consistent with their understanding of ISA. As a consequence of our analysis of subjective norms, we can assume that employees get cooperation about their engagement in ISA activities from their managers, supervisors, and co-workers. The present case demonstrates the significance of perceived behavioural control, which indicates that controlling perceptions may impact employees' intentions, allowing ISA activities to effectively engage in a suitable work environment. Because PMT is a practical framework for estimating an employee's intention to take preventive measures, some studies indicate that perceived vulnerability [17], [39] and response efficacy [40], [41] related to information security have a significant impact on information security policy compliance. This study found that almost all of their findings align with these findings. The study also found PMT to be among the best theoretical frameworks for explaining ISA intentions toward InfoSec behaviour adoption, which is consistent with previous results [17], [36], [39]. The purpose of GDT constructs is to treat employee criminal behaviour. The target of applying sanctions is to prevent or eliminate undesirable employee conduct. The imposition of sanctions helps to alter the behaviour of uncooperative staff to some degree [44] and raises awareness of illegal behaviour among other employees when penalties are implemented. As proven by prior studies [19], [27], [43], there is a significant positive relationship between the severity of sanctions and compliance with information security policies. While the results of this study confirm the findings of earlier research on the sanctions' severity and InfoSec's behaviour through ISA intention, they also suggest that as the likelihood of sanction severity rises, employees' intentions for InfoSec behaviour rise as well. Jaeger et al. [27] discovered that the sanctions' certainty did not affect the variance in information security policy compliance, which

confirms the results of this study. The study targeted public sector employees as a possible explanation for this non-significant relationship. This sector most certainly differs from the private sector in several ways; for example, employees in this sector work in a more stable environment, which may lower their motivation compared to private sector employees. Employees in the public sector might need more powerful ways to get them excited, such as recognition and responsibility.

The study's findings reveal that SETA programs strongly affect public institution employees' ISA intentions towards InfoSec behaviour. According to prior studies, SETA programs motivate employees to follow information security policies and procedures [20], [21]. When public sector employees get appropriate SETA programs, they will gain an essential awareness of security knowledge and abilities. They will also be able to show their commitment to the information security policy through their behaviour. Accordingly, they will be one of the most effective defence lines in safeguarding information assets and professionally responding to risks and attacks. Furthermore, the results showed that a positive ISA intention toward adopting InfoSec behaviour, organisational support, and InfoSec communication channels affected employees' adoption of InfoSec behaviour. The statistical analysis and the literature review show that the proposed model is both sound and efficient. A model for adopting information security behaviours in public organisations was contributed by determining the success factors that would influence the intentions of public sector employees to engage in ISA activities and adopt best behavioural practices. It is expected that the results of this research will be used by content development consultants to improve and enhance ISA materials and by SETA program developers and designers to prepare and design ISA and best practices programs and initiatives. The proposed model concentrates on the two aspects of behavioural intentions and actual behaviour to add to existing knowledge on ISA and best practices. In addition, it includes the facilitating conditions that positively influence employees' ISA (i.e., Organisational support and InfoSec communication channels) to enhance and correct actual behaviour in the process of ISA.

This study is one of the studies that envision increasing employee awareness and understanding of information security and reducing breaches through a combination of factors. This aggregation creates a new perspective that helps public institutions more effectively manage human ISA. We believe this research adds to this field's existing body of knowledge.

VI. Conclusion, Limitations and Future Work

The fast growth of information technology has made it simpler, more accurate, and more efficient to carry out organisational functions. Nevertheless, there is still a gap between how far technology has advanced and how much employees are aware of it, making it challenging for public institutions to preserve their assets. A lack of users' ISA causes many security risks and challenges. Through this study, we seek to strengthen and broaden research on the challenges of ISA in organisations by leveraging success factors extracted from three theories established on the principles of control, prediction, motivation, and deterrence. Public institutions may influence their employees' intentions to align with desired information security behaviour by employing control and prediction factors. Employees are also encouraged by motivational factors to practice security countermeasures and continuously maintain their knowledge and skills. Deterrence factors contribute to the control of criminal wrongdoing and, through them, can spread security awareness via understanding criminal behaviour. Usually, there are two aspects to SETA programs: the fundamental part and the institutional-specific. The fundamental part of all SETA programs is to determine and monitor the critical human threats and risks and employee behaviours linked to those threats and risks. The institutional-specific part is designed to address the requirements of employees and the institution. The institution's recognised risks and behaviours should influence the awareness efforts. Employees must be provided with these programs consistently. They must also be consistently evaluated. Furthermore, the research model has been expanded to include facilitating conditions that help make sure that actual InfoSec behaviour is in line with information security regulations and policies.

To further extend this study, it is necessary to identify the determinants that influence employees' engagement in ISA activities, their difficulties and obstacles, and their perspectives on them. Future studies might look at the implementation of ISA through alternative models and theories and extend the technical, organisational, environmental, and individual factors. Additionally, interviews and group discussions might be conducted to ascertain any underlying reasons for the lack of ISA, particularly in public institutions. Among the study's limitations is that it focused only on public-sector units in Oman. Consequently, the findings do not accurately reflect the behaviour of other sectors, such as the private, industrial, and financial sectors, resulting in a lack of representation. Future studies can incorporate a diverse range of sectors into their study sample.

Novel Oversampling Algorithm for Handling Imbalanced Data Classification

Novel Oversampling Algorithm

Anjali S. More, Dipti P. Rana
Department of Computer Science and Engineering
Sardar Vallabhbhai National Institute of Technology, Surat, Gujarat, India

***Abstract*—In the current age, the attention of researchers is immersed by numerous imbalanced data applications. These application areas are intrusion detection in security, fraud recognition in finance, medical applications dealing with disease diagnosis pilfering in electricity, and many more. Imbalanced data applications are categorized into two types: binary and multiclass data imbalance. Unequal data distribution among data diverts classification performance metrics towards the majority data instance class and ignores the minority data, instance class. Data imbalance leads to an increase in the classification error rate. Random Forest Classification (RFC) is best suitable technique to deal with imbalanced datasets. This paper proposes the novel oversampling rate calculation algorithm as Improvised Dynamic Binary-Multiclass Imbalanced Oversampling Rate (IDBMORate). Experimentation analysis of the proposed novel approach IDBMORate on Page-block (Binary) dataset shows that instances of positive class is increased from 559 to 1118 whereas negative instance class remains same as 4913. In case of referred multiclass dataset (Ecoli), IDBMORate produces the consistent result as minority classes (om, omL, imS, imL) instances are oversampled majority class instances remains unchanged. IDBMORate algorithm reduces the ignorance of minority class and oversamples its data without disturbing the size of the majority instance class. Thus, it reduces the overall computation cost and leads towards the improvisation of classification performance.**

Keywords*—Binary imbalance; multiclass imbalance; oversampling; random forest classification; classification

I. Introduction

Numerous ranges of applications in today's real-world deal with imbalanced data applications. Numerous domains specifically medical diagnosis text mining, tracking of financial transactions, telecommunication, and industrial and engineering applications [1,2,3]. Dealing with these applications attracts researchers to resolve the data imbalance challenge. For the rapid development of real-world applications, information management with imbalanced classification is a decisive task. The upcoming needs of this digitized world comprise the utilization of technologies that can handle complex unevenness within the data sample distribution within data. There are a variety of functional application areas which need to reshape unbalanced, complex, and huge volumes of data by incorporating sampling techniques [4, 5, 6].

Data sampling methods are trendy in addressing class inequality at the data level and generally show improvement in classification results. The existing sampling approaches show that there is performance inconsistency if it is applied on both binaries as well as multiclass imbalance data application. The existing imbalanced data applications and work depict that there is an excessive sample generation in the existing oversampling methods which diverse the classification accuracy towards the majority data sample class [7,8]. It also increases the computation cost due to excessive sample generation. Present scenarios also have a diversion in data size of majority data sample in oversampling process and ignorance of minority data sample class. Data sample ignorance in the minority class leads to missing important information and overfitting in the majority class due to excessive data generation in the oversampling process. These challenges motivated this research work to derive a novel oversampling algorithm.

Imbalanced data classification biases performance towards majority numbered class in case of a binary application or majority classes in case of multiclass applications [9]. Traditional approaches lean towards abridged accuracy due to the massive amount of biased data towards the majority [10]. The proposed research work deals with a novel oversampling rate algorithm. In the existing study, the sampling methods which are suitable for the binary imbalance category are not suitable for multiclass imbalance application domains. The proposed IDBMORate algorithm is targeted to calculate oversampling rate which is dynamically applicable to binary as well as multiclass data imbalance and get enhanced classification performance.

In the first attempt, the proposed novel oversampling algorithm deals with the dynamicity of data oversampling which applies to both categories. The second advantage of the proposed algorithm is it will not disturb the majority data instance class and only focus on oversampling the minority data sample class. These two advantages indicate the strengths of the proposed algorithm in terms of less computation time and enhanced classification performance. The main objective of the paper is to identify imbalanced application areas and study existing sampling techniques. The subsequent objective of this research study is to propose a novel oversampling algorithm that leads to performance improvement. Experimental analysis of proposed IDBMORate on selected

binary and multiclass datasets shows improved performance metrics.

A. Organization of the Paper

The research study in this paper is organized as follows. The next section deals with a brief review of the related literature study of binary and multiclass imbalanced application domains and suitability of classifier. The third section emphasis on existing sampling approaches. Subsequent fourth section deals with the study of proposed Improvised Dynamic Binary-Multiclass Imbalanced Oversampling Rate (IDBMORate) algorithm and experimentation. Experiment analysis is carried on both binary (Page-block Dataset) as well as multiclass imbalanced (Ecoli Dataset) for verifying the dynamicity of proposed algorithm. Subsequent section deals with computational results of proposed IDBMORate. The final section outlines the major advantages and dynamicity of the proposed research work.

B. Research Gap

Excess time and computation cost required for generating new data samples for balancing the data. Proposed IDBMORate overcomes this research gap by oversampling minority class without disturbing majority data class and improvises classification performance.

II. Imbalanced Application Domains

This section of the paper focuses on imbalanced application domains and the suitability of the classifier for binary and multiclass imbalanced application domains [11,12]. It also highlights the issues raised due to data imbalance [13,14].

A. Imbalance Application and Suitability of Classifier

Classification with Imbalanced Dataset (ID) deals with heterogeneous and other imbalances with a massive amount of data.

Fig. 1 depicts the compatibility flow of classifiers depending upon the type of massive and streamed data. It shows that traditional classifiers are best suitable for balanced datasets [15,16] and Random Forest Classifier is best suitable for imbalanced data applications [24].

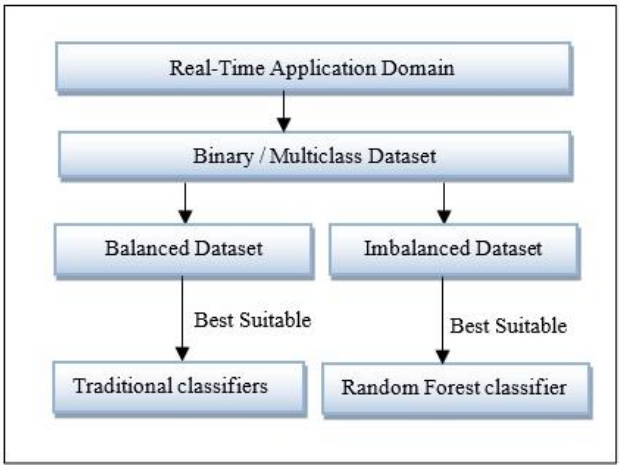

Fig. 1. Data Types and Suitability of Classifier.

B. Binary and Multiclass Imbalanced Application Domains

There is a list of numerous numbers of imbalanced applications which belong to class types as either binary imbalance or multiclass imbalance [17]. Table I nominates a list of selected applications with data domain analysis and categorization as binary, multiclass, or of both binary and multiclass imbalance. Binary classification techniques are the most progressive technique to deal with several applications such as medical diagnosis, and fault-finding activities in various business domains which always put forth the statistical results either belonging to one category of data or belonging to a second category [18,19,20].

TABLE I. Imbalance Applications with Domain and Category [11-22]

Sample Application		**Imbalance Category**
Diagnosis of cancer-infected patients and patient categorizing	Medical	Binary and Multiclass
Detection of an error occurring in code blocks in software projects	Software development	Binary class
Analyzing the count of faulty machines in industries	Industrial monitoring	Binary class
Multi-dimensional image categorization in various smart city applications	Hyperspectral image processing	Multiclass
Recognition of actions sequences and objects in videos	Mining of video	Binary and multiclass
Analyzing normal and dangerous actions	Action analysis	Binary class
Target specified classification with defined and varied frequency	Targeted classification domain	Multiclass
Analysis of literature relations in text	Mining of text	Binary class
Occurrence of frequent and rare activities in various domains	Activity recognition	Imbalance Multiclass
Recognition of annoyance and sentiment in text	Sentiment analysis	Binary and multiclass
Detection of normal and fraudulent transactions	Finance	Binary class
Categorization of deceptive and ordinary calls	Telecommunication	Binary class

To deal with the classification analysis of these binary and multiclass imbalance data applications, numerous approaches are discussed in the upcoming sections. Data imbalance approaches works at different data level or algorithmic level. At the data level based on the nature of the data, the approaches are categorized [23]. Table I summarizes selected applications, related application domains, and class categories.

III. Related Work

A. Existing Sampling Approaches

Sampling techniques are used to balance distorted data distribution Fig. 2 depicts categories of probability and non-probability sampling techniques [24].

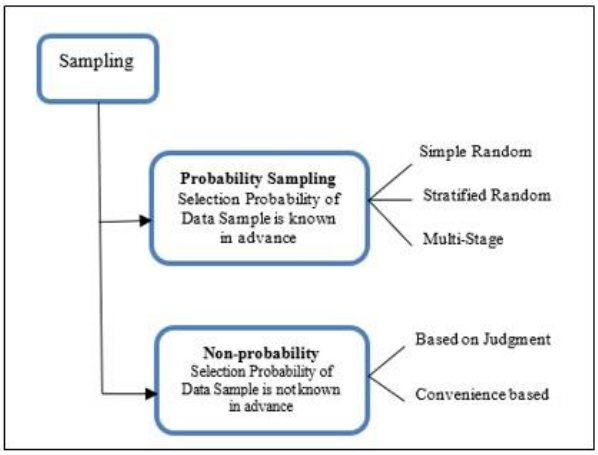

Fig. 2. Probability-based Sampling Strategies.

Both strategies have different sampling approaches to balance the dataset. Table II indicates the simple random sampling techniques steps [22], [23].

TABLE II. SIMPLE RANDOM SAMPLING ALGORITHMIC STEPS

Input: Imbalance data of sample size X provided	
Step:1	Take input as an imbalanced data set.
Steps:2	Distribution of dataset into x number of subsets with equal selection probability.

Table III indicates the stratified random sampling techniques steps [24].

TABLE III. STRATIFIED RANDOM SAMPLING ALGORITHMIC STEPS

Input: Imbalance data of sample size X provided	
Step:1	Take input as an imbalanced Data Set.
Step:2	Dataset distribution into "Strata".
Step:3	From each stratum select x as any random data sample.
Step:4	Merge the stratum x into the overall data sample.

Sample Case:

Game X has a team of 600 girl participants and 400 boy participant members. For applying a 30-number stratified random sample there is a need to select 12 boy participants from 400 and 18 girl participants from the overall count of 600 participants [25].

Table IV indicates the multistage sampling techniques steps.

TABLE IV. MULTI-STAGE SAMPLING ALGORITHMIC STEPS

Input: Imbalance data of sample size X provided	
Step:1	Take input as an imbalance data Set.
Step:2	Stage I sampling is based on one data attribute as selection criteria for all data samples provided in the data set.
Step:3	Stage II sampling is based on another data attribute as selection criteria for all data samples.

Sample case: Compilation of region-wise voters list based on numerous attributes like city, gender, etc. [26,27].

IV. PROPOSED ALGORITHM AND EXPERIMENTATION

This section of the paper deals with the evolution of the proposed algorithm Improvised Dynamic Binary-Multiclass Imbalanced Oversampling Rate (IDBMORate) to balance the imbalance ratio for both the category that is binary as well as multiple classes. The proposed algorithm targets the aim of oversampling minority data sample classes.

TABLE V. PROPOSED ALGORITHM

Algorithm: IDBMIORate	
	Input: Total # of Classes *C*, Distribution *D* Original Imbalanced Dataset *S*
	Output: Oversampling Rate of minority Class
Step 1	Calculate *n_min* through *D*
Step 2	*n_max = len(D)*
Step 3	Assign N= *S*
Step 4	*max = math. Ceil((n_max*(len(c)-1))/n_min)*
Step 5	Declare D, i=0, Declare N
Step 6	*while i < max*
Step 7	*Total samples = len(_N)*
Step 8	*Samples in min Sample Class=min(_D)* *pmin* =Calculate current ratio of minimum samples if (pmin < *(2/(3*lenI-1))) then* *current_min_class = sort_ values_D*
Step 9	End if Update Values of *_D and _N* *S[Class] = = current_min_class*
Step 10	._N = *append(samples_in_original_data)*
Step 11	_D = *sort_values(_N['Class']).*
Step 12	Update value of *i =i+1*
Step 13	Compute IOrate = _D – D
Step 14	*data = IOrate Data (IOrate, _N)*
Step 15	return *IOrate*

IDBMORate is successfully targeting data rescaling, selection of data, the invention of extra data, and transformation of data. The proposed algorithm deals with the dynamic approach of oversampling rate calculation.

Table V deals with the proposed IDBMIORate algorithm and Table VI deals with the related terminology.

Table VII deals with the data distribution of referred dataset.

TABLE VI. TERMINOLOGY USED FOR PROPOSED ALGORITHM

Key Term	**Specifications**
S	Original Imbalanced Dataset
C	Total number of Classes
N	Number of Total Data Sample Dataset
D	Data Distribution
n_{Min}	Number of Minority instance data Sample
n_{Max}	Count of Minority instance data Sample
RFC	Random Forest Classification

TABLE VII. DATA DISTRIBUTION SUMMARY

Dataset [28]	Total # of Instances	Imbalanced Category	# Data distribution according to classes
Page-blocks	5472	Binary	Positive 4913 Negative 559
Ecoli	336	Multiclass	cp 143, im 77, pp 52, imU 35, om 20, omL 5, imS 2, imL 2

A. Experimental Analysis of IDBMORate for Binary Datasets

For the Proposed Algorithm IDBMORate the experimentation has been carried out in Python Programming Platform for binary Dataset. Execution on Binary Imbalanced Dataset -1 is set Page-blocks with Random Forest Classification Model Total Data size: 5472.

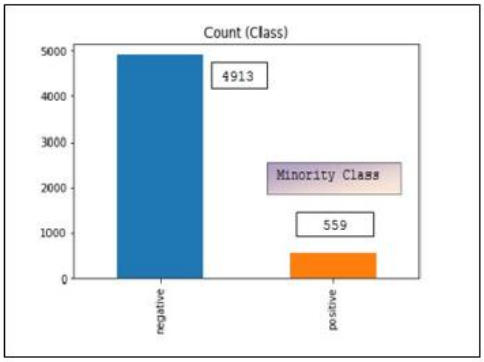

Fig. 3. Result before Sampling – Page-Block Dataset.

Fig. 3 specifies the distribution of class labels before sampling for class negative is 4913 and for class for the positive class are 559. Result after Sampling through IDBMIORate is as depicted in Fig. 4.

Fig. 5 deals with classification result of Page-block dataset with the proposed algorithm

Table VIII deals with the classification performance metrics of the proposed algorithm with RFC for the page block binary dataset.

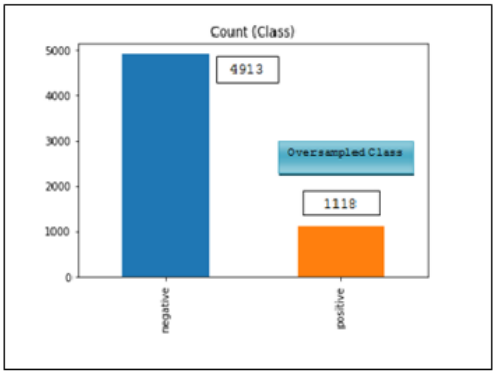

Fig. 4. Result with a Proposed Algorithm – Page-Block Dataset.

Fig. 8 depicts the multiclass classification result with the proposed novel sampling approach. Precision, Recall, F1 Score, and support parameters are used for measuring the classification performance for both page block (binary) and Ecoli (Multiclass) dataset.

TABLE IX. PERFORMANCE METRICS WITH A PROPOSED ALGORITHM FOR MULTICLASS-ECOLI DATASET

Performance Parameters / Class	Precision	Recall	F1- Score	Support
cp	0.96	1.00	0.98	44
im	0.81	0.96	0.88	26
imL	1.00	1.00	1.00	4
imS	1.00	0.50	0.67	8
imU	1.00	0.78	0.88	9
om	1.00	0.93	0.96	14
omL	1.00	1.00	1.00	7

Table IX shows the RFC classification result with the proposed oversampling rate algorithm to compute the effectiveness of the proposed algorithm.

V. CONCLUSION AND FUTURE WORK

This research work addressed binary and multiclass imbalanced application domains, associated problems, and approaches to dissolve data imbalance dynamically. The proposed algorithm Improvised Dynamic Binary-Multiclass Imbalanced Oversampling Rate (IDBMORate) balances the minority classes without affecting the majority class which minimizes the cost of computation. Experimentation analysis on dataset page block and Ecoli has been carried out. IDBMORate algorithm overcomes the problem of the generation of extreme synthetic data samples for the minority classes, which leads to improved classification accuracy with the Random Forest Classification Model. Experimental analysis shows that IDBMORate efficiently outperforms the existing oversampling techniques for both binary as well as Multiclass imbalanced real-life scenarios. (IDBMORate) balances the minority classes without affecting the majority class which minimizes the cost of computation. The Proposed algorithms Improvised Dynamic Binary-Multiclass Imbalanced Oversampling Rate proposed algorithm which shows improvised results for both binary as well as multiclass DATA. THE hybrid sampling method will be focused in the future to upgrade the performance. The more dynamic method can be focused to work in a distributed environment.

Predicting Malicious Software in IoT Environment Based on Machine Learning and Data Mining Techniques

Abdulmohsen Alharbi, Md. Abdul Hamid, Husam Lahza
Department of Information Technology
Faculty of Computing and Information Technology
King Abdulaziz University, Jeddah 21589, Saudi Arabia

***Abstract*—The Internet of Things (IoT) enable the IoT to sense and respond using the power of computing to autonomously come up with the best solutions for any industry today. However, Internet of Things have vulnerabilities since it can be hacked by cybercriminals. The cybercriminals know where the IoT vulnerabilities are, such as unsecured update mechanisms and malware (Malicious Software) to attack the IoT devices. The recently posted IoT-23 dataset based on several IoT devices such as Philips Hue, Amazon Echo devices and Somfy door lock were used for machine learning classification algorithms and data mining techniques with training and testing for predictive modelling of a variety of malware attacks like Distributed Denial of Service (DDoS), Command and Control (C&C) and various IoT botnets like Mirai and Okiru. This paper aims to develop predictive modeling that will predict malicious software to protect IoT and reduce vulnerabilities by using machine learning and data mining techniques. We collected, analyzed and processed benign and several of malicious software in IoT network traffic. Malware prediction is crucial in maintaining IoT devices' safety and security from cybercriminals' activities. Furthermore, the Principal Component Analysis (PCA) method was applied to determine the important features of IoT-23. In addition, this study compared with previous studies that used the IoT-23 dataset in terms of accuracy rate and other metrics. Experiments show that Random Forest (RF) classifier achieved the predictive model produced classification accuracy 0.9714% as well as predict 8754 samples with various types of malware and obtained 0.9644% of Area Under Curve (AUC) which outperforms several bassline machine learning classification models.**

***Keywords*—Machine learning; internet of things; malware; predictive modeling; cyber threats**

I. INTRODUCTION

The Internet of Things are internet-connected devices that can transfer data over a network. Nowadays lots of cyber-attacks have increased, the cybercriminals seek to exploit or damage data, disrupt computer devices and network resources. The term cyber generally, defines computer devices, network, internet and information technology. [1] Cyber threat is a possibility to successful cyber-attack that aims to harm computer system or network, steal sensitive data and gain unauthorized access. However, the IoT are vulnerable in terms of security; cybercriminals use malware attacks such as DDoS, ransomware, and IoT botnet attack to disable systems and networks. Study by Gotsev et al. [2] used different machine learning models to evaluate the performance of Machine Learning (ML) for attack detection.

The researchers used all the features of IoT-23 dataset [3] which has 21 features and they detected different types of malware attack on IoT devices such as DDoS, Okiru, HorizontalPortScan and other IoT botnets. Similar study by Nicolas Stoian [4] focused on the security aspect of the IoT by investigating the usability of ML approaches on anomaly detection. In the research, the dataset has been split into 80% for training and 20% for testing for each ML algorithms. In results, the best ML algorithm is Random Forest with a weighted average precision of 100%.

Chunduri et al. [5] used multi class classification to detect IoT botnet malware. Their aim is to build a classifier to detect IoT botnet attack and to get the best accuracy possible by using machine learning classifiers. They have used Network Traffic Analysis Tool (Zeek) [6] that monitors all the traffic on network for malicious activity. The PCA method was applied to minimize features and maximize the accuracy rate by using ML classification algorithms such as Decision Tree (DT) K-Nearest Neighbors (KNN), Support Vector Machine (SVM) and Naïve Bayes (NB). The traditional approaches using static analysis method is complicated in terms of examining malicious software that exposes IoT to security breach risks. Therefore, it is important to improve the method by utilizing machine learning and data mining techniques to make it safer and more effective in predicting malicious software in IoT network traffic.

In this research the IoT-23 dataset [3] was used and collected, analyzed, processed to predict benign and several of malicious software in IoT network traffic. Furthermore, in results for prediction models, RF algorithm achieved highest accuracy for predicting malicious and benign in IoT network traffic. Section II is about background of cyber threats, the literature review is reviewed in Section III, Section IV is methodology, Section V describes performance evaluation of ML classification algorithms, Section VI describes experiments and results for validation of predictive models of malicious and benign in IoT network traffic and Section VII is about discussion of the results.

A. Problem Statement

Cybercriminals use malware attacks on IoT devices to hack and disable IoT devices. The attacks make IoT devices less efficient and cybercriminals can steal sensitive information and personal data. The cybercriminals know where the vulnerabilities of IoT devices are and exploit them through malware attacks on the devices. The existing studies focus on detecting threats and ignore the significance of predicting malware threats that increase IoT devices' vulnerabilities. Moreover, none of the studies included malicious software as a threat to security in IoT devices. The studies have focused on end-to-end devices or attack surfaces. This research aims to predict malicious software in IoT network traffic in order to protect IoT devices and reduce vulnerabilities by using ML and data mining techniques.

B. Importance of this Research

The harmful effects of malware into IoT environment are exposure of IoT to security breach risks and stealing of sensitive information and personal data. Therefore, we collected, analyzed and processed benign and several of malicious software in IoT network traffic of IoT-23 dataset [3]. Four types of malicious software were chosen out of IoT-23 and we considered those that have more significant effect on the IoT devices, which are DDoS, C&C and various botnets like Mirai and Okiru. Types of IoT devices in IoT-23 dataset are Echo device, Hue device and door lock device. It is extremely important to predict malware in IoT network traffic in order to protect IoT devices and reduce vulnerabilities by increasing the security level for IoT devices and to improve the environment and make it more motivational. This research will be using machine learning and data mining techniques to make it safer and more effective in predicting malicious software in IoT network traffic.

Our contributions in this work are:

- Minimize features and maximize the accuracy rate by using PCA method and ML classification algorithms.
- Propose prediction model to predict malicious and benign in IoT network traffic by using supervised learning.
- Increasing the security level for IoT to improve the environment and make it more motivational.

II. Background

This section provides related background information and context to explain the objectives and relevant field of research of this work. The concept, types, and IoT network activities of malicious software and botnet are discussed. Then, the concept of cybercriminals using malware attack is addressed. Finally, the most important malware attack that cause security risks on IoT environment is introduced.

A. Cyber Threats

Nowadays lot of cyber-attacks have increased, the cybercriminals seek to exploit or damage data, disrupt computer devices and network resources. The term cyber generally, defines computer devices, network, internet and information technology [7]. Cyber-attack attribution is technique that tracks, identifies, and lays blame on the criminal of a cyber-attack or other hacking exploit. Cyberspace is the environment of the internet that involving a global of computer network or the internet to enable communications and data exchange activities. Cyber Threat Intelligence (CTI) generally is relying on the collection of information and its analysis with current or potential attacks that is threatening policy of the organizations [8]. Cybercriminals can be internal or external to the organization that is facing cyberattack. An attack on the computer devices, network or system performed by person who has authorization access is known as an insider attack. An attack that originates exposures from outside the organization and attempt to exploit IT equipment are known as external attacks [1]. Cyber threat is possibility to successful cyber-attack that aims to harm computer system or network, steal sensitive data and gain unauthorized access. Some top cyber threats are illustrated as following [9] [10] [11] [12] [13]:

B. Malware (Malicious Software)

Malware is computer code designed to disrupt and disable such as stealing sensitive data or taking control of computer system. Malware (Malicious Software) has remained the most common cyber threats since 2014. Approximately four million samples of malware on different devices are detected by security organizations in 2017. The increase of malware samples have escalated malware attacks.

C. Ransomware Attack

Ransomware is a type of malware, which restricts access to user files or a computer system till the victim pays a ransom. Ransomware is significant cybersecurity threat since it uses techniques to avoid detection system to attack legitimate users. Ransomware can be considered a part of malware and it has been evaluated as a separate threat, although it belongs to the malware category. Moreover, Ransomware is considered the most significant cyber-attacks nowadays.

D. Distributed Denial of Service (DDoS) Attack

It is a cyber-attack which is an attempt to compromise the availability of computer devices or network resources to make them unavailable to the legitimate or normal users. DDoS attack is aimed to send massive amount of superfluous requests in order to deny the server from responding to the valid requests immediately. Denial of Service (DoS) attack can damage the target that rely on an online presence, while DDoS attack strikes a target with several resources and is harder to stop DDoS attack.

E. Cyber Espionage

It is type of cyber-attack which is an act of obtaining confidential information without permission from the user of the information for economic, political, military or personal objectives. It includes utilization of the internet or a computer network over utilized proxy server, malicious software including Trojan horse and spyware. The targets of this attack are government and commercial sectors. Cybercriminals develop new tools and techniques to increase the number of attacks and the degree of damage caused to its victims.

F. IoT Botnet Attack

The Internet of Things (IoT) bot is a variant of a traditional botnet that contains a group of compromised computers, smart devices and sensors connected to the internet. IoT botnet attack is used by cybercriminals for causing damage such as financial and for illegitimate purposes in terms of control of malicious actors. Over 41% of all attacks are due to the vulnerabilities of the IoT devices and IoT botnet attack contribute approximately 13% total of attacks in various other information technology industries.

III. Related Work

Study by Gotsev et al. [2] used different machine learning models to evaluate the performance of ML for attack detection. They applied various ML classifiers such as Support Vector Machine, Random Forrest Naïve Bayes, Logistic Regression and Decision Tree. In the experiments, the researchers used all feature of IoT-23 dataset [3] which has 21 features. Furthermore, IoT-23 dataset contains labeled information of benign and malicious IoT network traffic. They detected different types of malware attack on IoT devices such as DDoS, Okiru, HorizontalPortScan and other. In testing results, DT and RF achieved highest accuracy detection which was 1.00% and LR classifier achieved 0.76% accuracy, SVM achieved 0.74% accuracy, while NB classifier had unsatisfied result and achieved 58% accuracy.

Similar study by Nicolas Stoian [4] focused on the security aspect of Internet of Things networks by investigating the usability of ML approaches of anomaly detection. The researcher used 14 features of IoT-23 dataset and applied statistical correlation to dataset in order to eliminate the data which was irrelevant to the label column. Furthermore, the research splitting the dataset into 80% for training and 20% for testing for each ML algorithms. In results, the best ML algorithm is Random Forest with a weighted average precision of 100%, another algorithm is AdaBoost with precision of 86% while Support Vector Machine has precision of 60% and Naïve Bayes with a weighted average precision of 76% Chunduri et al. [5] used multi class classification to detect IoT botnet malware. Their aim is to build a classifier to detect IoT botnet attack and to get the best accuracy possible by using machine learning classifiers. The researcher used IoT-23 dataset [3] which contains benign and malicious network traffic of IoT devices. They focused on six types of botnet attack which are Mirai, Bashlite, Torii, Hakai, Okiru and Muhstik, moreover they used Zeek (Network Traffic Analysis Tool) [6] that monitors all the traffic on network for malicious activity. Furthermore, the researchers selected 12 features of IoT-23 dataset; in results they applied ML classifiers to training and testing IoT-23 dataset. The best accuracy was achieved by RF 99.88%, GradientBoosting produced 99.36% and K-Nearest Neighbors achieved 96.14% while Support Vector Machine with 94.72% can be considered the least fit model. In study by Strecker et al. [14], the researchers compared the effectiveness machine learning classifiers based cyber security techniques on the IoT-23 dataset. They used seven features of the IoT-23 dataset and applied RF, SVM and KNN algorithms for IoT cyber security in 2021. Their result for malware detection, the highest accuracy is of RF 92.27%, the second-best accuracy is KNN 89.80% and SVM achieved 83.52%. In 2018, Mirsky et al. [15] built an Intrusion Detection System (IDS) with autoencoders for detection of online anomaly called Kitsune. The researchers have developed attribute extractor that consists in the following attribute categories which are Socket, Network Jitter, Host-MAC&IP and Channel. They have demonstrated on their results anomaly detection of Mirai botnet malware on IoT devices. In 2018, Meidan et al. [16] introduced a dataset called N-BaIoT for Bashlite and Mirai botnet malware that considering as Kitsune [17] attributes which have been implemented on nine different IoT devices. Ferrag et al. [18] have investigated the way seven contemporary Artificial Neural Networks (ANN) approaches perform training of the CICIDS-2018 and the BoT-IoT datasets. They have provided the details on overall accuracy, training time by using Deep Learning (DL) detection rate.

Potluri et al. [19] evaluates a Convolutional Neural Network (CNN) based network intrusion detection techniques. They used the NSL-KDD and the UNSW-NB15 datasets. These datasets are converted into an image such as format as part of the process. The researchers build the three layers of CNN to label for the attacks. The study is compared the GoogLeNet and ResNet50 with designed CNN approach that achieved the satisfying results, with accuracy rate achieved 91.14% on the NSL-KDD dataset and 94.9% on the UNSW-NB15 dataset. De La Torre Parra et al. [20] proposed a method for detecting attacks at the back-side and client end at the same time. The client's site uses a CNN model with micro security for the detection of DDoS, botnets, and phishing attacks. The authors designed a joint training method for minimizing the resource utilization for detection of attacks in IoT devices and maximized the usability of extracted features for using the back-end server. The scope of the study is limited to using the CNN model for detecting URL-based attacks aimed at the client's IoT device and the RNN–LTSM model at the back-end server for the detection of malware attacks.

The focus of the study by Pastor et al. [21] is to provide measures for the detection of these malwares using passive network-based monitoring. Network flow features were identified for this purpose according to relevancy, and they were used with deep learning models and machine learning models. The researchers used some algorithms i.e. C4.5 Random Forest (RF) and Deep Neural Networks (DNN) to compare their performance. The main aim was to monitor crypto mining and the detection of real-time flow. This was done through testing these models in complex scenarios using real servers and connections that were encrypted. Various features were employed to demonstrate the efficiency of these models against crypto mining.

Study by Li et al. [22] focused on Command and Control (C2) server that is employed by using a Domain Generation Algorithm (DGA) in order to generate communication between C2 and malware. This cannot be easily countered by using traditional methods like blacklisting. The researchers provide the framework of machine learning in order to deal with these threats. Real-time data were collected for one year using real traffic, and a deep learning model was proposed for

the classification of domains of DGA. Results showed an accuracy of 95.89%, 97.79%, 92.45% and 95.21% for framework classification, DNN model, clustering at the second level and HMM prediction, respectively.

The study by Sarker [23] presented the Cyberlearning for binary classification model in order to detect anomalies and classification of multi-class model of cyber-attacks. Features that are correlated to this were selected for an analysis of comprehensive nature. The empirical data on the effectiveness of this model was analyzed. This model takes the binary classification into account for evaluating the effectiveness in detecting anomalies and other cyber-attacks. The techniques for machine learning were employed. For the hidden layers, a security model that is based on an artificial neural network was presented, and the effectiveness for these was evaluated using various techniques. Security datasets NSL-KDD and UNSW-NB15 were examined to employ an experimental analysis. The findings were believed to provide a good reference to future research in the same field.

Another study by Li et al. [24] used a detection system called Significant Permission IDentification (SigPID). This system is designed with three levels without extracting the usage of Android permissions. These levels include pruning permission data to identify malicious apps and then classifying those malwares using only 22 significant permissions. These permissions are then compared with the baseline approach, and the final outcomes indicates the precision of up to 90% in F-measure, accuracy and recall as well. Their dataset contains 2000 malware and the SigPID is determined to have an effectiveness of 93.62 in the detection of dataset malware and effectiveness of 91.4% in detecting unknown malware. The researcher by Karanja et al. [25] used a novel approach towards analyzing and classifying malware. This is done using texture features and classical classifiers of machine learning that apply to the IoT malware. A low computation approach was employed by converting the malware binaries into images. This broke the environmental dependencies and platform barriers, considering the analysis of images is not limited to platforms. A 95% and 88% accuracy were achieved through a K-nearest neighbor and random forest classifier. The results showed that this method is applicable for real-time settings and can be employed for flagging off known IoT malware using preprocessed features of the image in known malware. D. Li and Q. Li [26] used a mixture of attacks that use multiple generative methods and yield adversarial malware with multiple manipulation sets. The adversarial training is used with a manipulated set with large cardinality. The robustness of malicious software detection against twenty-six evasion attacks is based on five methods using gradient-based, gradient-free, obfuscation, a mixture of attacks, and transfer the attack. The proposed methods improved the performance, but more research is required in the area of adversarial malware detection.

A. Data Mining Techniques

Data mining approaches in Internet of Things (IoT) systems are integrated to discover in terms of a range of well-established knowledge patterns such as supervised, unsupervised, semi-supervised, and statistical approaches. These data mining approaches enable classification, prediction and regression of upcoming streaming data to be able to be visualizing the knowledge and activate the sensors and actuators of the IoT systems. Numerous crucial data mining techniques are illustrated as following [27] [28] [29] [30]:

B. Classification

Classification in data mining is a popular technique that splits data points into various classes which assigns items in a collection to target categories or classes. It allows to organize dataset of all types, including complicated and massive dataset as well as small and simple ones.

C. Regression

Regression is a type of data mining technique utilized to predict numeric values given in a particular part of dataset. The most popular types of regression are linear and logistic regressions algorithms of machine learning. Furthermore, other types of regression can be performed depending on their performance on an individual dataset.

D. Prediction

Prediction in data mining is to predict the unknown values or outcomes. Prediction techniques in data mining discovers the correlation among dependent and independent variables and the correlation between independent variables. It predicts the identity of single variable based on the current description of some other related variable.

IV. Methodology

In methodology section, the author will show the chosen techniques and tools to implement the approach for predicting malicious and benign IoT network traffic by using machine learning and data mining techniques. Furthermore, The IoT dataset-23 was selected which has a labeled malicious and benign on IoT network traffic. In addition, data preprocessing was applied and used Principal Component Analysis (PCA) method for feature selection to make it suitable for a machine learning model. To achieve the goals of building a usable supervised machine learning model for predicting malicious and benign IoT network traffic, this research will be applying IoT-23 dataset [3] targeting Weka tools [31] for ML model and data Orange tools [32] for data mining techniques.

A. IoT Dataset Selection

A large dataset IoT-23 published in January 2020 [3] has been identified. IoT-23 consists of a labeled dataset with malicious and benign IoT network traffic, types of IoT devices in IoT-23 dataset i.e. Echo device, Hue device and door lock device. The IoT-23 dataset created by the Avast AIC (Artificial Intelligence and Cybersecurity) laboratory which is help for researchers to develop machine learning algorithms. IoT-23 dataset has twenty malicious captures executed from different IoT devices, in which 11 malware labels and one benign label have existed in IoT network traffic. Four types of malicious software have been chosen of IoT-23 and we consider those that have more significant effect on the IoT devices, which are DDoS, C&C and various botnets like Mirai and Okiru. Fig. 1 shows distribution of main labeled after preprocessing on IoT-23 dataset.

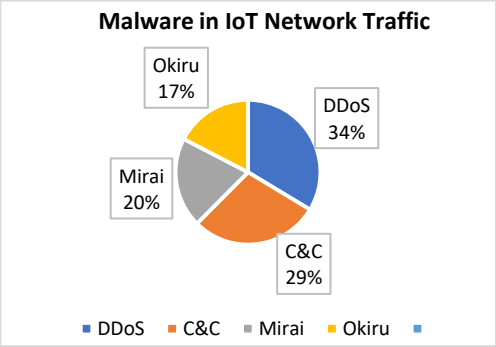

Fig. 1. Distribution of Main Labeled IoT-23 Dataset.

B. Feature Selection IoT-23 Dataset

After preprocessing IoT-23 dataset [3] the Principal Component Analysis (PCA) method was applied for feature selection. The IoT-23 dataset has 21 features and Weka tools [31] was used since it supports PCA method. After using PCA method, the IoT-23 dataset reduced to 18 features. The purpose of using PCA method is to find set of variables on IoT-23 dataset with less redundancy. Fig. 2 shows the main stages for feature selection using PCA method.

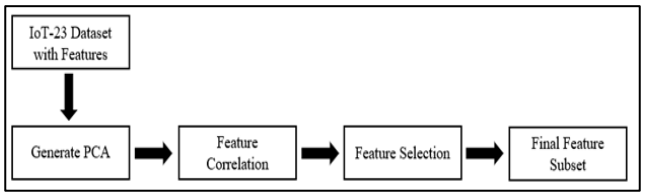

Fig. 2. Main Stages of the Feature Selection by PCA Method.

C. Principal Component Analysis

The PCA method was used for reducing the features of IoT-23 dataset. We eliminated these least important features for feature selection but do not lose original dataset completely. PCA method helps us to identify patterns in data of IoT-23 dataset based on the correlation among features. Furthermore, PCA method improved machine learning classification algorithms performance, removed correlated features and reduced overfitting by removing the unnecessary features in the IoT-23 dataset, which leads to minimizing features and maximizing the accuracy rate by using ML classification algorithms.

D. Supervised ML Models used for Prediction

In this research, the supervised learning model was used in terms of getting trained on a labelled dataset. A labelled IoT-23 dataset has two classes 0 and 1. 0 refers to benign while 1 refers to malicious, as binary classification we are predicting one of two classes in terms to know which features are malicious and benign of IoT network traffic. Fig. 3 shows prediction model for malicious and benign.

E. Weka Tools

Weka tools [31] is collection of machine learning algorithms for data mining tasks. It contains tools for data preprocessing, classification, clustering, regression and more. It is considered as an efficient tool for ML and data mining since it supports unsupervised and supervised ML algorithms.

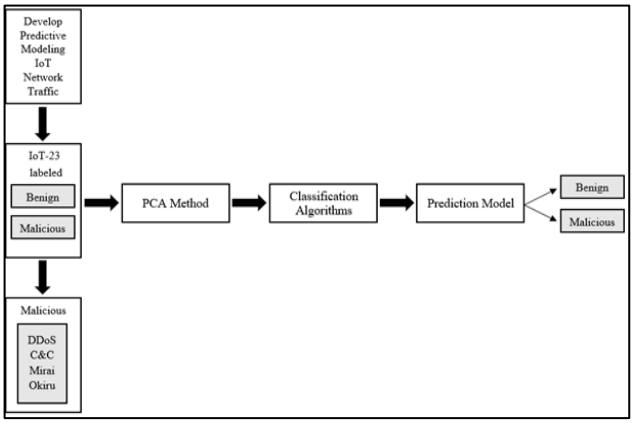

Fig. 3. Proposed Prediction Model.

F. Orange Tools

Orange tools [32] is an open-source platform to perform data analysis, machine learning and data mining Python scripting or visual programming. It contains prediction model that can predict the future based on previous attitude that happened before.

G. Classification Algorithms used in ML

Machine learning supervision was applied to train on a labelled IoT-23 dataset. A labelled dataset has two classes 0 and 1; 0 is benign and 1 is malicious. The labeled dataset is targeting to predict a packet which is malicious or benign. Furthermore, ML classification algorithms are applied since the labelled IoT-23 data has two classes. ML classification algorithms were used i.e. DT, RF, KNN, SVM and NB algorithms for prediction malicious and benign of IoT network traffic. Fig. 4 shows supervised ML classification algorithms used.

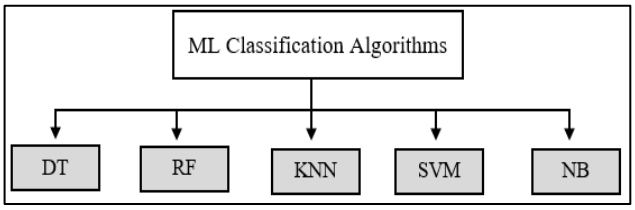

Fig. 4. Classification Algorithms used for Predication.

H. Training and Testing

For training and testing, the IoT-23 dataset was split into 70% for training and 30% for testing and 10-fold cross validation, to make it suitable for a machine learning models. Training or testing data is an approach to measure the accuracy of ML model. Moreover, machine learning classification algorithms were applied for training and testing model of ML.

V. Performance Evaluation

After training and validating ML models, some metrics are needed to identify the best model from a set of ML models. Our model of ML was developed to provide accurate prediction. Confusion matrix and evaluation metrics for classification model are used for predicting malicious and benign IoT network traffic. Additionally, four metrics used to

evaluate classification ML model which are accuracy, precision, recall and F1-score.

- **Accuracy** = $\frac{(TP+TN)}{(TP+FP+TN+FN)}$
- **Precision** = $\frac{TP}{(TP+FP)}$
- **Recall** = $\frac{TP}{(TP+FN)}$
- **F1-Score** = $\frac{2*(Precision*Recall)}{(Precision+Recall)}$

A. Confusion Matrix Model

Confusion Matrix Model (CMM) [33] [34] [35] [36] is applied to understand the performance of True Positive (TP), False Positive (FP), False Negative (FN) and True Negative (TN). Furthermore, CMM is used to describe the performance of the classifier model of test data for which the true values are known. Confusion matrix was applied for prediction malicious and benign as shown in Table I.

TABLE I. CONFUSION MATRIX

Confusion Matrix	Predicted Class: Benign	Predicted Class: Malicious
Actual Class: Benign	True Positive (TP)	False Negative (FN)
Actual Class: Malicious	False Positive (FP)	True Negative (TN)

B. Receiver Operating Characteristic (ROC) Curve

Receiver Operating Characteristic (ROC) curve was applied to show in a graphical way the trade-off between clinical sensitivity and specificity. The x-axis is false positive rate and the y-axis is true positive rate. Two metrics used to evaluate a ROC curve, Area Under the Curve (AUC) if equals 0.70% the model will be able to distinguish between true positive class and false positive class.

- **Sensitivity** = $\frac{TP}{(TP+FN)}$
- **Specificity** = $\frac{TN}{(TN+FP)}$

VI. EXPERIMENTS AND RESULTS

In the experiments, will present the results of the predicting malicious and benign of IoT network traffic by using various supervised machine learning classification algorithms. Four types of malicious software have predicted for each class which are DDoS, C&C, Mirai and Okiru. Performance model is evaluated using accuracy, precision, recall and F1-score. The IoT-23 dataset has split into 70% for training and 30% for testing and 10-fold cross validation, to make it suitable for a machine learning model. Experiments are done on prepared feature of IoT-23 dataset [3] using ML classification algorithms such as DT, RF, KNN, SVM and NB. This chapter also presents comparison of evaluation metrics for predictive model of the proposed technique with existing studies, for predicting malicious and benign IoT network traffic. The implementation of the ML model by Weka tools [31] and data mining techniques by Orange tools [32].

A. Malicious and Benign of IoT Network Traffic

The performance evaluation is computed using four metrics which are accuracy, precision, recall and F1-score. For training and testing by supervised learning (SL) the number of samples of malicious is 8K samples while benign is 43K samples as shown in Fig. 5 and Fig. 6. ML classification algorithms used i.e. DT, RF, KNN, SVM and NB for validation of malicious and benign in IoT network.

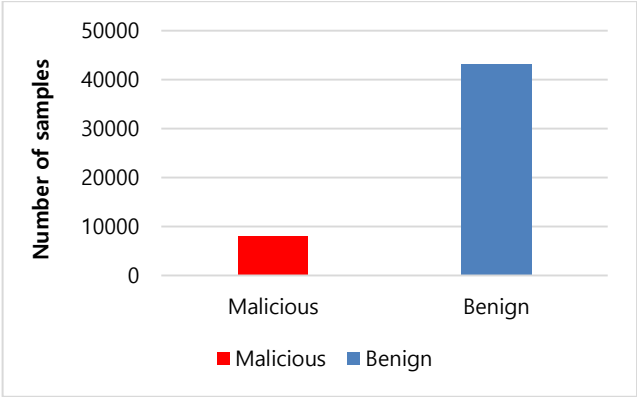

Fig. 5. Number of Samples Malicious and Benign.

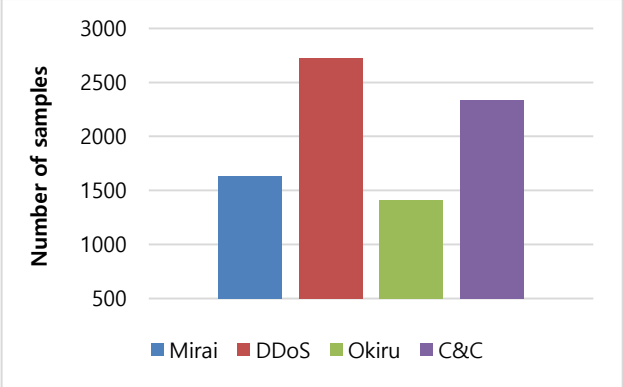

Fig. 6. Number of Samples each Type of Malware.

B. Performance Evaluation of ML Algorithms

Four metrics were applied for evaluating model of machine learning, the best results of ML classifiers algorithms were Random Forest and Support Vector Machine. Other ML algorithms obtained satisfying results, Table II shows performance evaluation of ML algorithms. Fig. 7 shows comparison performance metrics of ML algorithms, Fig. 8 comparison of ML algorithms using True Positive Rate (TPR).

TABLE II. PERFORMANCE EVALUATION OF ML ALGORITHMS

Classifier	Accuracy	Precision	Recall	F-1 Score
DT	0.9567	0.9580	0.9556	0.9553
RF	0.9848	0.9855	0.9850	0.9855
KNN	0.9674	0.9770	0.9773	0.9770
SVM	0.9840	0.9845	0.9850	0.9845
NB	0.9479	0.9668	0.9480	0.9544

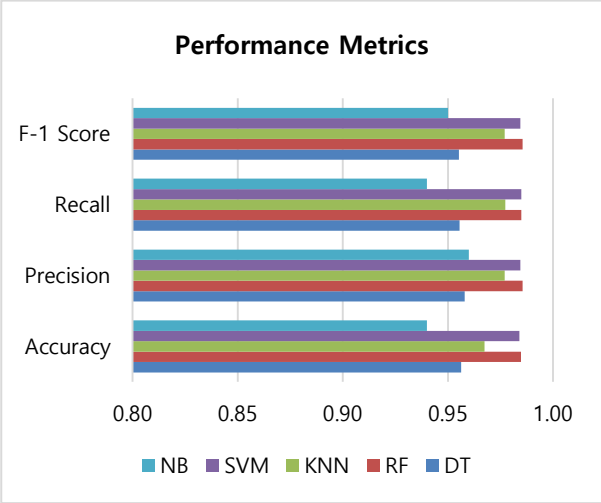

Fig. 7. Comparison Performance Metrics of ML Algorithms.

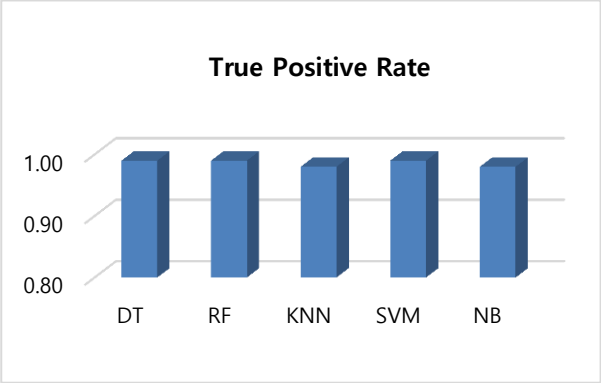

Fig. 8. Comparison of ML Algorithms using TPR.

C. Prediction Model for Malware of IoT Network Traffic

After training and testing ML model by Weka tools [31] Orange tools [32] was used for validating performance in terms of predicting malicious and benign in IoT network traffic. The results show RF algorithm is one the best accurate prediction mehods, this is due to the Classification Accuracy (CA) achieved 0.9714% while SVM algorithm obtained 0.7284% and we consider it obtained an inaccurate prediction, DT algorithm achieved 0.9141%, KNN obtained 0.9378% and NB obtained 0.8455%. As shown in Table III the number of samples for predicting malicious and benign in IoT network traffic. Fig. 9 shows a comparison of ML classifiers for predictive model accuracy.

TABLE III. VALIDATION A PREDICTION MODEL OF ML CLASSIFIERS

Classifier	Malicious	Benign
DT	12420	38854
RF	8754	42520
KNN	10733	40541
SVM	30753	20521
NB	21861	29413

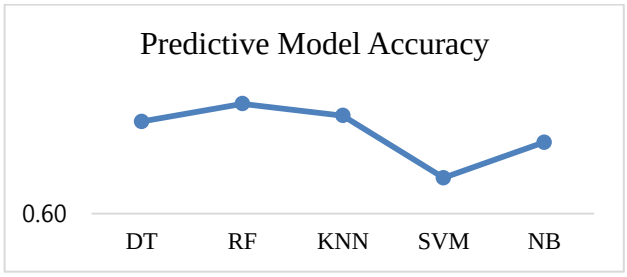

Fig. 9. ML Classifiers for Predictive Model Accuracy.

D. The Important Features for PCA Data Analysis

In Weka tools [31] Principal Component Analysis was used to reduce the features of the IoT-23 dataset [3]. We eliminate these least important features for feature selection but we do not lose original dataset completely. PCA method helps us to identify patterns in data of IoT-23 dataset based on the correlation among features. Furthermore, PCA method improved machine learning classification algorithms performance, removed correlated features and reduced overfitting by removing the unnecessary features in the IoT-23 dataset, which leads to minimizing features and maximizing the accuracy rate by using ML classification algorithms. PCA method considered the important features of IoT-23 dataset which are Ts, Uid, ID_orig.h, ID_orig.p, ID_resp.h, ID_resp.p, Proto, Service, Duration, Resp_bytes, Conn_state, Local_orig, Local_resp, Missed_bytes, History, Orig_pkts, Resp_pkts and Tunnel_parents. Fig. 10 shows a scatter plot after applied PCA method on IoT-23 dataset.

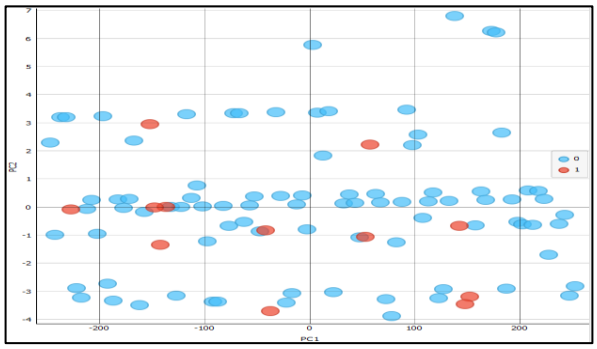

Fig. 10. Scatter Plot of Label IoT-23 Dataset.

E. Comparison with Previous Studies for Evaluating ML Models

The comparison of the machine learning algorithms with existing behavioural-based IoT-23 dataset is showed in Table IV. Gotsev et al. [2] used DT and RF classifiers and achieved 1.00% with four metrics. Nicolas Stoian [4] employed AdaBoost algorithm and it did not perform well as it achieved only 0.87% accuracy. Chunduri et al. [5] used RF and GBM algorithms and obtained highest accuracy rate, RF produced 0.9988% and GBM produced 0.9936%. Strecker et al. [14] obtained of RF classifier 0.9227% accuracy. Our model of ML produced the accuracy 0.9848% using RF classifier. In addition, model of ML achieved satisfied results for all ML classification algorithms with all metrics i.e. AUC, accuracy, precision, recall and f-1 score.

F. Confusion Matrix

After applying different ML classifiers, confusion matrix was applied i.e. True Positive (TP), False Positive (FP), False Negative (FN) and True Negative (TN). The x-axis describes predicted label and the y-axis describes true label. The results show as per DT classifier, 12999 predicted a packet is benign and it actually is, 1712 predicted a packet is malicious and it actually is not, 667 predicted a packet is benign but it actually is not, 4 predicted a packet is malicious but it actually is, as well as the other ML classifiers i.e. RF, KNN, SVM and NB shown in Table V.

VII. Discussion of the Results

The IoT-23 dataset has approximately 160K rows and 21 features from 20 malware traffic captured from different IoT devices i.e. Echo device, Hue device and door lock device in which 11 malware labels and one benign label have existed in IoT network traffic. This study found the RF classifier to be the best performing; produced an AC 0.9714% and AUC achieved 0.9644%. For predicting malicious software over the IoT network traffic, all ML algorithms were predicting well except SVM algorithm this is due to AC produced was 0.7284%. DT algorithm predicted 12420 of malware which predict DDoS C&C, Mirai and Okiru; as well as the other ML algorithms have predicted malware i.e. RF, KNN, SVM and NB. Moreover, PCA method helps to improve ML performance and decrease overfitting by removing the unnecessary features in the IoT-23 dataset in order to improve accuracy rate for prediction. The IoT-23 dataset was split into 70% for training and 30% for testing and 10-fold cross validation, to make it suitable for a machine learning model. This study had two limitations. First, the types of malicious software in the IoT-23 dataset is limited. However, as discussed previously, four types of malicious software have been chosen on the IoT-23 dataset. However, we consider these types of malicious software selected have more significant effect in IoT environment. Second, after applied predictive modelling, malicious software cannot be prevented on the IoT devices. This is because the experiments were performed by machine learning and data mining techniques for predictive modeling without preventing tools for malicious software such as Intrusion Detection System (IDS).

VIII. Conclusion and Future Work

In this research, ML classification algorithms and data mining techniques were used for predictive modeling for validation of prediction of malicious and benign in IoT network traffic. Types of malware and IoT botnet used in this study for predicting are DDoS, C&C and various IoT botnet like Mirai and Okiru. The PCA method was applied to determine the important features of IoT-23 dataset and this study has been compared with previous studies that used the IoT-23 dataset in terms of accuracy rate and other metrics. We achieved better accuracy rate of ML classification i.e. KNN, SVM and NB. The highest accuracy rate for models of ML is RF classifier which produced 0.9844% and SVM classifier produced 0.9840%. For prediction model of malicious and benign in IoT network traffic, RF algorithm obtained the best accurate predictive model and achieved AC 0.9714% and predicted 8754 samples of various types of malware such as DDoS, C&C and various IoT botnet like Mirai and Okiru. In future work, the researchers will extensively understand the behavior of various types of malware attacks in IoT. Furthermore, will study these types of malware attacks against machine learning algorithms-based IDS. Also will investigate and evaluate IDS to prevent malicious software in network traffic.

Power user Data Feature Matching Verification Model based on TSVM Semi-supervised Learning Algorithm

Yakui Zhu*, Rui Zhang, Xiaoxiao Lu
Marketing Service Center, State Grid Hebei Electric Power Co. Ltd, Shijiazhuang, China

***Abstract*—The existing model for identifying user data features based on smart meter data adopts a supervised learning method. Although the model has good identification performance under the condition of sufficient index samples, matching data are difficult to obtain and the marking cost is high in real life. The identification accuracy is significantly reduced when the matching data are insufficient or unavailable in the supervised learning method. In view of the above problems, based on the smart meter data, this paper proposes a feature recognition method for residential user data based on semi-supervised learning, which uses three indicators to evaluate the recognition performance of the proposed semi-supervised learning method for residential user data features and to find the appropriate feature selection method and data acquisition resolution. Then, explore the role of this method in real life when there is insufficient or unavailable matching data. Experimental results show that the performance of the proposed semi-supervised learning algorithm is better than that of the supervised learning algorithm, and the accuracy of the proposed algorithm is better than or close to that of the supervised learning algorithm.**

I. INTRODUCTION

With the continuous development of smart electricity business such as demand response and energy efficiency management, scholars at home and abroad have conducted in-depth exploration and research on the relationship between smart meter data and residential user data characteristics. The characteristic information of residential user data affects the electricity consumption behavior of residents, and conversely, the portrait information of residents can also be identified from their electricity consumption behavior and data [1]. Therefore, the topic of exploring the potential correlation between smart meters and residential user data characteristics is mainly divided into two categories: one is to explore the residential electricity load pattern and analyze how the user data characteristics affect the electricity load type; the other is to identify the residential user data characteristics through the residential electricity load characteristics [2].

The residential load has strong randomness, and the characteristic data of residential users can help power companies to better understand the characteristics of residential peak load and the reasons for changes in electricity consumption behavior. Scholars in China and abroad have done a lot of research on the first type of topic [3]. Wang Yi et al. proposed a new dynamic clustering method for power consumption behavior. Firstly, the symbolic aggregation approximation measure is used for each user to reduce the size of the data set, and the Markov algorithm based on time series is used to establish a dynamic energy consumption model, which converts a large number of load data curves into matrix form. Secondly, the typical power consumption pattern is obtained through the fast clustering algorithm based on the density peak, and then the Kullback Liebler distance is used to evaluate the difference in power consumption behavior, and the users are clustered. The example in this paper verifies the effectiveness of this method [4]. Wang Fei et al. used the density-based clustering algorithm DBSCAN to extract the seasonal typical electricity consumption patterns of each user and used the K-means clustering algorithm to cluster the electricity consumption patterns, and finally used the association rule mining algorithm to explore the potential relationship between the residential electricity consumption pattern and its user data characteristic factors [5]. These works deeply explore the factors affecting the electricity load pattern of users, which can effectively promote the implementation of energy-saving projects. However, these studies need to integrate a large number of user data characteristics, classify and manage users according to specific user data characteristics rather than load patterns, and make some personalized service policies for different types of families, which are more easily accepted and understood by non-professional technicians [6]. Therefore, how to automatically, intelligently, and accurately identify the characteristic information of resident user data has become the core work of the association. In recent years, there are many methods applied to identify the characteristics of residential user data in smart meter data.

In the research of user portrait recognition based on the smart meter data, the key task is to extract and select the features of smart meter data, which directly affects the upper limit of the performance of the user portrait recognition model [7]. In the existing literature, the extraction of smart meter data features is focused on a single domain (single time domain or single frequency domain), which fails to comprehensively analyze the potential rules contained in smart meter data from multiple perspectives [8].

However, the existing models for identifying user data features based on smart meter data all adopt the supervised learning method. Although it achieves good recognition performance when the index sample is sufficient, the recognition accuracy is significantly reduced when the

*Corresponding Author.

matching data is insufficient or unavailable [9]. However, in real life, it is difficult to obtain matching data, the cost is high, and it is time-consuming and labor-intensive. How to save the cost of sample labeling while maintaining good user data feature recognition performance is an urgent problem to be solved [10].

To solve the problems in real life, such as difficulty in obtaining matching data, high cost, time-consuming, and labor-consuming, this paper proposes a feature recognition method of residential user data based on semi-supervised learning based on extracting the time domain and frequency domain features of smart meters. This method can make full use of the potential rules contained in a small number of matching data and a large number of non-index data to explore the relationship between smart meter data and residential user data characteristics and reduce the cost of index marking. In this paper, the effectiveness of semi-supervised learning is verified by the real CER data set, and two main factors affecting the performance of the semi-supervised learning recognition algorithm are analyzed.

The main innovations of this paper are:

1) It decomposes an original average daily power consumption curve by adopting a discrete wavelet transform and extracting frequency domain characteristics;

2) The method of combining time domain and frequency domain features is helpful to improve the accuracy of portrait recognition.

3) The applicability and expansibility of the feature extraction method. Based on the combination of time domain and frequency domain characteristics, the resolution of smart meter data acquisition will have an impact on the results of portrait recognition.

The main contents of the paper are as follows:

1) It introduces the research motivation, background and research status of this paper, and puts forward the solutions to the existing problems.

2) It explains the basic principle of the technical content.

3) The data feature recognition method based on semi-supervised learning is introduced.

4) Through the experimental analysis, the technical advancement and reliability of the research content of this paper are compared and tested.

5) In the conclusion part, the research results of this paper and the future work are summarized.

II. Basic Principles of Semi-supervised Classification

Semi-supervised generative classification algorithms assume that different classes of data are generated by potentially different "sources", and that the samples of each class follow a probability distribution $p(x \mid y;\theta)$, where θ is the parameter of the probability density distribution function [11]. If the samples without index and the samples with index come from the same probability distribution, the samples without index whose index values are inferred can be used as training samples to improve the classification accuracy of the model [12].

The semi-supervised expectation-maximization (EM) algorithm is a typical generative classification model, which assumes that its data distribution conforms to the Gaussian mixture model, and that the data of each class follows the normal distribution [13]. The joint probability density of the sample data and the index can be obtained from the conditional probability density function of the class, as shown in (1).

$$p(x, y \mid \theta) = p(y \mid \theta)\, p(x \mid y, \theta) \tag{1}$$

The parameter vector of the model can be determined according to the samples with and without indicators, which is transformed into solving the optimization problem as shown in (2) [14].

$$\max_{\theta}(\ln p(\{x_i, y_i\}_{i=1}^{l} \mid \theta) + \lambda \ln p(\{x_i, y_i\}_{i=l+1}^{l+u} \mid \theta)) \tag{2}$$

Where, λ is the artificially set parameter. $x_1, x_2, \cdots, x_l$ is the sample with index, and $x_{l+1}, x_{l+2}, \cdots, x_{l+u}$ is the sample without index. The EM algorithm is used to solve this problem. First, a set of parameters is estimated according to the sample with index, and then the expectation is calculated (step E) [15]. The sample without index is marked according to the estimated parameters, and the maximum likelihood estimate is calculated. Maximize the maximum likelihood estimate (M-step) obtained by E-step, re-estimate and update the parameters, and then start the next round of E-step calculation, repeat this EM process until the parameters converge [16].

III. Feature Recognition Method of Residential User Data based on Semi-supervised Learning

A. Overall Methodology Framework

The process of identifying the features of residential user data based on semi-supervised learning algorithm can be divided into three parts, and the overall method framework is shown in Fig. 1.

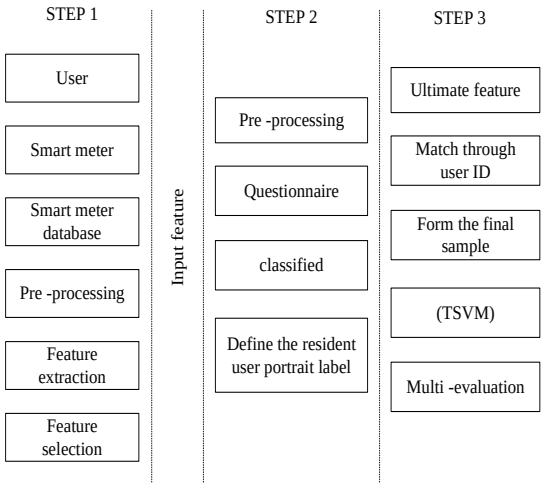

Fig. 1. Overall Method Framework of Resident user Data Feature Recognition Model based on Semi-supervised Learning.

1) First, remove the abnormal values and missing values of the smart meter data, then extract 54 time domain features and 24 frequency domain features. Normalize the features, and finally use the feature selection algorithm to screen the extracted load features, and select the input features of the subsequent identification model according to the importance ranking [17].

2) Sort out the questionnaire data related to user data characteristics, mainly analyze the user data characteristics that have a greater impact on power consumption, and classify and define the classification indicators for each type of user data characteristics according to the answer results of the questionnaire. The classification indicators can be used as real user indicators for the calculation of model performance indicators [18].

3) Match the finally selected smart meter data characteristics with the resident user data characteristic indexes through the user ID to form a final sample set. The semi-supervised learning method is used to train a small number of samples with indicators and a large number of samples without indicators to obtain the user data feature recognition model based on semi-supervised learning. Finally, the performance evaluation index is used to verify the effectiveness of the model [19].

B. Feature Selection

In this paper, three methods are used to select features respectively to facilitate the subsequent verification of the impact of different feature selection methods on semi-supervised learning to identify the features of residential user data.

1) Filtration: For the 78 data features extracted from the CER data set, the filtering method first uses the variance discrimination method, sets the variance threshold, and eliminates the features whose variance is less than the threshold (that is, there is no discrimination) [20]. Then the Pearson correlation coefficient method is used to calculate the Pearson correlation coefficient of the remaining features and the real user data feature identification classification index, and the R most important (i.e., most relevant) features are selected according to the coefficient value ranking [21].

2) Packaging method: For the packaging method, the Recursive Feature Elimination (RFE) method based on Logistic Regression (LR) algorithm is used in this section to select the features extracted from the CER data set. Firstly, a weight value is assigned to each original feature in the initial training. Secondly, the LR model is used to predict the classification index. Then the predicted classification index is compared with the real index to calculate the recognition error. The weight of each feature is updated according to the error, and the feature with the smallest absolute value of the weight is proposed in each round [22]. Repeat this step until the required number of features is reached. Finally, these features with larger weights are used as the input of the subsequent classification model. A schematic diagram of feature selection based on the LR-RFE algorithm is shown in Fig. 2.

3) Embedding method: The Random forest measures its ability to identify user data features by calculating the PI value of each feature. When calculating the importance of the extracted feature N, a decision tree i is created. The OOBErrori is first calculated. Then, the values of the out-of-bag data feature N are randomly rearranged, and the rest of the features remain unchanged to form a new out-of-bag data set OOBi. According to the new OOB, the OOBErrori is recalculated. The PI value of the feature N in the ith tree can be obtained by subtracting the results of the two calculations, and the calculation formula is shown in (3).

$$PI_i(N) = OBError_i^{'} - OOBError_i \tag{3}$$

The calculation process is repeated for each tree of the random forest, and the final PI value of the feature N can be obtained by summing and averaging the PI values of the feature N of each tree, as shown in (4).

$$PI(N) = \frac{1}{c}\sum_{i=1}^{c} PI_i(N) \tag{4}$$

C = ntree represents the number of decision trees used in the random forest. If the importance of a feature ranks high, it means that its value has discrimination between different samples. After the eigenvalues are randomly reordered on the out-of-bag data set, their discrimination for different user samples is reduced, thus improving the OOBErrori. Therefore, the higher the PI value, the higher the importance of the feature. The process of using the random forest algorithm to rank the importance of features is shown in Fig. 3.

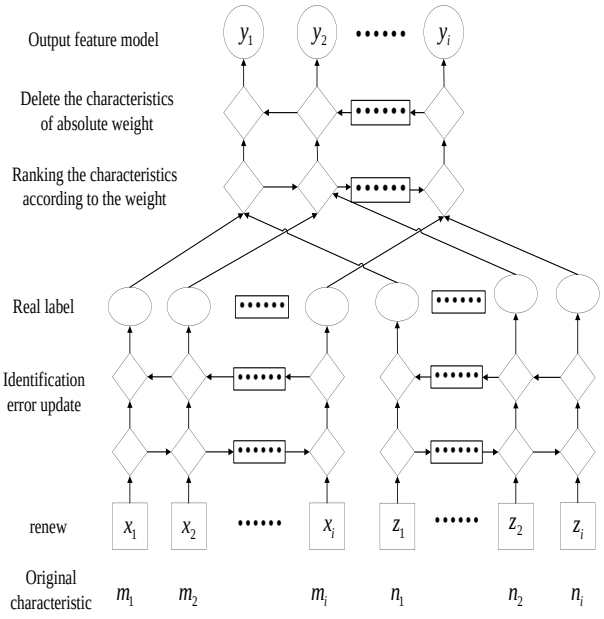

Fig. 2. Schematic Diagram of Feature Selection based on LR-RFE Algorithm.

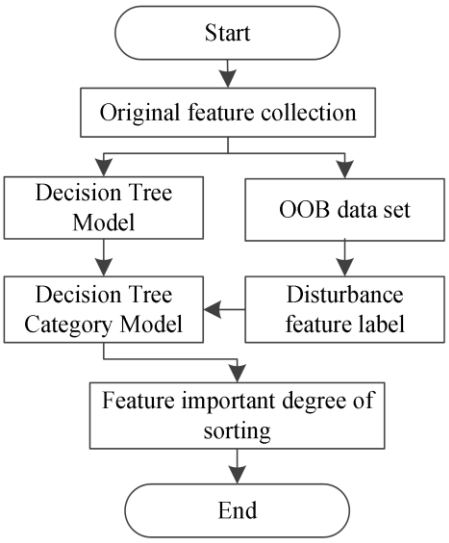

Fig. 3. Ranking Process of Feature Importance Calculated by Random Forest Algorithm.

C. Performance Evaluation Index

In this paper, the TSVM semi-supervised learning method is used to identify the characteristics of residential user data. Three performance evaluation indicators, namely ACC, F1-Score and AUC, are used to evaluate and analyze the recognition model.

When training the SVM classifier, five-fold cross validation is used to train the samples to verify the recognition performance of the data features of residential users more reliably. To evaluate the classification performance of the classifier from multiple perspectives, several evaluation indexes are given here.

- Accuracy

For user data features with M category indexes, the confusion matrix C of $M \times M$ can be calculated. J represents the number of features with the category index of m that are misclassified into the category index of n. If m = n, then Cm, n represent the number of correct classifications, and vice versa. Accuracy (ACC) can be expressed by formula (5).

$$Accuracy = \frac{\sum_{m=1}^{M} C_{m,m}}{\sum_{m=1}^{M}\sum_{n=1}^{M} C_{m,m}} \tag{5}$$

For the binary classification problem, the confusion matrix shown in Table I can be obtained by comparing the sample indicators identified by the classification model with the real sample indicators.

TABLE I. BINARY CLASSIFICATION CONFUSION MATRIX

	Positive	Negative
The prediction is positive	TP	FP
The prediction is negative	FN	TN

True Positives (TP): the number of samples that are actually positive and predicted to be positive; False Positives (FP): the number of samples that are actually negative and predicted to be positive.

False Negatives (FN): the number of samples that are actually negative and predicted to be positive.

True Negatives (TN): the number of samples that are actually negative and predicted to be negative. Therefore, ACC can also be expressed by the following formula (6):

$$Accuracy = \frac{TP + TN}{TP + FP + FN + TN} \tag{6}$$

- F1-Score

According to the confusion matrix, several performance evaluation indexes can be obtained.

Precision: The proportion of samples that are actually positive (positive) among the samples predicted to be positive (positive), as shown in formula (7).

$$Presicion = \frac{TP}{TP + FP} \tag{7}$$

Recall: The proportion of samples that are correctly classified as positive among all samples that are really positive (positive examples), as shown in formula (8).

$$\mathrm{Re}call = \frac{TP}{TP + FN} \tag{8}$$

F1-Score is a comprehensive index reflecting precision and recall, and its value range is 0 to 1. The closer the value of F1-Score is to 1, the better the recognition performance of the model is, and its calculation formula is shown in (9).

$$F1 - Score = \frac{2 \times Presicion \times Recall}{Presicion + Recall} \tag{9}$$

IV. EXPERIMENTAL ANALYSIS

A. Experimental Environment Setting

This paper also uses the open CER data set to analyze the data characteristics of six residential users. See Table II for details.

To verify the effectiveness of the proposed method, the recognition performance of TSVM semi-supervised learning algorithm is compared with four classical KNN, RF, SVM and MLP supervised learning algorithms, and two examples are set to verify the results.

To verify whether the recognition performance of the resident user portraits can be improved by adding frequency domain features on the basis of time domain features, SVM is used to train the features of smart meters, and the grid search method is used to optimize the SVM parameters. 80% of the user sample is the training set and 20% is the test set. The selection of the main hyper-parameters of SVM in the three cases of only time domain feature (Model 1), only frequency domain feature (Model 2), and combination of time domain and frequency domain (Proposed Model) is shown in Table III.

TABLE II. USER DATA CHARACTERISTIC DESCRIPTION AND INDEX DEFINITION TABLE BASED ON CER DATA SET

Number	User data Characteristics	User data characterization	Category	Indicators	Sample size
1	Employment	Employment status of the family's main earner	Hire	1	1423
			Not hired	2	1026
2	Population	Number of family members	Little (no<2)	1	1321
			Many (no.N3)	2	1128
3	Housing types	Housing types	Freestyle	1	1299
			Connection type	2	1104
4	Occupancy rate	Is the house unused for more than 6 hours per day?	Yes	1	1619
		Is the house unused for more than 6 hours per day?	No	2	345
5	Cooking type	Type of cooking facility	Electricity	1	1712
			Non-electricity	2	737
6	With or without children at home	With or without children at home	Yes	1	1964
			No	2	485

TABLE III. MAIN HYPER-PARAMETER SETTINGS OF SVM CLASSIFIERS

SVM	Model 1				Model 2			Proposed model	
serial number	Kernel	C	gamma	Kernel	C	gamma	Kernel	C	gamma
1	RBF	99	0.02	RBF	23	0.2	RBF	5	0.02
2	RBF	97	0.02	RBF	85	0.2	RBF	59	0.002
3	RBF	33	0.02	RBF	3	0.2	RBF	67	0.02
4	RBF	2	20	RBF	2	200	RBF	2	20
5	RBF	22	0.02	RBF	43	20	RBF	32	0.02
6	RBF	2	0.2	RBF	77	0.2	RBF	2	0.2
7	RBF	2	20	RBF	2	200	RBF	2	20

First of all, for the basic results of TSVM, the accuracy values of population, housing occupancy, cooking type and whether there are children in the house are higher than 75%, and the accuracy values of employment and housing type are between 60% and 70%. The recognition accuracy of all user data features is higher than 60%, which shows the basic effectiveness of the semi-supervised learning method proposed in this paper.

Comparing the TSVM semi-supervised learning algorithm with other supervised learning algorithms, when the proportion of index samples is set to 5%, for any user data feature, the recognition accuracy, F1-Score and AUC of TSVM are higher than those of other supervised learning algorithms.

B. Example 2 Experimental Setup and Result Analysis

To further verify the performance of the proposed method, the proportion of samples with index for the semi-supervised learning algorithm is set to 5%, and the proportion of samples with index for the supervised learning algorithm is set to 10 times that of the semi-supervised learning model, that is, 50%. Here, the LR-RFE-based feature selection method is still used to select the top 20 features that are correlated with the classification target value. In this case, the ACC, F1-Score and AUC values of the TSVM semi-supervised learning algorithm and the four supervised learning algorithms of KNN, RF, SVM and MLP to identify the characteristic indicators of residential user data are shown in Fig. 4.

In Fig. 4, for the TSVM semi-supervised algorithm, except for the user-data feature of population number, the recognition ACC values of other user data features are higher than those of other supervised learning methods. For the population, the ACC and AUC values identified by TSVM with only 5% of the matching data are slightly lower than those identified by the supervised learning method with 50% of the matching data, but the difference is not significant.

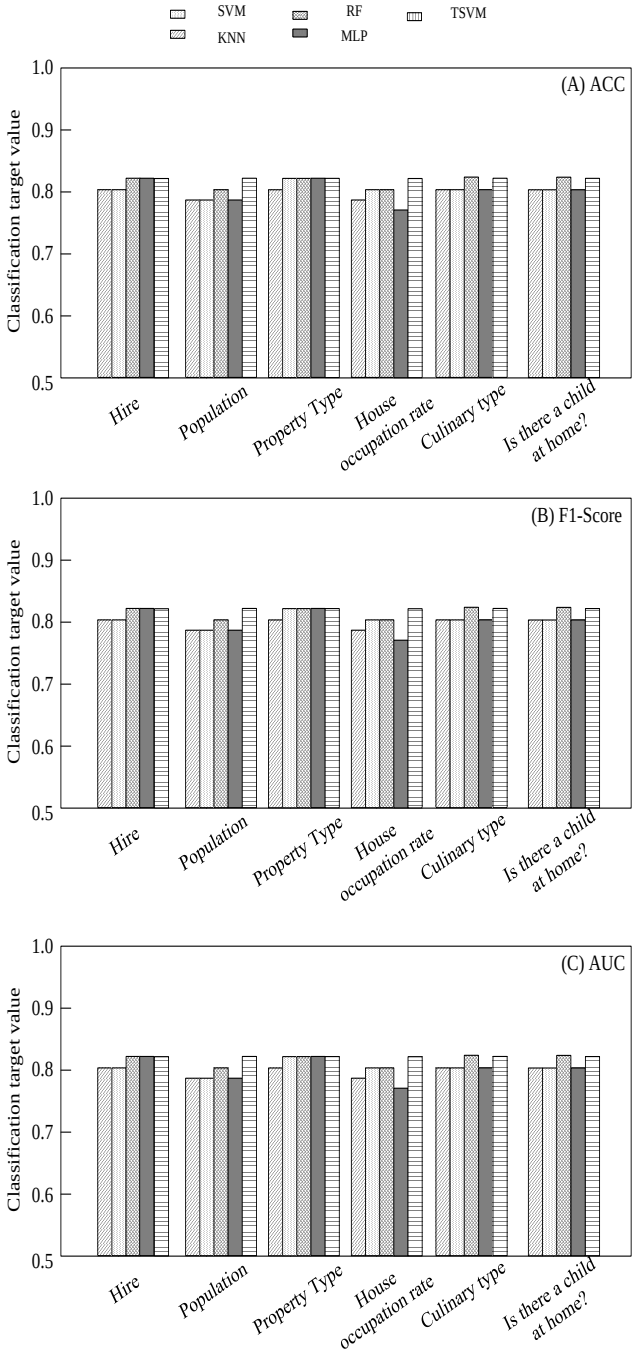

Fig. 4. Comparison of Semi-supervised and Supervised Recognition Algorithms.

V. CONCLUSION

In this paper, a feature recognition method for residential user data based on semi-supervised learning in the case of limited index samples is proposed. The main work includes:

1) Based on the extracted time domain and frequency domain features of smart meters, a feature recognition method for residential user data based on semi-supervised learning is proposed.

2) Then, the effectiveness of semi-supervised learning is verified by the real CER data set.

3) Two main factors affecting the performance of semi-supervised learning recognition algorithms are analyzed.

This method can make full use of the potential rules contained in a small number of matching data and a large number of non-index data to explore the relationship between smart meter data and residential user data characteristics and reduce the cost of index marking.

In future work, it is necessary to further explore the relationship between smart meter data and residential electricity consumption behavior habits, update the identification scenario, and integrate the user data characteristic information into residential load pattern forecasting, baseline load estimation or high demand response potential user identification from the user demand side.

***Abstract*—The 2019 coronavirus disease (COVID-19) caused pandemic and a huge number of deaths in the world. COVID-19 screening is needed to identify suspected positive COVID-19 or not and it can reduce the spread of COVID-19. The polymerase chain reaction (PCR) test for COVID-19 is a test that analyzes the respiratory specimen. The blood test also can be used to show people who have been infected with SARS-CoV-2. In addition, age parameters also contribute to the susceptibility of COVID-19 transmission. This paper presents the extra trees classification with random over-sampling by considering blood and age parameters for COVID-19 screening. This research proposes enhanced preprocessing data by using KNN Imputer to handle large missing values. The experiments evaluated the existing classification methods such as Random Forest, Extra Trees, Ada Boost, Gradient Boosting, and the proposed Light Gradient Boosting with hyperparameter tuning to measure the predictions of patients infected with SARS-CoV-2. The experiments used Albert Einstein Hospital test data in Brazil that consisted of 5,644 sample data from 559 patients with infected SARS-CoV-2. The experimental results show that the proposed scheme achieves an accuracy of about 98,58%, recall of 98,58%, the precision of 98,61%, F1-Score of 98,61%, and AUC of 0,9682.**

I. Introduction

Coronavirus 19 (COVID-19) is a highly contagious viral infectious disease caused by severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) [1]. SARS-CoV-2 can cause tissue damage and cause acute respiratory distress syndrome. It is rapidly increasing transmission rate which demands an early response to diagnose and prevent the rapid spread of this disease [2]. Currently, COVID-19 is being transmitted by human-to-human through air transmission that cause a wide spread of the disease [3]. One way to detect COVID-19 is through the Reverse-Transcriptase Polymerase Chain Reaction, also known as RT-PCR [4]. RT-PCR has limited resources, it has high specificity and high sensitivity [5]. However, according to the study of validation of the SARS-CoV-2 RT-PCR test [6], blood or hematological parameters showed high sensitivity and specificity as well as intra and inter-test precision and efficiency.

Machine learning can become an alternative for diagnosing and analyzing COVID-19 infection [7]. Machine Learning has been widely used to investigate and help in screening with suspected COVID-19 infection [8]. The implementation of machine learning in RT-PCR with blood assessments has a critical function for diagnosing COVID-19 and different respiration diseases. The parameters are involved white blood cells, C-reactive protein, neutrophils, lymphocytes, monocytes, eosinophils, basophils, aspartate and alanine, lactate dehydrogenase, and others. Those parameters have proven an excessive correlation in sufferers identified with COVID [9]. In addition, age parameters [10] also affect the susceptibility of COVID-19 transmission. Therefore, it motivates researchers to investigate parameters that significantly effect for covid-19 prediction.

This research presents a predictive model for diagnosing COVID-19 by considering C-reactive protein, neutrophils, lymphocytes, monocytes, eosinophils, basophils, aspartate and alanine, lactate dehydrogenase, including blood and age parameters. This research proposes a predictive model by using ensemble learning which involved Random Forest, Extra Trees, AdaBoost, Gradient Boosting and Light Gradient Boosting, then optimizes the best model with hyperparameter tuning. The experiments also investigate the best solution for imbalance data by implementing the existing sampling methods such as Random Under Sampling (RUS), Random Over Sampling (ROS) and Synthetic Minority Over Sampling TEchnique (SMOTE). The sampling class imbalance approaches is used to overcome imbalance data that has been carried out in the research related to Covid-19 [11]. This research is expected to obtain the best predictive model that can achieve high accuracy, recall, precision, f-score and AUC compared to the existing schemes.

II. Related Work

Several researches have proven the significant of blood exams for the diagnosis of Covid-19 [12] analyzing the blood

index of 69 COVID-19 sufferers. All have been dealt with on the National Center for Infectious Diseases (NCID) placed in Singapore. Among those sufferers, sixty-five underwent whole blood assume the day of admission. In addition, demographic facts inclusive of age, gender, ethnicity, and region have been furnished for this study. Around 13,4% of sufferers require in-depth care unit (ICU) care, specifically the elderly. During the primary examination, 19 sufferers had leukopenia (low white blood cells) and 24 had lymphopenia (low lymphocyte stage with inside the blood), with five instances categorized as severe (Absolute lymphocyte count (ALC).

The application of a Covid-19 diagnosis based on blood tests has previously been carried out to provide comprehensible answers primarily based totally on device studying techniques using public data from the Albert Einstein Hospital. Previously, data preprocessing was carried out for selection of blood features. Then normalization of features with z-score and use of iterative imputer method to fill in missing values is done. The remaining 608 patients, 84 of whom have been high-quality for COVID-19 showed with the aid of using RT-PCR [13]. In order to apprehend the decisions, a neighborhood Decision Tree Explainer (DTX) approach is performed to obtain the results.

Data from the Israel Albert Einstein Hospital located in São Paulo, Brazil are also used in the application of machine learning in the diagnosis of COVID-19 with hematological parameters. Pre-processing is done by selecting features using particle swarm optimization (PSO) and evolutionary search (ES). Furthermore, experiments were carried out with different machine learning techniques. The experimental results show that Bayesian networks [7] have superior performance compared to other techniques with an overall accuracy of 95,159%, kappa index 0,903, sensitivity 0,968, precision 0.938, and specificity 0,936.

A study was also conducted to identify SARS-CoV-2 positive patients from a total of 598 complete data and 5046 were not used because they were incomplete. A machine learning model, ANN was carried out to test based on the dataset obtained from the Israelta Albert Einstein Hospital, in São Paulo, Brazil by testing various hematological parameters. As a result, the flexible ANN model [14] predicts COVID-19 patients with high accuracy between the population in the regular ward AUC 94-95% and those not hospitalized or in the community AUC 80-86%.

Other research was conducted by building a two-stage test; in level one, no preprocessing technique is carried out even as in level preprocessing is emphasized to attain higher predictive effects. Blood samples from sufferers from Einstein Hospital in Brazil were amassed and used for prediction of the severity of COVID-19 with studying algorithms. The Tuned Random Forest algorithm [15] produced an accuracy of 0,98 with numerous preprocessing methods.

Based on the description of the related research above, the existing considers few parameters to diagnose COVID-19. There are a quite few research studies on blood exams for the diagnosis of COVID-19. However, studies on eosinophils, age and blood parameters are rare to find in literature. This study proposes a pre-processing KNN imputer data to overcome the large missing values. Then various data sampling class with imbalance approaches methods is used to find out the best sampling class for imbalance datasets. Whereas the prediction model generated from the data classification process using an ensemble, namely Extra Trees, Bagging Decision Tree, Random Forest, Ada Boost, Gradient Boosting and Light Gradient Boosting.

III. Preliminaries

A. Ensemble Learning Classification Model

Ensembles learning classification model can increase the computational costs [16], as it is necessary to train several individual classifiers, and their computational requirements can grow exponentially when dealing with large scales.

B. Extra Trees

The extra tree classifier creates a gaggle of unpruned decision trees in step with the standard top-down method. The predictions of all trees were combined to determine the ultimate prediction, through the majority alternative [17]. The extra tree classifier generates a random multiple of the choice tree with completely different sub-samples while not bootstrapping. The extra trees can avoid over-fitting issues and improves accuracy [18]. Efficiency is also the main strength of this study.

C. AdaBoost

AdaBoost is an iterative algorithm, in each iteration, instances that were wrongly classified in the previous iteration are given more weight. Sequentially apply the learning algorithm to reweighted the sample from the original training data. Initially, each instance is ssigned the same weight and iteration as the iteration, the weight of all misclassified instances is increased and the correctly classified instances are reduced [17]. The AdaBost algorithms [19] are defined by:

1) Minimize the error function with the formula

$$\mathrm{w_e} = \sum_{yi \neq km(xi)} w_i^{(m)} \exp(a_m) \tag{1}$$

2) Set the value a with the formula

$$a_m = \frac{1}{2} n\left(\frac{1-e_m}{e_m}\right), e_m = \frac{w_e}{w} \tag{2}$$

3) Update values if observing misclassification by formula

$$w_i^{(m+1)} = w_i^{(m)} \exp(a_m) = w_i^{(m)} \sqrt{\frac{1-e_m}{e_m}} \tag{3}$$

4) For other values using the formula

$$w_i^{(m+1)} = w_i^{(m)} \exp(a_m) = w_i^{(m)} \sqrt{\frac{e_m}{1-e_m}} \tag{4}$$

D. Gradient Boosting

Gradient Boosting is a machine learning algorithm that can solve regression and classification problems. Gradient Boosting generates a prediction model consisting of an ensemble of weak prediction models in the decision tree [20]. The construct of a gradient boosting call tree is to mix a series of weak base classifiers into one sturdy one. a conventional boosting methodology that weighs positive and negative samples, GBDT builds a world convergence rule by following the direction of the negative gradient [21]. The GBDT measures GBDT [21] are presented as follows.

1) Step 1: The values for the initial constants of the model β are given:

$$f0(x) = \arg\min \beta \sum_{i=1}^{n} L(yi, \beta) \tag{5}$$

2) Step 2: For the number of iterations m = 1: M (M is the iteration time), the residual gradient direction is calculated

$$y_i - \left[\frac{\partial L(y_i, F(x_i))}{\partial F(x_i)} \right] f(x) - f_{m-1(x)} \tag{6}$$

3) Step 3: Base classifiers are used to adjust the sample data and obtain the initial model. According to the least squares approach, the parameters of the model are obtained and the model *h (xi; am*) is installed

$$a_m = \arg\min_{a\beta} \sum_{i=1}^{N} \left[y_i^* - \beta h(x_i; a) \right]^2 \tag{7}$$

4) Step 4: Function loss is minimized. According to Eq. (4), the new step size of the model, i.e. the weight of the current model, is calculated.

$$\beta_m = \arg\min_{a\beta} \sum_{i=1}^{N} L\left[y_i^*, f_{m-}(x) = +\beta h(x_i; a) \right] \tag{8}$$

5) Step 5: the model is updated as follows

$$F_m(x) = F_{m-1}(x) + \beta_m h(x_i; a) \tag{9}$$

E. Light Gradient Boosting

Light Gradient Boosting Machine or LightGBM uses gradient enhancement in its construction, but light GBM does not divide the eigenvalues one by one, so it is necessary to calculate the splitting benefit of each eigenvalue. LightGBM algorithm on the model to improve forecasting accuracy and robustness [22]. It can indeed find the optimal split value, but it costs a lot, and may not be good for generalizing information when the amount of data is large [23]. Remembering the supervised training $setX = \{(xi, yi)\}_i^n$ LightGBM's target is to find approximation for a particular function $f(x)$ to a certain function $\hat{f}(x)$ which reduces the expected loss function value , $(y, f(x))$ as follows [24] :

$$\hat{f} = \arg\min Ey, xL(y, f(x)) \tag{10}$$

LightGBM integrates a number of T regression trees to approach the final model, which is.

$$f_T(x) \sum_{t=2}^{T} f_t(x) \tag{11}$$

$q(x), q \in \{1,2...., J\}$, where J denotes the number of leaves, represents the guideline of thumb of the choice tree and is the leaf node weight vector. Therefore, LightGBM could be educated additively inside the following steps:

$$T_t = \sum_{i=1}^{n} L(yi, f_{t-1}(xi) + f_t(xi)) \tag{12}$$

In LightGBM, Newton' technique simply approximates the target function. Where *gi* and *hi* indicate the first- and second-order gradient statistics of the loss function, let *Ij* show the instance set of leaf*j*.

$$T_t = \sum_{i=1}^{n} \left(\left(\sum_{i \in Ij} g_i \right) + \frac{1}{2} \left(\sum_{i \in Ij} h_i + \lambda \right) w_j^2 \right) \tag{13}$$

For the tree structure$q(x)$, the optimum leaf weight score of every leaf node $w*$ and therefore the extreme worth of T_t may be solved as follows:

$$w_j^* = -\frac{\sum_{i \in Ijgi}}{\sum_{i \in Ij} (h_i + \lambda) w_j^2} \tag{14}$$

F. Random Forest

Random Forest is an integrated learning method based on bagging. The essence is to apply the bootstrap method to the CART algorithm. Random Forest samples were taken using the bootstrap method, and then an independent decision tree model was built using the CART algorithm [25]. Random forest algorithm (for each type and regression) [26] are discussed as follows:

1) From Training n samples draw n_{tree} bootstrap samples.

2) For every of the bootstrap samples, develop classification or regression tree with the subsequent modification: at every node, in place of selecting the excellent break up amongst all predictors, randomly pattern m_{trv} of the predictors and select the excellent break up amongst the ones variables. The tree is grown to the most length and not pruned back. Bagging may be concept of because the unique case of random forests received while $m_{try} = p$, the wide variety of predictors.

3) Predict new facts by combining n_{tree} tree predictions (i.e., majority vote for type, common for regression.

G. Random Over Sampling (ROS)

ROS algorithm randomly replicates samples from the minority classes [27]. Oversampling [28] can be done by

increasing number of instances or minority class samples by production new instance or repeated multiple instances.

H. Random Under Sampling (RUS)

RUS technique at random eliminates samples from the bulk categories, till achieving a relative categories balance [27]. For the under-sampling approach, most of the category instances are discarded till additional a balanced distribution of information is achieved. This data merchandising method is completed every which way. Considering an information set with a hundred minority class instances and 2,000 magnitude class instances, a complete of 1800 categories that majority are going to be deleted randomly within the RUS technique. The dataset will be balanced with two hundred instances, it will be delineating with 200 instances, whereas minority also have 200.

I. Synthetic Minority Over-Sampling Technique (SMOTE)

SMOTE produces artificial samples from the minority class by interpolating existing instances that are terribly near to every other [27]. For the minority category within the information set, SMOTE initial selects the minority class data instance randomly. The distance from the sample set to several classes is calculated by the Euclidean distance *D*, and K-nearest neighbors are obtained. The Euclidean distance *D* is defined by:

$$D = \sqrt{\sum_{k-1}^{n} (X_k - Y_k)^2} \tag{15}$$

According to the proportion of the unbalanced data set, the sampling rate N is set. The six samples closest to D were selected as one group. Each sample group is connected to each other to generate several new samples at random, which are added to the data set and recycled [29]. This results in a new formula:

$$X_{new} = x_i + rand(0,1) * |x_i - x_j| \tag{16}$$

IV. Experimental Setup

Images are divided by 70% for training, 20% for validation, and 10% for testing. Then the YOLO architectural model is used from training and validation and then a data test is carried out with data testing and detecting disease. After that, a performance evaluation's carried out for the architectural model used. The block diagram of the proposed covid-19 classification is depicted in Fig. 1.

This study uses machine learning techniques to predict negative and positive cases using RT-PCR data with blood parameters. Before applying the machine learning classification method, data preparation was carried out by using several methods, namely, Remove non-blood parameter, Imputation Missing Values, Label Encoding Class and Normalization with Z-Score. The processed data was tested using several machine learning classification methods using an ensemble, namely Extra Trees, Bagging Decision Tree, Random Forest, Ada Boost, Gradient Boosting and Light Gradient Boosting. In testing the machine learning classification method, the best method was chosen based on the evaluation of the results in terms of accuracy, precision, recall, F-1score and AUC. The best method is optimized by searching for the best parameters by using hyper parameter tuning. Then, the results were compared before using hyper parameter tuning and after using hyper parameter tuning. The results of the best methods can be used for prediction of COVID-19.

A. Data Collection

The dataset is collected from the existing benchmark [30]. The dataset consists of 5644 patients treated at the Albert Einstein Israelta Hospital located in Saulo Paulo, Brazil. Kaggle makes data sets available for public access. Data was collected from 28 March 2020 to 3 April 2020, with more than 100 laboratory tests including blood test, urine test, SARS-CoV-2 test, RT-PCR test, presence of influenza virus [30]. The dataset consists of 89% missing values, so the missing value is handled by filling in the missing value using the KNN Imputer method using K = 5 [31]. Label encoding is done which aims to perform coding on the class label. Label Encoding serves to change the data format of numbers 0 to n_classes-1, this is intended to make data training easier. Normalization of the data was performed using Z-Score [32]. Then the best method is to optimize hyper parameter tuning using GridSearchCV. GridSearchCV taken from Scikit learn [33]. This study considers several features for classification as shown in Table I.

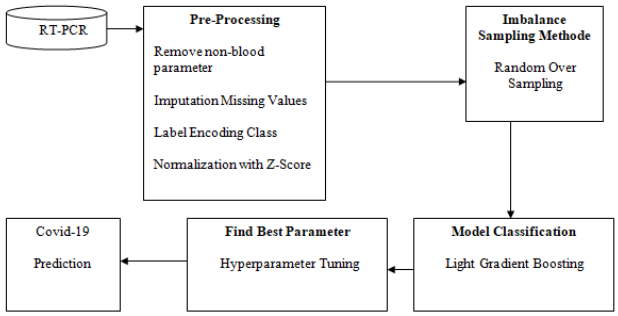

Fig. 1. Block Diagram of Covid-19 Prediction.

TABLE I. Selection of Features

No.	Features	No.	Features
1	Hematocrit	13	Red blood cell distribution width
2	Hemoglobin	14	Monocytes
3	Platelets	15	Mean platelet volume
4	Red blood Cells	16	Neutrophils
5	Lymphocytes	17	C-reactive protein
6	Mean corpuscular hemoglobin	18	Creatinine
7	MCH concentration	19	Urea
8	Leukocytes	20	Potassium
9	Basophils	21	Sodium
10	Eosinophils	22	Aspartate transaminase
11	Lactate dehydrogenase	23	Alanine transaminase
12	Mean corpuscular volume	24	Age

B. Split Validation

In this study, the experiments divide the data based on the ratio entered, for example the percentage of 80:20 [34]. There are 80% of the total amount for training set and 20% for test set.

C. Evaluation

To compare the overall performance of the proposed scheme, we decided on five metrics: accuracy, recall, precision, F1-Score and receiver running characteristic (ROC) curves, and the cost of the vicinity below the ROC curve (ROC AUC). Accuracy is the maximum generally used assessment metric for type. However, for imbalance facts type problems, accuracy won't be a great preference due to the fact accuracy regularly has a bias closer to the bulk class [35][36]. The accuracy can be defined by:

$$Accuracy = \frac{TP + TN}{TotalSample} \tag{17}$$

Recall is the collection of data that has been successfully taken from the part of the data relevant to the query [37]. The Recall is defined by:

$$\mathrm{Re}call = \frac{TP}{TP + FN} \tag{18}$$

Precision is part of the data taken in accordance with the required information [38]-[40]. The precision is defined by:

$$\mathrm{Pr}ecision = \frac{TP}{TP + FP} \tag{19}$$

The F1 score is the Harmonic Mean between precision and Recall [41]. The F-Score indicates how precise the classifier is (how many instances are correctly classified), as well as how strong it is (it doesn't miss a large number of instances). The F1-Score formula is defined by:

$$F1 - Score = 2\frac{\mathrm{Re}call * \mathrm{Pr}ecision}{\mathrm{Re}call + \mathrm{Pr}ecision} \tag{20}$$

The ROC curve represents the genuine advantageous rate (TPR) and fake advantageous rate (FPR). TPR represents the ratio of advantageous samples that have been successfully detected through the algorithm, and FPR represents the ratio of terrible samples that have been incorrectly labeled as advantageous. The expressions for TPR and FPR are as follows:

$$TPR = \frac{TP}{TP + FN} \tag{21}$$

$$FPR = \frac{FP}{TN + FP} \tag{22}$$

where TP is the number of true positives, TN is the number of true negatives, FN is the number of false negatives, FP is number of false positives.

V. Experimental Results

After pre-processing the data to overcome the missing value, performing a Z-Score then encoding the dataset class, testing the specified model without using the sampling class imbalance approaches method. Testing the model without sampling class imbalance approaches method is carried out first for further comparison with various sampling class imbalance approaches methods to be tested. The test results are listed in Table II.

The best accuracy was obtained by using extra trees method with an average accuracy of 98.40% for imbalance sampling method. While, the light gradient boosting achieved high accuracy with random under sampling than extra trees, AdaBoost, Gradient Boosting, and Random Forest methods. Overall, the extra trees method performs better than other method for different types of sampling method except random under sampling. The experimental results in terms of recall, precision, F1-Score, and AUC are listed in Tables III, IV, V and VI.

The classification of light gradient boosting method achieved recall value of 91.96%. The best recall result was obtained from sampling technique of without imbalance sampling method, random under sampling, SMOTE and SMOTE-Tomek. The experiments also evaluate the precision of the classification method; classification by using extra tree produced a high precision result except sampling technique of random under sampling. The classification of light gradient boosting method can achieve a good F1-Score and AUC score under various sampling techniques. The visual comparison of the accuracy, recall, precision, F1-score and AUC is shown in Fig. 2, 3, 4, 5 and 6.

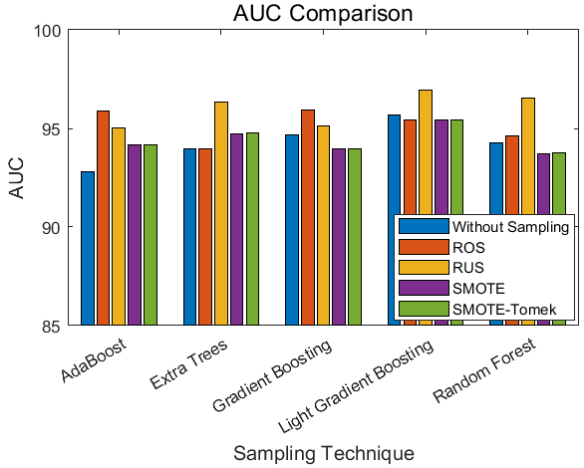

Fig. 6. The AUC of the Existing Classification Methods for Covid-19 Prediction.

The best AUC was produced by light gradient boosting with RUS sampling technique. Light gradient boosting with RUS sampling technique produces AUC score of 0.9693. It can be concluded that the best model that has improved majority of performance in terms of accuracy, precision, recall, f1-score and AUC is light gradient boosting. Light Gradient Boosting produces the best accuracy of 98.49%, recall on the RUS sampling technique is 97.32% and AUC is 0.9693. Furthermore, hyperparamater tuning tests were carried out to optimize the results of Light Gradient Boosting. The parameters used in the Hyperparameter tuning are listed in Table VII.

TABLE VII. SELECTION OF LIGHT GRADIENT BOOSTING PARAMETER ON HYPERPARAMETER TUNING GRID SEARCH

Parameters	**Value**
n_estimators	100, 400, 10
min_child_weight	3, 20, 2
colsample_bytree	0.4, 1.0
max_deph	5, 15, 2
num_leaves	8, 40
min_child_weight	10,30
Learning_rate	0.01,1

After going through the Grid Search process, the best parameters were found that could be tested on the Light Gradient Boosting model. These parameters can be seen in Table VIII.

TABLE VIII. SELECTION OF LIGHT GRADIENT BOOSTING PARAMETERS

Parameters	**Value**	**Parameters**	**Value**
boosting_type	'gbdt',	*n_jobs*	-1,

Table IX is a comparison of light gradient boosting before optimization of hyper parameter tuning and after optimization of hyper parameter tuning.

TABLE IX. SELECTION OF COMPARISON OF LIGHT GRADIENT BOOSTING

Evaluation	***without sampling***	***ROS***	***RUS***	**SMOTE**	**SMOTE-*Tomek***
Accuracy	97.78	98.58	97.25	98.31	98.31
Recall	97.78	98.58	97.25	98.31	98.31
Precision	97.83	98.61	97.65	98.34	98.34
F1-Score	97.83	98.61	97.65	98.34	98.34
AUC	95.68	96.82	96.88	95.88	95.88

The hyper parameter tuning has increased the accuracy of light gradient boosting with an accuracy of 98.58%. The comparison of recall light gradient boosting has increased in almost all tests using sampling techniques. Random forest before the sampling technique was 92.59%. The comparison of F1-score light gradient boosting after hyperparamerer tuning achieved 98.61% on the ROS sampling technique. Based on the results, it can be concluded that light gradient boosting with hyperameter tuning can improve the accuracy, recall, precision, F1-score and AUC. The use of the ROS sampling technique has some advantages in terms of accuracy, recall, precision, f1-score. With the conclusion that the results are 98.58% accuracy, 98.58% recall, 98.61% precision, f1-Score 98.61% and AUC 0.9682%. Based on the results obtained, the results of feature importance are shown in Fig. 7.

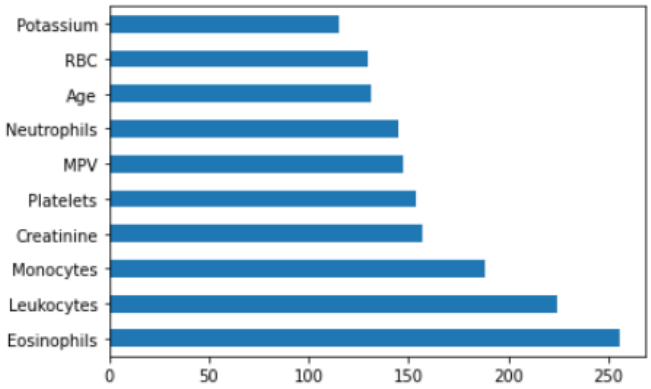

Fig. 7. Importance Features.

Based on Fig. 7, it shows that the first order important features in eosinophiles are. Followed by leukocytes, monocytes, creatinine, platelets, MPV, neutrophils, age, RBC and potassium. The addition of age in the proposed test becomes the seventh most important feature of the best model. The comparison with related research was conducted to assess the performance of the proposed research, the comparison results is listed in Table X.

TABLE X. SELECTION OF COMPARISON WITH RELATED RESEARCH

Model	Accuracy	Recall	Precision	F1 Score	AUC
proposed method	98,58	98,58	98,61	98,61	96,82
Alves *et al* [13]	88	66	91	76	86
Barbosa *et al* [7]	95.16	96.80	93.80	-	-

Based on the table above, it shows that the proposed model produces the best results for all evaluation matrices compare to the previous related studies. With the results of accuracy 98.58%, recall 98.58%, precision 98.61%, F1-Score 98.61% and AUC 0.9682. The visual comparison with related research studies is shown in Fig. 8.

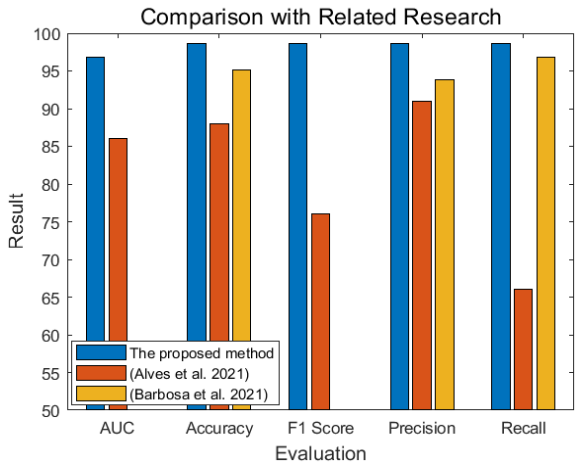

Fig. 8. Comparison with the Existing Studies.

VI. CONCLUSION

This paper has presented various classification methods for COVID-19 prediction. The classification method of light gradient boosting with hyper parameter tuning using ROS sampling technique perform better than the existing the classification methods such as extra trees, random forest, adaboost and gradient boosting for predicting the COVID-19 data. Eosinophils, blood and age parameters has potential become important parameters for COVID-19 prediction. The data was taken from kaggle.com with 5644 data, it shows a classification improvement based on the majority of performance in terms of recall, precision, f1-score and AUC score due to eosinophils, blood and age parameters. Hyper parameter tuning using ROS sampling technique achieved an accuracy of 98.58%, recall of 98.58%, precision of 98.61%, f1-score of 98.61% and AUC of 0.9682. The first important feature in these experiments is eosinophils; it can significantly influence the classification results, while age feature is in the seventh order of important features. In the future research, the proposed model has potential to predict monkey pox disease by identifying important features.

***Abstract*—Temporomandibular joint Disorder (TMD) is with multifaceted and complex signs and symptoms which makes day to day activities of an individual uneasy. Electromyographic (EMG) processing of related muscles recordings could provide an early and immediate detection of TMD. To detect the TMD using surface electromyography (SEMG) of Masseter and Temporalis muscle with discrete wavelet transform (DWT) using spectral coding. To analyze the data, a new feature selection approach in the spectral domain is proposed. For statistical analyses, SPSS version 24 is employed. The results of the study revealed that the proposed approach was able to improve the accuracy of the classification by implementing a combination of DWT and the Support Vector Machine (SVM). The proposed method also exhibited a significant improvement in its performance in terms of its accuracy with 93%. In addition, the statistical analysis revealed that the model was able to improve the mean rank of the experimental and control group.**

***Keywords*—Temporomandibular joint (TMJ); temporomandibular joint disorder (TMD); surface electromyography (sEMG); spectral mapping; discrete wavelet transform (DWT)**

I. Introduction

TMD is an orofacial disorder, which is characterized by joint noises and limitations in the range of motion. Complex and multidisciplinary symptoms related to the Temporomandibular joints (TMJ) are known to affect different parts of the body. Understanding the pathogenesis and possible reasons of these conditions can be challenging. The most common methods of diagnosing and management of TMD is with clinical evaluation followed by radiographic evaluation of images from, X ray, Magnetic resonance Imaging (MRI), cone beam computed tomography (CBCT) and Orthopantomogram (OPG). sEMG is a complementary tool that can be used to evaluate the efficiency and function of muscles by directly analyzing their electrical potentials. This technique has been widely used to diagnose and monitor the TMD as it is a noninvasive technique [1]. In recent development, EMG were processed using spectral coding where multi resolution signals are decomposed and entropy features are used in decision making of bruxism [2]. Various approaches of detection of TMD were developed in the recent research. The significance of usage of sEMG for the reliable detection of TMD is presented in this paper. For the analysis of a superimposed motor unit action a sEMG application for muscle function and its detection efficiency is outlined in [3]. In [4] the signal represents a weighted sum of various temporal and spatial motions of different electrical muscle activities. The analysis is developed as a set of different muscular movement of variation with course of observing time. A muscle imbalance detection based on muscle activity monitoring for TMD is presented in [5, 6]. The outlined approach in [7, 8] aims in developing the effect of temporary splint usage on the masticatory muscle using surface electromyography. The analysis of masticatory muscle activity after an orthodontic treatment using sEMG is discussed. In observing the deviation of masticatory muscle usage for TMD diagnosis an analysis for varying age group is presented in [9]. EMG signals are used in processing masseter and temporalis muscle using duty factors for different age group, and genders of patients having pain and pain free TMD is outlined in [10]. The analysis of TMD a short term observation of transcutaneous electrical nerve stimulation (TENS) observing pain concentration, pressure pain threshold (PPT) and EMG is outlined in [11]. The analysis of sEMG on the behavior of neck, trunk and masticatory muscle for different groups under rest and maximal voluntary clenching (MVC). Variation to sEMG activity for myofacial pain and non-pain condition is presented in [13, 14]. The variation in sEMG for Temporomandibular joint hypermobility (TMJH) for healthy and effective with mild and severe TMJH is presented in [15, 16, 17]. A discrete wavelet transform approach is proposed to analyze sEMG using Auto regression and the Shannon Entropies [18]. The proposed method with new energy-based spectral coding has advantages over the conventional approach and can provide better diagnosis.

The paper is divided into four sections. The first section introduces the concepts of TMD and EMG processing. The second section outlines the materials and methods. Third section describes the proposed approach for detecting disorder with results and discussion, and at the end section four concludes the study.

II. Materials and Methods

A. SEMG Signal Acquisition

This Experimental Analysis was conducted on 100 individuals with an age between 18 to 60 years. The subjects were notified about the procedure and a written informed consent is taken in accordance with the declaration of Helsinki [6]. Many people were omitted from the research because they had a history of orthodontic treatment, lip negligence, or prior tooth restoration [19]. The subjects underwent a complete dental history followed by radiographic evaluation using an Orthopantomography (OPG) by the Dental Practitioner. Based on the Doctors assessment, subjects were divided into two groups. The first group was healthy subjects called control and the second group was subjects with TMD called experimental group. Masseter and Temporalis Muscles of both groups were analyzed by recording the sEMG . The subjects were seated in a comfortable position before the recording was carried out. Since their jaw muscles reacted to changes in head position, no movement was allowed. They were next shown how to hold the mandible relaxed and intercuspal. They were also shown how to utilize cotton rolls to aid in clenching. Signals from the surface of the muscles were collected using a 2-channel electromyography machine. At the beginning of the sEMG recording, volunteer's skin is cleaned with 70% alcohol before the electrodes are placed on it. The participants were monitored for 10 seconds during which they were subjected to rest and clenching activities of 5 seconds each. Both scenarios were recorded using simultaneous electromyographic signals. The recordings were then processed using a 12-bit A/D converter. They are also subjected to a cut-off frequency of 10Hz to 1500Hz.After recording, the signal is filtered through a digital filter with a pass-band of 10Hz to 500Hz. The data were then analyzed using a computer algorithm known as MATLAB 2019. Processing of sEMG is carried out using time frequency analysis with wavelets.

B. SEMG Signal Processing

The proposed system architecture for EMG processing in TMD detection is shown in Fig. 1. The process involves in successive filtration of signal using high pass and low pass filters for a given scale levels. The wavelet function can be performed using two different algorithms: the Haar wavelet algorithm and the Daubechies algorithm (3). The goal of the wavelet function is to match the signal to the wavelet function that's being processed.

In this study Daubechies-4 wavelets with five levels of scaling is applied after comparing and getting better results with other wavelets and the decomposition is developed as a separation of finer spectral bands and residual elements given by

$$B[t] = \sum_{t=1}^{n} \xi[t] + \gamma[t] \quad (1)$$

Where, B[t] represent the spectral bands for a given scale level of 't' processed over a period of t=1..n, which is observed to be sum of spectral bands ξ and residual decomposed band γ. The spectral bands are derived from a set of filter blocks which are cascaded to develop a hierarchical decomposition of given signal, which results in filter spectral bands and residual components.

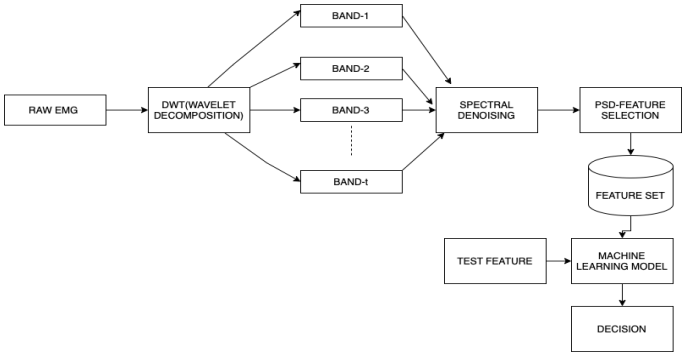

Fig. 1. Framework for Proposed Approach of TMD Detection: Raw EMG is Decomposed using DWT with Multiresolution Approach using Daubichew-4 Filter with Five Levels of Scaling for Denoising and the Reconstructed Signal is extracted with Features and Selected Feature.

The decomposed bands for the EMG signal represent a set of sub-spectral bands $\{\chi_0, \chi_1, \chi_3 \dots \dots . \chi_n\}$ which are derived by the signal filtrations of successive residual component of previous scale. The decomposed bands are defined as a set υ which are the subset of processing signal S given by,

$$\upsilon = \{\chi_0, \chi_1, \chi_3 \dots \dots . \chi_n\} \in S \quad (2)$$

In filtration, the maximum spectral band of each of the decomposed band is computed and average value is considered as filtering coefficients defined as,

$$f_i = \max(\chi_i)_{i=1 \text{ to } t} \quad (3)$$

$$F = \{f_1, f_2, f_3 \dots . f_t\} \quad (4)$$

$$F_{coeff} = \text{avg}(F) \quad (5)$$

The average over all decomposed band defines the distribution of varying peaks for each band. Maximum peaks of each band reflect the maximum spectral limit of the processing band. The filtration process performs a convolution operation of the decomposed band using computed filter coefficients for distortion removal. The filtration is performed as,

$$D_i = \text{conv}(\chi_i, F_{coeff}) \quad (6)$$

The denoised signal (Di) is processed for feature selection where the spectral densities of the filtered bands are computed. Spectral density illustrates the spectral energy concentric on a band. The spectral density is defined as the power spectral density (PSD) given as,

$$\text{PSD } (P_i) = \frac{1}{n}(\sum_{i=1}^{n} D_I) \quad (7)$$

Where, 'n' is the total number of coefficients in the band. For 't' scale bands the PSD are a set of PSD's given as {P_1, P_2, P_3 …… P_t}. In selecting features the computed spectral density is correlated and bands with PSD above the limiting value is considered as feature. The selection of feature vector is outlined in below algorithm.

Proposed Algorithm for Feature Selection:

Input: Denoised spectral bands of EMG signal (Di)

Output: Selected features

Process

Compute PSD (P_i) for obtained denoised band Di,

$$PSD\ (P_i) = \frac{1}{n}\left(\sum_{i=1}^{n} D_i\right)$$

Compute limiting threshold (L) given as,

$$= \frac{1}{4}\max(P_i)$$

Select feature using correlative method defined as,

$$Ft\ = \begin{cases} P_{i,}\ if\ P_i > L, \\ \\ 0\ else \end{cases}$$

End process

Features were selected for a limiting threshold value of 25%. Because most of the dominant values will be above this threshold. Lower values may be considered but might contain noise. The selected feature sets are trained for sparsely disturbed EMG signals of different test cases and a training process is performed to create a learning feature table. The learning feature sets is used for training a support vector machine (SVM) and testing is performed using the multi class model of SVM classifier. The processing system operates for training and testing operation, where a training process is an offline process and testing is developed as an online process. The simulation result and observations for the proposed system is presented in following section.

III. Results

A. Results of Signal Processing and Classification Model

The signal processing window of 300 coefficients is considered in processing the EMG signal. The processing window signals is iteratively processed to minimize the processing overhead and reflects a finer multi resolution details for processing signal. The EMG signal is processed for distortions with additive Gaussian noise, which are observed in the signaling domain generated due to surrounding environment and processing units. Multi resolution spectral bands using wavelet transformation is shown in Fig. 2. The decomposed bands reflect the variation of signal under different frequency resolutions.

The decomposed bands illustrate a magnitude variation under different frequency resolution [16]. These finer details give more selective characteristic of processing signal. The spectral energy density of each isolated band computed as PSD. A test of 10 iterations with varying Variance value from 0 to 1 is performed. The denoising efficiency is measured by an average Means square error (MSE), Peak signal to noise ratio (PSNR) and Root mean square error (RMSE) values.

The MSE is given by,

$$MSE = \frac{\sum_{i=1}^{n}(x-x')^2}{n} \quad (8)$$

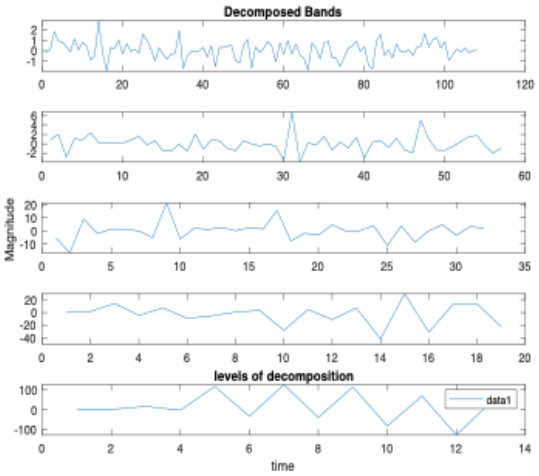

Fig. 2. Decomposed Spectral Bands for the Surface EMG Signal for Level 5 and Db4 Wavelet.

Where x is the actual signal of processing coefficients and x^' is the de-noised signal coefficients.

PSNR is given by,

$$PSNR = log_{10}\frac{peak(x')}{peak(x)} \quad (9)$$

and RMSE is given by,

$$RMSE = \surd MSE \quad (10)$$

Observations for the developed approach spectral mapped approach (SMAP) is compared with the existing approach of soft thresholding and auto regression model (AR) [18] for denoising performance. The observation of the developed approaches for denoising for different test samples is presented in Table I.

TABLE I. Denoising for Different Test Sample

Test sample	**Method**	**PSNR (dB)**	**RMSE**	**Time (Sec)**
S1	Soft threshold	34.9088	2.5115	0.156
	AR	45.4041	1.1643	0.031
	SMAP	50.8703	1.1756	0.015
S2	Soft threshold	34.4641	2.5064	0.175
	AR	45.4121	1.1642	0.029
	SMAP	50.8703	1.1756	0.019

The spectral coding of signal denoising eliminate distortion using a period of observation, wherein a discrete observation generate filtration for observing coefficients only which has lower filtration performance. More effective denoising results into an accurate signal representation. This result to improve the accuracy of detection.

The peak signal to noise ratio (PSNR) [18] value defines the signal strength to distortion in the processing signal. A higher PSNR defines higher signal strength in retrieved signal in reference to distortion level. The proposed method attained 51dB of PSNR which is 20dB and 8dB higher than the existing soft threshold and auto regression model respectively. Root

mean square error (RMSE) defines the standard deviation of the predicted signal compared to the original signal. The RMSE of the proposed method is 1.9 times lower than auto regression model and 2.1 time lower compared to soft threshold method.

The spectral peak values of the denoised signals are considered as a relative feature for EMG signal analysis. Detected peak levels of the processing signal is shown in Fig. 3. The spectral features are used for training the SVM model and classification of the test signal is performed for the developed multi class model [18]. Testing of developed approach is made over a sparse dataset of captured EMG samples under various postures. A k-fold test is performed where 1/kth part of the database is used for training and remaining is used for testing. The approach presented is outlined in MATLAB tool and validated for the retrieval Accuracy, sensitivity, specificity, Recall Rate, precision and computation time parameter [6]. Processing sEMG signal is captured at 5mv/sec for a period of 2 msec period.

The validation of the developed approach is performed using retrieval Accuracy, sensitivity, specificity, Recall Rate, precision and computation time parameter.

The observation for the developed system is computed for different test cases measuring the evaluating parameters. The observation for the developed approach for different classifier models, k-fold tests and varying interference levels are presented. The developed approach of Spectral mapped based classification is compared with the existing approach of Quadrant discriminant analysis and Naïve Bayes method [19]. Observation for different K-fold test for K=2 and 3 is given in Table II.

The classification performance of the proposed approach using spectral mapping method has 93% of accuracy with increases of noise variance the accuracy marginally reduced due to spectral domain processing compared to existing Quadrant discriminant analysis, KNN and Naïve Bayes classifier [19].

B. Statistical Data Analysis

Data was collected from a total of 100 respondents, who were divided into two groups: control (healthy) and experimental (patients). Of the 50 respondents in the control group, 29 were female and 21 were male. In the experimental group, there are 26 females and 24 males out of a total of 50 responses. Descriptive statistics were used to analyse the various variables within the group and sex. Two-way factorial analyses were performed to compare the mean values. The mean maximum amplitude of the subjects during rest and MVC was also estimated. The features were selected for the groups of female and male.

For all of the features, descriptive statistics were first calculated. The kolmogorov Smirnov test is used to check for normalcy, followed by a retest using the nomal Q- Q plot. We discovered that the data is not normally distributed and that the Kolmogorov-Smirnov P-value (.000) is less than.050. Furthermore, the largest observation is away from the primary diagonal in the Q-Q graph, indicating that the data is not regularly distributed. The data was then corrected for normality using log transformation, reciprocal transformation, and square root transformation. However, this method failed to convert the data into normal distribution. The results are presented in Table III. The non-parametric Mann-Whitney U test was used to investigate the significant difference between left temporalis and right temporalis rest and MVC among the participants.

IV. DISCUSSION

In this study, we evaluated the effectiveness of surface electromyography in detecting the temporomandibular disorders (TMD) with the help of time-frequency domain analysis using discrete wavelet transform. The novel approach for this study is to take out the spectral peak features after denoising the EMG signal for further classification and detection. The feature representation for diagnosis using entropy based approach outlined in [18] is constraint with the magnitude variation. The proposed approach offers an integral advantage of filtration and feature selection as single processing unit. Discrete wavelet transformation has shown a significant advantage in frequency domain decomposition because of the property multi resolution coding.

The study was limited due to the small number of subjects and the heterogeneous group. Since this disorder has complex signs and symptoms, we have considered only masseter and temporalis muscle activity. Other than muscle activity, Temporomandibular Joint sounds could be analyzed. Although the results of the study indicated that surface electromyography can identify patients with TMD, Surface electromyography is noninvasive and easier to operate but during recording possibility of noises due to surrounding or sensors is accumulated which needs to be preprocessed before the analysis. Intramuscular electromyogram (EMG) may help in pattern recognition. However, the individual will experience discomfort as a result of the intrusive electrodes. The goal of the study was to determine if a complex disease can be represented through a phenotype that allows for a straightforward clinical assessment. It also wanted to know how much of the variation in the development of the neuromuscular system can be reduced through the use of morphologies.

V. CONCLUSION

The purpose of this study was to devise a new method for decomposing and classifying surface EMG signals using spectral coding approach in order to extract useful information. The proposed method is based on spectral domain signal denoising, which highlights the lowest distortion and allows the system to retrieve the smallest signal feasible. The resulting technology can greatly enhance signal retrieval accuracy. Spectral energy peaks as feature sets when applied to multiclass machine learning models performed better with accuracy and other parameters. Support Vector Machine enhanced performance and it can help with the accurate diagnosis. The subjects with TMD exhibited significant different muscle activity at than those with the control group. The theme of the study also highlighted the importance of having a comprehensive understanding of the complex disease. This is because the lack of a descriptive taxonomy can hinder the development of effective treatments. Our understanding of TMJ issues lags behind that of pain disorders. The various themes of the study also highlighted the importance of having a comprehensive understanding of the complex disease. This is because the lack of a descriptive taxonomy can hinder the development of effective treatments. The multiple approaches that are currently utilized in the research and development of TMD should be combined with a systematic strategy.

A Deep Learning Approach for Viral DNA Sequence Classification using Genetic Algorithm

Ahmed El-Tohamy, Huda Amin Maghwary, Nagwa Badr
Information Systems Department
Faculty of Computer and Information Sciences, Ain Shams University
Cairo, Egypt

***Abstract*—DNA sequence classification is one of the major challenges in biological data processing. The identification and classification of novel viral genome sequences drastically help in reducing the dangers of a viral outbreak like COVID-19. The more accurate the classification of these viruses, the faster a vaccine can be produced to counter them. Thus, more accurate methods should be utilized to classify the viral DNA. This research proposes a hybrid deep learning model for efficient viral DNA sequence classification. A genetic algorithm (GA) was utilized for weight optimization with Convolutional Neural Networks (CNN) architecture. Furthermore, Long Short-Term Memory (LSTM) as well as Bidirectional CNN-LSTM model architectures are employed. Encoding methods are needed to transform the DNA into numeric format for the proposed model. Three different encoding methods to represent DNA sequences as input to the proposed model were experimented: k-mer, label encoding, and one hot vector encoding. Furthermore, an efficient oversampling method was applied to overcome the imbalanced dataset issues. The performance of the proposed GA optimized CNN hybrid model using label encoding achieved the highest classification accuracy of 94.88% compared with other encoding methods.**

Keywords*—Deep learning; sequence classification; convolutional neural networks; genetic algorithm; sequence encoding

I. Introduction

Viruses are the leading cause of infectious diseases and have a harmful impact on the human population. Recent examples of such viruses include COVID-19, SARS, and MERS. As a result of viral outbreaks, new vaccines have been developed for such pathogens [1]. When it comes to virus subtyping and taxonomy classification, the classification of a virus's genomic sequence is extremely vital to analyze and understand for faster production of such vaccines. A virus's genome is either made up of DNA or RNA, and it is referred to as a DNA virus or an RNA virus, accordingly [2]. An organism's genetic code is encoded in the deoxyribonucleic acid (DNA). Adenine (A), thymine (T), cytosine (C), and guanine (G) are the four nucleotides that the DNA consists of. These are referred to as the DNA nucleotide bases [3]. Each type of nucleotide has a binding to its complementary pair on the opposite strand in the double-stranded DNA. Adenine and cytosine form a pair with thymine and guanine, respectively. Single-stranded or double-stranded RNA are both possible for ribonucleic acid. T is replaced by U in RNA. The improvement of phylogenetic and functional research of viruses may be enhanced by the correct classification of genomic sequences [4,5]. Genomic sequences are classified into different groups based on their qualities, traits, or attributes, and this process is known as genomic sequencing classification. The more information is known about the virus, the closer an efficient vaccine can be developed quickly. Because viruses' genomic sequences may have little in common with those of other viruses, it is difficult to classify them. The genomic sequence can be classified using several different approaches. Machine learning models can be trained using well-understood sequences to predict the profile of unknown sequences [6]. As a new branch of machine learning, deep learning has emerged in the last several years. To represent data at increasingly higher levels of abstraction, these models employ multiple non-linear transformations. These models can deal with complex challenges because of their many hidden layers. Many studies have used machine learning and deep learning algorithms to analyze DNA sequences [6,7]. Manual feature extraction is used in these machine learning models [8]. On the other hand, this can lead to various complications, such as selecting features that do not lead to the optimal solution or missing out on key features. Most significantly, the main key features from the DNA dataset extracted are not clear. Besides, it is difficult to extract these features manually using traditional machine learning algorithms. Therefore, an automatic feature selection approach is proposed to overcome this issue. One of the greatest deep-learning methods for extracting important characteristics from a dataset is convolutional neural networks (CNNs) [9,10]. This study proposes an optimized convolutional neural network architecture for DNA sequence classification using genetic algorithm (GA) optimization layer as well as a long short-term memory (LSTM) layer. LSTM is a kind of recurrent neural network (RNN). It can process entire sequences of data effectively [11]. Besides, A genetic algorithm (GA) is proposed to optimize the deep learning model. GA is a heuristic approach inspired by the process of natural selection that is used in computer science and operations research [12]. It is a subclass of evolutionary algorithms (EA) that includes other metaheuristics. Genetic algorithms are commonly employed to generate solutions to optimization and search problems by utilizing bio-inspired operators such as mutation, crossover, and selection [13,14]. A genetic algorithm optimization layer was implemented to improve the accuracy of the classification model. The introduction of evolutionary algorithms such as genetic algorithms showed to optimize deep neural network weight matrix [15]. Thus, optimizing the weight matrix of the

convolutional neural network can achieve a better classification accuracy. It can also give better classification results for the LSTM models as the CNN layer output is used as an input to them. As a proof of concept, the optimized model was compared with and without the proposed GA optimization layer. The accuracy of the model with the GA optimization layer is shown to be better than the model without it. Moreover, a comparison was held using the same dataset with previously implemented models. The used dataset contains more viral sequences that may dominate the learning process which lead to a false increase in the overall accuracy. Therefore, an improved oversampling approach was applied to overcome the imbalanced dataset issue. The main contributions of this paper include a proposal of a hybrid deep learning model for efficient viral DNA sequence classification and an introduction of an optimization evolutionary algorithm to the proposed classification framework to improve the overall accuracy. In addition, an efficient oversampling approach is applied for handling the imbalanced dataset as well as increasing the dataset class variability. Besides, one-hot encoding is newly experimented on the viral DNA sequence dataset as an encoding method whereas k-mer encoding [16] and label encoding was used before. The paper is organized as follows: in Section II, the related work is reviewed. Section III describes the dataset and the different preprocessing techniques applied on the dataset. Then, the proposed approach is presented. In Section IV, the experimental results and comparisons with other models are demonstrated. Finally, the paper is concluded in Section V.

II. Related Work

Different studies employed several models and techniques for the classification of viral sequences. In [17], a new approach for classifying the Avian Influenza A viral (AIAV) sequences of the hemagglutinin (HA) and neuraminidase (NA) genes into subtypes using DNA sequence data and physicochemical properties is proposed. Mainly using machine learning techniques, four different classifiers, Naïve Bayes, Support Vector Machine (SVM), K-nearest neighbor (KNN), and Decision Tree were compared. The Decision Tree achieved the best accuracy of 95%.

In [18], the author proposed three models for the classification of different viral DNA sequences using raw DNA sequence data. The three classification models were CNN, long short-term memory (LSTM), and convolutional neural network bidirectional long short-term memory (CNN-Bidirectional LSTM). He used the Synthetic Minority Oversampling Technique (SMOTE) algorithm for data oversampling to overcome imbalanced dataset problem with two encoding methods: label encoding and k-mer encoding. Results showed that k-mer encoding achieved the best results with 93.16% accuracy of the CNN model.

In [19], the author used Random Forest and Artificial Neural Network models with metagenomic sequences that were taxonomically sorted into virus and non-virus categories. The algorithms attained accuracy considerably above the level of chance, with an area under the ROC curve of 0.79. There were two codons (TCG and CGC) that showed the most discriminative features for classification.

In [20], the author utilized combining two classification algorithms with ensemble techniques such as Xgboost and random Forest to improve the accuracy of classifying DNA sequence splice junction types for small example datasets. They achieved an accuracy of 96.24% for Xgboost and 95.11% for Random Forest.

The author in [9] developed a novel method for classifying DNA sequences using a convolutional neural network and treating the sequences as text input. The author employed one-hot vectors to represent sequences as input to the model. The approach was evaluated on 12 DNA sequence datasets. Significant improvements were found in all the previous models using his proposed approach for DNA sequence classification with improved accuracy up to 6.12% on the H3K4me3 dataset.

Most of the existing works tend to focus on training the classification models without any kinds of optimization both on the preprocessing step and prior to the classification step. Therefore, in this research, a hybrid deep learning model with a genetic algorithm optimization layer is proposed. The genetic algorithm layer is applied to optimize the weights of the CNN model. The CNN model is then utilized for classification as a separate model as well as an input to the LSTM and CNN-LSTM Bidirectional models. This will greatly improve the overall accuracy. Thus, the classification method uses the optimized genetic algorithm to generate CNN weights. As a prior step in data preprocessing, Adaptive Synthetic Sampling Approach (ADASYN) is used to handle the imbalanced dataset issues.

III. Materials and Methods

A. Dataset

The DNA dataset was extracted from the National Center for Biotechnology Information (NCBI) (https://www.ncbi.nlm.nih.gov). NCBI contains entire DNA sequences for viruses which is publicly available. The acquired virus DNA sequence datasets are COVID, SARS, MERS, dengue, hepatitis, and influenza. In addition, entire DNA sequences for Zika and EBOLA viruses were collected. A FASTA file for each sequence data was collected and downloaded for complete genetic sequences of each class label with sequence ranges from 8 to 38,012 nucleotides. The collected dataset consists of 86,637 inputs. A distribution of each class label and the count of samples in each label is shown in Table I.

TABLE I. Dataset Class Distribution

Class Label	Number of Samples
COVID	45216
SARS	7311
MERS	6735
Dengue	1994
Hepatitis	8577
Influenza	11862
Zika	1920
EBOLA	3022

As shown in Table I, the minority classes like MERS, SARS, Zika, Ebola, and Dengue have low counts unlike COVID, Hepatitis, and Influenza. To overcome this imbalanced dataset issue, the Adaptive Synthetic Sampling Approach (ADASYN) [21] was applied. ADASYN is used to generate synthetic data for the minority classes to oversample them to match the majority classes. ADASYN is a generalized form of the SMOTE (Synthetic Minority Oversampling Technique) algorithm. SMOTE [22] is an oversampling technique in which synthetic samples are generated for the minority data class. Random oversampling can lead to overfitting, which is why this approach helps alleviate that problem [23]. The main difference between ADASYN and SMOTE is that by using ADASYN the number of synthetic instances generated for samples that are difficult to learn is determined by taking the density distribution into account. As a result, difficult-to-learn samples can be used to adaptively alter decision boundaries. ADASYN works by locating the closest k-nearest neighbors of the minority class using Euclidean distance. Then, it chooses a random neighbor, and a line is constructed between the neighbor and the minority class data point. A synthetic sample is generated between them. Fig. 1 demonstrates how the synthetic data points are generated using ADASYN.

B. Data Preproccessing

The most important aspect of both machine learning and deep learning algorithms is preprocessing of data. It affects the accuracy of the proposed model drastically. DNA sequences, unlike text data, are sequences of consecutive letters without a space between them. No words or phrases can be found in the DNA sequence. As a result, k-mer encoding [16] is used for converting DNA sequences into word sequences. This preserves the nucleotide positions of each word in the sequence. Two vector encoding methods, one hot vector encoding, and label encoding are also used to represent the numerical values of the sequences [24]. One hot vector encoding, and label encoding are used because in contrast to image data, which is represented as a two-dimensional numerical matrix as an input to the CNN, text data is represented as a one-dimensional series of consecutive characters. As a result, it must be converted to numerical values to use as the input for the CNN model. A demonstration of both sequence encodings is shown in Fig. 2.

Thus, encoding is the process of transforming nucleotide categorical data into numerical data. In this research paper, three different types of encoding methods, Label encoding, one hot vector encoding, and k-mer encoding, were experimented with separately to encode the DNA sequence and convert it to the suitable numerical form for deep learning. Label encoding is a popular method for representing categorical data as binary vectors efficiently. For each of the four classes of nucleotides (A, T, G, and C), each one is represented as a number to form an array. A is given the value of 1, C is given the value of 2, G is given the value of 3, and finally, T is given the value of 4. An example sequence of (AACG) will be represented as an array of integers of (1,1,2,3). In decimal-binary vector encoding, one-hot vector encoding for DNA sequences is another way of representing nucleotide sequence data in numerical vector representation. Each nucleotide is represented by a binary vector of length 4. A is represented as (1,0,0,0), C as (0,1,0,0), G as (0,0,1,0) and T as (0,0,0,1). Each nucleotide holds a vector representation of 4x1 dimension. Finally, k-mer encoding transforms the complete DNA sequence into smaller substrings of length k, which represents a word. These words can be used effectively in natural language processing techniques.

C. Classification Methods

Three deep learning models were applied. One model consists of the CNN layer only. The other two models consist of two layers. The first layer of both models is the CNN layer. The CNN layer is used as a feature extraction layer. The output of the CNN layer is given as an input to the second layer. The second layer of the first model is CNN-LSTM. The second layer of the second model is CNN-Bidirectional LSTM. One of the main contributions of this work is applying a standard Genetic Algorithm (GA) to optimize each CNN layer in the models. The GA layer is used to optimize the weights in the CNN layer, which in turn improves the accuracy of the classification models [25,26,27]. Each model is trained and tested using three different encoding methods, label encoding, one-hot vector encoding, and finally using k-mer encoding. A summary of the proposed workflow with the models is shown in Fig. 3.

As demonstrated in Fig. 3, after the data preprocessing the GA layer is utilized to optimize the weights of the CNN layer. Then, the three models are used for the classification process.

This section demonstrates the classification methods in detail. In subsection 1, a detailed demonstration of the proposed genetic algorithm optimization layer will be presented. Following that, in subsections 2 and 3 the used classification models will be explained, respectively.

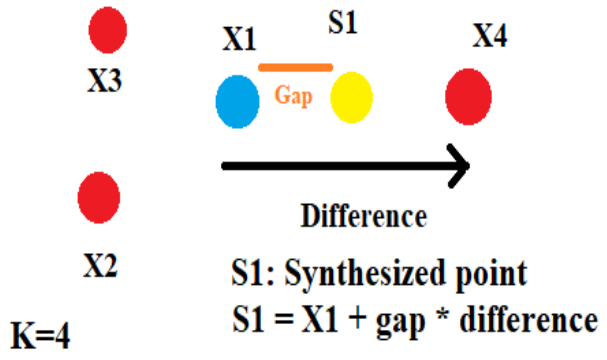

Fig. 1. Generation of Synthetic Data Points using ADASYN with k=4 as an Example and S1 Represents the Synthesized Point of the Minority Class where X_n Represents a Data Point.

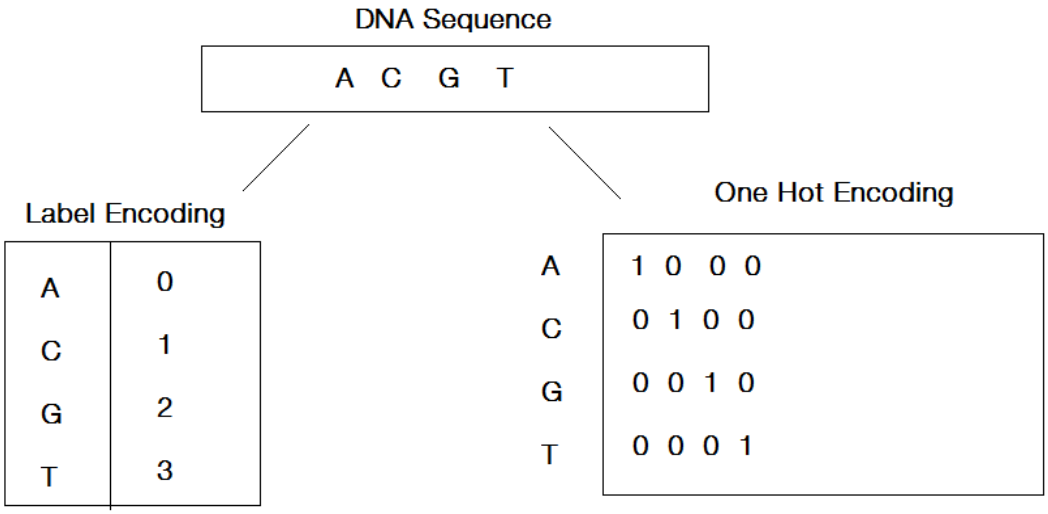

Fig. 2. Difference between One-Hot Encoding and Label Encoding for DNA Sequences.

1) Optimization layer using genetic algorithm (GA): Genetic algorithm [12] relies on biologically inspired operators including mutation, crossover, and selection to produce high-quality solutions to optimization and search problems. GA is mainly a heuristic approach for the optimization of search problems. It is used because the concern is about the optimization of the weights not how much time it takes. Thus, in this research, it is used to optimize the weights of the CNN layer.

The standard GA progression originally proceeds as follows:

- The population's initialization.
- Evaluating each member's fitness.
- Choosing parents to create children for the next generation.
- Parental cross-over to create offspring.
- Randomly mutating the offspring.
- Keep evaluating, reproducing, and mutating until the loss function is optimized.

The following are the proposed steps involved in integrating the GA with the CNN:

- Randomization of initial values of each chromosome.
- Substituting the CNN weights with the values of the selected chromosome.
- Using the newly obtained weights to update the weights of the CNN.
- Calculating the fitness of the present offspring by subtracting the resultant output from the goal output sequence.
- Repeating the simulation for all members of the population.
- Using a roulette strategy for selecting the parents of the next generation.
- Crossover of the parents to produce new offspring.
- Mutating the offspring with a 1% probability of mutation.
- Repeat the previous steps until the evaluation metrics or loss function is optimized. A pseudocode of the proposed GA algorithm is shown in Algorithm 1.

Algorithm 1: Genetic Algorithm for CNN Optimization

Input:
Population Number, *n*
Iterations, *I*

Output: Global best configuration of CNN weights O_{best}

Begin
Generation of population *n*
Random initialization of each chromosome in *n*
Set counter = 0
Compute the fitness function of each chromosome
While (counter < *I*)
Select chromosome pair using roulette
Calculate the fitness of the current offspring
Apply crossing over with 70% probability
Apply mutation with 1% probability
Replace old population with new population
Save the current configuration of offspring
Update O_{best}
Increment counter
End while
Return The best solution of configuration O_{best}

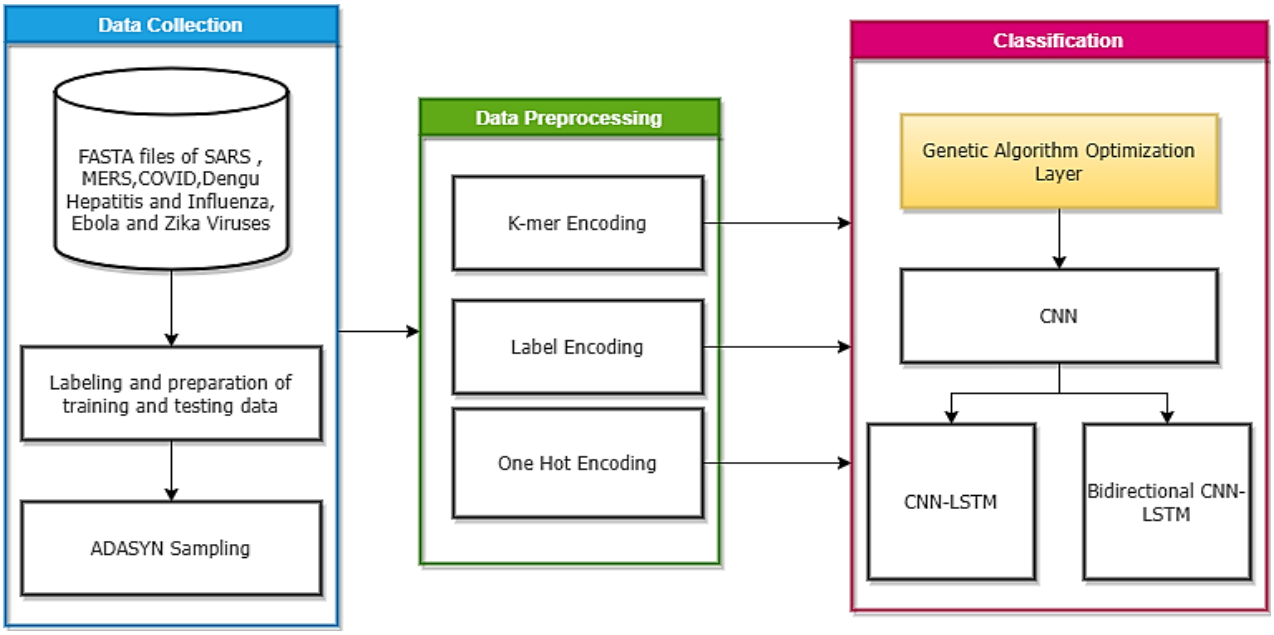

Fig. 3. Summary of the Proposed Workflow.

In the proposed GA algorithm, the chromosomes of the original GA reflect the CNN weights in GA. The population, which is made up of several chromosomes, is seeded at random. The number of weight vectors is represented by the number of chromosomes. The fitness function is the training set's accuracy. As a result, while using CNN, the optimization challenge entails maximizing the accuracy of the training set.

The first phase in the algorithm is the generation of the starting population. This is the first stage of the process. In the CNN model, the values of the hyperparameters are picked at random from the defined search spaces with the help of the python random module, which follows the uniform distribution. The fitness evaluation is the next phase. The validation accuracy and the average of the model's five highest training accuracy were both considered in the trials as fitness functions. The highest accuracy represents the highest fitness. The selection method employed is the roulette wheel. Then, the crossover and mutation stages proceeds. After the crossover occurs, the entire new generation gets mutated. Crossover is accomplished by picking hyperparameters between each parent at random in an equiprobable manner. Additionally, the parents are chosen equitably among the surviving. After forming a new generation, the procedure is repeated iteratively from the second step until the final condition is satisfied. The final condition in the context is the occurrence of a specified number of generations. The output of the algorithm is the configuration of the weight with the highest fitness.

In order to keep track of the GA configuration on each generation after evaluating the loss function, the complete parameters of the generation are saved in memory with its corresponding accuracy as well as the selected parents: a Boolean flag which represents if mutation occurs or not, the mutated individual if any and finally the crossing over Boolean flag.

2) Convolutional neural networks (CNN): In deep learning, Convolutional Neural Networks (CNN) [9] is a commonly used technique that may produce cutting-edge results for the majority of classification problems [9, 28, 29]. CNN not only works well in image classification, but it may also deliver accurate results when dealing with text data. CNN is mostly used to automatically extract the features from an input dataset, as opposed to machine learning models, which need the user to select the features from an input dataset. Text classification is processed using 1D CNN. CNN can only deal with numerical data. Therefore, the DNA sequence must be transformed into numerical values via one-hot encoding or label encoding. The CNN architecture extracts features from the input dataset through the use of a series of convolutional layers. After each convolutional layer, there is a maximum pooling layer, and the size of the derived features is lowered. This layer turns the words into a vector space model based on the frequency with which a word appears near other words in the text. For feature extraction, two convolutional layers with filters of 128 and 64 are used in the model, as well as a kernel of size (2 x 2) with ReLU as the activation function for the extraction of features. A max-pooling layer of size (2x2) is added to the feature map to minimize the overall size of the feature map. The softmax function [30] is utilized as the classification layer. In neural network models that predict a multinomial probability distribution, the softmax function is chosen as the activation function in the output layer. It produces an output that shows the probability of each class label. It can provide good results for multi-classification of DNA sequences. The CNN weights are already optimized due to the previous GA layer. Thus, the accuracy of the produced CNN layer is optimal for using it for the next models.

3) CNN-LSTM and CNN-bidirectional LSTM layers: Long Short-Term Memory (LSTM) [11] is an RNN that can learn the long-term dependencies in a sequence. It is used in the prediction and classification of sequences [10,11,26]. It consists of a succession of cells, each of which has three gates: input, output, and forget. In this situation, the LSTM will only retain certain information and discard others. The LSTM output gate uses the sigmoid activation function and the tanh activation function to analyze the cell state to determine what value can be produced. After the convolutional layers, a 100-memory-unit LSTM layer is added to the model to help predict classification labels. The CNN output features are sent into the LSTM layer for classification. Hybrid models using CNN and LSTM are commonly used in NLP tasks to increase classification accuracy [9,10,11,29,31]. Text classification has been improved by using this hybrid model. With dropout layers and regularization approaches, the overfitting problem is minimized in the LSTM modeling process. DNA sequence classification is performed using a bidirectional LSTM/CNN hybrid model. The model employs a CNN for feature extraction and a bidirectional LSTM for classification. Then, CNN is sent into the Bidirectional LSTM as an input. DNA sequence classification makes use of a bidirectional LSTM/CNN hybrid model. For classification, the model relies on a bidirectional LSTM and CNN. The bidirectional LSTM has two RNNs, one for the forward sequence and one for the backward sequence [32].

IV. Experimental Results

The experiments were conducted on a machine using an NVIDIA 1660Ti GPU processor with a RAM size of 16GB. The CPU of the machine was Intel Core i5-8300H @2.30GHz with 4 Cores and 8 logical processors. The models were trained and tested using Tensorflow [33] in python. The dataset was divided into 60% training, 20% validation, and 20% testing using 10-fold cross-validation.

Before the classification phase, the GA was experimented on with different parameters. Several number of generations to end the GA optimization were used. The best results showed that using 12 generations as the specified number of generations yielded the best results. Several mutation probabilities were also used but the one that yielded the best results was a 1% rate of mutation. The rate of crossing-over used was 70%. The categorical cross-entropy function was used in the case of one hot encoding while binary cross-entropy was used with other embeddings as a loss function in the training phase. The error between the actual output and the goal label, on which the weights are trained and updated, is calculated using the loss function of the GA algorithm. A variety of hyperparameters, such as filter size, layer count, and embedding dimension, were used to evaluate the CNN, CNN-LSTM, and CNN-bidirectional LSTM models but the same architecture is used and the same hyperparameters as [18] in testing and evaluation to correctly compare the results. The embedding layer has 8 dimensions, which is the initial layer. If a word appears often next to other words, this layer transforms it into the vector space. This layer, which employs random weights, is responsible for figuring out how each word in the training dataset should be embedded. For feature extraction, a 2x2 kernel with ReLU as an activation function and two convolutional layers with 128 and 64-bit filters are added to the model. Adding a max-pooling layer of size reduces the feature map dimensions (2x2). Using the flatten layer, the feature maps are finally turned into single-column vectors. A thick layer with neurons 128 and 64 receives the output. The number of filters in each layer are 128, 64, and 32, respectively. The embedding dimension of 32 and a k-mer length of 6 are included in the filter's dimensions. The models were trained with 10 epochs each for each of the encoding methods. The resultant training accuracy for each model is shown in Table II.

The same LSTM and LSTM/CNN hybrid models are used in [18] to correctly compare the results and improve upon the currently existing model after adding the GA layer and using ADASYN for oversampling as well as increasing the dataset variability. Increasing the number of class labels in the dataset and the number of input sequences also contributed to the overall better performance of the models. The accuracy increased as compared to [18] by the introduction of the two new class labels for the Zika and the Ebola virus as well as the additional data collected for the rest of the class labels. Label encoding achieved the best accuracy in the CNN classification layer in both training and testing thus it would achieve the best results in the remaining layers. This is because the CNN layer is used as an input to both the CNN-LSTM layer and the CNN Bidirectional LSTM layer. The models were trained and tested using GA optimization and without using GA optimization. Results show that GA optimization yielded noticeably better results in all label, one-hot and k-mer encodings than the results without GA optimization. Testing results and the results of the experiments using GA optimization and the same experiment without using the optimization layer are shown in Table III.

TABLE II. Training Accuracy of the Proposed Method

ENCODING METHOD	**CLASSIFICATION METHOD**		
	CNN	**CNN-LSTM**	**CNN Bidirectional LSTM**
Label Encoding	**95.12%**	**94.36%**	**93.82%**
One-Hot Encoding	94.57%	93.89%	93.22%
K-mer Encoding	94.51%	94.21%	93.55%

TABLE III. COMPARISON OF CLASSIFICATION MODELS WITH AND WITHOUT GA OPTIMIZATION LAYER USING DIFFERENT ENCODING METHODS

ENCODING METHOD	CLASSIFICATION METHOD					
	CNN		CNN-LSTM		CNN Bidirectional LSTM	
	Using GA Optimization	Without Using GA Optimization	Using GA Optimization	Without Using GA Optimization	Using GA Optimization	Without Using GA Optimization
Label Encoding	**93.51%**	92.92%	**93.27%**	92.78%	**93.20%**	92.14%
One-Hot Encoding	**93.77%**	93.16%	**93.54%**	93.02%	**93.44%**	93.13%
K-mer Encoding	**93.51%**	92.92%	**93.27%**	92.78%	**93.20%**	92.14%

With the addition of the GA optimization layer, label encoding, one hot encoding and k-mer encoding achieved an accuracy of 94.88%, 94.33% and 94.05%, respectively using the CNN model. Using CNN-LSTM, label encoding, one hot encoding and k-mer encoding achieved an accuracy of 94.42%, 93.51% and 93.9%, respectively. Finally utilizing the CNN-LSTM Bidirectional model, the accuracies were 93.74% for label encoding, 93.01% for one-hot encoding and 93.37% for k-mer encoding. On the other hand, without using the GA optimization layer the accuracy for each model was considerably less. CNN achieved an accuracy of 93.22%, 93.50% and 93.54% for label encoding, one hot encoding and k-mer encoding, respectively. Using CNN-LSTM model, label encoding achieved an accuracy of 93.5%, one-hot encoding achieved an accuracy of 91.59% and k-mer encoding showed an accuracy of 92.16%. Finally, CNN Bidirectional model achieved an accuracy of 91.35%, 92.16% and 92.46% for label encoding, one hot encoding and k-mer encoding, respectively. Among all the three encoding techniques, label encoding is shown to achieve the best results overall with the introduction of the GA layer and without using it.

In order to compare the results with [18], the two additional class labels Zika and EBOLA viruses were removed from the dataset and then the dataset was experimented on. Thus, the experiment was carried on using ADASYN for oversampling and the addition of the GA optimization layer in comparison with [18] who used SMOTE and the hybrid model without the addition of the GA layer. The resultant accuracies are shown in Table IV. Furthermore, only label encoding and k-mer encoding is demonstrated for comparison as in [18].

By comparing the results of k-mer encoding using GA and introducing two new class labels to the dataset and ADASYN oversampling method, the proposed method is proved to give better accuracy results than the previous model used by [18]. The best results from [18] were achieved using k-mer encoding. In the proposed method in this study the resulting accuracy using k-mer encoding were 94.05% using CNN, 93.9% using CNN-LSTM and 93.37% using CNN Bidirectional LSTM. Whereas it previously resulted in 93.16% using CNN, 93.02% using CNN-LSTM and 93.13% using CNN-Bidirectional LSTM without GA optimization and using SMOTE oversampling with less dataset sequences and less class labels. Thus, the proposed method achieved best accuracy using k-mer encoding in comparison to [18]. It also achieved the best overall classification accuracy of 94.88% using label encoding. The training and validation loss curves for the three encoding methods are shown in Fig. 4.

The accuracy curve shows that label encoding achieved the best training and testing results overall among all the three used encoding methods. One hot encoding showed similar results for both training and testing in CNN Bidirectional LSTM but better training accuracy using CNN and LSTM. Utilizing ADASYN resulted in better results in the overall training accuracy due to the optimized oversampling of the dataset in the minority class labels such as Zika and Dengue. As a limitation, improving the accuracy by introducing the optimization layer leads to an increase in computational time. Moreover, the generated synthetic dataset in the oversampling method might have some fuzzy class boundaries.

TABLE IV. COMPARISON OF CLASSIFICATION MODELS WITH GUNASEKARAN, ET AL. [18] USING GA OPTIMIZATION AND WITHOUT THE ADDITION OF THE 2 NEW CLASS LABELS

ENCODING METHOD	CLASSIFICATION METHOD					
	CNN		CNN-LSTM		CNN Bidirectional LSTM	
	Proposed Model	Gunasekaran, et al. [18]	Proposed Model	Gunasekaran, et al. [18]	Proposed Model	Gunasekaran, et al. [18]
Label Encoding	**93.51%**	92.92%	**93.27%**	92.78%	**93.20%**	92.14%
K-mer Encoding	**93.77%**	93.16%	**93.54%**	93.02%	**93.44%**	93.13%

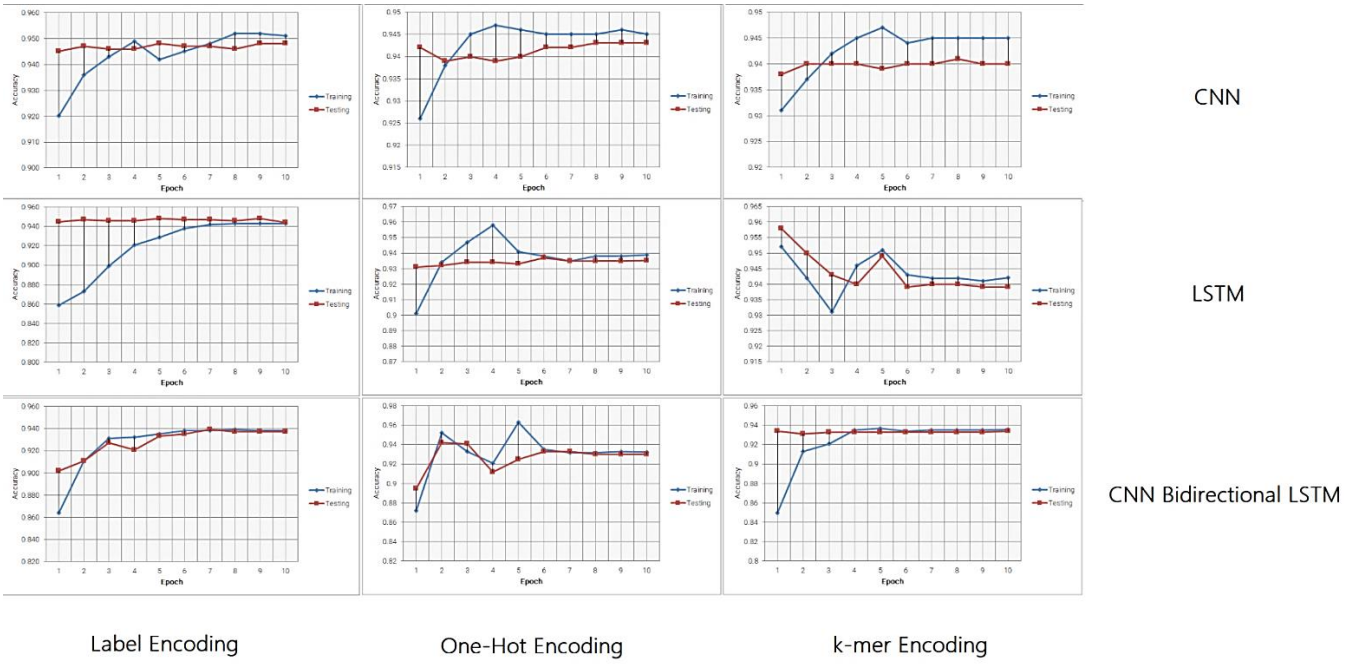

Fig. 4. The Resultant Training and Validation Loss Curves using GA Optimization and without using GA Optimization with all 3 Different Encoding Methods.

V. Conclusion

The classification of viral DNA poses a major challenge in recent years. The accurate classification of the DNA of pandemic viruses will greatly help in the production of vaccines and the identification of new pathogens. This study proposes an optimized method for the accurate classification of viral DNA utilizing genetic algorithm for optimization classification using a hybrid deep learning model. The proposed method uses a genetic algorithm to optimize the weights of the CNN model which enhances the overall classification accuracy. The study also utilizes ADASYN as an optimized dataset oversampling technique for the minority class labels. Three encoding techniques were experimented with which are label encoding, k-mer encoding, and one-hot encoding which was not used in previously proposed models. The experiments showed that the proposed optimization layer GA and ADASYN with the deep learning model outperformed previously proposed models on the same dataset in terms of classification accuracy. The models were then trained and tested with GA optimization and without GA optimization. The GA optimization drastically affected the accuracy of the models. As a result, label encoding was shown to achieve the best accuracy of 94.88% using CNN. Besides, k-mer encoding achieved an accuracy of 94.05% whereas the best results achieved by a previously proposed model were 93.16%. As a result, it is shown that the introduction of an optimization layer improved the overall classification accuracy. The introduction of more evolutionary or optimization algorithms in future research could improve the accuracy further. Furthermore, the use of an optimized oversampling technique yielded better overall accuracy. Therefore, by using ADASYN which is an optimized version of SMOTE yielded better results.

For future work, it is planned to introduce more viral DNA sequences in the training dataset and use other selection criteria for the GA selection algorithm which could further improve the accuracy of the classification. In addition, more optimization methods could be utilized.

***Abstract*—Data integration is a popular technique or method today for data converting and sharing within new application with different database format and location. The interaction of data from one application system to another application system requires an intermediary software or middleware that allows the data to be transferred or read systematically and easily. The development of dynamic algorithms allows data in various formats, whether structured or unstructured, to be transferred to various types of databases smoothly. A case study was conducted for the Bill of Quantity (BQ) data in the known Excel format generated through CostX software in a single sheet Excel file. It was transferred to a single workbook with multiple sheets with formulation generated automatically. Thus, an algorithm was developed and tested through the development of the J-Selaras System. This algorithm can remove the noisy data or data symbols that are not related in the excel single sheet (CostX) file and automatically transfer to multiple excel sheets with macros formulation quickly. The implementation results indicate a significant contribution where it reduces in execution time of BQ processes and manpower resources used.**

***Keywords*—Automated data integration algorithm; bill of quantity (BQ); CostX; single and multiple sheets; J-Selaras tool**

I. Introduction

This research case study focuses on Malaysian government agency, named as Jabatan Kerja Raya (JKR) which is responsible for the BQ for construction in a tendering process. The collaboration is done to solve the manual process in converting The CostX single sheet BQ into MS Excel multiple sheets with macro function.

The Malaysian Public Works Department or simplified as Jabatan Kerja Raya (JKR) Malaysia is the Malaysia's federal government department under the roof of Ministry of Works Malaysia (MOW), that is accountable for construction and maintenance activities on public facility and infrastructure [1]. The JKR Strategic Plan 2021-2025 was issued, and its outlines are five strategic themes. The initiatives in the strategic themes are to realize the government effort in achieving the Shared Prosperity Vision 2030. In the alignment to the first theme in the JKR Strategic Framework, the demands for a project delivery in terms of the completion within the stipulated time, within the budget and the stated quality becomes more prominent in fulfilling customer satisfaction.

There is the need to expedite the preparation of the contract document after signing of the Letter of Acceptance (LoA) by the contractor before the project is being awarded. Both the Government and the contractor must fulfil their obligations according to the contract's provisions. Typically, the contractor must provide the contract conditions, the tender drawings, the Bills of Quantities (BQ), and the other related documents throughout the process of tendering. These materials will be bound into the Contract Document after the LoA is issued. The contract document must be prepared within four (4) months upon signing of the LoA by the Contractor [2]. A Bill of Quantities (BQ) [3] is a document created by a quantity surveyor or cost consultant that contains information on certain sections. The sections may include Form of Tender, Information such as the scope of work, Requirements on certain material's quantity, Pricing schedule, Provisional sums, and Day works and the labor costs in a construction project. The BQ is an essential part of the tender. Without a suitable BQ, a tender is incomplete. The contractors can use this information and data to quote rates for their specific work.

*Corresponding Author

The purpose of BQ is to make the tendering process more uniform. Other objectives are to establish a transparent and exact method for valuing the project, to provide a thorough description of the work and its rates, as well as the overall cost. A solid BQ helps quantity surveyors in ensuring that individual contractors have filed valid tenders that comply with the specifications.

The CostX [4] is the offline database system using PostgreSQL. CostX is a Construction Management Software that is designed to serve a construction activity especially for Enterprises or Small Medium Enterprise company. The limitation of CostX is subject to the offline system and it provides the details of each itemize sections for construction in only single sheet. This research aims at solving the manual process of transferring BQ from CostX system into Excel format by providing the automated converting tool for BQ to ease the price generation during tendering activities. The delay in preparing the contract document is due to the lengthy time taken in the process of the Rationalizing of Rates for Bills of Quantities (RoBQ) which are the part of the contract document. The RoBQ needs to be carefully and thoroughly examined, the reasonableness of the tenderer price rates, and the reasonably adjusted price rates will become the BQ contract rates. The BQ contract rates will determine the value of the variation work if there are any variation during the construction period. If any, the value of the variation work will increase the cost of the project delivery and will affect the initial budget approved. Currently, in JKR, the RoBQ process is not yet adopting an information and Communication Technology (ICT), and therefore the process of the RoBQ will be time consuming.

Data integration [5] is the data combination from different sources to help data managers and executives analyze it and make smarter business decisions. In this project, we deploy integration of formatting in CostX system via PostgreSQL database [6] and MS Excel format into a structured MySQL database in generating standardized BQ pricing with a verification and validation from an accountable party for the user in construction company.

II. Proposed Methodology

The process of tendering process comprises of six steps as illustrated in Fig. 1. Step 1 consists of the filling up the BQ using CostX with PostgreSQL database [6] system and converted to Excel macro format that is stored in Cloud database. In step 2, the softcopy of BQ estimation in Excel format is given to the successful tenderers and shortlisted tenderers that is obtained from the tender appraiser officer. Then in step 3, the BQ in Excel format from the estimation department that is awarded to the successful tenderers is uploaded to the J-Selaras system. In step 4, J-Selaras system will create a pricing comparison table. Then in step 5, each price rates for each BQ will be analyzed using the cut-off concepts such as mean, max, average, and standard deviation figures. The adjustment price prior to the cut-off formula will be reviewed by the appointed reviewer and the verified officer in charge in step 6. The J-Selaras system will check for arithmetical error and the adjusted price is matched with the actual price in the contract tender as stated in the Letter of Acceptance (SST).

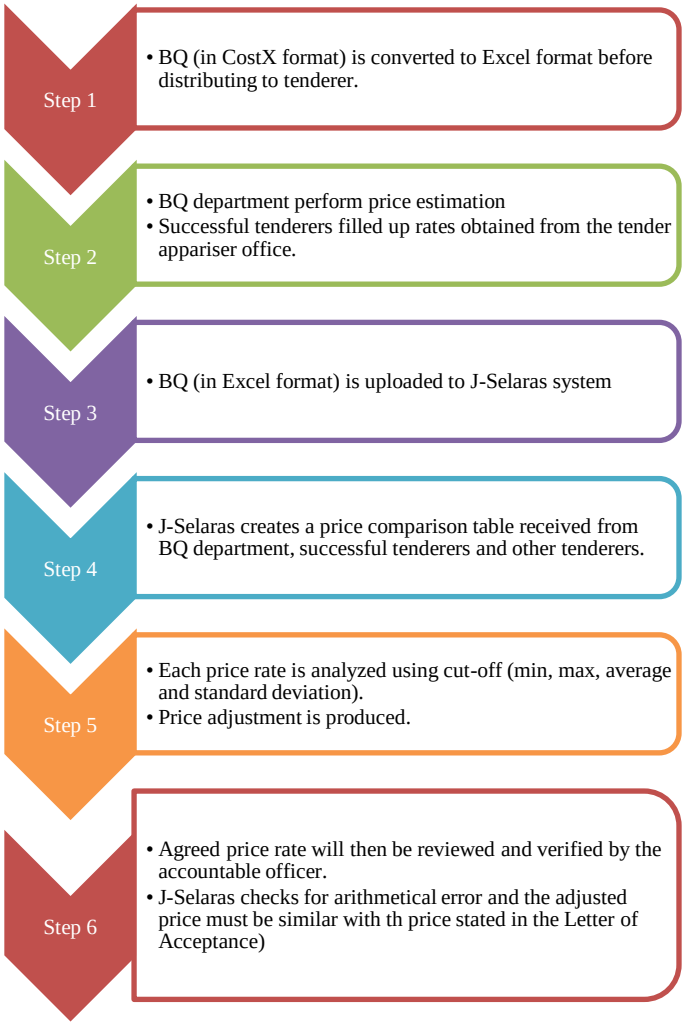

Fig. 1. Steps Involved in Data Transfer Process from CostX to Excel Format and the BQ Tender Price Adjustment Rate Determination Process.

III. J-Selaras Development Model

The J-Selaras converting tool is developed based on filtering algorithm as depicted in Fig. 2.

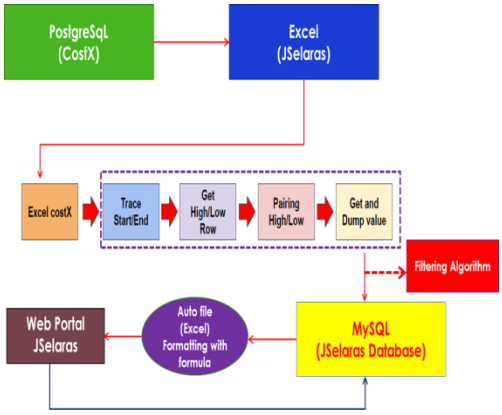

Fig. 2. J-Selaras Model.

The detail specification of BQ is first filled up into CostX system that is built with PostgreSQL database. Then, from CostX system, the BQ specification is downloaded in excel format and converted into J-Selaras system through filtering algorithm by first, tracing the Start and End (Start/End) keywords. Secondly, the cells that cover from Start to the End will be highlighted to get the High row to Low row. Thirdly, those cells involved in High and Low rows will be paired before getting all values involved in all the cells. Refer to next section for details on Filtering algorithm.

A. Filtering Algorithm

Fig. 3 shows the steps in filtering algorithm where the conversion is done from CostX file format into Excel format.

Pre-requisite: $\forall s \{s: each\ sheets\ in\ Excel\}$
Start
1. *Trace the Start and End Keyword*
2. *Focus the value from the highest row to the lowest row*
3. *Pair the value from the highest row to the lowest row*
4. *Get the value and dump into the MySQL database of J-Selaras system*

End

Fig. 3. Filtering Algorithm.

B. BQ Pricing Standardization

Prior to being processed through filtering algorithm, the Bill of Quantity (BQ) is now converted and saved into MySQL database in J-Selaras system in Cloud environment. The list of BQ price is not yet standardized. The generated price in BQ needs to follow the standardization price that is set by the construction company. All prices of the materials set in BQ is standardized according to certain formula such as Z-Score [7]. The formula involved in Z-Score are Standard Deviation (SD), Min, Max, and cut-off indicates the pseudocode for Z-Score formula used in BQ pricing. The pseudocode for a BQ applying the Z-Score formulation is depicted in Fig. 4.

Given the BQ price of items, then
Start
1. *Compute the rMin and rMax*
2. *Analyse the price with cut-off*
3. *J-Selaras propose the BQ price*
   - *3.1 If the proposed BQ price > 115% and < +10%*
     - *3.1.1 J-Selaras accept the proposed price*
   - *3.2 Else*
     - *3.2.1 J-Selaras accept the cut-off price*

End
End

Fig. 4. Pseudocode in Z-Score Formulation.

Z-score [8-9] is based on the calculation of mean and standard deviation of an attribute. It is a measurement of difference between individual value and the mean population, and then divided by standard deviation of population. The computed, Z-score (Z) provides each feature with a zero mean and a unit variance. The foundation of Z-score is where the mathematical Gaussian curve or 'Bell Shaped' curve is applied to the data under study [10-11]. The Z-score, Z as in [12] is expressed as follow:

$$\text{Z- Score} = \frac{x_i - \bar{x}}{s} \quad (1)$$

Where x_i is an individual value, $\bar{x}$ is mean of samples and s is standard deviation of samples. The Z-score technique was proposed in the study to analyze the comparison of each rate in the BQ between all the short-listed tenderer, the successful tenderer and the department's cost estimation [13]. Meanwhile, the proposed rates in the BQ to be agreed by the successful tenderer will be automatically generated by the system based on the cut-off formula i.e., the rate of an item description is derived from the average rates of the total number of all the short-listed tenderer including the rate of the successful tenderer and the rate of the department's estimate [14]. The cut-off formula and the Z-score technique are like the tender evaluation system format. The cut-off principle means the lowest acceptable rate to be certified. The tenderer will not be able to complete the project if the rate is too low i.e., the rate is lower than and below the cut-off.

In accordance with statistical methods, the setting of the cut-off rate is based on 'Mean' and 'Standard Deviation' of the shortlisted tenderer rate including the Department's Estimates (AJ) rates, after rate 'freak' is removed. The range of the cut-off rate is in between not exceeded above +10% (<+10%) and is not exceeded below -15% (<-15%). After all the tenderer price BQ have been uploaded in the J-Selaras, the system will automatically do the analysis based on the setting of the cut-off and the z-score formula in the J-Selaras. Simultaneously, the J-Selaras suggests the contractor rate if the rate is within the cut-off range or suggests the cut-off rate if the contractor rate is out of the range.

In finalizing BQ for the contract document, the appropriate choice of the reasonable rate can be ultimately determined whether to accept the rate of a successful tenderer or the rate generated by the system or the rate of past projects or the current market review rate [15]. The reporting of the analysis is in the tabulation as shown in the Fig. 5. The added value, the J-Selaras system can be as the data cost collection center for price rate and as a reference especially in preparing department's estimate for new project.

IV. Experimentation Result

The J-Selaras system is developed under machine specification of VivoBook_ASUS Laptop X415EA_A416EA, Windows 11, i5-1135G7 and 12GB RAM as in Table I.

TABLE I. Machine Specification

System Model:	VivoBook_ASUS Laptop X415EA_A416EA
Operating System:	Windows 11 Home Single Language 64-bit (10.0, Build 22000) (22000.co_release.210604-1628)
Processor:	11th Gen Intel(R) Core (TM) @ 2.40GHz (8 CPUs), ~2.4GHz
Memory:	12288MB RAM
Available OS Memory:	11982MB RAM

A. Graphical User Interface

J-Selaras consists of seven modules i.e., Sign-up/Login-Logout Module, Registration of User Profile module, Upload-Download of CostX file format module, Excel Standardization format module, Analysis of Price-rate module, Report generation module and Maintenance module. The J-Selaras system is accessible at https://my-developments.com/JSelarasV5. Fig. 6(a) depicts the login page of J-Selaras admin while Fig. 6(b) shows the new user registration of J-Selaras system. Once the registration successful, then user is directed to J-Selaras dashboard as shown in Fig. 6(c). Fig. 6(d) indicates the list of J-Selaras users that are currently active while Fig. 6(e) and Fig. 6(f) portray all J-Selaras *admin* users and *Pentadbir J-Selaras* users. Fig. 6(g) to Fig. 6(h) dictate the Darul Quran list of projects and sample of Darul Quran project respectively. Meanwhile, Fig. 6(i) states the BQ that is ready to be downloaded and edited the price and Fig. 6(j) shows the sample of generated BQ price. Finally, Fig. 6(k) illustrates the sample of summarized BQ by J-Selaras.

Sample of Summarized BQ.

B. *Simulation Result*

Table II plots the result of simulation on BQ generation between the manual processes with the automated J-Selaras system.

TABLE II. THE EVALUATION OF THE EXECUTION TIME IN SECOND (S) BETWEEN THE MANUAL BQ GENERATION WITH J-SELARAS BQ GENERATION

Project	File Size (KB)	Manual Time Process (Ms Excel)(s)	Jselaras Tools time Process (s)
BQ for Project A	297	18000	3
BQ for Project B	301	21600	4
BQ for Project C	294	18000	3
BQ for Project D	424	25200	4
BQ for Project E	600	27000	5

The difference of time execution is recorded as the performance measurement in comparing the manual process of using CostX system with the proposed J-Selaras system for BQ generation of Project A to Project B. The processing time is recorded in second and the results from Table II is plotted in Fig. 7.

The recorded data is based on the five projects (Project A, Project B, Project C, Project D and Project E), the Excel file size in kilobyte (KB) and the execution time processing of the five projects. The manual process enquires more than 18000 seconds as compared to J-Selaras system that generates the BQ from three to five seconds only. With automated conversion tool as J-Selaras, we may have 6K times reduction in generating the BQ.

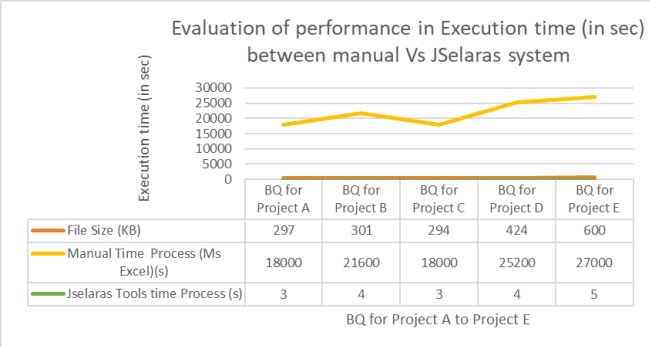

Fig. 7. The Execution Time of BQ Generation between Manual Process using CostX Versus Proposed J-Selaras System.

V. Conclusion

The proposed J-Selaras system has improved the time efficiency and eased the manual conversion done by the manpower. Despite the use of this converter (J-Selaras), the degree of error-rate might be reduced because of the automated conversion being done from the source file of Excel format in CostX system. Moreover, once the data is recorded and saved in centralized database such as MySQL in cloud database platform [16-17], the record keeping mechanism is structured for easy saving and retrieving at the admin own pace. The cloud database storage perhaps is resistant to difficulties in maintenance. The J-Selaras system may act as a construction tool which covers all activities in construction management to serve both top-level management as well as the operation level decision makers.

***Abstract*—Numerical algorithms are widely used in different applications, therefore, the execution time of the functions involved in numerical algorithms is important, and, in some cases, decisive, for example, in machine learning algorithms. Given a finite set of independent functions A(x), B(x), ..., Z(x) with domains defined by disjoint, consecutive, and not necessarily adjacent intervals, the main goal is to integrate into a single function F(x) = k1×A(x) + k2×B(x) + … + kn×Z(x), where each activation coefficient k, is one if x is in the interval of the respective domain and zero otherwise. The novelty of this work is the presentation and formal demonstration of two general forms of integration of functions in a single function: The first is the mathematical version and the second is the computational version (with the AND function at the bit level), which is characterized by its efficiency. The result is applied in a case study (Peru), where two regression functions were obtained that integrate all the waves of Covid-19, that is, the epidemic curve of the variable global number of deaths/infected per day, the adjustment provided a highly statistically significant measure of correlation, a Pearson's product-moment correlation of 0.96 and 0.98 respectively. Finally, the size of the epidemic was projected for the next 30 days.**

Keywords*—Covid-19; corona virus; function integration; Gompertz model; machine learning

I. Introduction

Numerical algorithms are important in different applications, they are made up of loops/iterations that contain functions, for example, the cost function in machine learning algorithms.

On the other hand, on some occasions, the integration of functions is necessary, that is, the union of independent functions $G_1(x)$, $G_2(x)$, …, $G_n(x)$, each one in different domains, that is:

$$\begin{aligned} &G_1(x)\,, \quad if\ x \in [x_1, x_1'] \\ &G_2(x)\,, \quad if\ x \in [x_2, x_2'] \\ &\quad\ \ldots \\ &G_n(x)\,, \quad if\ x \in [x_n, x_n'] \end{aligned}$$

Where the function $G_1(x)$ is defined if x is in the interval $[x_1, x_1']$, $G_2(x)$ if x is in the interval $[x_2, x_2']$, …, $G_n(x)$ if x is in $[x_n, x_n']$. Note: Domains are defined by disjoint, consecutive, and not necessarily adjacent intervals:

$$[x_1, x_1'] < [x_2, x_2'] < \cdots < [x_n, x_n']$$

Therefore, the objective is to present new procedures for integrating functions into a single function $F(x) = k_1 \times G_1(x) + k_2 \times G_2(x) + \ldots + k_n \times G_n(x)$, where k_i, with $1 \le i \le n$, is the activation coefficient, that is, it is one if x is in $[x_i, x_i']$ and zero otherwise.

What follows is to apply the results in a case study, that is, the integration in a single function of the different functions that represent the waves of the coronavirus disease (Covid-19). This emergency situation has made it a very important research topic in the entire scientific community [1]–[3].

The Covid-19 has caused deaths and infections since it began. The countries are going through the third and fourth waves and it is not known if others are coming, so it is necessary to build a general regression function for an unlimited number of waves.

The Gompertz model represents sigmoidal behaviour and is suitable for representing the spread of Covid-19. Epidemiologists, biologists, and others use this model for its advantages. There is a detailed review of the Gompertz model in [4]. Then, the study focuses on studying and understanding the global number of deaths/confirmed accumulated, applying the Gompertz model for several waves, that is, an integrated regression function with Gompertz functions ($G_1(x)$, $G_2(x)$, …) for each wave and the prediction of future behaviours. Predictions are important for decision-making in the political, economic, and other fields [5].

Artificial intelligence and its machine learning methods have been applied in different areas and better results have been obtained than traditional methods such as the traditional regression with the normal equation [6]–[11]. In our work, a program has been developed to carry out regression using machine learning, as a case study the country of Peru was selected, which has been one of the countries with the highest mortality rate per inhabitant.

The main part of the research is made up of theoretical results, which are permanent, because mathematical demonstration is used. But, in the application part, which has the purpose of highlighting the importance and usefulness of the results, it is limited to a case study (Peru).

Finally, the results obtained can be applied: In different functions without restriction (for example, in epidemiological functions: Logistics, Bertalanffy, Boltzmann, etc. or a combination thereof), in any data set (for example, Covid-19

data from other countries), in an unlimited number of functions (e.g., in various waves of Covid-19) and in general in all applications that require the integration of functions.

The rest of this research is organized as follows: Section II reviews the related work. Section III explains the methodology. Section IV describes the principal results, while Section V discusses the case study, and applications of the proposed results. Lastly Section VI summarizes the main conclusions of this work.

II. Related Work

Aferni et al. used a basic way of integrating two functions for two consecutive waves of Covid-19, the authors do not present a general way to integrate functions; in addition, it is not possible to generalize the result for more than two functions. In the integrated function F(x), values of zero and one are used for p and the sigmoidal-Boltzmann mathematical model was applied to study the Covid-19 spread in 15 different countries [4].

As far as we know, there is no other work related to the integration of functions. On the other hand, there are several research works regarding the spread of Covid-19 [12]–[14].

III. Methodology

Mathematical proof is the primary form of justification for mathematical knowledge [15]. It is a formal and rigorous method, its validity is permanent, that is, it remains forever. It has no margin of error and is not subject to the assumptions of statistical methods. For this reason, it was used in the first and main part of the investigation.

In order to highlight the importance and usefulness of the theoretical results, in the second part, a regression function composed of several Gompertz functions was built, specifically, for the Covid-19 data (Peru). Linear regression was used with a correlational hypothesis. Linear regression is still a useful and widely used statistical method [16].

A. Data

The data used was the global number of cumulative deaths/infections, which is freely downloadable from the Johns Hopkins University Resource Center repositories from day one to June 27, 2022.

B. Inflection Points and Second Derivative

Let $f(x)$ be a function, which is continuous at a point x_1, $f(x)$ can have a finite or infinite derivative at that point. If, when passing through x_1, the function changes the direction of convexity, then x_1 is called a point of inflection [17].

Second derivative [17], [18] of a function $\boldsymbol{f(x)}$. If x_1 is a point of inflection, and the function has a second derivative in some neighborhood of x_1, which is continuous at the point x_1 itself, then, $\boldsymbol{f''(x) = 0}$.

For example, in the case of Italy, the start of the second wave (inflection point) was calculated with the following procedure: First, a third degree polynomial regression was performed between day 75 and day 250 because it is the interval where the change point is found (in Fig. 1 the regression function is illustrated in blue), second, the inflection point is calculated using the second derivative, finally a red vertical line was drawn to highlight the start day of the second wave.

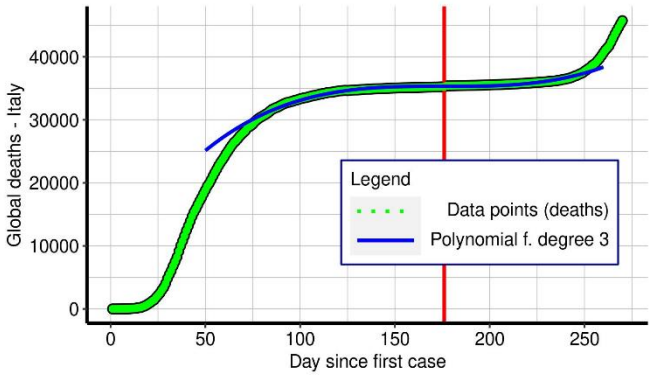

Fig. 1. Global Death by Days (Italy), Polynomial Function Regression of Degree 3 (Blue) and Inflection Point (Red Line).

The cubic regression function is given by (R statistical software was used):

$$f(x) = 7446.998 + 476.22x - 2.710676x^2 + 0.005140938x^3$$

The inflection point was obtained by calculating the second derivative and solving the equation $f''(x) = 0$, it is given by (the free Maxima software was used):

$$x = 175.7575498219713$$

Then, nonlinear regression can be performed using the Gompertz function or another for each wave.

C. The Gompertz Model

The Gompertz curve/function/model is a function for a time series, named after Benjamin Gompertz (1779–1865), who was born in the City of London) [19]–[22]. It is a special case of the generalized logistic function. In [23] the Gompertz function is described, classified, and explained, it has different variants, the best known is the following:

$$G(x) = a \cdot e^{-e^{b-c \cdot x}}$$

Also represented with the exp function as follows:

$$G(x) = a * \exp(-\exp(b - c * x))$$

Where, G(x) is the expected value (e.g., deaths) as a function of time x (for example days since the first case), a is the upper asymptote, b sets the displacement along the x-axis (translates the graph to the left or right), c is the growth-rate coefficient (which affects the slope), e is Euler's Number (e = 2.718281828459045), and exp(x) is e^x.

D. Fit Assessment Measures

The evaluation measures, known as goodness of fit measures that will be used in the research are the Pearson correlation coefficient (R) and the determination coefficient (R^2).

$$R^2 = 1 - \frac{MSE}{MST}$$

IV. RESULTS

To integrate several Gompertz functions (one for each wave) in a single formula, first the inflection points are calculated, then the regression is carried out to obtain the Gompertz (or other) functions and it ends up integrating the functions in a single formula. With this result, forecasts can be made.

A. Calculation of Inflection Points

It is achieved by performing the cubic linear regression (third degree polynomial) in the respective intervals, then using the second derivative of these functions, the inflection points are obtained, which can be interpreted as the day on which a wave begins (after a wave as seen in Fig. 1 and Fig. 2). In Peru, the first inflection point is day 253 and second is day 596.

B. Integration of Functions

Let's start with the basic case of the union of two functions that represent two successive waves (of deaths or another accumulated variable), for illustrative purposes the Gompertz function will be used, although the results of this section are general, that is, can be applied to other functions (e.g., the Boltzmann function).

Let $G_1(x)$ y $G_2(x)$, two Gompertz functions (without losing generality), which correspond to two successive waves, be integrated into a single function by adding a characteristic/variable in the database called p, which indicates with a single distinctive number all the rows (days) that correspond to a particular wave. The first wave is assigned a number (e.g., one), the second wave is marked with another number (e.g., two).

The data is structured as shown in Table I. In the case of Italy (as also seen in Fig. 1), from day 1 to day 175 belong to the first wave and from day 176 onward to the second wave. (Basic study for Italy that does not include integrated waves is found in [24] and [25]).

TABLE I. DATABASE OF THE GLOBAL NUMBER OF DEATHS ACCORDING TO DAY - ITALY, THE LAST CHARACTERISTIC (COLUMN) ON THE RIGHT INDICATES TO WHICH FUNCTION BELONGS

Day	***Date***	***Deaths global (Accumulated)***	***p***
1	2/21/20	1	1
2	2/22/20	2	1
...	...	...	...
176	8/14/20	35234	2
177	8/15/20	35392	2
...	...	...	...

Then, the integrated regression function is given by:

$$F(x) = (2-p) * G_1(x) + (p-1) * G_2(x)$$

In this way, if in F(x), p is replaced with 1, $G_1(x)$ is activated and $G_2(x)$ is eliminated, conversely, if p is 2, $G_2(x)$ is activated. The function F(x) can be simplified if values of zero and one are used for p as was done in [4], however, it is not useful for generalizing over n functions.

General case mathematical version, if several functions are considered, whose quantity is specified with the value of n, proceed as follows:

Let $G_1(x)$, $G_2(x)$, … , $G_n(x)$ be functions, which correspond to n successive waves, are integrated into a single function, controlling the activation through a coefficient C_p as follows: $F(x) = C_1 \times G_1(x) + C_2 \times G_2(x) + \ldots + C_n \times G_n(x)$ adding a feature (variable p) to the training samples, as the basic case (e.g. successive numbers 1, 2, 3, ... , p).

A table of coefficients is constructed to discriminate functions. Then, it is generalized with a new general formula for the coefficients.

TABLE II. COEFFICIENT TABLE FOR THE SUCCESSIVE FUNCTIONS

p	**$G_1(x)$**	**$G_2(x)$**	**$G_3(x)$**	**$G_4(x)$**	**...**	**$G_n(x)$**
1		1-p	1-p	1-p	...	1-p
2	2-p		2-p	2-p	...	2-p
3	3-p	3-p		3-p	...	3-p
4	4-p	4-p	4-p		...	4-p
...	...	...	...	...	...	...
n	n-p	n-p	n-p	n-p	...	

Then, the formula for the coefficients of the sequence of functions according to the parameter p, is given by:

$$C_p = \sum_{p=1}^{n} \frac{\prod_{i=1}^{p-1}(i-p)\prod_{j=p+1}^{n}(j-p)}{(\mathrm{n}-\mathrm{p})!\,(-1)^{p-1}(\mathrm{p}-1)!}$$

Where, p is the number of the function or wave, C_p is the coefficient for the function $G_p(x)$, n is the total number of functions to integrate.

Proof. Let the function be Gp(x), its coefficient is calculated as follows, the multiplication of (n-1) factors is required except the one corresponding to row p (to activate the function in question), the factors are described like column Gp(x) in Table II, it is achieved with two products $\prod_{i=1}^{p-1}(i-p)$ and $\prod_{j=p+1}^{n}(j-p)$ for factors above and below p respectively. Replacing p in the factors generates two factorials that offset by dividing (p-1)! and (n-p)! generated by the product of the top and bottom numbers. Finally, divide by $(-1)^{p-1}$ to nullify the negative result that occurs when p is even.■

Therefore, the final function is given by:

$$F(x) = \sum_{p=1}^{n} \frac{\prod_{i=1}^{p-1}(i-p)\prod_{j=p+1}^{n}(j-p)}{(\mathrm{n}-\mathrm{p})!\,(-1)^{p-1}(\mathrm{p}-1)!} G_p(x)$$

The advantage of this formula (mathematical version) is that it does not depend on a programming language, compiler, or binary representation of the numbers, but the disadvantage is the execution time required to calculate each coefficient, which is $\Theta(n)$, where n is the number of waves or functions,

specifically among others requires (n+1) multiplications and one division.

For example, if you have three waves, the coefficient for the first function $G_1(x)$ is given by:

$$F(x) = \frac{(2-\mathrm{p})(3-\mathrm{p})}{2}\mathrm{G}_1(\mathrm{x}) + \cdots$$

General case, the computational version (with function at the bit level). It is possible to perform the integration by a simpler method, that is, using bitwise operations, specifically using the bitwise AND (&) operator. Unlike the previous method, the p values for each group (function) must be recorded in powers of two starting from one, that is, 1, 2, 4, 8, 16, ..., 2^{n-1}:

$$F(x) = (1\&p)G_1(x) + \frac{(2\&p)}{2}G_2(x) + \frac{(4\&p)}{4}G_3(x) +$$

$$\ldots + \frac{(2^{n-1}\&p)}{2^{n-1}}G_n(x)$$

Where, the & operator represents the bitwise AND operator.

Proof. Given the conditions, the result of $2^{n-1}\&p$ is equal to 2^{n-1}, if and only if both operands have the same value (by the definition of the AND operation). Then only one division is required to get the 1, which finally selects the function.■

The method is simple and efficient, the execution time to calculate each coefficient is constant, but it requires the AND function at the bit level. In the statistical software R, it has the bitwAnd(a,b) function, which, according to the notation considered, calculates a&b. An empirical comparison of the performance of the two methods is not necessary, the difference is obvious.

Finally, source code is presented for the statistical program R that represents three integrated Gompertz functions. The method can be implemented in any other programming language (e.g., Python).

```
F = function ( x , p ) {
   bitwAnd(1,p)    * (ga*e^(-e^(gb-gc*x)) ) +
   bitwAnd(2,p)/2 * (ga2*e^(-e^(gb2-gc2*(x-a2) )) +dif1 ) +
   bitwAnd(4,p)/4 * (ga3*e^(-e^(gb3-gc3*(x-b2) )) +dif2 )
}
```

V. The Case Study

A. Case Study Analysis of the Global Number of Deaths from Covid-19 in Peru

To apply the procedure described in this work, the regression function of the global number of deaths from Covid-19 in Peru was analysed using three Gompertz functions for each wave. Day one corresponds to the first case of death that occurred on March 3, 2020, and the time series extends until June 27, 2022 (which makes up a total of 844 days). Fig. 2 shows the observed data (in green), the Gompertz1 function for the first wave (blue), the Gompertz2 function for the second wave (red), and the Gompertz3 function for the third wave (black).

To calculate the day on which the first wave ends and the day on which the second wave begins (with a growth in the number of deaths), a third-degree simple polynomial regression was carried out, to this formula the second derivative was applied as shown described in the methods section (for the purpose of finding the inflection point). On day 253 the first wave ends and on day 254 the second wave begins. The same procedure was carried out to calculate the second inflection point.

a) Regression Function: The formula of the regression function is:

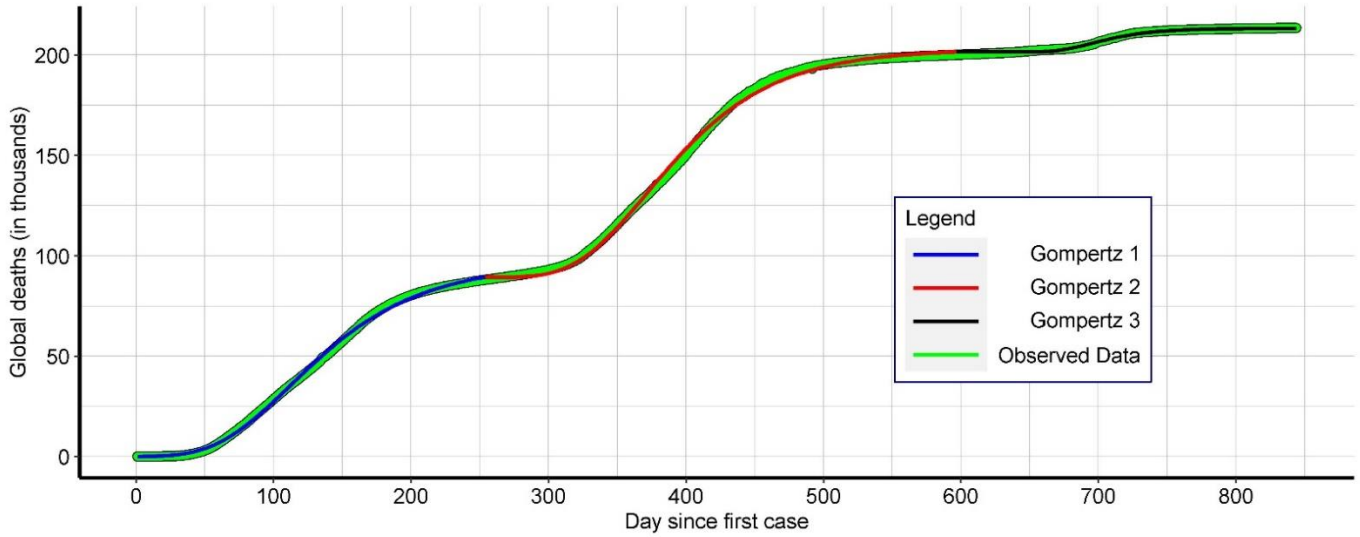

Fig. 2. Number of Global Death (in Thousands) by Day and Gompertz Regression Function - Perú (2020-2022).

$$F(x,p) = (1\&p)95.82221e^{-e^{2.095506-0.01870962x}} + \frac{(2\&p)}{2}\left(113.7772e^{-e^{2.307933-0.01948187(x-253)}} + 89.20994\right) + \frac{(4\&p)}{4}\left(11.72726e^{-e^{4.016593-0.04029681(x-596)}} + 201.5629\right)$$

This function is the one observed in Fig. 2, each wave with a different colour. The Gompertz model adjusted to the series of the accumulated number of deceased, reports a Pearson correlation coefficient R = 0.9577994 and an explained variance of 91.73797%, quite acceptable measurements of the adjustment made. The alternative hypothesis is accepted: the correlation is not equal to zero (t = 96.691, df = 842, p-value < 2.2e-16).

b) Prediction: The prediction was made for 30 days, in Fig. 3 you can see the projection that corresponds to days greater than 844 (green).

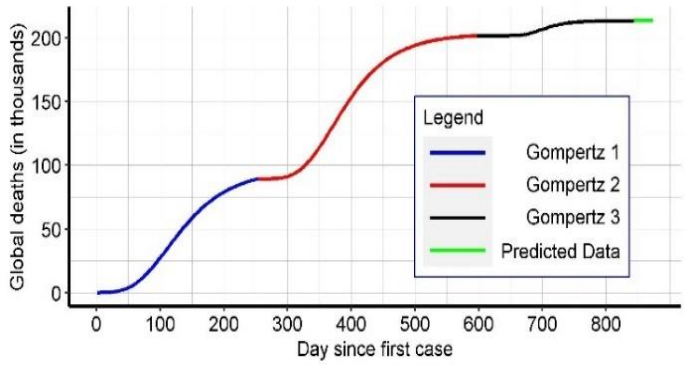

Fig. 3. Prediction of the Number of Global Death (in Thousands) by Day - Perú (2020-2022).

In Fig. 3, and particularly in the predicted data, a small increase is observed, so it is necessary to take measures.

B. Analysis of the Global Infected Number - Peru

The regression function of the global infected number (Covid-19 in Peru) was analysed using three Gompertz functions for each wave. Day one corresponds to the first infected case (March 3, 2020), and the time series extends until June 27, 2022 (which makes up a total of 844 days). Fig. 4 shows the observed data (in green), the Gompertz1 function for the first wave (blue), the Gompertz2 function for the second wave (red), and the Gompertz3 function for the third wave (black).

a) Regression Function: This function is the one observed in Fig. 4, each wave with a different colour. The Gompertz model adjusted to the series of the accumulated number of infected, reports a Pearson's product-moment correlation R = 0.9814708 and an explained variance of 91.73797%, quite acceptable measurements of the adjustment made. The alternative hypothesis is accepted: the correlation is not equal to zero (t = 148.63, df = 842, p-value < 2.2e-16).

$$F(x,p) = (1\&p)1263.777e^{-e^{1.892196-0.01259441x}} + \frac{(2\&p)}{2}1262.33e^{-e^{2.092404-0.01745463x}} + \frac{(3\&p)}{3}1402.889e^{-e^{11.10519-0.08365515x}}$$

In this case of the number of infections, no predictions are made because the last Gompertz curve G3(x) does not fit adequately to obtain consistent results. Finally, it can be said that the function integration method worked well in both cases (deaths and confirmed).

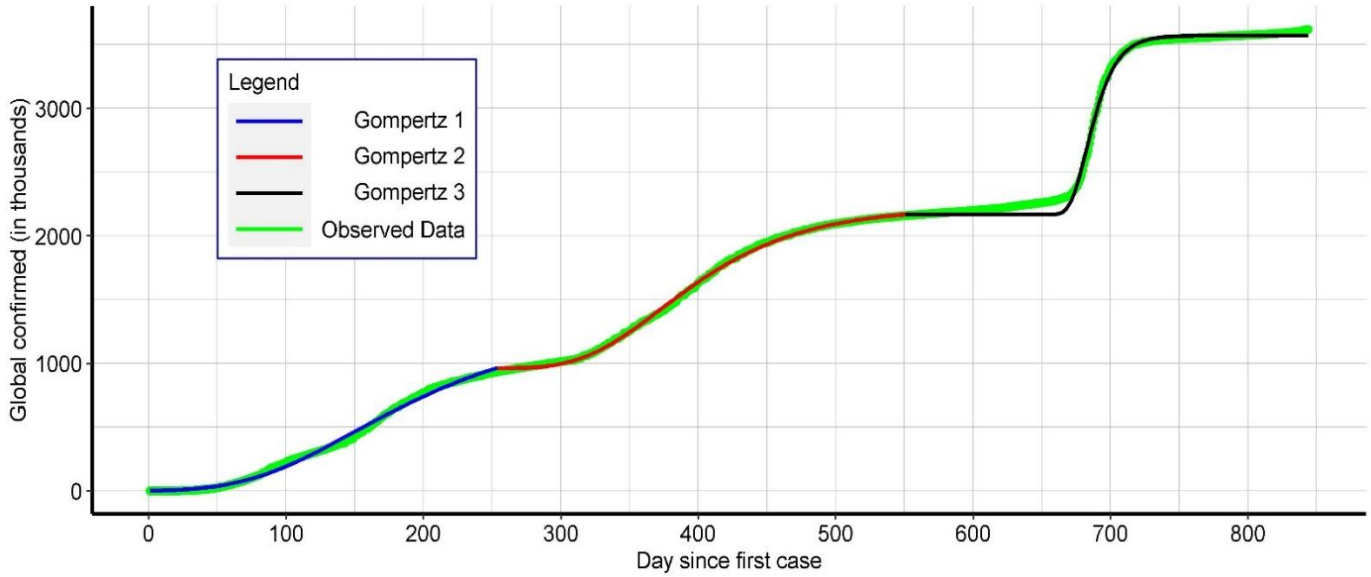

Fig. 4. Number of Global Infected (in Thousands) by Day and Gompertz Regression Function - Perú (2020-2022).

VI. Conclusion

The contribution of this research is the presentation and illustration of two ways of integrating *n* regression functions (which may correspond to n waves of covid-19 or others). The first is the mathematical version, independent of devices such as the binary representation in the computer, and the second one is the computational version that has the advantage of being simple and efficient in time, specifically, in the calculation of the coefficients (with a constant time complexity). These results are general in relation to the cited literature and have many applications.

The epidemic curve of the number of deaths/infections was obtained with three Gompertz models integrated into one function, the adjustment provided a correlation measure that is statistically quite reliable, so forecasts were obtained for 30 days, that is, for the month of July 2022, it is concluded that the model fits the data well and is good for forecasting. And, given the slight outbreak, it is necessary to follow preventive measures to prevent the spread of Covid-19 (with specific emphasis on Peru).

Finally, the detailed explanation and interpretation of the linear regression function and the Gompertz functions that compose it, are useful to describe and compare the waves of Covid-19, however, they go beyond the objectives of the research.

VII. Funding

The research has not received funds for this work.

VIII. Consent

Informed consent was obtained from all individual participants included in the study.

IX. Conflicts of Interest

The authors declare that they have no conflicts of interest.

***Abstract*—Now-a-days, a digital image can be found almost everywhere, and digital image processing plays a huge role in analyzing and enhancing the image so that it can be delivered in a good condition. Color distortion and loss of image details are the common problems that were faced by low-light image enhancement methods. This paper introduces a low-light image enhancement method that applied the concept of homomorphic filtering, unsharp masking, and gamma correction. The aim of the proposed method is to minimize the two problems stated while producing images of better quality when compared to the other low-light image enhancement methods. An objective evaluation was done on the proposed method, comparing the results produced by the enhanced method with other two existing low-light image enhancement methods. The results obtained showed the proposed method outshines the other two existing low-light image enhancement method in maintaining the image details and producing a natural looking image, achieving the lowest Mean Square Error (MSE) and Lightness Order Error (LOE) scores, and has the highest Features Similarity Index color (FSIMc), Features Similarity Index (FSIM), Structure Similarity Index (SSIM), and Visual information fidelity (VIF) scores. Future studies that should be made on this research are to implement dehaze and denoise functionality into the low-light image as well as enabling it to be applicable in real-time scenarios.**

Keywords*—Low-light image; gamma correction; homomorphic filtering. low-light enhancement; unsharp masking

I. INTRODUCTION

It is undeniable that digital image processing is important as it helps to enhance the quality of an original image. A low-light image, as its name suggests, is an image that is captured in a low-light environment. This type of image is typically found when the image is captured in the nighttime. Images captured during nighttime are lacking because the amount of light captured in the image is low. This would result in low visibility and details in objects that are captured and cause color distortion in the image.

Low-light image enhancement methods help to boost the features of objects captured in an environment where the light source is minimal. In a situation where hit-and-run occurred during nighttime and the car was captured in a CCTV, low light image enhancement methods can be used to obtain the visual information of image like the color of car, the shirt color of the driver, etc. and followed by digital image processing to gain more information on the accident occurs, for example, getting the car plate number to track the irresponsible driver. This becomes the motivation for the proposed low light image enhancement. To produce a clear and bright image, low-light image enhancement method like Retinex method, histogram equalization, neural network, gamma correction and homomorphic filtering were introduced [1]. A significant amount of research has been made on the methods of enhancing low-light image enhancement in recent years, however, there is still room for improvements in the techniques used to enhance low-light images. The problems faced in the enhancement of low-light images include color distortion and loss of image detail. Colors are hard to be distinguished in a low-light environment, thus, it is important to enhance low-light image while retaining the color of the image. Loss of image details is another problem faced during the enhancement process.

In this paper, homomorphic filtering, unsharp masking, and gamma correction techniques have been applied to create a low-light image enhancement method. The input image will be processed with homomorphic filtering where the parameters values of the Gaussian high pass filter available for customization have been applied and Fast Fourier Transform (FFT) is used so that the time taken for the process can be cut down. Subsequently, to sharpen the image, unsharp masking is applied to the image. Finally, the requirement for gamma correction of the image is defined into four different states, low, medium, high, and none depending on the luminance. The gamma will be influenced by the luminance of the image and different values will be set as the gamma according to the different states of the image. The contribution of the research are as follows:

- Introduced a method to enhance low-light images by classifying the state of low-light images into three stages
- Enhanced low-light images with minimal color distortion issues
- Preserved the image details and produce a more natural enhanced image

- Produced a better-quality image compared to the other two low-light image enhancement methods.

There are a total of eight sections in this paper. The first section introduces the existing low light image enhancement methods and the related works, as mentioned above. Section II describes the related works. Section III mentioned about the image enhancement techniques that were applied in the proposed method. The proposed method was explained in detail in Section IV followed by experimental results that are shown in Section V. Discussions were presented in Section V, and the final section would be concluding this research.

II. Related Work

Low-light image enhancement methods, namely Retinex method, histogram equalization, and neural network were some of the image enhancement methods that can be used to enhance a low-light image.

A. Retinex Method

The Retinex method uses the concept of human visual systems which perform automatic color and brightness adjustments on scenery that are captured by the human eyes [2]. This method expresses the image using the illumination and the reflection of the image [3]. Retinex methods include a Single-scale Retinex (SSR), multi-scale Retinex (MSR), and multi-scale Retinex with color restoration (MSRCR). SSR as well as MSR algorithms [4],[5] are algorithms that apply the Gaussian surround function on the input image. Both methods are used to obtain the reflection image by estimating the illumination level, the formula of SSR and MSR are listed below:

$$\text{SSR} = \log R_i(x,y) = \log I_i(x,y) - \log[\, Ke^{\left(-\frac{x^2+y^2}{\sigma^2}\right)} * I_i(x,y)] \quad (1)$$

Where $I(x, y)$ is the input image, $R(x, y)$ is the reflection image, i is the RGB color channels, (x, y) is the position of pixels in the image, K is the normalization factor while e is the exponential function, σ is the scale parameter, and * is convolution operator.

$$\text{MSR} = \log R_i(x,y) = \sum_{k=1}^{N} \omega_k \{\log I_i(x,y) - \log\left[Ke^{\left(-\frac{x^2+y^2}{\sigma^2}\right)} * I_i(x,y)\right]\} \quad (2)$$

Here, k is Gaussian surround scales, the number of scales is represented with N, and ω are the scale weights. MSR has the advantage of having multiple scales which further enhances the details of image and contrast and produces images with improved visual effect.

An issue of color distortion effect might occur with SSR and MSR methods which leads to the introduction of MSRCR method [6], [7]. In this method, the color recovery of each color channel, C will be calculated based on the proportional relationship between RGB channels of the raw image and used to overcome the color distortion problem, which is:

$$C_i(x,y) = \beta \times \log(\alpha \times \frac{I_i(x,y)}{\sum_i^3 I_i(x,y)}) \quad (3)$$

By combining color recovery of each color channel with MSR, the equation of MSRCR will be formed, where:

$$\text{MSRCR} = \sum_{k=1}^{N} C_i\, \omega_k \{\log I_i(x,y) - \log\left[Ke^{\left(-\frac{x^2+y^2}{\sigma^2}\right)} * I_i(x,y)\right]\} \quad (4)$$

Although MSRCR successfully solved the color distortion problem, it would lose image details in the bright region.

Retinex-based method is widely applied in low-light images, for instance, a fast algorithm based on Retinex was proposed by Liu et al. [8], where the low-light image will be converted to HSV color space, and linear function is used to stretch the gray level in V component followed by Retinex model which is applied to enhance the brightness of a low-light image. The method solved the problem of uneven brightness and make the low-light area clearer, yet there is a problem where this method will cause the details of the brighter area in the input image become vague due to the brightness enhancement. In [9], a Retinex model was able to produce a result where brightness and contrast were improved while preserving the details of the image as well as suppressed noise interference through performing various processing in illumination image estimation, reflection image acquisition, and post-processing. However, this method is time-consuming and causes noise amplification problems when input images have a higher amount of light loss. The low-light image enhancement technique by Shi et al. [10] also used the Retinex method and mixed with a generative adversarial network (GAN) to enhance an image under low-light conditions, although the method caused problems like noisy and overly enhanced results in low-light images, this method proved to be very useful in low-light images with very minimal light where the details of these type of image can be seen clearly. Another application of Retinex is observed in [11], where Retinex is applied in the low-light image for the purpose of autonomous vehicles, and successfully enhances the image illumination and improves the detection of the vehicle yet the problem of time consumed for the algorithm must be considered as the method should be working in real-time. In short, the Retinex method is useful in handling color distortion issues and sharpening capability but since Gaussian filtering is applied in the Retinex method, it can be a very complex, and the sharp boundary of an image might cause the image to be too bright.

B. Histogram Equalization

Histogram equalization (HE) is an image enhancement technique where in the grey level of the image, the smaller pixel population would be compressed whereas the larger pixel population is stretched to occupy a wide range [12]. The grey level of the image is then equalized. This method is widely used to improve image contrast [13] but it can cause over-enhanced noise and loss of edges of objects [14]. Using the principles of histogram equalization, the image can be described as:

$$I = \frac{n_{gL}}{Tp},\ (gL = 0, 1, 2, \dots, L-1) \quad (5)$$

Where I is the probability of grey level in the image, Tp is the total pixels in the image, gL is the grey level, and ngL is the number of pixels in grey level. The cumulative distribution function (CDF) of the grey level of the image I can be evaluated as:

$$\text{CDF} = \sum_{r=0}^{gL} I(r), \ (gL = 0, 1, 2, \dots, L-1) \quad (6)$$

Generally, histogram equalization (HE) performs equalized grey level distribution on the original image based on CDF to produce an enhanced image. This method can be executed in real-time, but it has the drawback of changing the brightness of the image. To tackle the problem faced in HE, mean preserving Bi-histogram equalization (BBHE) has been introduced which successfully preserved some of the original brightness of the image. However, it requires greater brightness preservation, which leads to the creation of the Minimum Mean Brightness Error Bi-Histogram Equalization (MMBEBHE) method [15]. This method successfully preserved more brightness and avoided excessive enhancement of the image, however, the Absolute Mean Brightness Error (AMBE) of every possible threshold level needed to be calculated through a full BBHE process would need a large computation process. Contrast Limited Adaptive Histogram Equalization (CLAHE) is another type of histogram equalization method introduced by Reza [16]. Through the algorithm, block effects in the enhancement process are weakened and enhancement of contrast has been limited using a threshold, which avoids overly enhanced contrast however one drawback observed is that the clip limit has to be manually entered. Another histogram equalization method was proposed by Zhuang and Guan [17], namely Mean and Variance based Sub image Histogram Equalization (MVSIHE) which enhances contrast and preserves details of the image; however, the methods are only tested in black and white images. Another method that used adaptive histogram equalization to enhance the contrast of probability distribution function was introduced by Sirajuddeen et al. [18] and able to enhance the image while preserving the details of an image, yet the method can cause oversaturation of color. Although HE can effectively improve contrast and image details, there are several drawbacks which include easily generated noise, color distortion, and image distortion.

C. Neural Network

A neural network is another method that is used to enhance and produce a clearer image with better quality. It is a method based on machine learning and since it is data-driven, the data collected are very important as they will affect the result produced. There are various types of image enhancement methods which apply the neural network, among them, deep convolutional neural network (CNN) technology has received a lot of attention [19]. Besides using a neural network to enhance a low-light image, it can also be used in denoising an image [20].

A low-light image enhancement method applying a neural network is introduced by Gómez et al. [21] which focuses on using CNN to improve low-light images that are captured from high-speed video endoscopy. They use a deep learning approach to enhancing the medical image that is targeted toward patients with laryngeal disorders, however, they lack ground-truth images. Thus, they introduce a method to generate darkened and realistic training images, and results show that the method proposed outperforms existing enhancement methods on the medical images. Besides, Ha et al. [22] applied CNN in CIELAB color space to enhance the low-light image. Their main idea is to split the low-light image into luminance and chrominance components before applying image enhancement on the respective components. The method proved to be very useful in removing undesired artifacts and preventing color distortion. Zero-Reference Deep Curve Estimation (Zero-DCE) is another low-light image enhancement method using a neural network that is proposed by Guo et al. [23] in which a set of best-fitting Light-Enhancement curves (LE-curves) would be estimated for the image using a Deep Curve Estimation Network (DCE-Net) and the enhanced image would be obtained after the curves are applied iteratively in the pixels of an image. The zero-DCE method can generate an image that fits various lightning conditions and performs well although there is a lack of reference images, however, the problem of the generated noises should be tackled in this method. A pipeline neural network is introduced by Guo et al. [24] which consists of a low-light image enhancement net (LLIE-net) and denoising for enhancement of the low-light image. They proved that MSR can be considered as CNN and using wavelet transformation to improve MSR results, thus, an end-to-end convolution network is proposed to enhance the low-light image. The method introduced can produce a quality image without needing to adjust the parameters manually but show lacking in some image as there is a limited dataset. The main drawback of using a neural network would include needing a lot of datasets to produce a well-enhanced image.

III. Image Enhancement Techniques

Homomorphic filtering and gamma correction are popular techniques that are used to enhance low-light image [25]. This section briefly introduces the two techniques.

A. Homomorphic Filtering

Homomorphic filtering is one of the techniques used in enhancing an image in the frequency domain [26]. Homomorphic filtering would convert the image to the frequency domain and enhance the image using Fourier transform and apply a high pass filter before converting the image back to the spatial domain [27].

Fig. 1 shows the homomorphic filtering process flowchart. Here, $F(x, y)$ is the input image whereas $G(x, y)$ is the enhanced image. Log represents logarithmic transform that will be applied on the input image, FFT is applied on both illumination and reflection component, then H (u, v) is frequency filtering function will be applied, the output is then inversed using IFFT, and applied Exp, that is exponential before producing the enhanced image. The image $I(x, y)$ can be represented as a multiplication of illumination, $L(x, y)$ and reflectance of an image, $R(x, y)$:

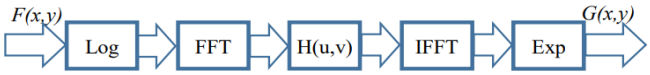

Fig. 1. Homomorphic Filtering Process Flowchart [1].

$$I(x, y) = L(x, y) \times R(x, y) \quad (7)$$

B. Gamma Correction

The gamma correction enhances the low-light image by adjusting the contrast of an image [28], enhancing the pixel intensity of the low-light area. The gamma correction method is also one of the fast and efficient ways to enhance a low-light image [29]. The general formula for this transformation is [30]:

$$g(x, y) = f(x, y)^{\gamma} \quad (8)$$

In this formula, γ is the gamma correction parameter, Fig. 2 shows some examples of gamma function transformation.

The output will be linear if γ = 1, which would return the same image. When γ>1, the low grey value area will be stretched, and the high grey value area will be compressed. In contrast, when γ<1, the low grey value will be compressed, and the high grey value will be stretched [31].

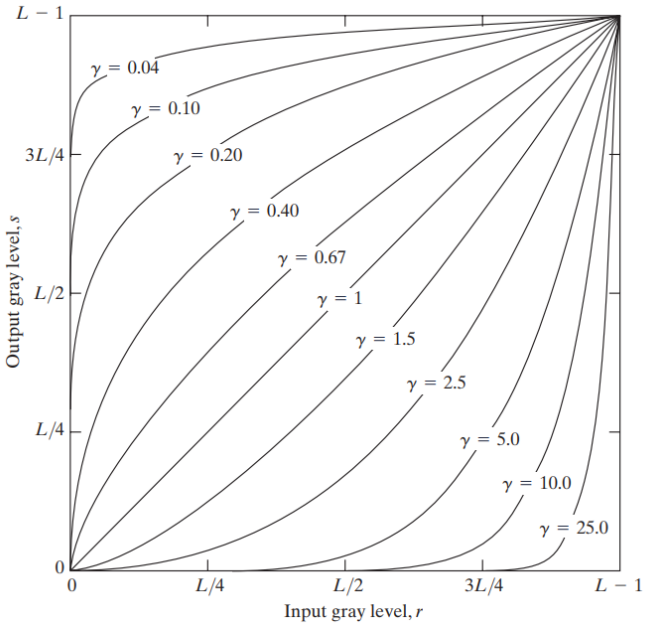

Fig. 2. Gamma Correction [30].

IV. The Proposed Method

A digital image can be expressed as $f(x, y)$, where all values in the function are discrete quantities and finite. The notation of coordinates, where the image has P rows and Q columns originating from point $f(0,0)$ is shown below [32].

$$f(x, y) = \begin{bmatrix} f(0,0) & f(1,0) & \dots & f(0, Q-1) \\ f(1,0) & f(1,1) & \dots & f(1, Q-1) \\ \vdots & \vdots & \ddots & \vdots \\ f(P-1, 0) & f(P-1,1) & \cdots & f(P-1, Q-1) \end{bmatrix} \quad (9)$$

To solve the problem of color distortion and loss of image details, this paper proposes a low-light image enhancement method using a homomorphic filtering method and gamma correction. Following are the steps carried out using the proposed algorithm:

1) Homomorphic filtering is applied on the RGB image
2) Unsharp masking is done on the enhanced image
3) Gamma correction based on the luminance of image is applied to produce the enhanced image.

Fig. 3 shows the algorithm flow diagram of the proposed method.

Fig. 3. Algorithm Flow Diagram of Proposed Method.

After getting the RGB input image, the first process applied was homomorphic filtering as it can keep the image details and remove the uneven regions of an image caused by light. The process was followed by unsharp masking to sharpen the image, aimed to retain the details of the image. The final touch on the image would be gamma correction, this technique was applied to further enhance the details of underexposed and overexposed objects while avoiding color distortion problems [33].

The following section will introduce the types of enhancement done on the low-light image.

A. Luminance and Contrast Enhancement

Homomorphic filtering would be used to enhance the luminance and contrast while normalizing the brightness of the image. The idea of this method is to separate illumination and reflectance while applying two different transfer functions to have more control. However, the Fourier transform cannot separate the product of two functions.

$$Fourier[f(x, y)] \neq Fourier[L(x, y)] \times Fourier[R(x, y)] \quad (10)$$

Thus, to apply homomorphic filtering, five steps will be required. First, logarithmic function is applied to the input image, note that the log of the image is expressed as illumination and reflectance of image [34].

$$log[f(x, y)] = log[L(x, y)] + log[R(x, y)] \quad (11)$$

Then, Fast Fourier transform (FFT) is applied on all items where:

$$W_M = e^{-\frac{i2\pi ux}{M}} \quad (12)$$

Applying (12) to Direct Fourier transform (DFT), and its inverse transform, they can be expressed as:

$$Fourier(u) = \sum_{x=0}^{M-1} f(x)\, W_M^{ux},\ u = 0, 1, 2, \dots\dots, M-1 \quad (13)$$

$$InverseFourier(x) = \frac{1}{M}\sum_{u=0}^{M-1} F(u)\, W_M^{-ux},\ x = 0, 1, 2, \dots\dots, M-1 \quad (14)$$

To speed up the Fourier transformation process, FFT algorithm is used instead. Here, the process of analyzing the input frequency of data would be faster as the time complexity of DFT is $O(n^2)$, whereas for FFT the time complexity is $O(n \log n)$. To find the FFT of the image, the equation can be expressed as [35]:

$$F(u, v) = FFT_L(u, v) + FFT_R(u, v) \quad (15)$$

Subsequently, Gaussian filter function, $H(u, v)$, is applied on (15).

$$H(u, v) = (\gamma_H - \gamma_L)\left[1 - e^{-c\frac{\left(\frac{H-u}{2}\right)^2 + \left(\frac{W-v}{2}\right)^2}{D_0^2}}\right] + \gamma_L \quad (16)$$

The default values chosen for the parameters to adjust the Gaussian filter are set to 1.05 for the high-frequency gain, 0.99 for the low-frequency gain, 2 for the constant, and 200 for the cut off frequency.

The constant, c to control the slope steepness, the high-frequency gain, γ_H is set to be greater than 1 and the low-frequency gain, γ_L is set to be lower than 1 to amplify the reflectance of the image while decreasing the illumination and enhancing the contrast of the image. Though there are many suggestions on how these values should be assigned, there are no actual suitable values for these parameters [36]. The values of the parameters can be changed and experimented on to produce a satisfying result. The high pass filter, $H(u, v)$ will then be applied on the Fourier transform, where it will allow high-frequency component while reducing the low-frequency component.

$$S(u, v) = H(u, v)\, FFT_L(u, v) + H(u, v)\, FFT_R(u, v) \quad (17)$$

Followed by Inverse Fast Fourier Transform (IFFT) being applied on the image:

$$s(x, y) = FFT^{-1}\{S(u, v)\} \quad (18)$$

After that, the enhanced illuminance and reflectance of image will be obtained, and to recover the original image, exponential function will be used to reverse the log applied in (11).

$$g(x, y) = exp^{\,s(x, y)} \quad (19)$$

B. Image Details Enhancement

After enhancing the luminance and contrast of the image, the edges of objects in the image would be enhanced so that the details of the image will not lose easily. Thus, unsharp masking would be applied to the image. Box blur method is chosen for the blurring process, Mask is then obtained with the formula of:

$$f_{blurred}(x, y) = \frac{1}{k^2} * \begin{bmatrix} 1 & 1 & \cdots & 1 \\ 1 & 1 & \cdots & 1 \\ \vdots & \vdots & \ddots & \vdots \\ 1 & 1 & \cdots & 1 \end{bmatrix}_{k^2} \quad (20)$$

Where k here denotes the size of the kernel used for the low-pass filter. Here the value of k is set to 3. Therefore, a 3x3 matrix is used. The reason for using a low kernel size, 3x3 matrix is because the number of pixels that will be blurred will increase as the size of the kernel increases [37] and it would also affect the overall luminosity of the image. Mask is then obtained with the formula of:

$$g_{mask}(x, y) = f(x, y) - f_{blurred}(x, y) \quad (21)$$

After that, result of unsharp masking is obtained using (22), Where $\lambda = 1$ to apply the unsharp mask.

$$g(x, y) = \lambda\,[\, g_{mask}(x, y) + f(x, y)\,] \quad (22)$$

C. Brightness Enhancement

The last step before producing the enhanced image is to perform gamma correction on the enhanced image based on the luminance of the image. In this stage, the gamma value will change according to various luminance to prevent over-enhancement of the already enhanced image. It also controls the overall brightness of the image that is shown on the monitor screen and does not cause serious color distortion.

Here, an algorithm has been proposed to enhance the image where the image will be changed according to the different luminance of the image. The main concept is to separate the luminance of an image into three stages, that is when the luminance is equal to 30, 60, and 120. The reason for separating to three stages is to determine whether the low-light enhancement effect should be low, medium, high, or none. If the low-light image is dark, where the luminance of the image is equal to or lower than 30 then it needs high enhancement, the gamma will be configured to 0.4, else if the low-light image is moderately dark, where the luminance is equal or lower than 60 but higher than 30, the enhancement of the image will be done moderately, where gamma will be set to 0.75. When the luminance of the image is lower than 120, the image will be considered slightly unclear, then a low amount of enhancement will be applied to the low-light image, where the gamma will be set to 0.8. Finally, if the luminance of the image is higher than 120, the image will be considered a clear image, therefore the gamma will be set to 1. The value of gamma is determined empirically after testing various values on the low-light images. Fig. 4 shows the concept of the proposed idea.

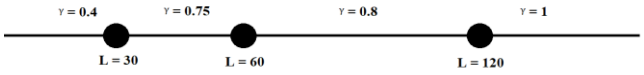

Fig. 4. Concept of Proposed Idea.

Therefore, the pseudocode of the gamma correction applying the proposed concept is:

If the Luminance < = 30,

then set γ = 0.4.

Else if Luminance < = 60,

then set γ = 0.75.

Else if Luminance < 120,

then set γ = 0.8.

Otherwise set γ = 1,

Mathematically, it can be represented as:

$$g(x, y) = \begin{cases} \gamma = 0.4 & if\ L \le 30 \\ \gamma = 0.75 & if\ L \le 60 \\ \gamma = 0.8 & if\ L < 120 \\ \gamma = 1 & otherwise \end{cases} \quad (23)$$

In short, the proposed method was tuned to enhance the luminance, contrast, image details and brightness of the image.

V. Experimental Results

TID2013 dataset [38] has been chosen to evaluate the potential and effects of the proposed method. MATLAB version R2021b running on a laptop with Intel Core i5-8250u CPU operating at 1.60 GHz with physical memory of 8.00 GB was chosen to obtain the results. A comparison between the proposed method with the LIME [39] method and DYNENH [40] method has been made. A visual comparison between the results of "Wall", "Caps", "Portrait", "Barn", "Forest", "Airplane", "Lighthouse", and "Flower" is listed in Fig. 5.

A. Visual Analysis

Visual comparison made in Fig. 5 showed that the images that were enhanced using the LIME method caused an over-enhancement problem and caused color distortion and loss of image details in the enhanced image. The color distortion can be observed in the overly enhanced image of the lighthouse where in the ground truth, the roof of the house beside is dark brown whereas, in the enhanced image, the color of the roof has turned bright and reddish-brown color. Besides, the loss of image details occurred in the LIME method as there are some figures in the lighthouse image which was unable to be captured clearly. Another apparent image that showed an over-enhancement problem with the LIME method is the airplane. The color of the letters 'SIX-SHOOTER' has become a sky-blue color instead of the deep blue color in its ground truth. Forest image has also shown an obvious color distortion after being enhanced with the LIME method, where the enhanced image shows bright yellowish-green bushes and trees compared to the original dull green color. On the other hand, the DYNENH method gives rise to the problem of the loss of details in the image. This can be seen in the airplane image, where the low-light image is not properly enhanced, making the image turn dark and blurry. After getting the input of low-light image, homomorphic filtering will be applied to the low-light image, enhancing the luminance of the whole image, followed by unsharp masking that enhances the contrast of the image and sharpens the edges of the image so that the details of the image will be seen clearer, finally, the gamma correction will be done on the image according to the image's luminance, gamma if then arranged according to the luminance of the image, as proposed in our method.

Fig. 5 shows the proposed method had successfully minimize the problem of color distortion and loss of image details while enhancing low-light images. In addition, the color and brightness of the enhanced image are similar to the ground truth.

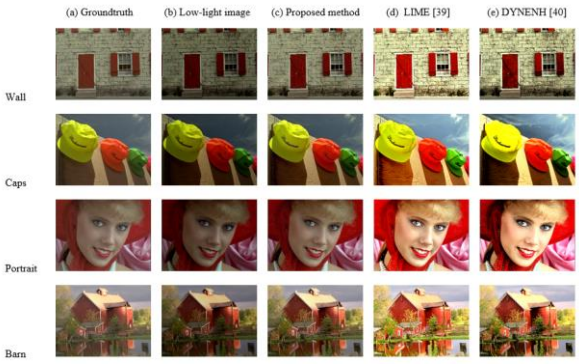

Fig. 5. Visual Comparison between Enhanced Low-Light Images.

B. Image Details Preservation

An objective evaluation has been chosen to compare the differences between the three low-light image enhancement methods, which include Features Similarity Index (FSIM), Features Similarity Index color (FSIMc) [41], Mean Square Error (MSE), and Structural Similarity Index (SSIM) [42]. FSIM and FSIMc have proven to be effective and consistent in evaluating image quality by measuring the image chromatic features, and higher FSIM and FSIMc indicate that an enhanced image is more similar to the ground truth. MSE is a full-reference quality metric that finds the average of squared intensity differences of distorted and reference image pixels. The smaller MSE represents small errors, and the enhanced image is similar to the ground truth. Besides that, SSIM is used to compare normalized pixel intensities' patterns, therefore a higher SSIM value represents the higher similarity of structural features between the ground truth and the enhanced image [42],[43],[44].

Table I shows the evaluation result for the preservation of image details. The proposed method has proven to be best as compared to the LIME and DYNENH methods. The FSIMc, FSIM, and SSIM are the highest among all the compared methods which indicate that the proposed method can preserve the details of the image better when compared to the other two. The proposed method has adjusted the luminance and contrast of the image using the frequency domain method and applied the unsharp masking method to enhance the edges of the object in the image, therefore producing enhanced images that are similar to their originals. Besides that, the proposed method also has the lowest MSE values when compared with the other two methods.

C. Naturalness Preservation and Visual Information

The naturalness preservation and visual information of the enhanced image were also evaluated. Lightness order error (LOE) has been used to assess the naturalness preservation of the enhanced image [45]. The lower LOE represents better naturalness preservation as LOE shows the value of lightness distortion in the image. Visual information fidelity (VIF) can measure the accuracy which relates to the quality of visual information that is perceived by the human visual system [46],[47]. It helps in identifying the distortion of visual information in the enhanced image, therefore a higher VIF means a better image quality. Table II shows the value of LOE and VIF of the images for each method.

TABLE I. EVALUATION ON IMAGE DETAILS PRESERVATION

Image	Evaluation	Proposed Method	LIME [39]	DYNENH [40]

	VIF	**0.6613**	0.4554	0.3920

According to the results, the proposed method has the lowest LOE and highest VIF among all the other methods, proving that it can enhance low-light images and produce a better image with the lowest value of lightness distortion and highest accuracy compared to the other two methods.

VI. DISCUSSION

The luminance and contrast of low-light image was enhanced during the homomorphic filtering, which had the advantage of maintaining details of image while also removing the uneven regions of images that were caused by light. To tackle the issue of loss of image details, unsharp masking would be used to sharpen the image and produce clearer edge for the object. This step also prevents the loss of the object edges in the image on the following step, that is gamma correction. Gamma correction would show the details of objects that are underexposed or overexposed while avoiding color distortion problem. The results shown in Section V had proved how the proposed method excelled than the other two existing methods. The proposed method had successfully preserved the details of image, achieving the highest FSIMc, FSIM values compared to the other two existing methods, that is, above 0.9, showing its effectiveness in recovering the chromatic features of the image. Besides that, it also achieved the SSIM values above 0.8, showing the similarity of the pixels' pattern between the enhanced image and the ground truth. Additionally, the proposed method managed to have lowest MSE among the three, reaching the lowest value of 183.0 in the "Barn" image. Homomorphic filtering and unsharp masking have contributed a lot in maintaining the details of the images. Aside from preserving the details of the image, the proposed method also showed its capability in enhancing the low-light image while preserving the naturalness of image and visual information. It managed to achieve lowest LOE and highest VIF scores. Gamma correction played a big role in showing the details of underexposed and overexposed objects while avoiding the color distortion problems, which led to a more natural looking image. Therefore, all three processes involved in the proposed method are important in maintaining the chromatic features of image, its structure, as well as enhancing the image and producing a natural looking image. The proposed method in this research has successfully enhanced a low-light image and produced an enhanced image with minimal color distortion and with clear details. The results showed that the proposed method has better visual quality compared to other methods. The proposed method also achieved the lowest MSE and LOE scores, and the highest FSIMc, FSIM, SSIM, and VIF scores. This proves that the proposed method has the lowest color distortion and is the best in preserving the details of the image, thus outperforming the other two low-light image enhancement methods.

VII. CONCLUSION

This research has successfully created a method in the gamma correction stage that enhances the low-light image using the concept of separating the luminance of the image into three stages and enhancing them with specified gamma according to the stage it belongs to. Compared to other low-light enhancement methods, the proposed method performs better in minimizing the color distortion errors, retaining the image details, and producing a more natural enhanced image. Additionally, the proposed method can preserve features of the image better compared to the other two low-light image

enhancement methods. Although the proposed method can enhance the image with minimal color distortion and is able to produce an image with clear details, it is not tuned to remove the haze of a low-light image, and this might cause difficulties when the low-light image is taken in a hazy environment. Besides that, since the parameters of the values for the high pass filter are determined empirically, they have to be adjusted manually rather than using the default values to produce a satisfying result. As the image enhancement becomes more important in digital images, there will be a lot of improvements made to the proposed method before it can be applied in daily lives. The future work will be focused on improving the method so that it can dehaze and reduce the noise in low-light images; these functionalities are important as low-light images might be captured in a hazy situation, for an instant a hazy day, and a noisy low-light image should be considered. Another thing to work on is to upgrade the method so that it can be applied in real-time applications. The method had the drawback of being unable to utilize the best high pass filter for the low-light image since the values of parameters for the high pass filter had to be adjusted manually for some images. In the future, an algorithm should be implemented for the high pass filter so that it can automatically find the best values for the parameters of the high pass filter.

ACKNOWLEDGMENT

An Ensemble of Arabic Transformer-based Models for Arabic Sentiment Analysis

Ikram El Karfi, Sanaa El Fkihi
ENSIAS, Mohammed V University, Rabat, Morocco

***Abstract*—In recent years, sentiment analysis has gained momentum as a research area. This task aims at identifying the opinion that is expressed in a subjective statement. An opinion is a subjective expression describing personal thoughts and feelings. These thoughts and feelings can be assigned with a certain sentiment. The most studied sentiments are positive, negative, and neutral. Since the introduction of attention mechanism in machine learning, sentiment analysis techniques have evolved from recurrent neural networks to transformer models. Transformer-based models are encoder-decoder systems with attention. Attention mechanism has permitted models to consider only relevant parts of a given sequence. Making use of this feature in encoder-decoder architecture has impacted the performance of transformer models in several natural language processing tasks, including sentiment analysis. A significant number of Arabic transformer-based models have been pre-trained recently to perform Arabic sentiment analysis tasks. Most of these models are implemented based on Bidirectional Encoder Representations from Transformers (BERT) such as AraBERT, CAMeLBERT, Arabic ALBERT and GigaBERT. Recent studies have confirmed the effectiveness of this type of models in Arabic sentiment analysis. Thus, in this work, two transformer-based models, namely AraBERT and CAMeLBERT have been experimented. Furthermore, an ensemble model has been implemented to achieve more reasonable performance.**

Keywords*—*Transformers; BERT; ensemble learning; Arabic sentiment analysis

I. Introduction

Given the tremendous amounts of Arabic digital content that has been produced in the last couple of years, an increasing number of research works have been devoted to the automatic processing of this language. In this regard, different techniques have been used to classify a specific text. Many studies have addressed this task by making use of basic machine learning models such as Naïve Bayes (NB) and Support Vector Machine (SVM). The authors in [1] addressed Arabic text classification using SVM and NB combined with the N-gram feature. The best accuracy of SVM was achieved without the N-gram, as for NB the best accuracy was achieved when the N-gram feature was considered. Whereas the authors in [2] introduced their Arabic Jordanian twitter corpus, then evaluated N-grams and stemming techniques together with TF-IDF or TF weighting schemes. Experiments have been carried out by making use of SVM and NB. Results showed that training SVM model on top of stems and bigrams using TF-IDF could give better performance compared to NB model. In a similar work [3], the authors performed sentiment analysis on Arabizi text which is Arabic text written in Latin alphabets. For experimentation purposes, the authors used NB and SVM classifiers. Besides, they evaluated the filtering step, which consists of removing stop words and mapping emojis to their corresponding Arabic words. Results indicated that SVM model outperformed NB model. However, filtering step did not greatly improve the accuracy.

Recently deep learning models such as Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM) have proven to be efficient for analyzing Arabic content. Many researchers have relied on deep learning models to tackle Arabic sentiment analysis task. In [4] performed a binary sentiment classification in Arabic. Initially, they applied preprocessing to clean input texts. Next, a word embedding layer has been used to represent texts as numerical vectors to be fed to the LSTM layer. Finally, a SoftMax layer followed to predict the polarity of the text. The experiments showed quite good results with an accuracy ranging from 80% to 82%. In another work [5] the authors made an empirical comparison between deep learning models (LSTM, CNN) and other machine learning models for both binary and multiclass classification using different datasets. The paper showed that deep learning models are effective for larger datasets. In contrast, basic machine learning algorithms perform well on smaller datasets.

More recently, with the increasing popularity of transformer models, sentiment analysis task has been significantly improved in terms of performance. Transformer models have replaced deep learning models and achieved state-of-the-art results on many automatic language processing tasks such as sentiment analysis [6], named entity recognition [7], question answering [8], and many other tasks.

The ineffectiveness of the existing methods performing sentiment analysis in Arabic is the main motivation for proposing a transformer-based ensemble method. In the last few years transformer language models alone led to significant improvements in sentiment analysis. Hence, making use of the advantages of this type of models to investigate more reliable approaches is indeed necessary to tackle sentiment analysis in Arabic being a morphologically rich language. In this paper, we propose an ensemble model that combines the strengths of two transformer language models.

Many different disciplines have made significant use of ensemble approaches to address text classification. However, there is relatively few studies on the use of ensemble methods in Arabic sentiment analysis. The primary goal in this paper is to propose an ensemble model that combines two base transformer models namely AraBERT and CAMeLBERT into a single model. To the best of our knowledge this is the first

study that investigates the ensemble of transformer-based models in Arabic sentiment analysis. Experimental results demonstrate that the proposed ensemble method outperforms stand-alone classifiers and majority voting ensemble model.

The rest of this paper is structured as follows. Related works will be introduced in Section II. The overall proposed methodology will be discussed in Section III. Experiments and results are given in Section IV. Then conclusions are drawn in Section V.

II. Related Work

Given the effectiveness of transformer-based models, there have been various transformer models used in Arabic sentiment analysis. The widely utilized models are Multilingual BERT, AraBERT, and MARBERT [9]. The author in [10] addressed sentiment analysis in Modern Standard Arabic (MSA) and other Arabic dialects such as Levantine, Egyptian, and Gulf. The author opted for three-way classification according to three scales (positive, neutral, and negative) and using different algorithms, namely: Naive Bayes classifiers (NB), Support Vector Machine (SVM), Random Forest Classifier, and BERT model (Bidirectional Encoder Representations from Transformers). The best results are obtained with BERT model reaching an accuracy score of more than 83%. The author in [11] addressed sarcasm and sentiment detection using two variants of transformer-based models, namely AraELECTRA and AraBERT. Evaluation results showed that AraBERT performs the best in terms of accuracy for both sarcasm and sentiment detection. In a similar work, [12] addressed the same tasks: sarcasm detection and sentiment analysis. The authors have examined six BERT-based models including: MARBERT [13], QARiB [14], AraBERTv02 [15], GigaBERTv3 [16], Arabic BERT [17], and mBERT [18]. MARBERT achieved promising results for both tasks.

Several studies in the literature investigated ensemble methods in Arabic sentiments analysis. The authors in [19] investigated different deep learning models to improve Arabic sentiment analysis accuracy. The authors proposed an ensemble model combining a Convolutional Neural Network (CNN) model and a Long Short-Term Memory (LSTM) model. To evaluate their model, they used the ASTD dataset [20] which consists of 10000 tweets. In this work, they focused only on opinion classification, hence the objective class tweets were removed. To construct their ensemble model, they experimented different CNN models and LSTM models with different hyper-parameters. The best CNN model is obtained by configuring the parameter fully connected layer size to 100. As for LSTM, the best model is obtained by using a dropout rate of 0.2, based on the best CNN model and the best LSTM model they built an ensemble model where the final predicted class is obtained using soft voting. Results show that the ensemble model achieved better results in terms of accuracy and F1-score compared to LSTM model and CNN model. In another study [21] , the authors introduced their approach to address three SemEval related sentiment analysis subtasks in Arabic. First Subtask (A) addresses Message Polarity Classification, then Subtask (B) addresses Topic-Based Message Polarity Classification, finally Subtask (D) which addresses Tweet quantification. The authors proposed two systems, the first is developed using their previous proposed sentiment analyzer [22] based on a scored lexicon. The second system is an ensemble of three different classifiers namely Convolutional Neural Network using Word2vec, Multilayer Perceptron and Logistic Regression. Using voting between the three classifiers the authors determined the final outcome. Evaluation results showed that their systems outperformed all the other systems by achieving an accuracy of 0.58 and 0.77 on Subtask A and Subtask B respectively, as for Subtask D their system outperformed the other systems as well by achieving 0.127 in terms of KLD score.

It seems clear that none of the existing ensemble methods has addressed Arabic sentiment analysis by making use of transformer language models. Accordingly, this study will be focusing on investigating the use of transformer language models in Arabic sentiment classification as well as proposing an ensemble technique based on transformer models to enhance classification accuracy.

III. Proposed Methodology

This section presents the methodology proposed in this paper. We will be discussing the background of transformer-based models and the models adopted in this work. Then, describe the proposed ensemble model architecture.

A. Background

A variety of neural network architectures have been proposed and used for text classification tasks, including sentiment classification. Among these numerous architectures, the best adapted architecture to sequential data is recurrent neural networks (RNNs). They have demonstrated to be effective on data where elements order is important. For example, in a sentence, the order in which words occur has a significant impact on the meaning of that sentence. Since its introduction, RNNs have been the state-of-the-art for capturing and processing dependencies in sequences. Nevertheless, it also has its drawbacks, it has been proved that RNNs cannot process large sequences of text such as long paragraphs. Moreover, in practice, data is processed sequentially, which makes it difficult to perform parallel computing using RNNs. Recently, a new architecture called Transformers has been introduced. Similar to RNNs, transformers use attention mechanism and inherit the encoder-decoder architecture of the sequence-to-sequence models to deal with sequential data. However, its architecture does not involve recurrent networks in order to speed up the training process. Transformers were firstly introduced by [23], and they were initially designed to perform translation. As illustrated below in Fig. 1, a transformer consists of two blocks, on the left, the encoder stack, and on the right, the decoder stack. The encoder stack is made up of a multi-head self-attention layer and a fully connected feed forward network. In addition to these two layers, the decoder stack has one more layer called the masked multi-head attention layer. As transformer architecture does not rely on recurrence, word position is not provided. To preserve this information positional encoding technique has been introduced. In addition to the input embedding vector, a positional vector with the same dimension as the input embedding vector is added to capture the context of a word in a sentence.

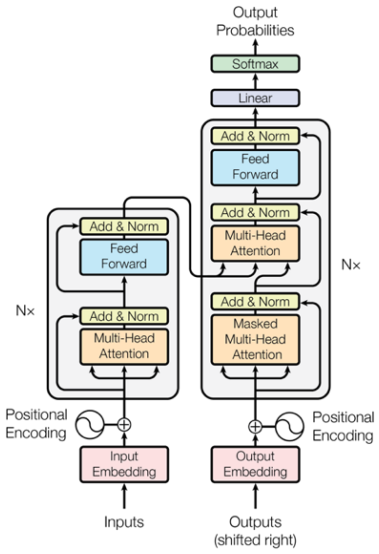

Fig. 1. Transformer Architecture [23].

Transformer-based models include three types of models: encoder-only, decoder-only, and encoder-decoder, following a brief introduction to each type of transformers, its architecture and its applications.

1) Encoder-only models: In this type of transformers only the encoder part is needed. A vector representing the input sequence is fed to the first encoder block that consists of a bi-directional self-attention layer and a feed-forward layer, the output of this block is passed to the following encoder block, which itself is composed of two layers. Each encoder block tries to enrich the embedding vector with contextual information. The final encoder block outputs the last contextual encoding. This type of transformer is suitable for tasks such as text classification or named entity recognition. The most popular examples of this type of models are: BERT [18], ELECTRA [24], and RoBERTA [25].

2) Decoder-only models: In decoder models only decoder stack is used. It consists of N identical decoder blocks; a single decoder block is composed of three layers. The first layer is a masked multi-head attention layer, in which future information is masked and only previous positions in the input sequence have attention. Similarly, to the encoder block, the next layers are multi-head self-attention layers and a fully connected feed-forward network. Decoder-only based models are also called autoregressive models and are more suited for tasks such as text generation. The most widely used models trained with decoder-only architectures are GPT (Generative Pre-trained Transformer) [26].

3) Encoder-decoder models: Also called sequence-to-sequence models, this type of models is implemented using both blocks: encoder block and decoder block. In the encoder block, the whole sequence is considered, whereas in the decoder block for a given word, only the words that precede are considered. Encoder-decoder models are best suited for tasks that involve the input of a sequence of items (words, letters, etc.) and then outputs another sequence. This architecture can be applied in the case of machine translation or question answering, where a sequence of words is treated sequentially and the result is also a sequence of words. Recently, many encoder-decoder based models have been introduced.

B. Transformer Language Models for Arabic

Transformers were initially introduced as a novel architecture for translation. Ever since, they have been mostly used for natural language processing. In sentiment analysis task, pretrained transformer language architectures have significantly improved the performance of models. Each model has its own size and trained on different type of datasets. Table I summarizes the most applied models in Arabic text classification.

In this paper, we have selected some of the most effective Arabic transformation models in sentiment analysis in Arabic. Each of these models is based on different architectures and trained using different Arabic variants. Hereafter, we discuss each of the selected models and their architecture.

1) AraBERT [27] pretrained BERT model using a pretrained dataset of 70 million sentences, collected from Wikipedia dumps, Arabic news websites and two large corpora: Abulkhair Arabic Corpus [31] and OSIAN [32]. AraBERT comes in two versions AraBERTv0.1 and AraBERTv1. In this study AraBERTv0.2 is used for experiments.

TABLE I. SUMMARY OF ARABIC PRETRAINED MODELS

Model name	Ref	Size	Source	Data type	Parameters
Multilingual BERT	[18]	-	Wikipedia	MSA	110M
AraBERT	[27]	24GB	Wikipedia+ Abulkhair Corpus+ OSIAN+ news websites	MSA	136M(base) 371M(large)
ArabicBERT	[17]	95GB	Wikipedia+ OSCAR+ other sources	MSA/ Dialect	110M(base) 340M(large)
CAMeLBERT	[28]	167B	Gigaword+ Abulkhair Corpus+ OSIAN+ Wikipedia+ OSCAR+ dialectal corpora+ OpenITI corpus	MSA / Dialect/ Classical	17.3B
MARBERT	[13]	128GB	Twitter API	MSA/ Dialect	160M
Arabic ALBERT	[29]	-	OSCAR+ Wikipedia	MSA	12M(base) 18M(large) 60M(xlarge)
GigaBERT	[16]	-	Gigaword+ Wikipedia+ OSCAR	MSA	125M
XLM-RoBERTa	[30]	2.5TB	CommonCrawl	MSA	270M(base) 550M(large)

2) CAMeLBERT [28] implemented their Arabic pre-trained language model on top of three variants of Arabic: Modern Standard Arabic (MSA), dialectal Arabic, and classical Arabic. The authors evaluated the proposed model by making use of 12 datasets to address five tasks: Named Entity Recognition, POS tagging, sentiment analysis, dialect identification, and poetry classification.

C. Ensemble Models

Ensemble learning is a technique that combines multiple machine learning models to improve the performance of the learning model and achieve a higher accuracy score than would be achieved by any single model in the ensemble. In this study, two ensemble techniques have been evaluated. The first technique is the majority voting. It is the most commonly used technique for ensemble learning. The second technique is based on calculating the sum of raw outputs of each model in the ensemble.

1) Majority voting: In majority voting, the final output of the ensemble model is determined by counting for each class the number of votes of multiple models. The class with the majority of votes is predicted.

2) The proposed method SUM: As illustrated in Fig. 2, that represents the proposed ensemble model. Firstly, a raw text is fed to the model as input, then transformed into vector representation so that it can be processed with encoder-decoder approach. Then the decoder-block of each model outputs probabilities for each class. Finally, the output is obtained by calculating the weighted sum of the probabilities from the same class, then for each class, the argmax operation is applied to find the class with higher probability value.

For a given text, let PAr_{Neg} and PAr_{Pos} denote the probabilities predicted with AraBERT model for the class Negative and the class Positive respectively. Whereas, $PCaM_{Neg}$ and $PCaM_{Pos}$ denote the probabilities predicted with CAMeLBERT model for the class Negative and the class Positive respectively. For each class, the final probability is obtained by calculating the weighted sum of both probabilities, namely the probability given with AraBERT model and CAMeLBERT model. Weights values are not selected randomly, the main reason of selecting weight values 0, 7 and 0, 3 for CAMeLBERT and AraBERT respectively, is that CAMeLBERT model tend to perform well on the majority of the datasets (see Table II). Thus, we considered 70% of the probability generated by CAMeLBERT model and 30% of the probability generated by AraBERT model. The final probabilities are calculated using the following equations:

$$PF_{Neg} = (0.3 \times PAr_{Neg}) + (0.7 \times PCaM_{Neg})$$

$$PF_{Pos} = (0.3 \times PAr_{Pos}) + (0.7 \times PCaM_{Pos})$$

Next, the final output corresponds to the index with higher probability value.

$$\text{Final Output} = \text{argmax}([PF_{Neg}, PF_{Pos}])$$

Therefore, if the output index is 0, the model will assign to the input text the class Negative, and if the output index is 1 the model will assign Positive.

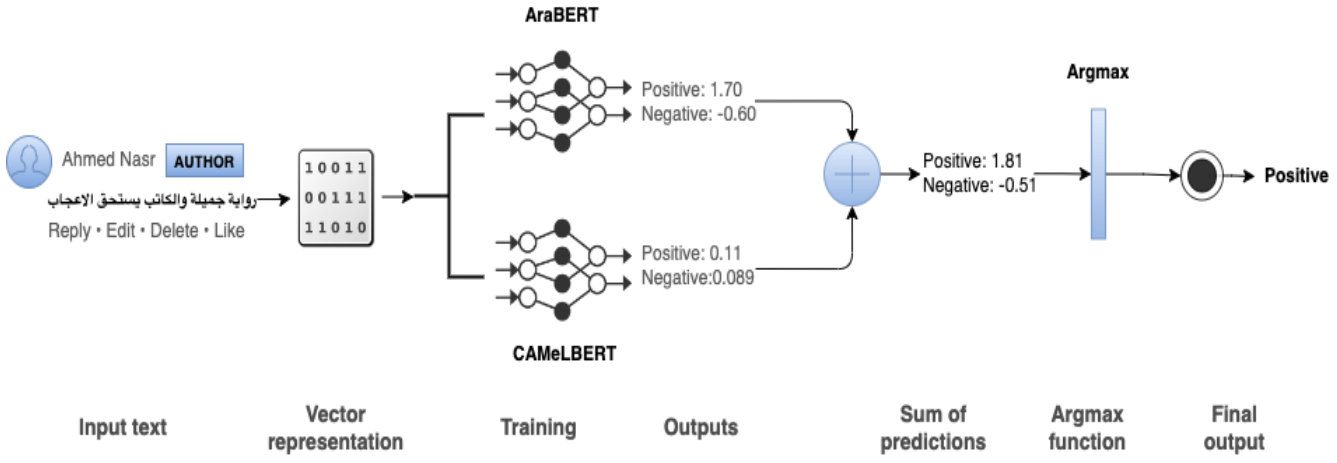

Fig. 2. The Architecture of the Proposed Ensemble Model (SUM).

TABLE II. ACCURACY RESULTS OF DIFFERENT MODELS ON THREE PUBLICALY AVAILABLE ARABIC DATASETS

IV. Experiments

In this section, we discuss the implemented models and their results. Two transformer language models are experimented namely CAMeLBERT and AraBERT, an ensemble of these two models, as well as majority voting ensemble model.

A. Dataset

For experimentation purposes, in this work we consider four datasets of different sizes and sources. The first dataset is Twitter dataset collected by Abdulla et al,. [33] composed of about 2000 tweets, written in MSA and Jordanian dialect. And consisted of 958 negative tweets and 993 positive tweets. The second dataset is Arabic Gold-Standard Twitter dataset collected by Refaee and Rieser [35] composed of 6512 tweets, divided in three classes: Negative, neutral, and positive. The negative class contains 1941 tweets, the neutral class contains 3694, and the positive class contains 876 tweets. In this study we perform a binary classification, thus only Positive and negative classes are utilized. The third dataset is Arabic sentiment tweets dataset (ASTD) proposed by [19] which contains 10006 tweets written in MSA and Arabic dialect. Tweets are labeled as one of four classes: negative, positive, neutral, and objective. As this study focuses on binary classification only positive and negative tweets are considered. After data preprocessing, we are left with 1684 negative tweets and 799 positive tweets. The fourth dataset is a dataset that we have proposed in a previous work [36] which is consisted of 1299 Modern Standard Arabic books reviews with a balance between positive and negative reviews. Reviews are collected from Goodreads website and annotated manually. After data collection, each given text is decomposed into tokens. Then, Arabic stop words are filtered out as they do not hold any information. The next step is normalization, where elongation, hamza, and diacritics are removed. Finally, all emoticons and emojis are deleted based on a preselected list of the most commonly used emoticons and emojis.

B. Results

To investigate the effectiveness of the proposed ensemble model three models have been implemented, including two transformer language-based models: AraBERT and CAMeLBERT and majority voting model. All models are trained on the same training set, which represents 80% of the whole dataset, and tested on the same testing set composed of the 20% remaining data. For each of the four datasets the models are trained and tested on both balanced and unbalanced datasets. Performance results of the proposed ensemble method are compared with stand-alone models and majority voting ensemble model. The models are evaluated using accuracy, F1-score, precision and recall metrics. The mathematical formulas of each of the used metrics is defined as follows:

$$Accuracy = \frac{TP + TN}{TP + FP + FN + TN}$$

$$Precision = \frac{TP}{TP + FP}$$

$$Recall = \frac{TP}{TP + FN}$$

$$F1 = \frac{2 \times precision \times recall}{precision + recall}$$

Where, TP, FP, TN, and FN refer to "True Positive", "False Positive", "True Negative", and "False Negative" respectively.

Table II shows the performance of each model on balanced and unbalanced datasets compared to existing models. As can be seen, it is clear that ensemble models provide remarkable improvement over baseline models. Majority voting model has achieved the best accuracy score on unbalanced Gold dataset with an accuracy score of 90.78% followed by our ensemble model with 89.01%, whereas on Twitter, and ASTD datasets the best accuracy score is achieved by our proposed ensemble model SUM. On Twitter dataset SUM model achieved an accuracy score of 96.16% with unbalanced dataset followed by majority voting model and CAMeLBERT model with the same accuracy score of 95.65%. As for ASTD dataset our proposed model outperformed all other models by achieving the first best accuracy score of 89.38% on balanced dataset, the second-best accuracy score is achieved by majority voting model with 87.53% on unbalanced dataset.

The results of all proposed models on our dataset are shown on Table III. AraBERT model has achieved better results than CAMeLBERT in terms of accuracy and F1-score. On the other hand, the performance of ensemble models varies from one model to another. Compared to the proposed ensemble model, majority voting model has failed to improve the performance. It has achieved an accuracy of 94.98% against an accuracy of 95.75% achieved by AraBERT. Whereas, our proposed ensemble model has reached the best results in terms of accuracy and F1-score. The mediocre performance of majority voting may be explained by the size of the dataset and the number of combined models.

TABLE III. COMPARISON OF DIFFERENT MEASURES OF PERFORMANCE ON OUR DATASET

Model	Accuracy	F1-score	Recall	Precision
AraBERT	95.75	95.72	96.09	95.35
CAMeLBERT	92.66	92.66	93.75	91.60
Majority Voting	94.98	94.78	92.19	97.52
SUM (ours)	**96.53**	**96.50**	**96.88**	96.12

In summary, the best results have been achieved by our proposed ensemble model on balanced datasets. Thus, it is obvious from the conducted comparative experiments that training models on balanced data can improve classification performance, it can help models to learn better and achieve better accuracy results.

V. CONCLUSION

In this work, we have implemented an ensemble model based on two transformer language models, namely AraBERT and CAMeLBERT. The proposed ensemble model was evaluated on top of our balanced dataset composed of modern standard Arabic book reviews. In addition, to investigate more the performance of our proposed model it has been trained on top of three other datasets namely Twitter dataset, Gold dataset and ASTD dataset. Compared to majority voting and the two stand-alone transformer-based models, our proposed ensemble model has achieved the highest score of accuracy and F1 metrics on all datasets. In this paper, we have proposed a domain-independent model, the proposed ensemble model has achieved state-of-the-art on several datasets of different sources and domains. Thus, researchers can adopt our proposed model to address sentiment analysis in Arabic regardless of data type (MSA/Dialect) and domain. To continue working towards improving the model's performance, for future work, we plan to experiment more transformer models, combine multiple models and evaluate all possible combinations to determine the optimized model. Finally, we will be considering increasing the size of our training set as accuracy increases with the size of training data.

ENSAH, Abdelmalek Essaadi University
Tetouan, Morocco

***Abstract*—Now-a-days, the use of No-SQL databases is one of the potential options for storing and processing big data lakes. However, searching for large data in No-SQL databases is a complex and time-consuming task. Further, information retrieval from big data management suffers in terms of execution time. To reduce the execution time during the search process, we propose a fast and suitable approach based on the quantum Grover algorithm, which represents one of the best-known approaches for searching in an unstructured database and resolves the unsorted search query in O ($\sqrt{n}$) time complexity. To assess our proposal, a comparative study with linear and binary search algorithms was conducted to prove the effectiveness of Grover's algorithms. Then, we perform extensive experiment evaluations based on ibm_qasm_simulator for searching one item out of eight using Grover's search algorithm based on three qubits. The experiments outcomes revealed encouraging results, with an accuracy of 0.948, well in accordance with the theoretical result. Moreover, a discussion of the sensitivity of Grover's algorithm through different iterations was carried out. Then, exceeding the optimal number of iterations *round* ($\frac{\pi}{4}\sqrt{N}$), induces low accuracy of the marked state. Furthermore, the incorrect selection of this parameter can outline the solution.**

Keywords*—Big data; data management; information retrieval; quantum computing

I. INTRODUCTION

In the last decades, database management systems have occupied a significant area in IT due to their efficiency in managing massive amounts of heterogeneous datasets. Indeed, the investigation of database research leads to the evolution of special concepts, processes, and algorithms. However, big data lake, recent big news, depicts a recommended solution for dealing with heterogeneous datasets in any format, structured, semi-structured, or unstructured. Thus, numerous contributions, such as No-SQL databases, have been offered for the optimization of processing times on the Big Data Lake [1] [2] [3]. Faced with this challenge, this paper aims to investigate the data lake optimization queries through an efficient and powerful approach based on the Grover algorithm. As the volume of data generated grows, the requirements for a large data processing supercomputer has attracted increasing interest due to their various applications. Therefore, using quantum computers as very fast calculators represents one of the hot topics for accelerating big data processing. It allows us to drastically reduce the execution time when searching for data in a large space. The Grover algorithm was introduced as one of the most beneficial algorithms for data lakes.

Although various classical data retrieval methods have been proposed, most of them remain heavy in query execution for a big data space, which is characterized by volume, variety, and veracity, among other v-properties. This constitutes a significant issue, as several applications are defined in large-scale environments with heterogeneous data in which the majority of the data is unstructured, almost 80%. Furthermore, searching in an unstructured database using quantum algorithms is one of the most widely used techniques to speed up classical search algorithms. It allows finding a more generic research solution to a very wide range of problems [4]. The search time required for a database depends on the size of the database and the quantum hardware. Therefore, it turns out that it is necessary to analyze the design of the quantum circuit.

To address the execution latency issue when searching in a challenging big data space. In this paper, we propose to investigate data lake optimization queries using an efficient and powerful approach based on the Grover algorithm, which is the fastest quantum algorithm for searching an unsorted database with a quandratic complexity of O ($\sqrt{(N)}$) time, as opposed to classical algorithms with a linear complexity of $O(N)$ time. Roughly speaking, a standard analogy for Grover's algorithm is to look up the name of a person in a phone book who only knows their phone number. The phone book remains an unsorted database, and a classical search algorithm appears tedious. On average, this would take N requests, or $N/2$ in the worst case, depending on the position of the desired element, with N denoting the number of entries in the telephone annuaire. Yet, if the correlation between phone name and number is encoded or embedded with quantum bits, the search phone number is reduced approximately to $\sqrt{(N)}$ requests. Thus, quantum computing is a fast-evolving domain, and it is reaching significant accelerations compared to classical algorithms [6] [7] [8] [9]. Considering the speed at which data is growing every day, it is necessary to think of powerful algorithms with the ability to process data quickly and efficiently. Based on this, the principal motivation of this research article is to propose the quantum design of the Grover algorithm and benefit from its speed-up to efficiently manage and extract the hidden relevant information from the heterogeneous data lake. Our proposed, implement IBM Quantum Composer to build the Grover quantum circuit. Indeed, IBM provides multiple quantum computers to the public through its IBM cloud service, accessible via the

application programming interface such as Qiskit [5]. The experiments prove Grover's algorithm as one of the most beneficial algorithms for data lakes.

The remainder of this article is organized as follows: Section II provides the necessary background for readers to fully understand our article. Section III presents the different stages of Grover's algorithm. Moreover, results and discussions are examined in Section IV. Finally, we conclude with a summary and some perspectives in Section V.

II. Related Work

In this section, we review some preliminary and necessary background information needed for the readers to fully understand the rest of our article. We start by examining the data lake concept as a storage space for heterogeneous data sources. Thus, we will give an overview of all the concepts related to quantum computing.

A. Data Lake Concept

In the last decades, the amount of data produced every day is absolutely horrible. So-called big data refers to the exponential growth of massive data. In this context, J. Dixon [10] introduced the data lakes concept to address the challenges and issues induced by big data. Among one of the principal issues studied in the literature is metadata management, proposed with the objective of avoiding the transformation of data lakes into data swamps, i.e., useless data [11] [12] [13] [14]. Thus, data lakes have evolved into data management solutions capable of meeting big data needs and producing a high level of advanced data analysis. They accept various data sources and can accommodate a resilient ecosystem for making creative, data-driven business determinations. Also, Data Lake has a data-centric approach, which refers to an architecture in which data is the primary and permanent asset. Therefore, the data lake has developed as a strong and adaptable concept better suited to data analytics, allowing enterprises to take advantage of this complicated data and generate new commercial industrial activities. While traditional ETL is used in data warehouses to prepare data for integration into a structured relational database, ELT (Extract, Load, and Transform) paradigms are used in data lakes to process unstructured data [15] [16] [17]. Data is loaded into the lake "as-is", with no data transformation. This makes it easier to set up jobs because all that is required is a declaration of the origin and destination locations. As a result, one can reduce the time spent on the data transformation phase, which is considered the most expensive stage in any data project, accounting for over 60% of the total time spent on the project.

Since 2016, the contributions of data lakes in both industry and the academic community have been growing. But most of the data lake proposals are abstract and depend on a specific use case. In our case, we will try to project Grover's algorithm into the data lake as being an unstructured data search space. Since this algorithm applies to unstructured data, it adapts perfectly to the data lake to find crucial information stored in the lake.

B. Quantum Computing

Today's conventional computers are marked with "classical bits" (cbits), which are the basic units of data. With one bit, it takes either the value 0 or 1. Yet, this type of computer faces a limit when challenged with a multivariate problem. In this case, each calculation is a unique path to a unique result. Furthermore, classical computers are less efficient in terms of computation compared to quantum computers due to the limits of classical physics principles, which constitute the core of classical computer components [18] [19]. Thereby, due to recent hardware advancements, quantum computing is a rapidly evolving research field. The principles of quantum mechanics enable quantum computers to solve certain classes of problems very quickly compared to classical computers. Such as factorization and searching databases [21] [22] [23]. Moreover, quantum computers are classified as supercomputers because they exploit the strengths of quantum mechanics, including the quantum superposition principle and entanglement [20]. The superposition principle reflects the possibility of considering a quantum system to be in multiple states at the same time. While quantum entanglement defines the correlation between two (or more) quantum particles even though they are distantly separated.

Following the classical nature of the binary bit, the qubit tries to design a superposition of the states $|0\rangle$ and $|1\rangle$. Since a quantum system can be prepared in a superposition state, the quantum computer can perform 2^n calculations in a single physical step, where n represents the number of qubits used during this process [24]. Furthermore, the quantum computer can execute jobs in exponentially fewer steps than a conventional computer. A qubit can be expressed as a unit vector in a complex vector space, C^2. Constantly written in the form of ket and bra, which corresponds to the notation of Dirac [25]. Hence, the qubit at state zero is written as $|0\rangle$ and the qubit at state one is written as $|1\rangle$. $|0\rangle$ and $|1\rangle$ represent the basis vectors in the complex vector space of quantum states. A Bloch sphere, observed in Fig. 1, is used as a geometric representation of the qubit. The state $|1\rangle$ is represented by the south pole of the sphere, while the state $|0\rangle$ is represented by the north pole. A state $|\psi\rangle = \alpha_0 |0\rangle + \alpha_1 |1\rangle$ is defined as the angle point (θ, ϕ), where α_0 and α_1 validate the normalization condition, i.e. $\alpha_0^{\ 2} + \alpha_1^{\ 2} = 1$. Thus, it is written in the geometric form with $\alpha_0 = cos\ \theta/2$ and $\alpha_1 = e^{i\phi} sin\ \theta/2$. Yet, the Bloch sphere can be very useful as a geometric representation to visualize the quantum state and its transformation.

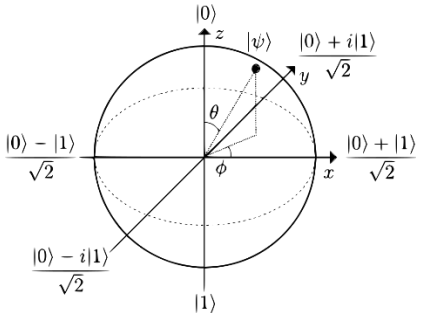

Fig. 1. Bloch Sphere [19].

Further, quantum computing, as one of the rapidly emerging research topics, has fundamentally altered the computing world. Quantum software development continues to be one of the most active investigative study fields [26]. This implies the proposal of new algorithms that adapt to a specific type of new information processing technology. Therefore, quantum computing fascinates the scientific community of researchers because it shows the computing power of big data in a reduced time. Thereby, quantum computing could stimulate scientific progress by leveraging quantum mechanical theories.

However, before we can assess the quantum computer's advantages, several restrictions must be addressed. The most famous one is the decoherence phenomenon, which is the major obstacle. Indeed, to calculate much faster than a conventional computer, the quantum computer uses superposition and entanglement of states that are significantly more sensitive to the environment than classical states [27]. The more qubits you add to a system, the more parallel operations you will increase. Then, since the environment interacts with qubits, quantum measurement uncontrollably changes quantum states. This is called decoherence and is caused by a variety of factors in the environment, including changes in magnetic and electric fields, radiation from nearby hot objects, or uncontrolled interactions between qubits, among others. Subsequently, decoherence affects the state of superposition and disrupts quantum information processing. It is the biggest barrier to the development of quantum technology. Furthermore, it is crucial to examine quantum computing technologies and algorithms.

1) Technologies of quantum computing: The quantum computing field has seen tremendous technological *advancement* over the past decades. Nonetheless, the state of the art related to quantum computing technologies [28] is provided by web giants, such as IBM, Google, Intel, and Microsoft. IBM is one of the major corporations that has made significant investments in quantum computing [29]. At the time of writing this article, IBM had almost 12 simulators, which had up to 5000 qubits, corresponding to a simulator called "simulator stabilizer". Thus, there is a simulator with only one qubit, which corresponds to a simulator called "ibmq armonk". IBM's simulators employ IBM QISKit, a highly handy python library, to process asynchronously run jobs [30] [31]. Qiskit is an open-source framework for quantum computing. It provides the necessary tools that can be used to create and manipulate quantum programs and run them on prototype quantum devices on the IBM Q Experience or simulators on a local computer. Furthermore, once a job process is completed, the user receives the results in the form of the job run time (seconds) and the measurement of each state. Moreover, IBM provides multiple quantum computers to the public through its IBM cloud service. The ibmqx5 is a 16-qubit superconductivity-based quantum computer, ready through an Application Programming Interface (Python-API) called QISKit.

2) Quantum algorithms: In the quantum computing era, a quantum algorithm is a quantum computation solution that works on a practical quantum model [32]. It is often designed as a quantum circuit. Moreover, a classical (or non-quantum) algorithm is a sequence of instructions for solving a problem. One of the most well-known classical search algorithms is that of sequential and interval search.

a) Sequential search: One of the most basic and simplest search algorithms that fall under the category of searches is linear. This type of algorithm works sequentially (without jumping) through a list by comparing each element with the value we want to find [33]. In the worst case, the time complexity corresponds to the order of N, indicated as O(N), where N represents the number of elements in the list. This algorithm has the advantage of not requiring the list to be sorted because it works regardless of the order in which the list's elements appear. However, finding the element you're seeking takes a long time. As long as the number of elements in the list is large, the algorithm takes a lot of time.

b) Interval search: One of the frequently used implementations in interval search is the binary search. In fact, the search space must be ordered. Furthermore, this sort of algorithm divides the collection of elements that make up the search space into intervals [34], such that if the search value is smaller than the value in the middle of the interval, in this case, the search is not performed only at a level of less than half the interval. Otherwise, the search is carried out at the upper level. This process is repeated until the element marked is found in logarithmic time.

III. GROVER'S ALGORITHM

The study of quantum algorithms has recently been one of the most difficult scientific issues that has radically transformed the way people think about computers. Indeed, quantum computing remains a part of worldwide reality, and its advancement cannot be overlooked. Working on this research topic was also the goal of former researchers [35]. The principles of quantum physics, like, for example, the use of superconducting quantum processors, have a major peculiarity [36]. Exercising superconducting quantum circuit technology enables the researchers to contribute a list of contributions related to the quantum algorithms. In 2016, IBM introduced the Quantum Experience program, which provides a set of online quantum simulators that allow anyone interested to execute their quantum circuit [37]. The IBM Quantum Experience handbook gives users a hands-on experience with all of the criteria for building a quantum circuit that solves a specific problem perfectly.

Grover's algorithm offers a quick search through a mass of unstructured data to find the desired information. It has proven a significant speedup compared to the classical algorithm and produced a promising result, motivating extensive investigation into the viability of applying Grover's algorithm to a variety of domains. In this paper, we examine a search space of size N with no prior knowledge of how the data will be presented. This problem has a polynomial complexity with classical solutions, whereas the quantum search algorithm has a quadratic complexity $O(\sqrt{(N)})$ [38]. Through this paper, we have proposed an overview in algorithmic form, summarizing

the different stages of Grover's algorithm. As shown in algorithmic prototype 1.

Algorithm 1 Grover's Algorithm for data lake

Input: Heterogeneous datasets form a data lake $DL = \{x_0, x_1, x_{N-1}\}$

Output: Get the index of the marked element $x^* \in N$

Step 1: The quantum register's initialization:

Set the state of all qubits $x \otimes^n$ to the state $|0\rangle$ and set the oracle qubit to $|1\rangle$ state : $|\psi_0\rangle = |0\rangle \otimes^n |1\rangle$

Step 2: Deploy the register in a distributed uniform superposition:

Apply the Hadamard gate H:

$$|\psi_1\rangle = \frac{1}{\sqrt{N}} \sum_{i=0}^{N-1} |i\rangle \otimes \frac{|0\rangle - |1\rangle}{\sqrt{2}}$$

Step 3: Repeat Grover's iterations:

for round($\frac{\pi}{4}\sqrt{N}$) times; do

a- Apply the oracle:

$|x\rangle \rightarrow (-1)^{f(x)} |x\rangle$

b- Execute Grover operator (reflection about the mean)

1. Apply $H \otimes^n$
2. Conditionally shift phase
3. Apply $H \otimes^n$

End for

Step 4: Quantum register measurement

Finding the index of the target element in a list of $N = 2^n$ entries is the problem of searching in an unordered list. With n denoting the number of qubits and N denoting the list's length. Moreover, an unstructured search is commonly expressed as a database search query in which we want to find an item that meets a set of criteria specified in the query. We refer to the problem search as "unstructured" because we have no control over how the data is organized in the database. If we have an ordered database, we can use a binary search to find the predicted element in logarithmic time. However, if we don't know the sequence of the database items, the task remains difficult to complete in terms of execution, and we can't get better results with the conventional approach. If there is no indication of where the desired item might be found, in this case, any classical algorithm must examine each element individually. Furthermore, the number of tries required to find the sought item equals the number of items in the list. As we can see, using quantum mechanics principles, only $O(\sqrt{(N)})$ attempts are required. To meet this requirement, Grover's algorithm uses two registers, the first one linked with quantum qubits, in which we shall create a superposition of all 2^n basis states $\{|0\rangle, ..., |2N-1\rangle\}$. This can be done by applying the Hadamard gate to all the initial qubits. While the second register is linked to classical bits to persist the measurement results, it takes either the value of *0* or *1*. For the sake of precision, we describe the different stages of Grover's algorithm:

A. Initialization

The Grover algorithm starts by initializing the qubits in the state $|0\rangle$ by performing a uniform superposition of all basic inputs. A Hadamard quantum gate, given by the matrix (1), is implemented to create a superposition of the set of quantum states [39].

$$H=\frac{1}{\sqrt{2}}\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix} \quad (1)$$

By applying the Hadamard gate to state $|0\rangle$, we obtain the following state.

$$\frac{1}{\sqrt{2}}\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix}\begin{bmatrix}1\\ 0\end{bmatrix} = \frac{1}{\sqrt{2}}\begin{bmatrix}1\\ 1\end{bmatrix}$$

Which has mapped:

$$|0\rangle \rightarrow \frac{|0\rangle + |1\rangle}{\sqrt{2}}$$

If we instead initialize the qubit to $|1\rangle$ and apply a Hadamard gate:

$$\frac{1}{\sqrt{2}}\begin{bmatrix}1 & 1\\ 1 & -1\end{bmatrix}\begin{bmatrix}0\\ 1\end{bmatrix} = \frac{1}{\sqrt{2}}\begin{bmatrix}1\\ -1\end{bmatrix}$$

Which has mapped:

$$|1\rangle \rightarrow \frac{|0\rangle - |1\rangle}{\sqrt{2}}$$

As a result, to generalize the Hadamard gate application to the initial state $|0\rangle$, we obtain the following formula:

$$H^{\otimes n} |0\rangle = \sum_{i=0}^{N-1} \alpha_i |i\rangle$$

Where α_i represents the amplitude probability. Indeed, all quantum states have the same amplitude, i.e., $\alpha_i = \frac{1}{\sqrt{N}}$.

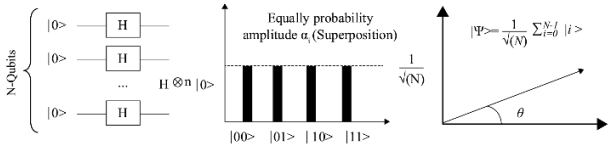

Fig. 2. The Grover Algorithm's Initialization Step.

As illustrated in Fig. 2, for the case of the number of qubits $N = 4$. Therefore, the number of possible states corresponds to $N = 2^n = 2^2 = 4$. Each state is associated with equiprobable amplitudes, $\alpha_i = \frac{1}{\sqrt{4}} = \frac{1}{2}$.

B. Oracle

After having initialized the circuit with the Hadamard gate to create a superposition of quantum states, Grover's algorithm will proceed through its first iteration, which corresponds to what is known as the quantum oracle. The oracle, also known as a "black-box" function, modifies the quantum state of the item's index we're seeking [40] [41]. The change of the quantum state by the oracle Grover was performed without transforming it into a classical state. If the system is located in the right state, then the oracle will turn the phase by the angle π. Otherwise, no action will be taken. The function f corresponds to the oracle expressed as follows:

$$f(x)=\begin{cases}1 & if\ x\ is\ the\ correct\ state\ ,\\ 0 & Otherwise\ .\end{cases} \quad (2)$$

The quantum circuit implements the function *f* described by the unitary operator denoted by *O*.

$$O|\psi\rangle = \sum_i \propto_i (-1)^{f(i)} |i\rangle \quad (3)$$

The function *f* verifies the searched item by transforming the sign of its probability amplitude if *f(x) = 1*. Otherwise, nothing happens. To illustrate the operation of the oracle, we take an example of two qubits. To create a superposition state, we apply the Hadamard gate.

$$|\phi\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |01\rangle + |10\rangle + |11\rangle) \quad (4)$$

Suppose that the item we're looking for is the index marked by $|i\rangle = |i^*\rangle = |10\rangle$. By applying the oracle to the state $|\phi\rangle$, we get the state $|10\rangle$ signed by a phase of factor -1. Grover's algorithm oracle step is depicted in Fig. 3.

$$|\phi\rangle = \frac{1}{\sqrt{2}}(|00\rangle + |01\rangle - |10\rangle + |11\rangle) \quad (5)$$

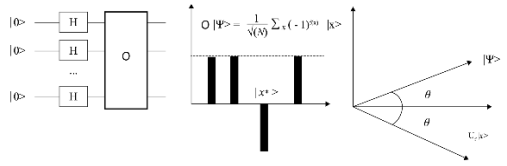

Fig. 3. The Grover Algorithm's Oracle Step.

C. Amplification

The amplification step performs a reflection around the average of the amplitudes. It flips the target state by increasing its amplitude probability and decreasing other states. Yet, this step can be implemented by a combination of the following gates: *HRH*. Here, *H* designates the Hadamard gate, and and *R* designates a phase shift transform [21]. Fig. 4 depicts Grover's algorithm amplification step.

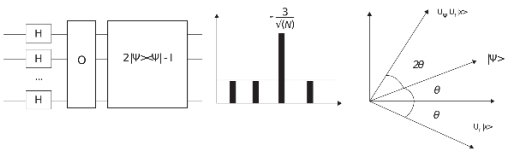

Fig. 4. The Grover Algorithm's Amplification Step.

D. Measurement

The measurement of each qubit in a quantum circuit is performed as the last step of the calculation to produce an output in the classical bit [42]. Indeed, we cannot say that a qubit has an actual value, but rather that it contains a probability of being found in a particular state when measured. Moreover, the measurement step is necessary to derive a result from the quantum state computation. The quantum gate associated with this step (the measurement gate) represents the only non-reversible quantum gate.

IV. Results and Discussions

Suppose we want to find the name of a well-described article with a set of metadata (Fig. 5). Each article that exists is indexed by an integer belonging to segment $\{0, \ldots, N-1\}$. Given that, we're looking for an article with an index $i = I^*$. The articles are not ordered, and we need to get a particular record from the list of articles. If we use the classical algorithm, we may be lucky and find the article we are looking for in the first index, i.e., $i = I^* = 0$, or we may not find the article until the last index $i = I^* = N-1$. Furthermore, for a search in the unstructured database, an average of approximately *N/2* (or *N* in the case where we found the article in the last index) of queries is required to find the article that adapts to the search criteria. It is important to point out that in the case of a uniform probability, we have a probability of *1/N* of finding an article among the *N* articles. Then, we can prove the average number of queries needed to find the right article, according to the equations below.

$$\sum_{i=1}^{N} i\frac{1}{N} = \frac{1}{N}\sum_{i=1}^{N} i,$$

$$\sum_{i=1}^{N} i = \frac{N(N+1)}{2},$$

$$\frac{1}{N}\sum_{i=1}^{N} i = \frac{1}{N}\frac{N(N+1)}{2} = \frac{(N+1)}{2} \approx \frac{N}{2} \quad (6)$$

Grover's algorithm bettered the classical search method by a quadratic speedup. The computer scientist, Grover, found a quantum search algorithm that requires only $O(\sqrt{(n)})$ steps. Suppose, for example, N=1000; the classical search algorithms do 1000 iterations (or 1000/2 = 500 in the worst case) to find the search record. However, the Grover algorithm will only perform $\sqrt{(1000)}$=100 iterations. Consequently, Grover's algorithm exhibits a significant acceleration. We cannot do great than a quadratic speedup with a complexity of order $\sqrt{(N)}$. The *N* articles are numbered from 0 to *N−1*, requiring *n* qubits to represent the list of articles (with $N = 2^n$). We can represent all *N* articles using only the principle of superposition with *n* qubits. A quantum state, $|\psi\rangle$ is designed by a column vector of size $(2^n, 1)$ whose values are probability amplitudes. Each probability amplitude is associated with a well-defined article that is identified by an index *i*.

$$|\psi\rangle = \begin{bmatrix}\alpha_0\\ \vdots \\ \alpha_m\end{bmatrix} \rightarrow \alpha_0|0\rangle + \alpha_1|1\rangle + \quad (7)$$

The article of index *i* is linked to the probability amplitude α_i. As a result, the probability of finding the article we're seeking is extremely close to 1, and the amplitude of all other probabilities is close to 0.

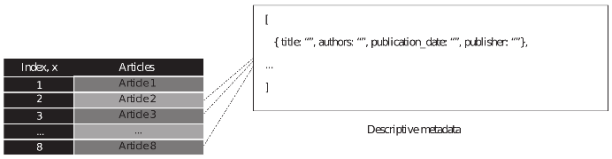

Fig. 5. Searching a List of Articles.

A. Use Case Application

Considering Data Lake (*DL*) as a database that stores heterogeneous data regardless of its format. Then, *DL*, which is made up of *N = 8* data sources, is derived from scientific

databases (Fig. 5). Each data source represents a scientific article, which is identified by a collection of descriptive metadata such as title, authors, and publication date, as well as the path where the paper is placed, which provides the paper's unique identity (*ident*). While $ident \in \{0, \ldots, N-1\}$, we want to find the article titled *X*, which contains an identifier id_k. To meet this requirement, we must first meet the prerequisite:

$f(id_k) = 1$.

Then,

$$O_f |X\rangle = -|X\rangle . \quad (8)$$

Let us express the different quantum states at each step shown in the circuit. Let's start with the first state $|\psi_0\rangle$, and end with the last state $|\psi_f\rangle$.

$$|\psi_0\rangle = |000\rangle \quad (9)$$

Subsequently, by applying the Hadamard gate, the state $|\psi\rangle$ becomes.

$$|\psi_0\rangle = H^{\otimes 3} |000\rangle = \frac{1}{\sqrt{8}} \sum_{i=0}^{7} |i\rangle = \frac{1}{2\sqrt{2}} \sum_{i=0}^{7} |i\rangle . \quad (10)$$

Consider that we are looking for the element which has the index $i = 5$. Then, $|i\rangle = |5\rangle = |101\rangle$ (Fig. 6 depicts the quantum circuit that corresponds to determining the quantum state $|101\rangle$). At this point, we need to specify the oracle operator that will be used in our use case. Indeed, when solving an NP problem, the defined oracle operator can mark the corresponding state. Therefore, the oracle operator must mark the element with the index 101 that we are looking for. Then, we have.

$$O_f |101\rangle|-\rangle = -|101\rangle|-\rangle.$$

$$O_f |i\rangle |-\rangle = |i\rangle |-\rangle \ if \ i \neq 5. \quad (11)$$

After specifying the sought state, we need to define a vector orthogonal to it, denoted by $|u\rangle$ as expressed below:

$$|u\rangle = \frac{1}{\sqrt{7}} \sum_{\substack{i=0, \\ i \neq 5}}^{7} |i\rangle, \quad (12)$$

$$|u\rangle = \frac{|000\rangle+|001\rangle+|010\rangle+|011\rangle+|100\rangle+|110\rangle+|111\rangle}{\sqrt{7}}$$

Then, we have

$$|\psi\rangle = \frac{\sqrt{7}}{\sqrt{8}} |u\rangle + \frac{1}{\sqrt{8}} |101\rangle = \frac{\sqrt{7}}{2\sqrt{2}} |u\rangle + \frac{1}{2\sqrt{2}} |101\rangle. \quad (13)$$

With this equality, one can determine the value of the angle θ as follows:

$$\theta = 2 \arccos\left(\frac{\sqrt{7}}{2\sqrt{2}}\right) \approx 41.4° \quad (14)$$

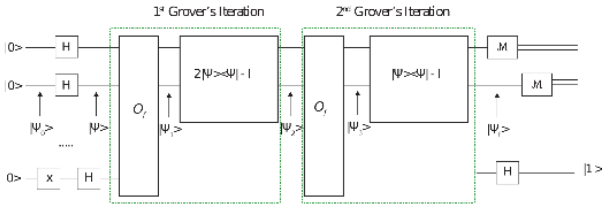

Fig. 6. Grover's Algorithm Quantum Circuit over an Unstructured Database of Eight Elements.

The next step is intended to apply the oracle operator $|\psi_1\rangle |-\rangle$. As a result, we get.

$$|\psi_1\rangle|-\rangle = O_f (|\psi 1\rangle|-\rangle) ,$$

$$= \frac{|000\rangle+|001\rangle+|010\rangle+|011\rangle+|100\rangle-|101\rangle+|110\rangle+|111\rangle}{\sqrt{7}} . \quad (15)$$

Note that quantum state $|101\rangle$ is the only one that has a minus sign. It is now suitable to rewrite $|\psi_1\rangle$ as follows:

$$|\psi_1\rangle = |\psi\rangle - \frac{1}{2\sqrt{2}} |101\rangle. \quad (16)$$

Or it can be expressed as

$$|\psi_1\rangle = \frac{\sqrt{7}}{2\sqrt{2}} |u\rangle - \frac{1}{\sqrt{2}} |101\rangle \quad (17)$$

Eq. (16), is useful for the next step's calculation. Since we are going to apply the formula $(2 |\psi\rangle \langle\psi| - I)$. The formula of Eq. (17), is useful to schematize the quantum state $|\psi_1\rangle$. Yet, the $|\psi_1\rangle$ state represents the reflection of $|\psi\rangle$ respecting the state $|u\rangle$. In the next step, we will apply the reflection again around the average.

$$|\psi_2\rangle = (2|\psi\rangle \langle\psi| - I) |\psi_1\rangle \quad (18)$$

By using Eq. (16), we get

$$|\psi_2\rangle = \frac{1}{2} |\psi\rangle + \frac{1}{\sqrt{2}} |101\rangle \quad (19)$$

Therefore, by using Eq. (13), we get

$$|\psi_2\rangle = \frac{\sqrt{7}}{4\sqrt{2}} |u\rangle + \frac{5}{4\sqrt{2}} |101\rangle \quad (20)$$

To assert that the angle between $|\psi\rangle$ and $|\psi_2\rangle$ is θ, note that

$$cos(\theta) = \langle\psi_2|\psi\rangle = \frac{1}{2} \langle\psi|\psi\rangle + \frac{1}{\sqrt{2}} \langle\psi|101\rangle = \frac{3}{4} \quad (21)$$

Which conforms with equality (14). This completes the first iteration of the Grover application designated by *G*. The second and final application of the Grover operator is similar to the first one. The next step in our examination is the analysis of the state $|\psi_3\rangle$, which is found by applying the oracle operator, as shown below:

$$|\psi_3\rangle = \frac{\sqrt{7}}{4\sqrt{2}} |u\rangle - \frac{5}{4\sqrt{2}} |101\rangle \quad (22)$$

Using Eq. (16), we get

$$|\psi_3\rangle = \frac{1}{2} |\psi\rangle - \frac{3}{2\sqrt{2}} |101\rangle \quad (23)$$

It is important to note that the state $|\psi_3\rangle$ represents the reflection of the state $|\psi_2\rangle$ with the state $|u\rangle$. Finally, the last step is to apply the inversion around the mean.

$$|\psi_f\rangle = 2(\langle\psi|\psi\rangle - I) |\psi_3\rangle \quad (24)$$

Using the two equations (13) and (23), we get

$$|\psi_f\rangle = \frac{-\sqrt{7}}{8\sqrt{2}} |u\rangle + \frac{11}{8\sqrt{2}} |101\rangle \quad (25)$$

It is self-evident θ that is the angle formed by the two quantum states, $|\psi_f\rangle$ and $|\psi_2\rangle$. Note that the amplitude of the marked state $|101\rangle$ is greater than the other quantum states $|i\rangle$, with $i \neq 101 = 5$. Subsequently, measuring the state based on

the computation will project it into quantum state 101 with the following probability:

$$p = \left|\frac{11}{8\sqrt{2}}\right|^2 = \left|\frac{121}{128}\right| \approx 0.945 \quad (26)$$

Therefore, after two iterations of applying Grover's operator, the chance of getting the sought result, which corresponds to the state $|101\rangle$ achieves an accuracy of nearly 94.5%. In the rest of this use case, we will show how important it is to know the major impact of the number of iterations of the Grover algorithm on accuracy. Suppose the number of iterations is unknown in advance. In this case, we will perform additional Grover iterations as follows:

$$|\psi_5\rangle = \frac{-\sqrt{7}}{8\sqrt{2}}|u\rangle - \frac{11}{8\sqrt{2}}|101\rangle = \frac{-1}{4}|\psi\rangle - \frac{5}{4\sqrt{2}}|101\rangle \quad (27)$$

The stage of the inversion around the mean induces the state $|\psi_6\rangle$, which is represented.

$$|\psi_6\rangle = 2(\langle\psi|\psi\rangle - I)\,|\psi_5\rangle$$

$$= 2(\langle\psi|\psi\rangle - I)\,(\frac{-1}{4}|\psi\rangle - \frac{5}{4\sqrt{2}}|101\rangle)$$

$$= \frac{-7}{8}|\psi\rangle + \frac{5}{4\sqrt{2}}|101\rangle$$

$$= \frac{-7}{8}(\frac{\sqrt{7}}{2\sqrt{2}}|u\rangle + \frac{1}{2\sqrt{2}}|101\rangle) + \frac{5}{4\sqrt{2}}|101\rangle$$

$$= \frac{-7\sqrt{7}}{16\sqrt{2}}|u\rangle + \frac{13}{16\sqrt{2}}|101\rangle \quad (28)$$

The measurement of the state $|\psi 6\rangle$ turns out to be us.

$$p = \left|\frac{13}{16\sqrt{2}}\right|^2 = \left|\frac{169}{512}\right| \approx 0.336 \quad (29)$$

Now, if we perform a measurement on the other states, the corresponding probability is calculated as below:

$$p = \left|-\frac{7\sqrt{7}}{16\sqrt{2}}\right|^2 = \left|\frac{343}{512}\right| \approx 0.67 \quad (30)$$

Table I shows the performance of the Grover algorithm according to the number of iterations. We notice that the probability of finding a solution for a search space of a specified size varies according to the number of iterations.

TABLE I. PERFORMANCE MEASUREMENT OF THE DIFFERENT ITERATIONS OF GROVER'S ALGORITHM

Simulator	*No. of Grover Iterations*	*Accuracy*
ibm_qasm_simulator	1	0.78
	2	0.945
	3	0.67

Therefore, if we continue the number of Grover iterations after the optimal number of *round*$(\frac{\pi}{4}\sqrt{N})$, the probability of finding the sought state decreases while the probability of error increases more and more. In the event of exceeding the number of iterations, which in our instance is two, the accuracy decreases by a percentage of 0.275. Thus, we report the empirical implementation of Grover's quantum search algorithm on the IBM quantum simulator with three qubits. Fig. 7 illustrates well the theoretical results that we have carried out. The QISKit code for the implementation can be found on my GitHub under the link: https://github.com/cherradii/Grover_Quantum_Search_Alg.

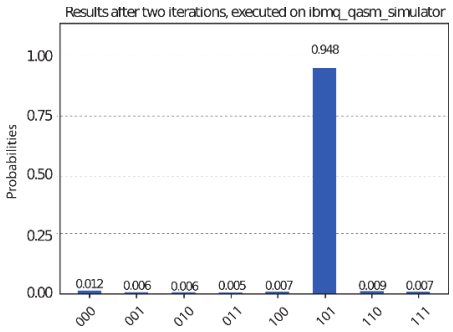

Fig. 7. Searching for Quantum State $|101\rangle$.

B. Iteration of Grover's Algorithm

Grover's algorithm is made up of a quantum subroutine named Grover's iteration, noted *G*, which is broken down into two steps:

- Apply the oracle U_f
- Apply the diffusion operator *G* on the first *n* qubits.

The iterations of Grover's algorithm are seen from a geometric point of view as a rotation in the two-dimensional space wrapped by the two vectors $|\alpha\rangle$ and $|\beta\rangle$. $|\alpha\rangle$ denotes normalized states of the sum of all targets, and $|\beta\rangle$ denotes normalized states of the sum of non-targets. The initial state $|S\rangle$ can be written as follows:

$$|S\rangle = sin\,(\theta)|\alpha\rangle + cos\,(\theta)|\beta\rangle \quad (31)$$

When looking in a search space of $N = 2^n$ items, there are *M* targets for searching ($0 \le M \le N$). Since $sin\,(\theta) = \sqrt{\frac{M}{N}}$, Apply Grover's operator (*G*) to states $|S\rangle$ for *k* times.

$$G^k|S\rangle = sin\,((2k+1)\theta)|\alpha\rangle + cos\,((2k+1)\theta)|\beta\rangle \quad (32)$$

When this appears, the target state will be explored with the probability of success *P*, formulated as follows:

$$p = sin^2((2k+1)\theta)) \quad (33)$$

Set $k = \frac{\pi}{4}\sqrt{MN}$, The Fig. 8 corresponds to the probability of success according to the proportion of target states in Grover's algorithm. To make things easier, let us set the proportion of the target as $\gamma = M/N$.

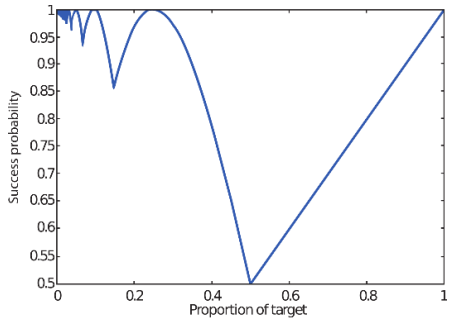

Fig. 8. The Success Probability of Grover's Algorithm.

To make things easier, let us set the proportion of the target as γ = M/N. Analyzing Fig. 8, we notice that the minimum probability that Grover's algorithm can reach is about 50% when γ = 0.5. Therefore, when 1/4 ≤ γ ≤ 1/2 the success probability of the proportion target declines rapidly. In return, when γ ≥ 1/2 the success probability of the proportion target gradually increases until it reaches 100% full accuracy when γ = 1.

C. Comparison of Grover's with Classical Algorithms

The practical implementation of Grover's search algorithm proved the efficiency in terms of its accuracy. After analyzing the different iterations, we found that the algorithm's effectiveness is influenced by the number of iterations. Moreover, applying the Grover algorithm iterations for a total number of *round* ($\frac{\pi}{4}\sqrt{N}$) times is the best choice to maximize the success probability of Grover's quantum search algorithm. Further, the quadratic reduction complexity of the quantum search Grover algorithm presents a major advantage over classical algorithms and exceeds any known classical algorithm of sub-exponential complexity. As shown in Fig. 9, Grover's quantum algorithm complexity time and classical counterpart algorithms.

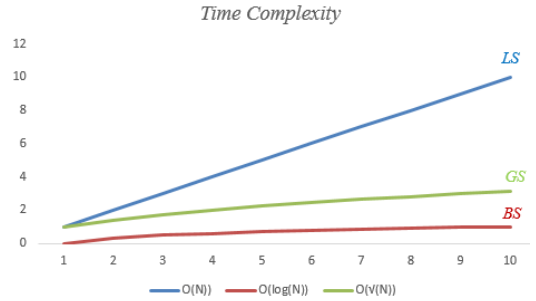

Fig. 9. The Average Number of Steps Needed to Find a Solution.

Therefore, a benchmark examination comparing the conventional search algorithms like sequential and interval search with the quantum Grover algorithm is still required. Table II shows a benchmark study between classical search algorithms and their counterparts, Grover's quantum search.

TABLE II. COMPARISON BETWEEN THREE DIFFERENT SEARCH ALGORITHMS

	Binary Search	***Linear Search***	***Grover Search***
Time complexity	*O(log(N))*	*O(N)*	*O(√(N))*
Database requirements	Database must be sorted	No requirements	No requirements
Algorithm type	Divide and conquer	Iterative	Iterative and parallel
Implementation	Medium	Easy	Hard

According to the comparison in Fig. 9, the binary search is the most sophisticated search, but it requires that the data be sorted, which is no longer possible with unstructured data. Linear search can override binary search if the targeted element exists at the beginning. However, being a search request for one or more elements in the heterogeneous database that contains data in different formats (structured, semi-structured, and unstructured), like the case of a data lake, Grover's algorithm remains the most efficient compared to the classical searching algorithms. Consequently, quantum algorithms are more prominent and highly recommended thanks to their quadratic acceleration, which is very fast compared to exponential acceleration, which corresponds to classical algorithms.

V. CONCLUSION

In this paper, an interesting algorithm is used to solve the search problem for unstructured datasets. We have investigated a clear procedure for making use of the potential of the quantum search Grover algorithm by proposing the design and implementation of the algorithm, including the prevalence effect of the number of iterations to decrease data processing time in unsorted databases. Based on this solution, our experimental results are very encouraging, and demonstrate the usefulness of Grover's algorithm to be applied efficiently to solve the search problem with high accuracy. Thus, from the benchmark search algorithms discussed in Section IV.C, we have retained that Grover's algorithm appears the best solution to the search problem in an unstructured data space. An important future perspective consists of moving to a higher dimension to solve the larger space search challenge with a large number of qubits.

***Abstract*—Covid-19 imposes many bans and restrictions on news, individuals and teams, and thus social networks have become one of the most used platforms for sharing and destroying news, which can be either fake or true. Therefore, detecting fake news has become imperative and thus has drawn the attention of researchers to develop approaches for understanding and classifying news content. The focus was on the Twitter platform because it is one of the most used platforms for sharing and disseminating information among many organizations, personalities, news agencies, and satellite stations. In this research, we attempt to improve the detection process of fake news by employing supervised machine learning techniques on our newly developed dataset. Specifically, the proposed system categorizes fake news related to COVID-19 extracted from the Twitter platform using four machine learning-based models, including decision tree (DT), Naïve Bayes (NB), artificial neural network (ANN), and k-nearest neighbors (KNN) classifiers. Besides, the developed detection models were evaluated on our new dataset, which we extracted from Twitter in a real-time process using standard evaluation metrics such as detection accuracy (ACC), F1-score (FSC), the under the curve (AUC), and Matthew's correlation coefficient (MCC). In the first set of experiments which employ the full dataset (i.e., 14,000 tweets), our experimental evaluation reported that DT based detection model had achieved the highest detection performance scoring 99.0%, 96.0%, 98.0%, and 90.0% in ACC, FSC, AUC, and MCC, respectively. The second set of experiments employs the small dataset (i.e., 700 tweets); our experimental evaluation reported that DT based detection model had achieved the highest detection performance scoring 89.5%, 89.5%, 93.0%, and 80.0% in ACC, FSC, AUC, and MCC, respectively. The results obtained for all experiments have been generated for the best-selected features.**

Keywords*—Machine learning; fake news; twitter; covid-19; correlation coefficient

I. Introduction

Over the years, many researchers have tried to identify fake news spreading on social media. Fake news is a source of spam capable of influencing perception, knowledge, and measuring methods [1]. Fake news has the potential to reach individuals through social media, cause damage to the economy and manipulate political outcomes. Fake news can be described as misinformation directed to deceive people [2]. In recent years, fake news has been shared on various social media. Generate a health concern to obtain advertising revenue for financial or political gain. When a particular news story is published, supporters of the news tend to share complete information without any falsification. However, those whose opinions do not correspond to the mentioned information. They resort to sharing the same information with some modifications of their own. As a result, the distinction between real and fake news has gained the attention of organizations such as Facebook, Google, and Twitter. Many researchers are making sustained efforts to combat the spread of fake news. Understanding the language in news stories is difficult because different people understand language differently. That is why the same news can be considered real or fake by a different group of people. The spread of fake news on these platforms leads to a loss of credibility and financial loss.

In 2019, a new virus called Covid-19 was reported in Wuhan, China, and the Covid virus has spread to various other parts of the world and has killed many people. At first, it was claimed that it was transmitted from animals to humans. Research and various experiments to find an effective treatment for covid-19 has become a very urgent need. Covid-19 has opened the door to spreading false news on various social media platforms such as Twitter, Facebook, and Instagram, which has misled many users worldwide. Misleading information and news about the disease are shared on the Internet from various sources, some of which are not trusted. It is well known that spreading false news about Covid-19 on social media can contribute to stress and health anxiety and lead to serious consequences for society's awareness and reaction to vaccination against Covid-19, such as misinformation about false treatments, anti-vaccination propaganda, and theories of the plot.

With advancements in processing technology, machine learning models, and deep learning techniques, user intervention can be replaced by assigning pattern identification tasks to computers. On the other hand, very little research has been done on applying linguistic and deep learning techniques for accurate classification of fake news among research done; the accuracy achieved is so high. This paper discusses the classification of fake news related to Covid-19 using Machine Learning Algorithms (MLA) and will focus on the news spread on the social media platform Twitter. This is done by enhancing the process of detecting fake news using machine learning algorithms such as Decision Tree (DT), Naïve Bayes (NB), K-Nearest Neighbors (KNN)

classifiers, and Artificial Neural Network (ANN) that can manage and distinguish real and fake news about Covid-19.

A. Problem Statement

Fake news in people's lives is a spam source that can affect people's general perception and knowledge [1]. Fake news can be described as a specific type of misinformation sent and directed to deceive people [2]. In recent years, a new term in the scientific arena is (electronic flies), especially with the massive development of digital media and communications and the spread of social media platforms and their direct and frightening impact on the behavior of individuals. Especially when directing society to a studied destination by publishing news to serve a specific issue, which leads to new terms such as digital propaganda, digital war, digital armies, and electronic terms. [3]. When a global news story is published, news sites and organizations race to share their coverage and stories on social media. Proponents tend to share information in its complete authenticity without change. However, those whose opinions do not correspond to the published information and may materially harm them, resort to sharing the same information with some modifications of their own, which leads to the existence of complete real news and fake news, which leads to confusion in people's understanding of the truth. Hence the distinction between real and fake news has received considerable research interest. And influential organizations, such as Facebook, Google, and Twitter, are making sustained efforts to combat the spread of fake stories. Since the start of the COVID-19 crisis, much false news has spread rapidly on social media about the disease, its symptoms, and the number of infections, as well as fake news about vaccines and their side effects. Detecting and distinguishing between real and fake news has posed a challenge to researchers regarding the accuracy of the results, the speed of obtaining them, and the stability of the technique used.

B. Research Contribution

The main contribution of this research is proposing a model to detect fake news on a Twitter platform using MLA and meta-date (attributes for a Twitter account). The model used MLA to build the behavior of members of evaluation panels and to resolve the multiplexing between their judgments. This study contributed the following:

- Collecting correct and fake tweets and corresponding metadata to create a dataset that will be publicly available for other researchers in the same field.
- Designing and developing an accurate model to detect fake Covid-19 news on Twitter using an MLA and Twitter's meta-data.

II. Literature Review

Due to the proliferation of large volumes of false content during the pandemic, the study around Covid-19-related misinformation became a popular area of research. Several methods were proposed to differentiate and verify the real and fake news for Covid-19 from different datasets and resources. Authors of [4] used deep learning algorithms in their study. The proposed model was based on the tweet's text and other tweet's features extracted online from Twitter, such as favorite count, retweet count, source, length, verified, the user URL, friend/followers count, statuses/followers count, and sentiment. The proposed method achieved an accuracy of 79% compared with SVM (72%) using Sheryl Mathias and Namrata Jagadeesh's dataset and the fake news data repository "FakeNewsNet." Recall reached 100% using RF, while the DT reached 94%. RF has 85% for the precision and 83% for the F1 score. In [5], the authors proposed a system for fake detection news consisting of two main categories: MLA and DNL. He used the FakeNewsNet dataset containing news content, social context and spatiotemporal and disasters, PolitiFact, and gossip police information to identify fake news on social media. The performance measure results were as follows: LSTM (Two layers) regarding disasters dataset (accuracy 98.6%, precision 98.55%, recall 98.6%, F1-score 98.5%). The Modified LSTM (one layer) obtained the best testing results: regarding the disasters dataset (accuracy 86.74%, precision 86.98%, recall 86.74%, F1-score 86.6%).

Regarding the PolitiFact dataset, the best testing results are obtained by the modified LSTM (two layers) (accuracy 83.93%, precision 86.66%, recall 83.93%, F1-score 83.31%). Regarding the gossip police dataset, and finally the Modified LSTM (one layer) regarding gossip police dataset (accuracy 83.82%, precision 84.85%, recall 83.82%, F1-score 83.7%). In [6], they applied several NNs, LSTMs, ensemble methods, and attention mechanisms to detect fake news on Twitter and other media platforms. Their models for fake news classification are based on the sentiment analysis of users in social media. They used the architectures to detect patterns in their data, where patterns can be anything such as unusual capitalization, random exclamations, question marks, etc. Various datasets were also used for evaluation, like the PolitiFact dataset, FakeNewsNet dataset, and twitter's advanced search functionality. The results showed that the LSTM achieved the highest accuracy: 88.78%. The detection performance was 73.29% in the CNN, 80.62% in the LSTM, 83.81% in the bidirectional LSTM, 88.78% in the CNN + Bidirectional LSTM, and 57.58% in logistic regression.

In [2], they proposed a Fake news tracker to identify false news and prevent propagation. Deep learning models were used to classify the encoder site consistent with deep LSTMs with two layers and 100 cells. The obtained accuracy on the PolitiFact dataset was 63.3% and 74.2% on the Buzzfeed dataset. In [7], the researchers used two MLAs: SVM and RF. They achieved the best result on SVM: precision of 50%, recall at 30%, and F1 score at 60%. On the other hand, RF achieved a precision of 88%, recall of 89%, and F1 score of 89%. In [8], the contributors used a supervised learning classification to train and test the manually and automatically annotated datasets to ensure annotation quality. The proposed method includes six different ML algorithms, four different features with each algorithm, and three pre-processing techniques. This method achieved: an 87.8% F1-score classification result with the manually annotated corpus, the automatically annotated corpus F1-score of 93.3%, and the highest precision value was obtained using the n-gram TF-IDF feature with the LR classifier (87.8%), finally LR classifier (93.4%) on manually and automatically annotated corpora.

On the other hand, in [9], the authors used six machine learning algorithms: NB, KNN, RF, C4.5, BN, and SVM. The

train is based on a 10-fold cross-validation model. This study created a dataset of tweets collected using Twitter's streaming API spanning three months. The average accuracy of the cross-validation model for C4.5 was up to 98%, followed by RF, which had an average accuracy of 97.4%. The C4.5 outperformed all the other models. The Naive Bayes algorithm had the worst performance, with an average accuracy of 85.5%. In [10], they used three MLAs: NB, LR, and SVM, with two features: word embedding and word frequency approach. At the practical level, they collected one million Arabic tweets from the Twitter streaming API related to Covid-19. This study found that ML classifiers can correctly identify fake news-related tweets with an accuracy of 84%. In [11], the authors found that J48 has performed the best for the BuzzFeed Political News dataset with an accuracy of 0.655, while Classification via Clustering (CVC) has the worst accuracy of 0.501. For the Random Political News dataset, Sequential Minimal Optimization (SMO) algorithm has the highest value among the twenty-three algorithms, with an accuracy of 0.680.

In the same context, [12] discussed methods for detecting fake news using different sets of features extracted from the news text. One of the used feature sets was stylometric features, including the presence of uppercase letters and quoted content. Such features can be significant for detecting fake news and highlighting the importance of the writing style of news. Also, the write prints feature set extracted contains the content-specific, structural, linguistic, and syntax-based features. The model achieved an accuracy of 86% for stylometric features with a gradient boosting classifier. In [13], the authors used Bag-of-Words and TF-IDF, syntactic and semantic-based using Word2Vec and FastText. This method used two datasets for testing, and the results showed that the SVM model using TF-IDF obtained the best F1-Score value in both testing data. The model obtained an F1-Score of 92.21% in Testing Data 1 and 93.33% in Testing Data 2. In [14], the researchers tried to detect fake news using deep learning techniques such as LSTM, CNN, and BERT. The obtained accuracy results were LSTM 91%, CNN 93%, and BERT 98%. While in [15], they used four MLA classifiers: LR, SVM, DT, and Gradient Boost, to perform a binary classification to detect fake news and benchmark the annotated dataset. The proposed method curated and released a manually annotated dataset of 10,700 social media posts and articles concerning Covid-19 news, and it achieved the best performance of 93.32% F1-score with SVM.

Other noticeable models were found in [16-20]. In [16], machine learning was utilized to detect fake news published through social media such as Twitter and Facebook. The used ML algorithms were NB, SVM, BERT fine-tuning, and SBERT. The experiments found that SVM achieved the best results with F1 Validation of 93.28, compared to 90.62 using NB, 80.88 using BERT, and 78.18 using the SBERT technique. In [17], they proposed a detection method to distinguish and verify the fake news for Covid-19. This method achieved accuracy with the DT classifier at 92.07%, and the RF classifier accuracy achieved 94.49%. They proposed a model to classify news within different categories using SVM and TF-IDF. The classification precisions were 97.84% and 94.93% for BBC and 20 Newsgroup datasets. Also, in [19], the authors detect fake news in Covid-19 using a linear SVM, RF, LR, NB, and MLP. The evaluation was conducted using a large dataset containing 10,700 manually annotated social media posts and articles. The results showed that SVM achieved the best performance with 95.70 accuracies compared to others. SVM 95.7%, RF 90.79%, LR 95.42%, NB 93.32%, MLP 93.60%. In [20], they utilized an n-gram classifier to detect fake news. The TF-IDF feature extraction method estimated RF, DT, and SVM. This method achieved an accuracy of 0.73 for SVM and 0.78 for passive-aggressive.

Moreover, in [21], they used an n-gram classifier to detect fake news. SVM was estimated with the TF-IDF feature extraction method. The accuracy achieved 0.92. in [22], the authors used ten MLAs with seven feature extraction techniques to detect fake or real news. They tested their proposed classifier on 3,047,255 tweets concerning Covid-19. The best performance measures they achieved in NN, DT, and LR classifiers, were 99.7%, 99.9%, and 99.8%, respectively. In [23], they utilized two fundamental ML classification techniques within the meaning of text analytics. They identified common sentiments attached to the pandemic using the Coronavirus (COVID-19) Tweet and R analytical software. As Covid-19 approached the top level in the USA United States used clear textual analytics carried through needed text data visualization. The proposed method accuracy achieved 91% for long Tweets, including the Naïve, and an accuracy of 74% with a shorter tweets. While in [24], the study attempts to realize the rationale behind people's use of certain media, which was extended by an "altruism" motivation. The data were analyzed with Partial Least Squares (PLS) to determine the effects of six variables on the outcome of fake news. The researchers used Nigerian citizens as study samples, and the dataset contained 385 samples used in the experiments. The study showed that altruism is the most significant predictor of fake news sharing without using machine learning techniques. Furthermore, in [25], the researchers collected 2.7M posted by over 690k unique users. They noted that 18.66% of the tweets were posted by verified users (who constitute only 0.81% of the unique users). They collected 748k Arabic Language Tweets in addition to propagation networks of a subset of 65k Tweets to enable the research related to natural language processing, information retrieval, and social network analysis. This method used Twitter search API to retrieve the data daily between (January 27, 2020–March 31, 2020). The study did not use any MLA on the study and did not supply any results related to evaluation results. In addition, the collaborators of [26] collected a dataset containing 4072 news articles from Webhose.io regarding fake news about Covid-19. This method used linguistic features and conducted experiments with baseline classifiers, LSTM, and dense layer. The proposed method’s accuracy was between 70% and 80%.

Eventually, by reviewing the literature, researchers focused on studying real/fake tweet detection using popular machine learning algorithms. Some researchers used DL and NLP to discover the nature of tweets. Researchers have achieved excellent results through machine learning algorithms (using natural languages). But natural languages differ in understanding from each other, so the published tweet/news may be true in a specific language and for people who know

the details of the language, while the tweet/news is misleading for people who do not understand the language in which the news/tweet is published. On the other hand, the results that can be obtained using (NLP) can be obtained similar results if using machine learning algorithms with (metadata) provided by Twitter API. Note that the authors of [4] have used common MLA and DL algorithms and reached excellent results using common machine learning algorithms and (metadata). From our point of view, I think using common machine learning algorithms is sufficient if their results are excellent compared to the results reached by researchers when using DL algorithms. The author will use them during this study and compare them with the results of [4]. In this study, a proposed model will be presented that uses machine learning algorithms and Twitter metadata to improve fake news detection and real news by identifying features that affect the accuracy of results.

III. Materials and Method

This section presents the research methodology and the steps that were followed to achieve the goal and objectives of this research. The proposed approach is decomposed into data collection, feature selection, machine learning implementation (classification), and metric evaluation. Fig. 1 summarizes the steps of the proposed system.

A. Dataset Collection

This study will collect a data set using the Twitter API. To use Twitter's metadata, the metadata will be used as features of the dataset. It is one of the most important contributions of this research study, as the data set available on the different platforms provides a data set consisting of the tweet and the status of the tweet only (0/1, true/false) and does not provide the metadata that we need for the study. To implement and train the proposed model. We need a labeled data set, which enables the data set (tweets) to be sent to medical bodies specializing in Covid-19 to determine the type of tweet that is healthy/false. The dataset usually contains various forms of text, numbers, and language combinations, as well as some retransmission hashtags or tags; our dataset is extracted from the social media giant (Twitter) and used to detect fake news from real news after selecting key features from the data descriptive and humane evaluation of the data set by staff with medical backgrounds to determine appropriate features subsequently.

B. Feature Selection

Feature selection is a good way to infer features with a strong and effective effect, which improves accuracy results. The algorithm's time is not wasted on non-valued features. Many feature selection methods are available in the literature based on the abundance of data with hundreds of variables leading to high dimensional data. Feature selection methods provide a way to improve prediction performance, reduce computation time, and better understand a data set in machine learning or pattern recognition applications [27]. We can define a feature as an individual measurable characteristic of the experimental process. Through a combination of features, any machine learning algorithm can perform classification. Also, feature selection aims to select a small subset of relevant features from the feature pool obtained by removing inappropriate, redundant, or worthless/annoying features. [28]. There are common search strategies to select features, such as Information gain using a univariate information filter class applicable to classification [29], Minimum redundancy and maximum relevance: using a multivariate information filter class applicable to classification [30], and Correlation: using univariate information filter class applicable to regression [31], Correlation-based feature selection (CFS): using multivariate information filter class applicable to classification, regression [31], Fisher score: using univariate information filter class applicable to classification [28], and Spectral feature selection (SPEC) and Laplacian Score (LS): using univariate information filter class applicable to classification [30]. Based on our study and experiments and using Correlation-based feature selection (CFS), we noticed that some features do not affect the accuracy of the results even if they are excluded. For example, the gender and nationality of a news writer do not affect human opinion when checking the authenticity of real news from fake news. In this study, the feature selection is based-on correlation and ranking, as will be explained with an example in the next section. We examined each feature with the target "class," recorded all results, and compared results to each other to select the best features and then used these features on our proposed model. Our dataset had thirty-five features before medical panel validation (which will be discussed later).

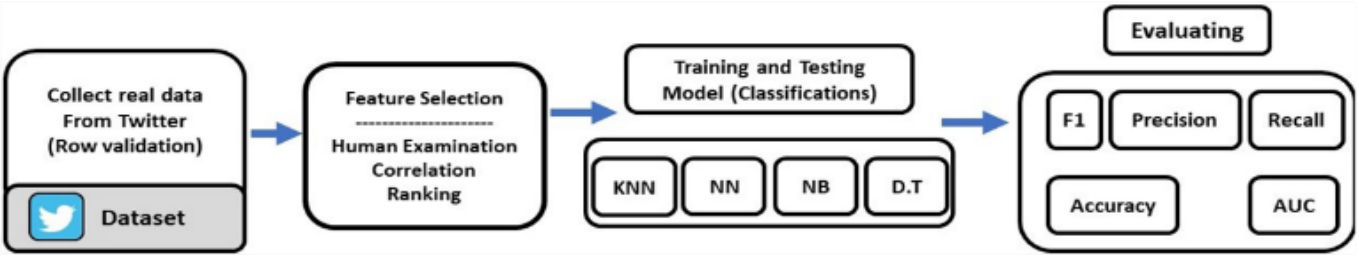

Fig. 1. The Proposed Model Architecture.

C. Machine Learning Implementation (Classification)

This study will collect a data set using the Twitter API. To use Twitter's metadata, the metadata will be used as features of the dataset. It is one of the most important contributions of this research study, as the data set available on the different platforms provides a data set consisting of the tweet and the status of the tweet only (0/1, true/false) and does not provide the metadata that we need for the study.

1) DT parameters:

- The minimum number of cases in papers where the algorithm will not create a division less than this limit, which would put less than the specified number of training examples in any branches.
- Split subset, Sub-division, where the algorithm is divided by a given number of instances.
- Tree depth limits the classification tree's depth to the specified node number.
- The majority (%): the algorithm depends on the division of the contract after reaching the specific majority threshold.
- Induce and build a binary tree (split into two child nodes).

2) KNN parameters:

- Distance Metric calculates the distance of 1 test observation from all other observations of the training dataset and then finds K nearest neighbors. To calculate the distance, we can use the following not exclusively: "Manhattan," which is the sum of all attributes' absolute differences, of all attributes, or "Mahalanobis," which is the distance between point and distribution. Or "Euclidean," which is the distance between two points, or "Chebyshev," which is the greatest of absolute differences between attributes.
- Weight: has two types: "Distance" is the closest neighbors of a query point have a greater influence than the neighbors further away, and "Uniform" is all points in each neighborhood are weighted equally. [32].

3) ANN parameters:

- Neurons are defined as the element that represents the number of neurons in the hidden layer. e.g., a neural network with three layers can be defined as 2, 3, 2.
- Activation is divided into "Logistic," the logistic sigmoid function. "Identity" is the no-op activation useful to implement linear bottleneck. "ReLu" is the rectified linear unit function. "Tanh" is the hyperbolic tan function.
- Regularization parameter alpha default value 0.0001.
- The solver for weight optimization contained "SGD "stochastic gradient descent."L-BFGS-B" is an optimizer in the family of quasi-Newton methods. "Adam" is a stochastic gradient-based optimizer that works relatively well with thousands of training samples or more in terms of training time and validation score. However, "L-BFGS-B" can converge faster and perform better.
- A Maximal number of iterations is 200 [32].

D. Evaluating Metrics

It is now well known that error rate is not an appropriate evaluation criterion when there are unequal costs. This paper uses F-measure and AUC (Area under the ROC Curve) as performance evaluation measures.

1) F1-measure is the mean of precision and recall. This takes the contribution of both, so the higher the score, the better, as shown in equation 2. The F1-measure is calculated by multiplying (Precision and Recall by 2) value divided by the total of precision and Recall.

$$\mathrm{F-measure} = (2 \times \mathrm{Prec} \times \mathrm{Rec})/(\mathrm{Prec} + \mathrm{Rec}) \quad (1)$$

2) AUC has proved to be a reliable performance measure for imbalanced and cost-sensitive problems. Given a binary classification problem, a ROC curve depicts the performance of a method using the (FP, TP) pairs. FP is the false positive of the classifier, and TP is the true positive. AUC is the area below the curve [33]. The calculation for FP and TP is shown in equations three and 4.

$$False\ Positive\ (fp) = FP/(FP + TN) \quad (2)$$

$$TruePositive\ (tp) = TP/(TP + FN) \quad (3)$$

3) The confusion matrix is a table that illustrates and displays a performance rating model on a data set whose true values are already known. It is the best way to understand the behavior of the technique and algorithm used to show the statistics and the relationship between the expected results. As shown in Table I.

TABLE I. CONFUSION MATRIX

	Predicted Positive	**Predicted Negative**
Actual Positive	(True Positives)	(False Negatives)
Actual Negative	(False Positives)	(True Negatives)

4) Precision is an evaluation metric measuring the percentage of positive cases out of the expected positive cases. Equation 5 shows how to calculate Precision. [34].

$$Precision = TP/(TP + FP) \quad (4)$$

5) The recall is the part of the relevant documents that have been successfully retrieved. The recall is calculated as shown in equation 6 [34].

$$Recall = TP/(TP + FN) \quad (5)$$

6) Accuracy is the most used metric to judge models, which is calculated by summation of true positive values and true negative values divided by summation of true positive and false positive and true negative and false negative,

according to equation 7, Where the values of TP, TN, FP, and FN were taken from the confusion matrix.

$$Accuracy = (TP + TN)/(TP + FP + TN + FN) \quad (6)$$

7) Matthew's correlation coefficient (MCC) is a statistical measure of the strength of the relationship between the relative movements of two variables. The values range between "-1", "0" and "1" as the following explanation: Correlation of "0" shows no linear relationship between the movements of the two variables, the Correlation number is greater than "1" or less than "-1" means that there was an error in the correlation measurement, and Correlation of "-1" shows a perfect negative correlation, while a correlation of 1.0 shows a perfect positive correlation. [35]. Matthew's scale is associated with the F1 scale. As the F1 scale rises, the higher the Matthew scale rises.

$$MCC = \frac{TP \times TN - FP \times FN}{\sqrt{(TP+FP) \times (TP+FN) \times (TN+FP) \times (TN+FN)}} \quad (7)$$

IV. Results and Discussion

This section presents five stages of the experimental setup: experimental environment, dataset collection, cleaning dataset and pre-processing setup, dataset evaluation, result, and analysis (selection features and finally presents the accuracy results), recommendation, and future planning work.

A. Experimental Environment

As an intelligent adaptive approach, several phases describe the relationship between phases, where the outputs from a specific phase can be considered inputs for the following phase. In addition, moving to the next phase should ensure that the previous phase is completed. And to ensure that it will reach the best result, all ML algorithms and computational techniques were performed on a personal computer with an Intel(R) Core (TM) i5-2410M CPU @ 2.30GHz, with 8 GB of RAM and 512 GB SSD hard disk.

B. Dataset Collection

The dataset was obtained from the social media platform (Twitter) Orange App ver. 3.30.2 Using the text extraction extension, this program helps extract tweets easily by obtaining permission from Twitter to use its tweets in scientific research. Operations (correlation/ranking, classification, and all evaluation results) were performed through Python version 3.8. Orange is the software of a Python-based component. Visual programming software for data mining, machine learning, and data analysis. Data is presented visually, and App allows classification and clustering. Table II shows useful details for getting tweets using Orange App and Twitter Add-on; as we explained earlier, Orange was used as a program through which tweets are fetched using the secret key granted by Twitter.

We contacted Twitter to get API Key and developer account to search and collect real tweets from the original resources. This method also provided access to Twitter attributes used as features in this study. Table III displays a set of meta-data (Attributes) from the Twitter App using API and python command to get a user objects directory, known as Twitter's (metadata). For example (followers count, retweet count, likes, time, author- Verified, username, ID), this study focused on testing metadata as features to find out which (features) achieved the best Accuracy results F- measures, recall, Precision, MCC.

TABLE II. Twitter API Variables

Variables	Description
Twitter API Key	API key, secret, token, and Bearer token are simple encrypted string that identifies an application without any principal
API Key Secret	
Access Token	
Bearer Token	
Query Word list	Hashtag you are searching for, e.g., COVID-19
Languages	Searching by language (English, Arabic…etc.)
Max tweets	The maximum tweets count
Search type:	default "content, Target search type

After that, we collected 14,000 tweets, as shown in Table IV, and a sample of 675 tweets was taken for the study. The dataset will be available to researchers for research purposes and research studies. The dataset has been cleaned and prepared to get features used in our proposed model and applied machine learning algorithms to it. To exclude useless features such as (date, id_str, id, entities, user, longitude, latitude, user_truncated, place, user_producted, user_description), which have frequent data values, and delete unwanted row heads from the dataset, an ML test must be implemented to dataset after cleaning.

TABLE III. List of Attributes

Attribute	Description
user_statuses_count	The number of tweets and retweets made by the user
user_listed_count	represents the number of public lists this user is a member of (registered as a member of the list/group)
user_followers_count	The number of followers the account currently has
user_protected (if true)	Indicates that user has chosen to protect his Tweets
user_description	represents the description of the current user account
Id	Integer-unique number of this user (the current user)
Number of Likes	The number of likes that are recorded on a specific tweet for the current user
created_at	The date on which the current user account was created on the social networking platform (Twitter)
user_location	The location that the user (the account holder) specified for this account
Tweet	The text of Tweet posted on Twitter for current user
source_url	URLs included by user in the text published Tweet
Lang	The language the user registered as the mother tongue in the account upon creation
in_reply_to_user_id_str	If this field contains a string of the original Tweet owner ID, the represented Tweet will be a reply
in_reply_to_status_id_str	If this field contains a string of the original Tweet owner ID, the represented Tweet will be a reply

Attribute	Description
in_reply_to_screen_name	If this field contains the screen name of the original Tweet author., the Tweet will be a reply
Entities	The set of features extracted from the Tweet body (user_mentions, hashtags, media, symbols)
user_favourites_count	The number of times of users liked a particular tweet
user_friends_count	The number of users who follow a particular account
user_verified (if true)	Indicate that the user has a verified account
number of retweets	The count of a user has retweeted a specific Tweet
URL	URL contained in the text of the published Tweet.
truncated	If the retweet exceeds the text length limit of the original Tweet, the value of this field is valid and is expressed as a Boolean value.
Source	it is a utility for posting a Tweet and is expressed as a string formatted in hypertext language (HTML). It indicates the source from which the tweet was launched (a website or application from a smartphone, whether Android or iPhone)
Id_str	each Twitter user is unique and has an identifier string, represented by this field, and is considered a property of the user (tweeter)
User	it represents an object describing the user who posted the tweet. It has several attributes: (screen_name, location, screen_name)
geo_enabled	this field indicates that the user has allowed the ability to geotag their Tweets, if true.
retweet_count	this field indicates the number of times a Tweet was retweeted by any user who posted a Tweet
is_quote_status	this field indicates whether the Tweet was quoted
in_reply_to_user_id	Contains a valid representation of the original Tweet owner ID, so the tweet represented was a reply.
in_reply_to_status_id	If contains a valid representation of the original Tweet owner ID, the tweet represented was a reply.
favorite_count	The number of tweets liked by the user over the life of the account
display_text_range	The length of the text of the tweet, bearing in mind that the Twitter platform imposes on the user a specific number of characters for a single tweet, and it cannot be exceeded within the same tweet
default_profile	It represents a Boolean value and indicates that the user has not changed the background of his user profile; if the value of the field is true, and if the value is false, then the user has changed the background of the image
Has_background_image	If the field value is true, the user wants to use the uploaded background image.

TABLE IV. THE DATASET INFORMATION

	Column	Non-Null Count
1	display_text_range	14000 non-null
2	entities	14000 non-null

C. Cleaning Dataset and Pre-processing Setup

The data cleaning process started by removing the empty rows and, incomprehensible symbols, useless attributes (date, time, language, latitude, longitude, in reply to, and location). Also, change feature values from Boolean to numeric (true/false → to 1/0).

D. Dataset Evaluation

After collecting and revising the dataset and having 675 tweets in finalizing step; the following steps were followed:

Some personal tweets were excluded (for example … Pfizer's second graft dose was taken, and I am on my way to take a booster dose of grafts...) to reach 542 tweets. For the next step. The medical panel validated the tweet content as fake/real news by humanly evaluating those with medical backgrounds by sending the dataset, which contained 542 tweets, to the medical panel. A data set consisting of two fields has been sent (Tweet, True/False rating) to get the medical opinion and evaluation tweets and select it as "Class" for the dataset and other attributes as features (Num-Likes, Num-Retweet, Author Followers Count, Author Listed Count, Author Favorites Count, Author Friends Count, Author Statuses Count and Author verified). The number 'True' will be selected for the real Tweet, and 'False' will be selected for the fake Tweet. The Tweet (content) will only be used to classify it, and then it will be excluded before it is entered into the classification algorithms; we exclude any feature that contains text such as the name of the Tweet author or the description of the Tweet author, and we convert the value (true/false) to "0" for the false tweet and "1" For the correct tweet, We combine it with the rest of the features (Num-Likes, Num-Retweet, Author Followers Count, Author Listed Count, Author Favorites Count, Author Friends Count, Author Statuses Count, and Author verified), to get the final dataset for the study.

E. Experimental Result Analysis

After collecting the datasets, author excluded the tweet from the dataset and applied the proposed model to test and train machine learning algorithms on it, as following steps:

Importing Dataset: In this step, import and read the data set, using Python commands and show data set information, and repeat false tweets and is represented at zero number as well as the correct tweets and are represented in one number and all of which are represented by Class. This means that the data set is almost balanced.

Correlation: In this step, Correlation was used through Python commands to get the most useful features in terms of interconnection between them. The features that most affect the result are identified by Dataset Correlation, one of the most important commands in the Python library because it identifies features that affect the accuracy of the results when machine learning algorithms are applied to the dataset. Remember that all the features have been checked with the class feature, as we will explain in the next step. Fig. 2 shows the important and best features that affect the accuracy of the results. Fig. 2 shows the important and best features were (Num-Likes, Num-Retweet, Author Followers Count, Author Listed Count, Profile use background images, user default profile) Where the result of the impact of features (Num-Likes, Num-Retweet, 0.98) and features (Author Followers Count, Author Listed Count,0.89) and features (Profile use background images, user default profile,0.59) in other words if we remove any one of correlated features the evaluation result will reduce.

Feature selection: We applied the proposed form in two stages: The First Phase is to find the best class. Due to the number of tweets, we obtained in a huge data set (14000 tweets) and where the medical team could not be done; Because the huge number of tweets began to test selected features of metadata to be our class, and all the features were checked, and the class we reached was the author verification, several likes, and re-tweet as a "class." The proposed form was applied to the data set with the ML CALSIFIERS (DT, KNN, ANN, NB, LR, RF, SVM). The results were unreasonable and can arrive in workbooks (RF and DT) at 9.9%, and the difference between the right and false tweets and which were "0" and "1" (as a class), was not balanced. It is clear through the data set results that we will have to balance the data again, leading to an increase in samples that do not exist or excluding samples affecting the accuracy we will receive. After that, randomized random sampling method and random sampling method were used to balance our data set, but we found that the random sample with excess factors had disadvantages (have increased the sample with non-realistic values), and this led to incorrect resolution for results, in addition, The random sampling method also defects (sample is deleted that may contain data affecting resolutions)—the results as shown in Table V.

The second phase: A sample of 670 tweets was taken after cleaning the data set and reading Tweets by removing unnecessary or unnecessary tweets. Where the revised final data set reached 543, the authors are keen to be balanced as much as possible, avoiding the problem of non-balanced data. The data set was sent to the specialized medical authorities to evaluate Tweets. Then, the authors applied the proposed form to the data set. The authors have done the following: It should be noted that each feature was examined with target "Class" one-by-one consequentially and recorded the results to reach the best results, and through this process, it was found that (Num-Likes, Num-Retweet, Author Followers Count, Author Listed Count) are the most influenced result in the accuracy and improved results and found that features: Author Favorites Count, Author Friends Count, Author Statuses Count and Author verified had reduced the accuracy results as Table VI and Table VII shown. However, the correlation and ranking method helped to find the best correlation features, which was achieved with our next step.

Training and Testing Dataset: The dataset was divided into 70% for training and 30% for testing using python; the Machine learning algorithms (DT, NB, KNN, NN) were used because it is the best classifier for (Binary dataset attributes) and also easy and fast classifiers. The parameters settings for Classifiers were as follows: (A) DT parameters:[minimum number of instances in leaves (10), the smallest subset(5), maximal tree depth (30), the majority reaches (95%)], (B) KNN parameters: [number of neighbors (5), metric (Euclidean), weight (Uniform)], and (C) ANN parameters: [Neurons(100,), activation (Relu), solver (Adam), regularization by default (0.0001), maximal number of iterations(200)]. Classifiers have been applied using Cross-validation by (3, 5, 10, 20) folds. The best result was achieved after applying machine learning algorithms to the dataset using Cross-validation with 20 folds as follows: Decision Tree (DT) and Naïve Bayes (NB) achieved the highest value of Accuracy in Evaluation Results it was 89.5%, K-Nearest Neighbors (KNN) achieved 88.9% value of Accuracy in Evaluation Results, the Neural Network (NN) has 82.1% in Evaluation Result of Accuracy as shown in Table VIII.

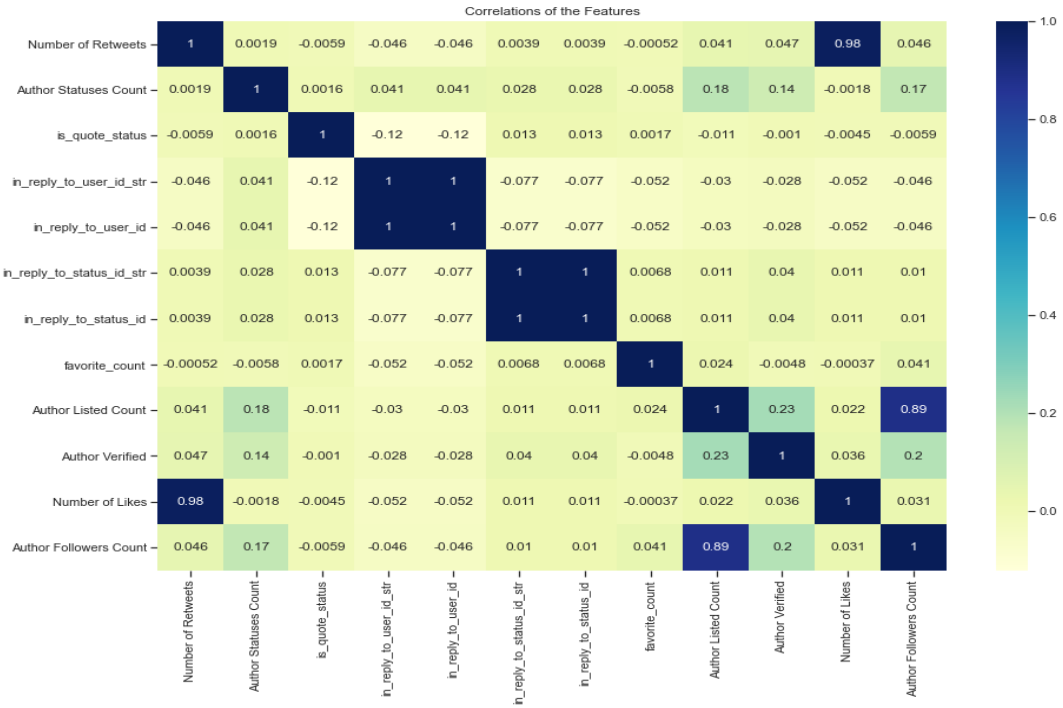

Fig. 2. Best Features Selected by Correlation.

TABLE V. RESULT OF 14000 TWEETS

	NB	0.92	0.88	0.88	0.88	0.88
	DT	0.89	0.82	0.82	0.82	0.83

TABLE VIII. EVALUATION RESULT FOR CLASSIFIERS

Model	**AUC**	**Acc**	**F1**	**Rcl**	**Prc**
DT	0.928	0.895	0.895	0.895	0.897
NB	0.960	0.895	0.895	0.898	0.899
KNN	0.923	0.889	0.889	0.889	0.889
ANN	0.894	0.821	0.821	0.821	0.839

On the other hand, this proposed model is a classification based on meta-data because of the advantages of using meta-data (it can represent directly and easily). The results of testing classification algorithms plots for the AUC-ROC curve, as shown in Fig. 3.

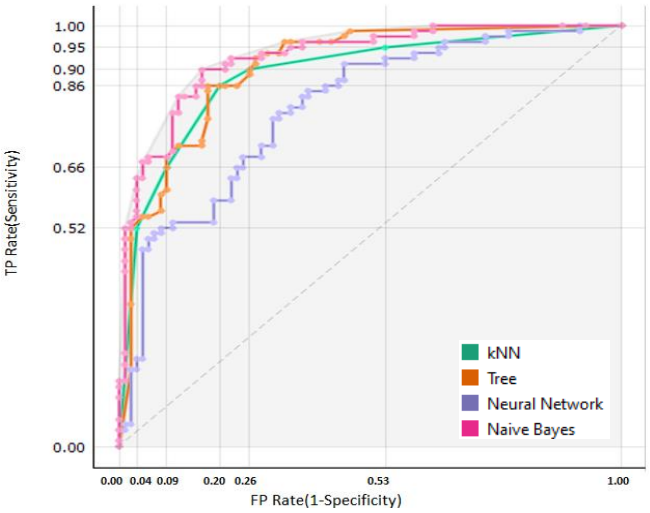

Fig. 3. AUC-ROC Curve.

The figure shows the ROC curves of the tested algorithms and plots the curve for each algorithm, which compares the classification models tested during the study. The curve shows a false positive rate on the x-axis (1-specificity; the probability that the target = 1 when the true value = 0) versus a true positive rate on the y-axis (sensitivity; the probability that the target = 1 when the true value = 1). The figure shows that the closer the model curve approaches the left boundary and then the upper bound of the ROC area, the higher the accuracy of the classifier/model. Due to the costs of false positives and negatives, the figure can determine the optimal classifier and the threshold for the Naïve Bayes classifier as shown in the figure and, therefore, the highest threshold. Area Under the Curve (AUC), It is clear from the figure that the AUC of the Naïve Bayes (NB) ROC curve is higher than the other classifiers of the KNN, NN, and DT ROC curve. Therefore, we can say that Naïve Bayes did a better job categorizing the positive category in the data set.

F. Discussion and Summary

This research has presented a proposed model to detect fake news on the Twitter platform using machine learning algorithms. The results obtained by applying AI algorithms to our selected features to detect fake news on the Twitter platform show the following results:

- The best Accuracy (CA) achieved by Decision Tree (DT) with 89.5% with these parameters: [minimum number of instances in leaves (10), the smallest subset (5), maximal tree depth (30), the majority reaches (95%)].
- K-Nearest Neighbor KNN achieved the best Precision PR with 90.2% with these parameters: [Number of Neighbors (5), Metric (Euclidean), Weight (Uniform)].
- The best Recall RC achieved by K-Nearest Neighbor KNN and Naïve Bayes NB with 87.837% with these parameters:[Number of Neighbors (5), Metric (Euclidean), Weight (Uniform)] for KNN.
- The best F1-Measure achieved by K-Nearest Neighbor KNN with 89% with these parameters: [Number of Neighbors (5), Metric (Euclidean), Weight (Uniform)].
- K-Nearest Neighbor KNN achieved the best Mathieu's Correlation Coefficient MCC with 0.8008.
- We found that when (listed count and followers count) increase, the value of the Target Class is “1” and if the count of (listed count and followers count) is less than 2000, the result of the target Class is "0", with considering the error rate. Table IX shows all results achieved in the Evaluation/confusion matrix and MCC Results.

TABLE IX. EVALUATION RESULTS

	TP	FP	FN	TN	CA	PR	RC	F1	MCC
KNN	65	7	9	81	0.89	0.90	0.88	0.89	0.80
DT	63	7	11	81	0.89	0.9,	0.85	0.88	0.78
NB	65	11	9	77	0.86	0.85	0.88	0.87	0.75
ANN	62	18	12	70	0.82	0.78	0.84	0.81	0.63

The results in Table IX show the following:

KNN: The proposed model was able to find out the following:

- Predict 65 truthful tweets and 81 false tweets.
- Failed to predict seven truthful tweets and nine false tweets.
- Predicting the correct news with a precision of 0.90.
- Predicting the incorrect one (Recall) of 0.87 MCC was 0.8, and this value near ($^{+}$1) means perfect accuracy.
- The KNN Evaluation result was the best.

DT: The proposed model was able to find out the following:

- Predict 63 truthful tweets and 81 false tweets.
- Failed to predict seven truthful tweets and 11 false tweets.
- Predicting the correct news with a precision of 0.90.
- Predicting the incorrect one (Recall) of 0.85
- MCC was 0.7, and this value near (+1) means good accuracy.

NB: The proposed model was able to find out the following:

- Predict 65 truthful tweets and 70 false tweets.
- Failed to predict 11 truthful tweets and nine false tweets.
- Predicting the correct news with a precision of 0.85.
- Predicting the incorrect one (Recall) of 0.87.

- MCC was 0.7, and this value near (+1) means good accuracy.

ANN: The proposed model was able to find out the following:

- Predict 62 truthful tweets and 70 false tweets.
- Failed to predict 18 truthful tweets and 12 false tweets.
- Predicting the correct news with a precision of 0.77.
- Predicting the incorrect one (Recall) of 0.83.
- MCC was 0.6, and this value was greater than 0.5 and less than +1; this means the ANN achieved the worst accuracy in the proposed model.

In comparison with other approaches presented by other researchers, this approach presents the following:

- Using machine learning algorithms and choosing different attributes (author listed count, author follower count, num of retweets, num of likes). At the same time, other approaches, such as Y. Madani, M. Erritali, and B. Bouikhalene, concluded that the results obtained through machine learning algorithms and Twitter attributes (status count, friends count, follower count) are the same, which we used in our proposed model.
- Using different classifiers like NLP, SVM, RF, and LR, they concluded that the results of machine learning algorithms are better than those obtained from deep learning algorithms.
- The proposed model accuracy achieved was 89.9%, while Y. Madani, M. Erritali, and B. Bouikhalene's present frameworks achieved an accuracy of 79%.
- Y. Madani, M. Erritali, and B. Bouikhalene used Sheryl Mathias and Namrata Jagadeesh's dataset. Still, the researcher collected the dataset and labeled it as the proposed model needs, and the stages were unique, and hard to pick the right tweets.

Finally, the researcher concluded that DT is the best classifier to enhance the detection of fake news on Twitter. The best attributes to enhance the accuracy were author listed count, author follower count, number of tweets, and number of likes.

V. Conclusion and Future Work

This paper presented an improved fake news detection by exploring the methods, techniques, tools, and algorithms used previously on previous proposed models and systems. The authors discussed the classification of fake news related to Covid-19 using machine learning algorithms (ML). The authors concentrated on news on Twitter by enhancing the process of detecting fake news using Machine learning algorithms such as decision tree (DT), Naïve Bayes (NB), K-Nearest Neighbors (KNN) and Artificial Neural Network (ANN) classifiers that can handle and distinguish the real and fake news about Covid-19. Also, the authors proposed a model to detect fake news on a Twitter platform using MLA and meta-date (attributes for a Twitter account). The performance and evaluation of the KNN classifier are the best because the F1 scale recorded by KNN is the highest, the MCC was 0.80%, and the best accuracy for the DT classifier was 0.895%. Moreover, the authors collected correct and fake tweets and corresponding metadata to create a dataset that will be publicly available to other researchers in the same field. In this study, the authors highlighted fake news by applying the proposed model, training, and testing using machine learning algorithms; the authors found that the (Num-Likes, Num-Retweet, Author Followers Count, Author Listed Count) have influenced the results of accuracy and improvement of the effectiveness of the results. Finally, the authors designed an effective and accurate model to detect fake Covid-19 news on Twitter using an MLA using some important features (i.e., Author Followers Count, Author Listed Count). After completing the current research and considering the above results, this research suggests working on text mining to work deeply on the content of the tweet (text) by using, for example, Natural Language Processing and Deep Learning Algorithms, which might be worthy of increasing enhancement of evaluation results. Also, using different languages of Tweets like Arabic and French. Greek. etc., to achieve the best result of evaluation results. On the other hand, the researcher suggests using the largest dataset to enhance the results and applying the proposed model to other platforms and other algorithms techniques.

***Abstract*—Quality is the degree of excellence of a product and one of the most important factors of software projects that mainly defines user satisfaction and success of the project. Software methodologies represent a variety of tasks, processes, and roles to manage time, cost, and quality. The invention, innovation, and diffusion for technological advancement creates challenges of software projects, thus several existing methodologies albeit with limited scope. A software product is highly influenced by the latest technology and distributed project management opportunities. Management issues are introduced for a virtual project management environment when resource persons are in another corner of the world. To resolve the problem, this research presents a new software project management model (4-LPdM) with alternative actions and practices to effectively manage. The model was presented to 20 different organizations and 29 respondents gave feedback who had experience between 1-16 years in multiple sections of software engineering. The model is evaluated based on the factors of advanced PMBOK 4.0 (scope, cost, quality, resource, risk, plan) and two (management, sustainability) additional features according to the demand of experts. This research illustrates statistical analyses to examine the significance of the proposed model besides a comprehensive comparative study of the traditional methodology.**

***Keywords*—Software development methodology; project management; 4-layered plan-driven model; quality factors; sustainability**

I. Introduction

Software engineering is continuously upgrading with its area of application and research with the advancement of technology by accepting new opportunities and overcoming challenges. The capability and features of the software are increasing with efficient data handling and adding smart functionalities. Smart devices, industrial automation, artificial intelligence equipment, and digital business concepts enhance opportunities for software industries and researchers. An industry expert or researcher can work from any corner of the world through a distributed working environment. Software engineering process management methodologies are improving since the commence of the waterfall model (1956) and followed by various normalized water-fall models (1956-1985), spiral (1986), scrum (1990-1995), rational unified process (RUP, 1996-1998), extreme programming (XP, 1999), agile manifesto (2001), lean (2003), 5th value agile manifesto (2008), DevOps (2009), and Kanban (2010) [1]. Besides methodologies, a set of software quality models is working to improve the quality of the software are McCall's Quality Model (1977), Boehm's Quality Model (1978), IEEE Quality Model (IEEE Std. 729-1983), ISO 9126 Quality Model (1991-2011, ISO/IEC 9126) [2-3]. Plenty of standardization organizations are also working to improve the software project management approach by providing guidelines [4]. But till now 83.9% of information technology (IT) projects completely failed (stop without delivery) or partially failed (compromise with quality) according to Standish Group CHAOS report 2018 [5]. Harvard business review reports that one-sixth of projects run over budget by 200% and 5-15% of projects are failed [6]. Moreover, the project management institute noticed 80% were completed on time without significant wastage of money but the quality is very poor [7] and 75% of IT executives found that their projects were doomed usually from the beginning [8].

So, practitioners, researchers, standardization bodies are working to improve the quality of software products and deduct project failure rates. Digital transformation introduces newer challenges in software industries. Rapidly upgrading technology, increasing functionalities, and changing infrastructure make the software project crucial [9]. Artificial intelligence, cross-platform, Internet of Things, blockchain, continuous development and deployment, progressive web applications, and low-code developments are new trends in software industries [10] that demand more specification of software project information. Near future software engineering becomes close to system engineering that demands structured methodology and architecture for reliable system development with variability features [11]. Furthermore, a distributed software project management system introduces new challenges with diversity culture, different time zone, language barriers, lack of collaboration and communication, trust and ownership of intellectual property, unjustified requirement specification, integration hassle, and lack visionary practice

[12]. A methodology accelerates the project execution process, managing resources, enhancing formal practice, improving sustainability, and ensuring projects quality. Nowadays, systems are improving from on-premises to cloud infrastructure, microcontroller based to industry IoT automation with machine learning, deep learning or reinforcement learning and faces big data challenges (volume, variety, veracity, velocity). Project migration inherits a high grade of complexity with the broader challenge of data collection, specification, sharing, transformation, and analysis when a new technology is being adopted. A well-structured methodology keeps maintainability, portability, and scalability scope with standard guidance and documentation practices.

Current issues in software projects and roles of methodology to address the challenges and make a project successful are mentioned in the introduction. The article is followed by a literature review that consists of reasons for software project failure and the importance of upgrading methodologies. Section III proposes a methodology that is illustrated by Fig. 1 and elaborates on its functionalities in the sub sections. The research methodology discusses ways of evaluation of the proposed methodology. The proposed methodology brings quality of process and product in an architecture. It consists of process, task, and people under the quality control framework. Section V discusses detailed outcome of the study and concludes in section VI with limitation, future work and remarks of contribution.

II. Literature Review

Project management approaches are improving by introducing new inventions in process, tools, and management. Software process management methodologies involve the invention to complete projects effectively. Software development endeavors are affiliated with the practice of a creative project management approach. Software projects are regularly related to innovation in management to overcome the challenges of the fast and dynamic changing of technologies and focus on the best services and products. A higher degree of creativity and flexibility are required in practice with the innovative process of methodology. This section consists of short literature on the reasons for project failure, the role and progress of methodology, and the existing gap.

A. Software Project Failure and Methodology

A project executes by a group of team members with distinguished responsibility that might be varied from organization to organization and project to project based on the type and nature of the project, mission and vision of the organization, and business goals. Potential stakeholders work in a team to make a project successful, but a significant number of projects fail to include its' users. A project commences with a determination to complete on time and budget, but it faces difficulties in the execution period with factors related to process, task or person. As a result, it becomes a challenging project and if the project team is unable to overcome issues it will fail. A project has a chance to face challenges by the wrong strategy of a project or organization [13], wrong or unrealistic planning [14], lack of stakeholders' support [15], and weakness of project management professionalism [16]. Discenza and Forman show the importance of adequate technical and non-technical resources, maintaining scarce resources, promoting effective communication, utilization of technical tools, and managing stakeholders' decisions by using operational metrics to make a project successful [17]. Kulish noticed that complexity of the design and code linearly related to the number of errors in a product. Time constraints of the project, human intervention factors, and miscommunication enhance projects' complexity [18]. Reasons for project failure are associated with people, technology, process, company, leadership, and business goals [19]. Uncertainty or risk is one of the most important reasons which makes a project fail [20] and it appears from stakeholders, technology, or nature. A model and methodology can set roles to develop an effective personality of stakeholders that could contribute to reducing the risk of a project [21]. A methodology approaches a systematic workflow and control of the project. It views on justified requirements, helps to estimate logical cost and effective hours, guides to incorporate change management, keeps standard documentation, ensures tracking on functional review, monitors, and controls on the project, allows backtracking if need (few cases), encourages formal communication among stakeholders, and helps to measure the size of the team of potential stakeholders [22].

B. Commonly used Methodologies

Software process management methodologies have distinguished features and each one has special contributions in software engineering. The waterfall model is the first formal and most influential in software engineering [23]. It has sequential logical phases where one phase accepts feedback for the previous stage. The fundamental waterfall model is modified by overlapping functionalities of phases to utilize time and resource effectively [24]. But it is rigid with fixing requirements and confirming documentation at the earlier state of the project; moreover, users can share their suggestions only at the beginning. So, it is not appropriate for the projects where the requirements can change after execution of a project. The incremental approach is applied in software project management to bring more flexibility, where the client gets a solution part by part and the user can give feedback until the end of the project; iterative scope allows to give a partial solution and it should be updated by the several numbers of iterative feedback from users [25]. But iterative and incremental approaches have no standard architecture, so it is difficult to update and maintain the software. Too much user interaction in an iterative approach increases the scope of arguments. For example, the Spiral model is an iterative approach that is appropriate for high-risk and complex projects but difficult to implement time and cost constraint projects [26]. V-model integrates testing in all phases of the model to ensure the quality of the product [27], but not suitable for high risk, complex, object-oriented, and the project with moderate requirements. Parallel processing is initiated by the Rational Unified Processing model (RUP) which is time constraints iterative system, but it only focuses on functional requirements [28]. These are called heavyweight documentation-oriented plan-driven methodologies.

The agile approach brings innovation in software project management that helps to complete a task on time and does not support heavyweight documentation practice [29]. Agile

methodologies are adopting a heterogeneous number of dynamic software projects where an organization's environment changes rapidly [30]. Agile is suitable for an organization that has a high probability to change management policy-procedure, tools and techniques, and working environment [30]. The agile manifesto is the foundation of agile families and scrum is popular in the agile family and it helps to manage complex projects by integrating creativity [31-32]. Extreme Programming (XP) allows customer interaction that operates by short iteration, Cristal methodology tailors' business goals and Agile Software Process (ASP) supports faster development [33]. Kanban method emphasizes business agility and realistic planning to deliver software products just-in-time [34]. Dynamic system development methodology (DSDM) emphasizes quality products in time constraints with limited iteration [35].

Build and fix is a methodology with lack of architecture and formal feedback which is reactive, and problems are fixed only when they occur. Waterfall is a liner approach where each phase is completed before continuing another one and there is lack in formal change management as well as feedback collection before completion of a project. V-shape is like waterfall but more concentrated on verification and validation in each phase and ignored risk analysis. Prototyping consists of three variations named rapid prototyping used for testing, evolutionary prototyping used for incremental improvements of the design, and operational prototyping improves the speed of production. Incremental consists of multiple cycle of development where entire process can restart any time that allows to change requirements and update a system. Spiral introduces risk analysis in iteration where new requirements are funneled and allows testing earlier. Agile is an umbrella of multiple methodologies that focuses on efficient and iterative development in an agile team.

Software methodologies could be divided into two major categories: plan-driven, and agile. Plan-driven are heavily weighted with documentation and rigid with a systematic approach. On the other side, agile methodologies are light weighted and have time constraints. Both approaches have pros and cons, such as plan-driven is process-oriented and it does not support requirement change frequently while agile methodologies face problems in maintenance and upgrading of a product.

Project management activities consist of methods, tools (e.g. Gantt Chart, network diagram, work breakdown structure), software (Microsoft Project), decision-making methods like feasibility study, risk analysis, and communication plan with collaborative tools: video conferencing [36]. The recent study (2019) of Walker and Lloyd noticed that project management work would be positive for non-routine workers by accepting advanced technology in the 2030s because of the border-free distributed working space [37].

C. Current Project Management Issues

Unclear scope, time constraint, requirement changes, poor communications, managerial weakness, lack of formal practices, unrealistic resource allocation and planning, and insufficient testing are the common issues in software project management. But due to the technological advancement new challenges are appearing for AI, IoT, and big data projects. Technological projects need information specification for accuracy, reusability, scalability, and maintainability. Artificial intelligence applications, IoT software, and big data platforms use huge information that need to be specified explicitly by concept, role, and axiom [38-39] and descriptive logical or ontological presentation that improves ambiguity-free information for a shared domain [40]. Sarker et al. proposed a structure to develop and practice own methodology to consider effective internal and external stakeholders' participation for each project based on the user requirements and business goals [41]. Explicit information specification with ontology, descriptive logic, graphical presentation can reduce complexity of a project and improve communication among stakeholders [46]. A monolithically presented methodology with controlled language use to generalize the process of the methodology and improve integrated performance [44]. A methodology should consider sustainability factors into the product and encourages sustainability practices in project implementation [45].

Project management tools support to manage a project virtually and resource person can be distributed to the world that reduce office management cost, access talent from any corner of the world, and increase productivity; but need to overcome the challenges like virtual monitoring, multicultural team, trust on distrusted employee, and virtual communication [50].

4-LPdM proposed a formal approach, well defined framework, focus on information specification and four layered quality assurance that will reduce the issues of AI, big data, IoT, and distributed projects besides resolving regular issues.

III. Proposed Model

4-Layered Plan-driven Model (4-LPdM) (Fig. 1) distributes the tasks into phases that are arranged in a logical order of waterfall architecture, but four transitions are specified called the layers. The first layer consists of requirement analysis and scheduling of the project, the second layer for in-depth design purposes, the third layer consists of coding and testing for both unit and system, while the fourth layer performs formal closing of the project. Furthermore, it shows the importance to specify the stakeholder, task, tools-techniques for each layer that helps to guide the model.

A. Phase-1: Requirement Specification

The first layer (Fig. 1) consists of requirement collection and analysis from the respective sources where the users, experts, manager, and system analyst are the main key persons to accomplish the tasks. A user can share the visible requirements of functions that are required for the system. An expert will justify the requirements based on the demand of the market and competitors' values. A system analyst can support a manager to make decision for requirement fixing, technology selection, and cost benefit analysis. The 4-LPdM shows interest in recognizing, defining, measuring, and analyzing the requirements to sustain, improve, monitor and control. This phase maps business functions to the software process. Moreover, the planning phase has plenty of tasks that guide monitoring and control of the project. It suggests the utilization

of tools, applications, and techniques to monitor, track, and control a project. This phase asks to develop stakeholder management policy, feedback accepting procedure, and communication plan. A good plan should consist of concrete goals, milestones, and tasks that are specified by date and tracking number. It also includes cost, time, and resource allocation for each task. Risk management activities are included to identify and take mitigation plans at the beginning of the project. Moreover, the feasibility study will help to measure the outcome of the project concerning customer/user requirements (functional and non-functional) and business goals of the vendor and client by cost-benefit analysis. The technical, operational, and ethical feasibility study will improve the acceptance of the system. This layer sets actions to fulfill the vision and mission of the project and achieve business goals. The quality team of this layer will review quality factors so that manager could incorporate required quality functions and information specification to lead IoT, big data, AI and distributed projects.

B. Phase-2: System Design

Designers design the interface by incorporating accessibility and usability requirements; data design consists of standard specification, convention and controlled language for the project and management information; efficient databases consists of normalized tables with required integrity and constraints; control language (algorithm, pseudocode, descriptive logic, predicate logic for reducing misunderstanding), diagrams (context diagram, data flow diagram, entity-relationship diagram, sequence diagram, flowchart, etc.), interface, etc. In this phase (Fig. 1), feedback is expected from users, experts, and system analysts to ensure completeness and quality of the system. It keeps scope of the interaction of potential stakeholders. The design phase becomes more flexible than the traditional waterfall model because until the finalization of the design the user can change requirements. Customer interaction and satisfaction are extremely important for approving the design and passing the phase. System analysts can clarify requirements if required to the designers and they will finalize the architecture of the software. This phase concluded with structured documentation of earlier stages that could be shared through a distributed system, controlled by the manager, and flexible for reusability. This phase is more important to ambiguous free information specification for big data, IoT, AI projects and how to ensure effective communication in virtual project management.

C. Phase-3: Development and Deployment

The third layer (Fig. 1) corresponds to the development, testing, and deployment phase which starts with coding. Effectiveness of the development and testing of a project is dependent on the quality of the design and explicit specification of data is mandatory for virtual or distributed project. The approved design of the previous phase is transformed into a programming notation according to a computer language. Programmers can easily convert the controlled language expressions of documentation and design materials. A standard notation can be easily converted to a program and support for test case generation. Unit testing is simultaneously performed by the quality control unit and developers. Experts are suggested to do template-based testing for accuracy and efficiency. A module consists of related units that are integrated and again tested by experts. The system is tested by quality control before handover to the customer, as well as after deployment, a short time of user training and testing is suggested so that users can use and manage the software effectively. This methodology focuses more activities in previous three phases to reduce complexity of fourth phase. Our proposed methodology supports to keep stand documentation that will improve maintainability, scalability, and portability for a project.

D. Phase-4: Formal Closing

If the deployment test is satisfactory, then only it can be released for operation and the project enters in closing state (Fig. 1). A project teaches a lot of lessons to the stakeholders. Especially, mainstream project execution members get good experience related to technology, management, and communication. The closing layer of the project guides to analyze recently passed experiences so that team members can enhance their potential for future projects. In addition, it improves archiving quality to ensure reusability for further requirements; it helps to update project level or organization level policy procedure, and it is a good motivation for team members. 4-LPdM keeps formal documentation for reusability, maintainability, and scalability for an existing project, but it could be reuse for similar types of more future project and improve sustainability practice too. Project assessment and strategic planning will be easier for formal documentation practice.

E. Capability Study of 4-LPdM

The proposed model is developed based on the demand of the near-future software project highly influenced by artificial intelligence, big data processing, embedded system, and significant risk for technological change. These systems require highly specified information by role, axiom, and concept. Moreover, there is a scope to hire (virtual environment) global talents for the project software projects. This section consists of the following capabilities of 4-LPdM.

F. Project Management Capability

The 4-LPdM specifies the smallest unit of tasks for accurately measuring the size, functional dependencies, and complexity of the project. The project manager and his team define the errand and the execution team performs accordingly. The model prescribes to maintain standardization guidelines and values. Concerning requirements gathering, it gives importance to the client, system analyst, and experts from business and market domains. The design is developed based on the analysis of requirements that stop the scope creep possibility. Time, cost, and assets allocation ensure effective utilization at the micro-level. Critical risk mitigation and communication plans improve the awareness and responsiveness of the stakeholders. 4-LPdM blends the system development model and project management to improve the quality of products and processes. It gives the importance of utilizing tools and techniques for effort estimation, realistic plan development, stakeholder management, and formal documentation practice that will ensure an effective management process.

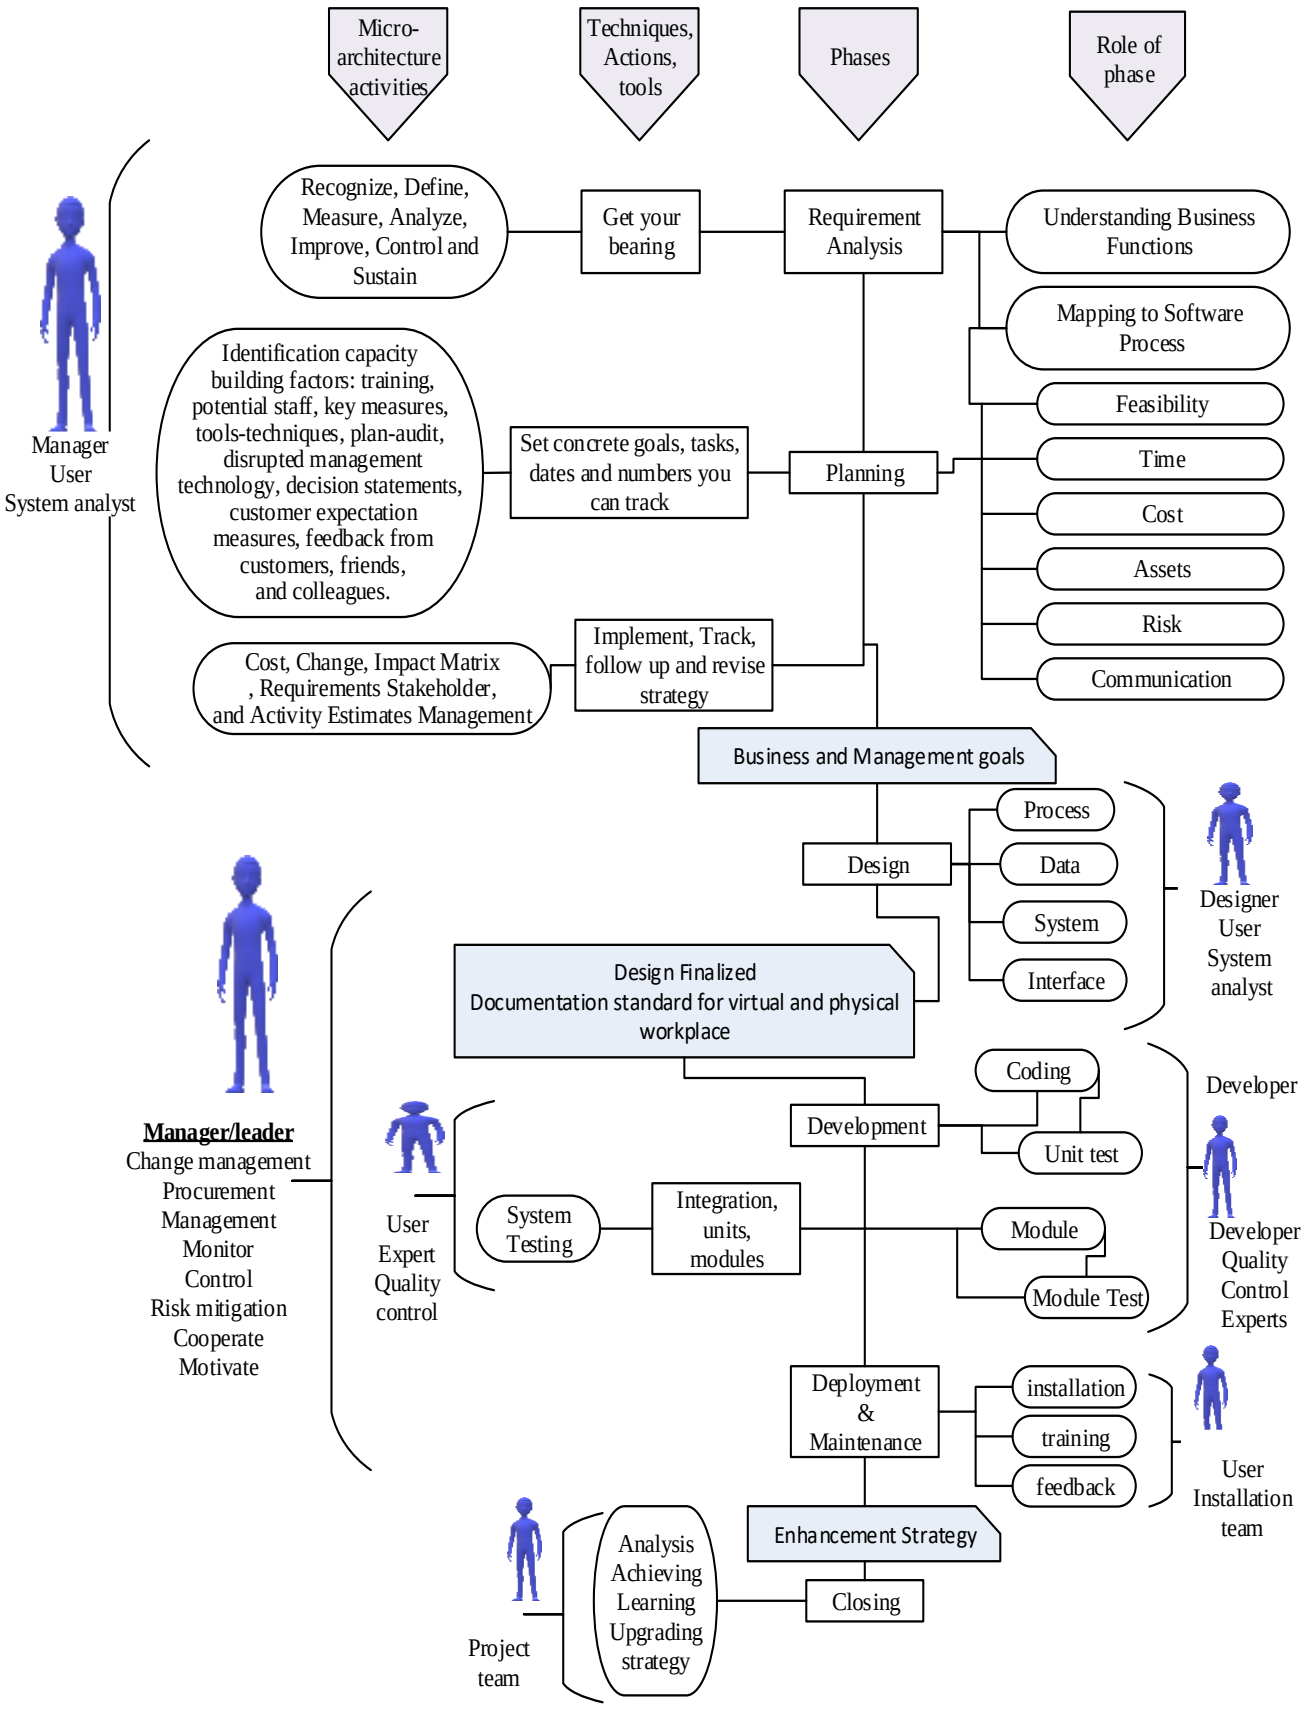

Fig. 1. 4-Layed Plan-Driven Model (4-LPdM).

G. Timeframe for a Phase

4-LPdM specified four major layers instead of phases of traditional methodologies due to incorporate project management capabilities; and each phase is specified with actions, process and respective stakeholders but not fixed the timeframe that depends on the size and complexity of the functionalities and resource availabilities. External stakeholders' requirements and business needs also influence the calculation of time. 4-LPdM suggests that a manager should consider additional time for meetings, communication, and analysis for each level besides resource specification. Moreover, it shows importance to implement project management tools and techniques to calculate, visualize, and manage schedule.

H. 4-LPdM and Quality Control

4-LPdM is highly visible to present the task with the designed required stakeholder, tool, technique, and process that should be maintained by the execution team. The visibility features of the methodology help to determine the realistic time, cost, and resources to improve quality. Customer or user involvement significantly impacts the methodologies, and it specified the purpose of their interaction for a particular task or process. It allows customer interaction more than the heavy-weighted traditional methodologies and reduces over-interaction of light-weighted methodologies, so it ensures reasonable and justified customer interaction that improves customer satisfaction. The model proposed for specialized project management of near-future software development with artificial intelligence, smart infrastructure with IoT, and big data processing for knowledge retrieval. So, it explicitly specifies each task, process, and domain information on standard documentation (e.g., controlled language) to reduce ambiguity which enhances project management capability and quality.

Traditionally time, cost, and scope are considered the most significant influential factors of a software project to maintain the quality; that is updated by the project management body of knowledge (PMBOK 4.0) with six factors: scope, budget, quality, schedule, risk, resources [42] [44]. Mohammed et al [43] developed a six-pointed star model to evaluate the effectiveness of their proposed model with factors time, product (scope), risk, cost, and resource [43] [45]. Customers want to get a product on time within their budget and that should carry all functionalities so quality is described by customers' satisfaction and business goal of the organization. Fig. 2 is the quality model that consists of four factors to ensure the quality of the project based on the traditional model of scope, cost, and time. The project team considers a project as a successful project when the customer is satisfied with functional and non-functional requirements within schedule, budget, and scope. The task of a project is executed by a systematic process that should be well documented according to standardization guidelines. Effective resource allocation reduces extra cost, and an appropriate tool accomplishes a process on time without compromising the quality of the product. Stakeholders are guided by the model to practice formal documentation and responsible resource utilization that improve the efficiency of the workflow. The comprehensive and concrete quality control model is proposed (Fig. 2) to guide the execution of 4-LPdM. 4-LPdM is the main contribution of this research that will guide software practitioner to enhance the organizations' quality in software project management and improve quality of the product. This model inspires to practice guidelines of standardization organizations but not recommend for certification (individual choice). It is also suggested for standard organizations that has capability of utilizing tools and technologies.

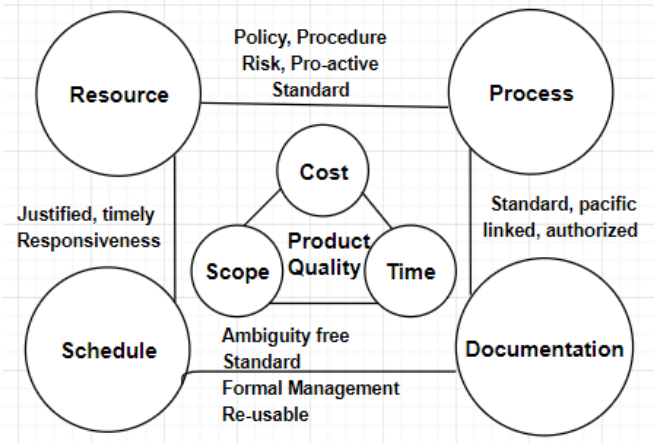

Fig. 2. Quality Control by 4-LPdM.

IV. Research Methods

This section consists of data collection and analysis. Individual expert opinions are collected to determine the validity and efficiency of the proposed model. Furthermore, the proposed model is presented to the experts before data collection. Scope, cost, time, quality, sustainability, risk, resource, and management are considered influential factors according to the suggestion of experts of software developing companies. According to the project management body of knowledge (PMBOK 4.0), the advanced model of triple constraints consists of quality, scope, resource, budget, risk, and schedule known as influential factors of software project management. But management is one of the most vital factors to make a project successful; and sustainability improves quality by reducing wastage of resources: time, cost; and assets. So, management and sustainability are the additional two factors that are considered for the evaluation of this model. Software Requirement Specification (SRS) and milestone of a project are controlled by scope factors; a realistic plan is developed and executed with schedule factors; the budget parameters are justified by the return of the investment; resource factors are used to ensure efficient utilization of assets; sustainability factors improve the quality of process and product, while overall satisfaction is measured by the quality factors. Furthermore, complexity, understandability, and appropriateness are three more criteria that are considered for general reflection. Validity and efficiency checking of the proposed model is the main aim of the identification of the aforementioned factors.

For evaluation, a set of well-known software firms are invited from Bangladesh and abroad who have local and/or international experience. 29 representatives from 20 organizations were accepted to attend the evaluation process who were trained by poster and online presentation. They study

the proposed methodology and try to implement their project (exiting / new project) for a month and evaluate based on the findings. Participants are selected from different levels of experience manager, developer, lead developer, software engineers, and system analysts, and more than 50% have multiple levels of experience including free lunching, individual, and teamwork.

A survey was conducted to collect feedback from experienced people of software firms. 29 respondents give feedback who are from 20 different organizations and 3 of them have freelancing experience. There were two different sections in the questionnaire: i) respondent and his/her organization's information was in section-1 and ii) section-2 carries responses for the proposed model. Table I (a) shows the respondents' experience in software production. Table I (b) describes the mostly practicing methodologies of the organizations. Survey respondents were related to all phases of the software development life cycle. They had different experiences on different types of projects. System analysts, designers, requirement engineers, developers, managers, testers, marketers are the common types of respondents. Respondents' current position in their organization is described in Table I (c). Table I (d) illustrates the respondent's professional experience.

TABLE I. RESPONDENTS' ANALYSIS

(a) Production Classification		
Respondent's Experience	**Frequency**	**Percentage**
Local Production	10	34.48%
International Product	11	37.93%
In house Product	4	13.79%
Local & Global Product	4	13.79%
(b) Practicing Methodology		
Respondent's Experience	**Frequency**	**Percentage**
Waterfall Methodology	3	10.34%
Agile Methodologies	15	51.72%
PRINCE2 Methodology	2	6.90%
Self-developed Methodology	7	24.14%
Other Methodologies	2	6.90%
(c) Respondent Position		
Respondent's Experience	**Frequency**	**Percentage**
Developer	5	17.24%
Lead Developer	9	31.03%
Manager	5	17.24%
System Analyst	4	13.79%
Software Engineer	6	20.69%
(d) Respondents' Experience (Years)		
Respondent's Experience	**Frequency**	**Percentage**
1-4 Years	8	27.59%
5-8 Years	13	44.83%
9-15 Years	6	20.69%
More than 15 Years	2	6.9%

V. EVALUATION

This section illustrates the statistical analyses of the collected numerical responses. These analyses aim to show the influence of each factor and how the management is related to each other. Table II shows the statistical analysis that compares eight factors in the form of Relatively-Importance. This methodology supports resource management (0.8344828) mostly and least interest in cost management (0.7609195). Table II is summarized from the data analysis of Appendix A. There is not much variation among the eight measuring factors (standard deviation). Appendix A describes the summarized result of collected responses that consists of all achieved frequency of 29 participants. Total frequency and computed percentage weight are represented according to the Likert scale. The significance of each factor of the proposed model is reflected in Appendix A, hence it shows that "strongly disagree" and "disagree" are too much less than comparatively "strongly agree" and "agree". Hence, only the "strongly agree", "agree", and "neutral" frequency table is illustrated in Fig. 3.

The average score for all factors is in between 3 and 4 of Likert scale (strongly agree=5, agree=4, neutral=3, disagree=2, strongly disagree=1). Fig. 3 represents responses for each sub-category (for example scope has three subcategories (A, B, C) and satisfactory is comparative more than any other options. The average score of all sub-categories is the final score for each category. 3.8 to 4.2 are the average score of the proposed model that is very near to agree (4) on the Likert scale. For example, the Likert scale value is multiplied with the average value of each factor then again calculate the average for all responses of this domain (scope, plan, etc.). Thus, average score represents the positive feedback in all aspects with minor variation. Standard deviation from 2.4 to 2.8 and according to the empirical role, it shows more than 95% response lies beside the means (i-1 to i+1). Relative importance is calculated (R_i=1/5N_i ($5n_5$+$4n_4$ +$3n_3$+$2n_2$+$1n_1$)) and presented in Table II to show the importance of factors. The values are very close to each other, and the range is 0.7609195 to 0.8344828 indicates correlation.

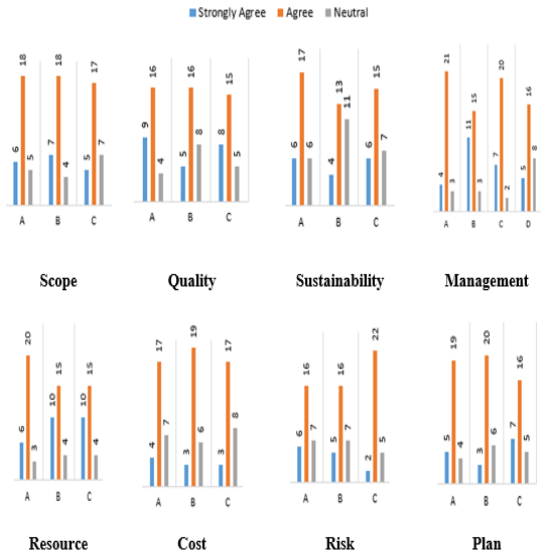

Fig. 3. Frequency Graph for All Measuring Factors.

TABLE II. STATISTICAL ANALYSIS OF THE 8 FACTORS

Factor	Mean	Standard Deviation	Relatively Importance
Scope	4.1944828	2.7620831	0.8045977
Quality	4.0344828	2.4832522	0.8068966
Sustainability	3.862069	2.410228	0.7724138
Management	4.0775862	2.8300027	0.8155172
Resources	4.1724138	2.699799	0.8344828
Cost	3.8045977	2.7849991	0.7609195
Risk	3.908046	2.8326754	0.7816092
Plan	3.954023	2.8490392	0.7908046

TABLE III. OVERALL SATISFACTION

4-LPdM Implementation		4-LPdM Understanding		Appropriate for Projects	
Complex	20.7%	Easy	31%	Medium to large	72.4%
As usual	55.2%	Acceptable	58.6%	Small to medium	13.8%
Simple	24.1%	Difficult	10.4%	All	13.8%

Therefore, the relative importance ranks indicate positively correlated with other factors. Table III shows general aspects of three measures of complexity of the model, understanding the functionality of the model, and when it is suitable. The average percentage (55.2%) of respondents found that it is as usual as others in terms of complexity. 20.7% considered the presentation of the methodology is complex while 24.1% feels it is simple for them. The respondent understands from the presentation and poster and after implementation their project 10.4% feels difficult due to the explicit information specification. 31% feel easy to understand for implementation but more than 58% recommended as acceptable. This methodology is recommended for medium to large projects (72.4% in Table III) because of the extra activities for information specification that will accelerate cost for the small projects.

A. Comprehensive Comparative Study

Waterfall involves users and customers only at the initial stage of the project, so it freezes requirements and documentation at the first phase. It also faces uncertainty problems and measuring the progress of the project is difficult too. The proposed model allows customer interaction and requirement flexibility until the design is finalized as well as risk and quality management mitigate uncertainty. The agile methodologies aim to accomplish a project in a short time that could compromise with quality, and lack of documentation practice makes problems in the re-usability of design and code. Furthermore, new employees struggle in an agile team for technology transfer and highly functional dependency projects. A well-structured and documentation practice of the proposed model demolishes the issues of agile methodologies. Spiral is good for high-risk, complex, and without time constraint projects but time and budget are crucial factors of any project, but the proposed model is suitable for medium to large projects with time constraints. An iterative approach does not fix requirements at the early stage that may cause ambiguous requirement specifications, it allows more customer interaction and informal practice that could make problems to accomplish a project in time and budget. The proposed model allows user interaction only before fixing the design. In addition, its' formal practice of communication and documentation addresses the limitation of the iterative model.

4-LPdM adopts the plan-driven because more information specification is required for the smart information system, artificial intelligence applications, and big data analytics. Descriptive logic is proposed for documentation due to ambiguity reduction and demolish language barriers in distributed project management; moreover, it can easily convert to computer language. Sustainability is focused to ensure the re-usability of documentation and soft resources for a project to another project. The project management approach is integrated with the system development life cycle to improve the management process, risk reduction, and maximize resource utilization. It is validated by common six factors but also considered other special challenges that appear for new technologies like cloud computing, mobile applications, IoT, AI, and big data project. Table IV describes the role of the proposed methodology for IoT, AI, data science, and distributed projects for current days.

TABLE IV. OVERALL SATISFACTION

Project	Special Features	Role of 4-LPdM
IoT	Connectivity, sensing, scale, dynamic, intelligence, energy, safety, integration [47].	IoT devices should be active and act according to the outcome of intelligence applications. Edge, fog, or cloud computing perform sensing data processing where data processing and sharing is an important activity. 4-LPdM specifies data design (Fig. 1) and suggests formal documentation (Fig. 2) to minimize risk.
AI	Complex training algorithms, computation power, data selection and security, integration, and infrastructure [48].	4-LPdM formal analysis, documentation, and review for each layer; minimize complexity and help to select appropriate algorithms; improve data quality and security; support data interrogation; and manage with a suitable infrastructure. It suggests explicit data specification and design that can improve logic, axioms, grammars, and role fixing for AI applications.
Data Science	Weakness in data literacy and culture, measuring of data science project, stakeholders' cooperation, and trust on solution [39][49].	Stakeholders' cooperation is one of the most important factors in data science to achieve business goals, and (Fig. 1) the proposed methodology includes shareholders in the quality frame (Fig. 2). It also allows explicit data specification [46] and communication roles in the planning phase. It integrates capacity building factors, staff training facilities, measuring tools and techniques, customer interactions, and feedback-accepting systems (Planning phase of Fig. 1) to improve trust.
Distributed	Communication, culture, ownership, misunderstanding, knowledge transfer woes, and hassle of integration [12].	Distributed project management system is new and becoming popular to access low wage technical employees from another part of the world or practicing procurement management for a part of the project. 4-LPdM has a plan-driven approach and recommends using control languages to reduce misunderstanding, support knowledge transfer, and improve communication.
Mobile apps	More interactive with usability and accessibility functionalities [52].	Proposed system will support for interactive, usability, and accessibility features specification in system design phases that will be usable for further similar type projects.
Cloud projects	Public and hybrid clouds project faces migration challenges [51].	Cloud infrastructure become popular due to the pay as you model and small companies migrated to cloud platform. If an on-premises project is completed with 4-LPdM it will be easily migrated to public cloud due to the formal documentation and explicitly project data specification.

VI. CONCLUSION AND LIMITATIONS

A quality project management approach is extremely important to accomplish a successful software project within a predefined time and budget. Furthermore, a product's quality depends on the quality of the process, tasks, and stakeholders that is guided by a methodology. The literature review reveals the importance of mitigating the existing limitations and gaps in software methodologies. Moreover, a methodology should be adaptable and predictable with people, tasks, and processes. The proposed methodology is going to fill up the gap and reduce the limitations by introducing a concrete framework of micromanagement architecture, project management approach, and system development phases. It will enhance the managerial capability by formal process and practice with maximizing stakeholders' responsibility. A quality control unit is adjusted with each stage of the project that will ensure quality and minimize risk.

This model is developed and evaluated according to the opinion of experts and the survey result positively indicates the importance of the proposed model. Statistical analyses (means, standard deviation, relative importance) are applied for scoring the result and positive feedback is reflected in all factors. Therefore, it is appropriate for any standard software developing company.

This is a simplified model that separates virtual management functionalities from the traditional approaches. It overlooked the explanation of traditional phases that will enable an adaptation of existing traditional approaches. The standard software firms that have specific business goals can access talent from any corner of the world. It avoids the complexity of a virtual project management. An ad-hoc or special software could be managed by online procurement management, but it is not logical for a standard organization to host everything in outsourcing without proper utilization of organizational resources. Management software is much more complex with additional functionalities, integration opportunities, monitoring, and control strategies. E.g., this model only performs unit testing in the virtual environment and a user can attend testing in distance mode. While the integrated system is considered into the organization (physical mode). In the future, this work will be extended for a fully virtual mode project management approach.

Limitations: 4-LPdM is a common methodology that is proposed for any software project but considered to resolve latest issues (Section II) too. So, it is evaluated by different types of practitioners (Table I) and based on the six common criteria of general perspective (Table II) to show the overall acceptance for any software project. Number of participants and duration of practice could be increased for further study. It could be extended to the specific software project of AI, IoT, big data and evaluated by the respective experts. Moreover, distributed, or virtual project management approach can implement and evaluate too.

ACKNOWLEDGMENT

The proposed models are evaluated by a group of experts during June-August 2020. We are thankful to the valuable experts who have distinguished experiences in the software industry. Their support is appreciable and makes our research successful. This data is not used for any commercial purposes.

APPENDIX A

Practitioners' Data Analysis

It consists of the analysis of responses of all individual question. There are six major criteria validated by practitioners and each of them divided into 3 to 4 sub criteria to get more accurate reflection. Each question is having criteria for the proposed methodology. For example, the score of resource is the average score of A. how much supportive for hardware/software resource utilization, B. how much suggestive for proper utilization of human resource, and C. how much guided for resource sharing and responsibly handling? There are 29 participants and 6, 20, and 3 are the responses for strongly agree, agree, and neutral; and their percentage are respectively 20.69, 68.97, and 10.34.

TABLE V. OVERALL SATISFACTION

Factor	Questions	Strongly Agree (Response and %)	Agree (Response and %)	Neutral (Response and %)	Disagree (Response and %)	Strongly Disagree (Response and %)	Total and %
Scope	A. The proposed framework will guide to clarify the scope of the project	6	18	5	0	0	29
		20.69	62.07	17.24	0	0	100
	B. It will help to monitor the scope of the project	7	18	4	0	0	29
		24.14	62.07	13.79	0	0	100
	C. It will help to meet the scope	5	17	7	0	0	29
		25	85	35	0	0	100
Quality	A. The proposed framework will help to quality product	9	16	4	0	0	29
		31.03	55.17	13.79	0	0	100
	B. It will improve client satisfaction	5	16	8	0	0	29
		17.24	55.17	27.59	0	0	100
	C. It will suggest a quality working environment	8	15	5	1	0	29
		27.59	51.72	17.24	3.448	0	100
Sustainability	A. The proposed framework will improve economic sustainability	6	17	6	0	0	29

***Abstract*—Deep Learning is a relatively new Artificial Intelligence technique that has shown to be extremely effective in a variety of fields. Image categorization and also the identification of artefacts in images are being employed in visual recognition. The goal of this study is to recognize COVID-19 artefacts like cough and also breath noises in signals from real-world situations. The suggested strategy considers two major steps. The first step is a signal-to-image translation that is aided by the Constant-Q Transform (CQT) and a Mel-scale spectrogram method. Next, nine deep transfer models (GoogleNet, ResNet18/34/50/100/101, SqueezeNet, MobileNetv2, and NasNetmobile) are used to extract and also categorise features. The digital audio signal will be represented by the recorded voice. The CQT will transform a time-domain audio input to a frequency-domain signal. To produce a spectrogram, the frequency will really be converted to a log scale as well as the colour dimension will be converted to decibels. To construct a Mel spectrogram, the spectrogram will indeed be translated onto a Mel scale. The dataset contains information from over 1,600 people from all over the world (1185 men as well as 415 women). The suggested DL model takes as input the CQT as well as Mel-scale spectrograms derived from the breathing and coughing tones of patients diagnosed using the coswara-combined dataset. With the better classification performance employing cough sound CQT and a Mel-spectrogram image, the current proposal outperformed the other nine CNN networks. For patients diagnosed, the accuracy, sensitivity, as well as specificity were 98.9%, 97.3%, and 98.1%, respectively. The Resnet18 is the most reliable network for symptomatic patients using cough and breath sounds. When applied to the Coswara dataset, we discovered that the suggested model's accuracy (98.7%) outperforms the state-of-the-art models (85.6%, 72.9%, 87.1%, and 91.4%) according to the SGDM optimizer. Finally, the research is compared to a comparable investigation. The suggested model is more stable and reliable than any present model. Cough and breathing research precision are good enough just to test extrapolation as well as generalization abilities. As a result, sufferers at their headquarters may utilise this novel method as a main screening tool to try and identify COVID-19 by prioritising patients' RT-PCR testing and decreasing the chance of disease transmission.**

***Keywords*—COVID-19; median filter; deep learning; Mel-scale spectrogram; sound classification; constant-Q Transform**

I. Introduction

COVID-19 is an unique SARS disease which first surfaced in 2019 and has since spread over the world, producing a worldwide pandemic [1]. In accordance with the World Health Organization's (WHO) April 2021 report [2] there really are currently over 150 million documented illnesses including over 3 million deaths. Moreover, across over 32.5 million new cases and 500,000 fatalities, the USA has the highest overall number of illnesses as well as deaths.

These large numbers have placed a strain on numerous healthcare systems, particularly given the virus's propensity to cause more genetic variants and spread faster among people.

Recent studies have now employed relatively new artificial intelligence (AI) algorithms to recognise and categorise COVID-19 in CT and X-ray images [3]. Several studies (including CT scans as raw data) used machine and also DL techniques to distinguish among healthy and infected subjects with a discriminating accuracy of much more than 95% [4-9]. The capability of different classifiers including such support vector machines (SVM) and also convolutional neural networks (CNN) to identify COVID-19 in CT images with few which was before stages is the great contribution of these investigations. Additionally, some publications have used DL with supplementary feature fusion approaches as well as entropy-controlled enhancement to detect COVID-19 in CT images [10-13].

In light of the above, this research proposes a thorough deep learning technique for COVID-19 identification using coughing as well as breathing signals (**Fig. 1**). The suggested method might be used as a quick, low-cost, as well as readily distributed COVID-19 pre-screening tool, particularly in locations where the virus has spread rapidly. Despite the fact that the current gold new standard for detecting viral infection, RT-PCR, seems to have a good success rate, it has several drawbacks, such as high costs for equipment and chemical agents, the require for expert medical and nursing staff for tests, breaches of social separation, as well as the long time it needed to achieve outcomes (2-3 days).

*Corresponding Author.

As a result, the construction of a DL model removes the majority of these constraints, resulting in stronger resurrection in the medical and financial domains of many countries.

All of the techniques to sound classification utilise machine learning (ML) and DL. ML classification methods include SVM [14] and decision trees [15], while DL classifiers include CNN models (AlexNet [16], VGGNet [17], GoogleNet [18], ResNet [19]). CNN image classification models are built for speed as well as efficiency. The below are the study's major contributions:

- A novel DL strategy for recognizing COVID-19 from a set of tones.
- The proposed model enhances sound recognition effectiveness by employing a Mel-scale spectrogram and CQT method to convert sound into image.
- Nine DL training models are employed to achieve optimal efficiency.

The present study is structured as follows: Section II of this study examines the existing literature. Section III highlights the major properties of the dataset. Section IV includes a presentation of the proposed COVID-19 cough as well as breath tones model. Section V displays the test findings, whereas Section VI gives the paper's conclusions.

II. Related Work

The rest of the published studies mentioned here used ML and statistical analytics to detect COVID-19 disease. There has been less research that applies CNN and transfer learning on coughing signals datasets to determine the features of normal as well as coronavirus patients. Additional studies on DL with simpler efficiency assessments are thus needed. In this research, a novel model using DL, CQT, and a Mel-scale spectrogram was developed to detect COVID-19. According to the research study here, it is suggested that cough sounds be used to diagnose COVID-19. In fighting the COVID-19 epidemic, the advances are much more efficient and quicker.

This section investigates the much more available research on COVID-19 diagnosis that use coughing signals. As a result, the most recent evaluation of DL for coughing signal scan processing is addressed. This section includes details about the use of ML and also DL in sound detection. The stages of signal categorization can be classified into three phases: pre-processing, extraction, and classification. The core of tone detection study is concentrated on sound generation as well as recognition using classic machine learning approaches [20–22]. This paper concentrated on categorizing and identifying breathing and coughing sounds caused by COVID-19 virus infected individuals. Schuller et al. [23] used CNN to create a deep learning strategy to identify raw breathing as well as coughing in COVID-19 patients. Researchers improved the CNN method, which employs breathing as well as coughing sounds to test whether a person has COVID-19 or is fit. The suggested model is about twice as effective as the typical starting point. The CNN model achieved an overall score of approximately 81%, indicating that a DL model can deliver the best results with the available data.

A CNN model for COVID-19 is shown audio categorization proposed via frequency cepstral coefficients (MFCC) in [24]. The VGG 16 architecture is used in two learning strategies. The provided model achieved an overall of nearly 71 percentage as well as a sensitivity of 81 percentage using a high-quality outcomes method. The authors of Ref. [25] established a methodology for distinguishing COVID-19 and healthy sounds. For training and evaluation they employed 1838 coughs and 3597 other signals divided into 50 groups. In accordance with the study, the DL-based multi-class classifier scored about 92 percent, overall total accuracy. Prior to the COVID-19 pandemic, other research, like [26], to identify cough sound occurrences, a transfer learning technique applied. The NN models are developed in two stages: pre training & fine-tuning, after which the decoded data is collected by a Hidden Markov Model (HMM). In this work, three cough HMMs and one non-cough HMM are included to the proposed model. The experiments were carried out using a dataset generated from twenty two people suffering from various respiratory illnesses. This approach demonstrates that the qualifying deep model can now achieve a 90% precision level. M. aly et al. [27] proposed a classification model to identify COVID-19 in their investigation. The offered dataset contains 1600 wave coughing as well as breathing tones. To convert signal to image, the Mel-scale spectrogram method was utilised. Based on the data, the recommended model's overall accuracy, sensitivity, as well as specificity reached 99.2%, 98.3%, and 97.8%, respectively.

In [28], the author proposed a classification model for pneumonia and asthma. Their approach used MFCC, Shannon entropy, as well as non-Gaussian distributions to quantify signal parameters, and all these attributes have been determined to be the basis for artificial neural network classifiers. The suggested technique has 89 percent sensitivity as well as 100 percent accuracy. The results demonstrate how this technique may be applied to distinguish between pneumonia as well as asthma in public environments. According to [29], the goal of this study is to characterize the unique coughing sounds tones of COVID-19 artefacts in signals from various real-life scenarios. The model provided here tends to take two crucial stages into consideration. Converting the signal to image is the first step, which is improved using the scalogram approach. The second step is feature extraction as well as classification. The dataset utilized comprises 1457 wave coughing tones (755 from COVID-19 as well as 702 from healthy). The machine learning classifier's overall sensitivity and specificity were approximately 94% and 95 %, respectively.

An obvious and common problem with most previous COVID-19 research is that it uses a small dataset. Big data is preferred to little data because the higher the sample size, the more exact your estimations will be. Small data has a few advantages. For example, tiny data makes visualization, examination, as well as knowing what is going on in the data much simpler than enormous data. Furthermore, the innovation of this study is in the development of a DL model based on CQT as well as Mel-scale spectrogram-based breath and cough recordings into this DL model, which performs

much better than conventional respiratory auscultation devices. Where, electronic stethoscopes are preferred because they are more accessible to a larger population. This is essential for obtaining medical data regarding COVID-19 patients in a responsible way, while keeping isolated behavior amongst persons. Moreover, this research examined patients from India, whose COVID-19 has a unique genetic variant likely of eluding the immune system as well as most available immunizations. As a result, it focuses attention on the ability of artificial intelligence algorithms to detect this viral illness in persons with this unique variant, even those who are asymptomatic.

AI design does not need a large amount of memory. This is a good strategy for the future expansion of telehealth and smartphone applications for COVID-19 (or other pandemics) that can offer real-time information and efficient and quick exchanges between patients and healthcare professionals. As a result, as a COVID-19 pre-screening tool, this enables for better and quicker isolation as well as contact tracing than presently existing methodologies.

III. Dataset Characteristics

The dataset for this investigation was obtained from a project aimed at creating an available dataset for pulmonary sounds of normal and unwell patients, which also included participants with COVID-19, according to coswara [30]. Ever since, it has gathered information from over 1,600 people from all around the world (Male: 1185, Female: 415; mostly Indian population). Crowdsourcing was used to gather breathing, coughing, and speech sound using an interactive online app tailored for smartphone devices [31]. All voices were recorded with a smartphone microphone and recorded at a frequency of 48 kHz. All audio samples (in.WAV file) were chosen at random to employ a web interface that enables many writers to review each audio file while also improving labelling performance and accuracy. There are now 120 COVID-19 instances in the database, representing a one-to-ten ratio as compared to normal (control) patients. To produce a balanced dataset, all COVID-19 participants' data was assessed, and the exact number of assessments was assigned randomly from the control participants' data. Furthermore, just two types of breath sounds, shallow and deep, were captured from each patient and used for subsequent research.

The proposed model was developed to classify breathing as well as coughing in order to offer it in a public dataset. This is used by the diagnostic engine. Classifiers for breathing as well as coughing are applied to determine if a sound is connected with COVID-19. We utilized data from the breathing dataset in addition to the COVID-19 and healthy tones dataset to assess the classifier.

IV. Proposed Model

Fig. 1 presents the suggested COVID-19 cough and breath sounds classification model. The architecture design of the proposed Deep Learning cough-breathing classification model is shown in Fig. 2. The presented DL cough classification model needs pre-processing, feature extraction, and classification. The suggested model consists of two major phases. The first phase is feature extraction, which transforms sound to picture using CQT and a Mel-spectrogram, and the second step is feature extraction and classification model. Deep Learning models such as GoogleNet, ResNet18, ResNet34, ResNet50, ResNet100, ResNet101, Mobile-Netv2, NasNetmobile, and SqueezeNet are used in feature extraction and classification. GoogleNet, ResNet, Mobile-Netv, NasNetmobile, and SqueezeNet are the most extensively used Deep Learning transfer learning models. Deep Learning models were employed in the suggested model's learning, validating, and assessing processes for feature extraction and classification.

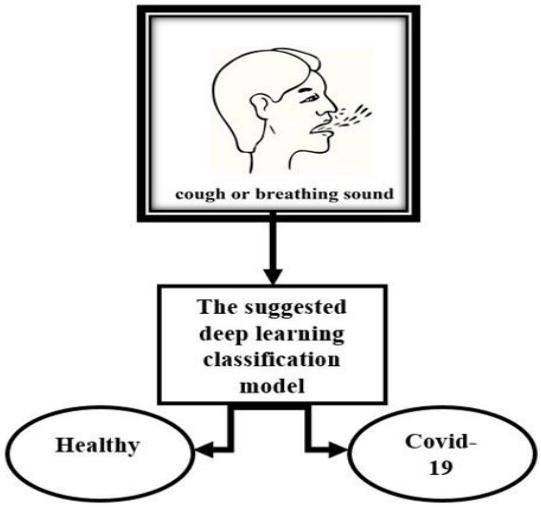

Fig. 1. The Suggested Deep Learning Classification Model.

A. Constant-Q Transform (CQT) and Mel-Scale Spectrogram

Human ears do not register variations across all frequency ranges equally. As frequency increases, it becomes increasingly difficult for individuals to distinguish between separate frequencies. The sound wave will be represented digitally by the voice recording. The CQT transforms a time-domain audio input to a frequency-domain signal [42]. To generate a spectrogram, the frequency will be converted to a log scale, and the amplitude will indeed be converted to decibels (db). The spectrogram will just be translated onto a Mel scale to generate a Mel spectrogram. In order to accurately imitate human ear behaviour using DL models, we employed the Mel scale to quantify frequencies. Each equivalent length among frequencies on the Mel- scale sounds equally distinct to human ears. To transform frequency from Hertz (f) to Mel (m), the Mel-scale utilizes the following equation:

$$m = 2595 \times \log(1 + f/700) \quad (1)$$

A Mel-scale spectrogram is a spectrogram with frequencies estimated in Mel. A Mel-scale spectrogram is a short-time Fourier transform (STFT) value [32]. The CQT and a mel-scale spectrogram are employed in two ways in this work. To decrease noise, the 1-D electrocardiogram (ECG) data will be first standardized. Second, the preprocessed signals are presented to a 2-D mel-scale spectrogram using Continuous Wavelet Transform (CWT). As illustrated in

Fig. 3, the ECG employs CWT to transform the signal from time domain to frequency domain. Convolution using only a median filter utilised to decrease low and high-frequency noise. Small amplitude features of the ECG that are of physiological or clinical importance are generally obscured by noise and interference. Because noise's bandwidth overlaps that of desired signals, basic filtering is insufficient to enhance the signal-to-noise ratio (SNR). The CWT typically uses findings to determine the resemblance of a wave to an evaluation function such as the Fourier transform (FT). The (CWT) is a time-frequency analysis method that differs from the more common (STFT) in that it enables for unlimited high-frequency signal feature localisation in time.

The CWT will accomplish this by using a variable window width proportional to the observer scale—flexibility that will provide for the separation of high-frequency features. The CWT is distinct from the STFT in that it is not limited to using sinusoidal analysing functions. The CWT of function $x(t)$ is measured using equation (2). Where, $\beta(t)$ is father signal, mostly in the time and frequency domains, $\beta(t)$ is a continuous function. (x) is the scale parameter's continuously varying values, and (y) is the position parameter's continuously varying values.

$$CWT(x,y) = (\sqrt{x})^{-1} \int_{-\infty}^{\infty} f(t)\beta(t - y/x)dt \quad (2)$$

The coefficients of CWT coefficients provide a matrix filled with located and scaled wavelets. The father signal's goal is to provide the generation fundamental characteristic of the child signals. Cough tones and breath sounds were separated from the dataset. The COVID-19 and normal groups' symptomatic breathing and coughing sounds were compared over time to see whether there had been any differences (Fig. 3).

B. Deep Learning Models

Many successful pre-train CNNs are capable of passing learning. Furthermore, they require dataset preparation and analysis at the input layer. A multitude of procedures and combinations are used to build the networks. MobileNetV2 and NasNetMobile are 2 DL models for smart phones. MobileNetv2's design has 155 layers as well as 164 connections [33, 34]. Separable convolutions are employed in mobile design, are utilized in MobileNetv2. NasNetMobile's mobile edition is divided into twelve sections. NasNet is a flexible CNN composed of fundamental construction components enhanced using recurrent neural networks [35]. A cell is made up of only a few actions that are frequently duplicated due to the network's required size. The layer Global Average Pooling [36] was used, which significantly minimises forwarding error prediction failure.

SqueezeNet is a small network designed to provide a more compacted alternative to AlexNet [37]. It has nearly 50 times less parameters than AlexNet yet performs three times quicker. SqueezeNet's core ideas are as follows:

- Approach one is to use 1×1 filters instead of 3×3 filters.
- Approach second: decrease the input channels to 3×3 filters.
- Approach three: reduce the network late in the process such that the convolution layers have huge activation maps.

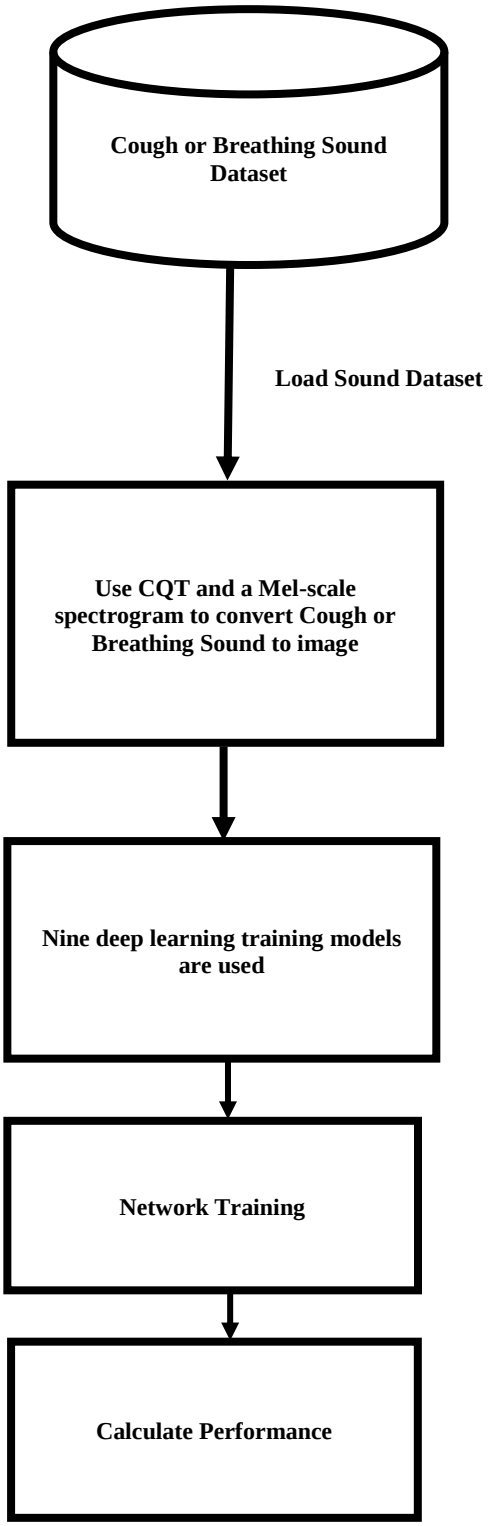

Fig. 2. The Presented COVID-19 Coughing and Breathing DL Classification Model.

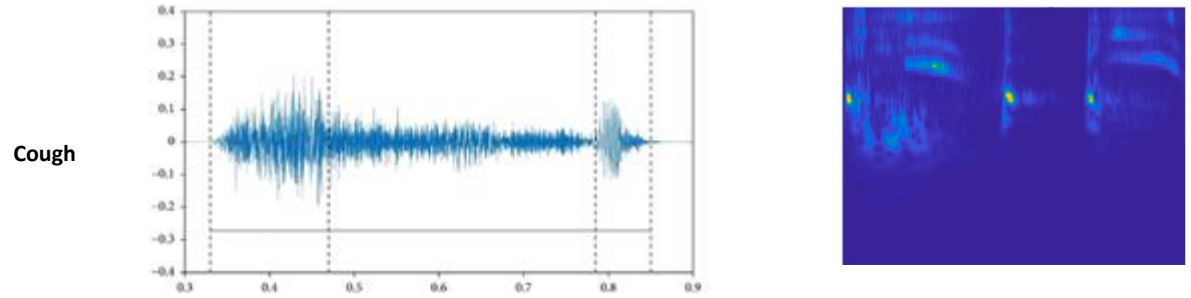
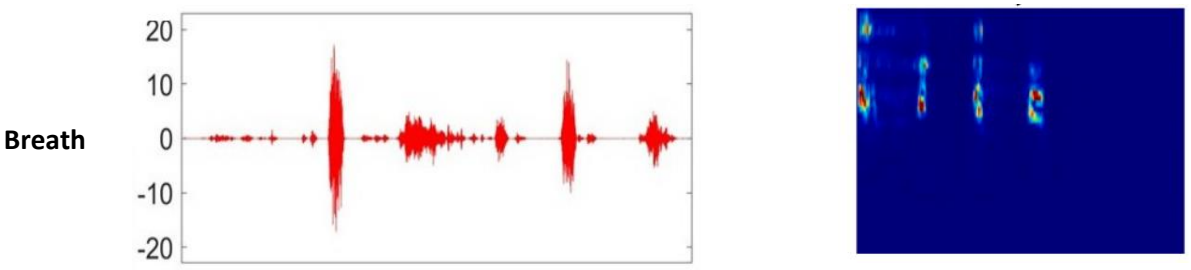
The SqueezeNet design contains 15 layers, with 5 distinct layers and 2 convolution layers.



(a) Healthy



(b) COVID-19

Fig. 3. A Mel-Scale Spectrogram and Constant-Q Transform of an Electrocardiogram of Covid-19 and Healthy Cough and Breath Sounds.

The Residual Network is a well-known deep learning model (ResNet). The development of these Residual blocks lessened the difficulty of training very deep networks, and the ResNet model is founded on them. ResNet provides several models, like 18/34/50/101/152. ResNet18 has 18 convolutional layers and a 33 filter. The ResNet-34 design entailed placing shortcut links onto a plain network in order to convert it into its residual network counterpart. In this scenario, the plain network was impacted by VGG neural networks (VGG-16, VGG-19) with a 33 filter in the convolutional networks. The ResNet-34 design contains 34 convolution layers. Regardless of the fact that the Resnet50 architecture is centered on the preceding generation, it differs in one significant way. Large Residual Networks, like as ResNet101 (101 layers) as well as ResNet152 (152 layers), are constructed utilising extra 3-layer blocks. Also when network depth is raised, the 152-layer ResNet had significantly decreased complexity.

GoogLeNet is constructed on numerous extremely small convolutions to significantly reduce the amount of parameters. The GoogLeNet architecture contains 22 layers, although the parameters have been reduced from 60 million (AlexNet) to 4 million. GoogLeNet has nine inception modules to investigate clustering and network inside a network. During the inception modules, the module range is computed, and the entirely connected layers are deleted. Pooling parameters in the inception modules decreases the number of parameters. In furthermore, a shadow network and also an auxiliary classifier were used to enhance the findings [38].

A CQT is used to transform a time-domain signal to a frequency-domain signal, that is then evaluated with many resolutions. The use of a Mel-scale spectrogram to display signal characteristics, in addition to its ability to distinguish biometrically, distinguishes this paper. In light of this, the signal processing system maintains its morphological difficulties. This implies that ML based on basic classifiers may be unsuccessful in identifying complex signals. We sent an image through CNN's DL, which showed to be the most effective in detecting visual morphology. The DL model output has not been equal. As a result, the current study intended to create the most representative DL models for image categorization (GoogleNet, ResNet18/34/50/100/101, MobileNetv2, SqueezeNet, and NasNetmobile).

V. Experimental Results

The provided DL model is performed in transfer mode using the suggested basic training setup (batch norm epsilon= e^{-3}, weight decay= $\boldsymbol{e^{-3}}$, and batch norm decay= 0.5, and dropout= 0.5). The batch size= $\mathbf{8}$, as well as the learning rate = $\mathbf{0.02}$, which was lowered till it reached $\boldsymbol{e^{-5}}$ automatically. The Deep Learning models are tested for 20 hours on a DELL PC with a 2.4 GHz Intel Core (TM) i7-M520 CPU, MATLAB R2016 64-bit, and 16 GB RAM running Windows 10 as well as tensorflow's Deep Neural Network library (CuDNN).

The dataset was divided into three parts: 80% for training, 10% for validation, and 10% for testing. We used both labelled and assessment data in our investigation. Validation accuracy is a classification score that is used to assess the learning technique as it proceeds. The size of the dataset determines the split ratio. To ensure the maximum level of model efficiency, an appropriate balance between training and testing must be attained. Furthermore, there is no immediate

reaction to the process or parameter pushes one over the brink. The results of each DL transfer model are shown in **Table I**, with an initial learning rate of 0.02 and 22 epochs. The batch size was set to eight, and early ending was permitted if there was no change in accuracy. It was revealed that by using more samples, the model output improved [39]. Stochastic Gradient Descent with Momentum (SGDM) [40] was the optimizer technique used in this study to improve detector performance. To prevent over-fitting issues with the Deep Learning net, we adopted the dropout approach [41]. As indicated in eq. (3), the teaching criteria were the loss function $L(x,t)$, which is defined as the total of binary plus box loss functions. Also, Eq. (5) and (6) are used to calculate the regression loss L_{re}:

$$L(x,t) = L_{cl}(x_c) + \delta[b > 0]L_{re}(z,z^*) \quad (3)$$

Where, $(\boldsymbol{z_a}, \boldsymbol{z_b}, \boldsymbol{z_w}, \boldsymbol{z_h})$indicates the bounding boxes of $\boldsymbol{z}$ and $\boldsymbol{z}^*$, $\boldsymbol{w}$ as well as $\boldsymbol{h}$ signify the box's width and height respectively, and $\boldsymbol{x_c}$ denotes the predicted score class $\boldsymbol{c}$. Non-background boxes at zero are defined by $\boldsymbol{\delta}[\boldsymbol{b} > \boldsymbol{0}]$. The bounding box as well as the classification loss $\boldsymbol{L_{cl}}$, are involved in the regression loss, as seen in eq. (4).

$$L_{cl}(x_{c^*}) = -\log(x_{c^*}) \quad (4)$$

$$L_{re}(k,k^*) = \sum_{i\in(a,b,w,h)} V_{LI}\,(k_i - k_i^*) \quad (5)$$

Where,

$$V_{LI}(p) = \begin{cases} 0.5p^2, if\ |p| < zero \\ |p| - 0.5,\ otherwise \end{cases} \quad (6)$$

A. Examination of Performance

Testing can yield a positive result, demonstrating the Deep Learning models' dependability. The confusion matrix is a statistical performance calculation approach used in study. Among the six statistical metrics are accuracy, sensitivity, specificity, precision, the F1 score, and the Matthews Correlation Coefficient (MCC). **Fig. 4** and **Fig. 5** show the confusion matrices for the two categories (COVID-19 as well as Healthy). Eq. 7 was used to get as close to the truth as feasible

$$accuracy = [N_{TP} + N_{TN}]/[(N_{TP} + N_{FP}) + (N_{TN} + N_{FN})] \quad (7)$$

Where, N_{TP}, N_{FN}, N_{TN}, and N_{FP} are No. of correctly labeled, mislabeled, clearly labelled instances of the remaining classes and incorrectly labelled instances of the remaining classes respectively. The efficiency of the five ResNet models (ResNet 18/34/50/100/101) is shown in Fig. 4(a, b, c, d, e), and the overall accuracy is 98.9%, 91.4%, 93.1%, 92.9%, and 90.1%. The confusion matrix of the test for the GoogleNet model is given in Fig. 5(a), as well as the accuracy rate is 89.9%. Fig. 5(b, c, d) depicts the performance of MobileNetv2, NasNetMobile, and SqueezeNet, with accuracy rate of 89.2%, 88.9%, and 86.9%, respectively. Because of the tiny dataset, Resnet18 obtained the maximum accuracy. The accuracy of DL models' predictions was quantitatively tested. Both sensitivity and accuracy are widely utilized classification efficiency metrics. Eq. 8 and 9 are applied to calculate Sensitivity and Precision. Fig. 6 depicts the sensitivity and specificity of the nine Deep Learning models.

ResNet101 has a sensitivity of 95.6% when it relates to distinguishing COVID-19 persons' breathing sounds. ResNet18 does indeed have 98.1% specificity, meaning that it can detect people who do not have COVID-19. Precision, F1 score, and MCC are calculated using Eq. 10, 11, and 12. **Fig. 6** depicts the accuracy, F1 score, as well as MCC for the nine Deep Learning models. ResNet18 does have the highest accuracy of 96.4%, indicating that it generates more relevant findings than the other models. In **Fig. 6**, the DL model's efficiency is assessed by a test with a high F1 score of 95.9% for ResNet18. Finally, the MCC demonstrates that the more statistically reliable rate performed well in all four categories of the uncertainty matrix. ResNet18 has the highest MCC of 91.8 percent.

$$Sensitivity = N_{TP}/(N_{TP} + N_{FN}) \quad (8)$$

$$Specifcity = \frac{N_{TN}}{(N_{TN}+N_{FP})} \quad (9)$$

$$Precision = N_{TP}/(N_{TP} + N_{FP}) \quad (10)$$

$$F1\ score = 2 \times N_{TP}/(2 \times N_{TP} + N_{FP} + N_{FN}) \quad (11)$$

$$MCC = \frac{N_{TN}\times N_{TP} - N_{FP}\times N_{FN}}{\left(\sqrt{(N_{TP}+N_{FP})\times(N_{TP}+N_{FN})\times(N_{TN}+N_{FP})\times(N_{TN}+N_{FN})}\right)} \quad (12)$$

B. Examination of Performance Discussions and Comparative Analyses

In Fig. 6, the outcomes of the suggested method for applying deep learning DL models in the breathing dataset implementing CQT as well as Mel-scale spectrogram images of COVID-19 illness and healthy are shown. Fig. 7 shows how our proposed approach can effectively recognise data. The present study's innovations include the employment of CQT and a Mel-scale spectrogram with deep learning models to characterise signal characteristics and biometric identification capabilities. The core of related research focuses on classifying breathing and coughing signals through ML. Table II analyses the performance of several techniques in terms of accuracy. The authors in [23, 24] employed a small dataset that included the actual COVID-19 coughing sound sample in a comparable investigation. Much of the prior study has been on distinguishing between coughing and non-coughing tones. We noticed this when analysing the effectiveness of Deep Learning transfers methods in detecting COVID-19 cough sounds using the SGDM, when cough signals occur often, the efficiency of all Deep Learning techniques improves significantly. While having the greatest performance, our detection model's efficiency is just 98.9% relying on the SGDM optimizer, the learning data correctness and the effort to analyse the labelled data. Every inaccuracy in data recording that evaded our notice, on the other hand, is most likely to influence the reported outcomes. Table III demonstrates the accuracy of the proposed suggested model when implemented to the Coswara dataset. The state-of-the-art models are labelled in the first left column. According to Table III, the proposed technique achieves high accuracy compared to the other models. The findings of this study, as well as those of another study mentioned in the related works section, indicate that specific latent properties of coughing sounds may well be successfully exploited for DL identification of a variety of respiratory issues. As it

differentiates between normal and COVID-19 coughing, the coughing can be used as a preliminary diagnostic technique. We study the use of a Mel-scale spectrogram of tone as a return to Deep learning to see if the model is greater than effective at identifying medical images to tone. ResNet as well as GoogleNet were proved to have great accuracy in this work despite being recognised as deep variants of DL transfer models. For mobile versions, NasnetMobile as well as mobilenetv2 provide great precision. For assessment, the tests are done on a separate dataset that consists of audio wave files. Resnet18 was much more effective than GoogleNet, while resnet34/50/100/101 was much more effective than GoogleNet. NasnetMobile outperformed Mobilenetv2m and Squeezenet in terms of accuracy. The case is used in the experiments to assess the existing classification model's efficiency and consistency. According to the results, the resnet18 model has the greatest classification accuracy on cough as well as breath signals from the confirmed COVID-19 dataset. The DL classification outperforms conventional CNN classifications in matching coughing and breathing sounds of COVID-19 sufferers. As an outcome, it could really aid in diagnosis by alleviating clinicians of the stress connected from the first sound of the COVID-19 cough as well as breath.

TABLE I. DEEP LEARNING MODELS SETUP

VI. CONCLUSION

The current study created innovative DL models for breath and cough sound classification that focus on sound and might aid in COVID-19 transmission controls. The proposed model combines two key components. The initial method was using a CQT as well as a Mel-scale spectrogram to transform sound waves into images. The second component is the construction of universal features as well as extra classification utilising deep transfer models (GoogleNet, ResNet18, ResNet34, ResNet50, ResNet100, ResNet101, MobileNetv2, SqueezeNet and NasNetmobile). Around 1,600 people from all over the world (1185 men and 415 women) supplied data to the collection (mostly the Indian population). With the better classification performance employing coughing sound CQT and a Mel-spectrogram image, the current proposal outperformed the other nine CNN networks. For symptomatic patients, the accuracy, sensitivity, and specificity were 98.9%, 97.3%, and 98.1%, respectively. The Resnet18 network is the most dependable for symptomatic patients who use coughing as well as breathing tones. When applied to the Coswara dataset, we discovered that the suggested model's accuracy (98.7%) outperforms the state-of-the-art models (85.6%, 72.9%, 87.1%, and 91.4%) based on the SGDM optimizer. The suggested study's findings contribute to key suggestions for future ML and DL research. Our results can be comparable to a scalogram, another common type of time-frequency representation. Given its high overall accuracy, the suggested study will require more replication before it may be used in other healthcare applications. This work opens the door for the use of DL in COVID-19 diagnosis by proving that it is a rapid, time-efficient, and low-tech solution that does not violate social separation criteria in pandemics like COVID-19.

MFCC and Texture Descriptors based Stuttering Dysfluencies Classification using Extreme Learning Machine

Roohum Jegan, R. Jayagowri
Department of Electronics and Communication Engineering
BMS College of Engineering
Bangalore, India

***Abstract*—Stuttering is a type of speech disorder which results in disrupted flow of speech in the form of unintentional repetitions and prolongation of sounds. Stuttering classification is important for speech pathology treatment and speech therapy techniques which decreases speech disfluency to some extent. In this article, a method for prolongation and repetition classification is presented based on Mel-frequency cepstral coefficients (MFCC) and texture descriptors. Initially, MFCC and filter bank energy (FBE) matrix are computed. Gray level co-occurrence matrix (GLCM) and Gray level run length matrix (GLRLM) textural features are extracted from these matrices. Laplacian score-based feature selection approach is employed to choose relevant features. Finally, extreme learning machine (ELM) is utilized to classify the speech audio event as repetition or prolongation. The algorithm is evaluated using UCLASS database and has achieved improved performance with classification accuracy of 96.36%.**

Keywords*—Voice disorder; Mel-frequency cepstral coefficients; gray level co-occurrence matrix; GLRLM; Laplacian score; extreme learning machine

I. Introduction

Speech forms a major part in day-to-day communication and is used by humans to express their emotions and to exchange their ideas. Thus, speech helps in the efficient communication of ideas that determines how a person thinks and feels. Speech is a special gift to the mankind because animals and other species cannot speak [1]. Stuttering is classified as one of the speech disorders and is identified by reiteration of utterances, phonics, phrases, or terms; elongation of sounds during utterance; and interventions in speech called as blocks [2]. Even though there is no complete cure for stuttering at present, there are numerous speech pathology approaches that may aid to decrease speech disfluency to certain extent. To judge the performance of the stutterers before and after the treatment, stuttering assessment is needed. Generally, Speech Language Pathologist (SLP) manually enumerates and categorize eventuality of disfluencies such as prolongations and repetitions in a stammered speech. But, this type of evaluation is unpredictable, uncertain, intuitive, cumbersome and erroneous. Hence it would be worthy if the stuttering assessment can be carried out automatically enabling the SLP to spend more time with the stutterer in treatment session.

This article presents a new statistical feature based on MFCC and FBE matrix to enhance stuttering event classification using UCLASS database. Prolongation and repetition event are discriminated using GLCM and GLRLM features extracted from MFCC and FBE matrix and ELM classification. Laplacian score- based feature selection algorithm is employed to discard irrelevant features resulting in improvement in the classification rate. The proposed feature extraction approach improves the prolongation and repetition classification accuracy to a greater extent. Moreover, best features are selected using Laplacian score-based feature selection algorithm, thereby, minimizing the computational complexity.

The rest of the paper is organized as follows: In Section II, the past solutions for the predetermined problem via different algorithms, classification and feature extraction techniques are presented. In Section III, the proposed method for speech dysfluencies has been discussed with brief description of each method in separate subsections. In Section IV, the simulation results of the work are discussed, and Section V presents the conclusion of the work with the future scope.

II. Literature Review

This section presents different objective approaches proposed for stuttering event classification based on various features, datasets and classifiers. In [3], automatic detection of syllable repetitions is presented using correlation of 1/3 octave spectra. The correlation features are used to identify repeated syllables with similar spectral components. Acoustic and pitch related descriptors including MFCCs, formants, tonality (pitch), zero crossing rate (ZCR) and energy are employed to classify repetitions and prolongations using Artificial Neural Networks (ANN) in [4]. The accuracy obtained using the ANN based classification was 87.39%. Line spectral frequency (LSF) representation features are extracted and classified using three different classifiers: MLP, RNN and RBF resulting 98-100% detection rate in [5].

LP-Hilbert transform based MFCC (LH-MFCC) based feature extraction method is presented to classify three different dysfluencies using Gaussian Mixture Model (GMM) classifier [6]. These features efficiently capture temporal and spectral parameters of utterances resulting in 94.98% accuracy rate. To enhance classification accuracy, a decision fusion

technique is introduced, based on combination of different acoustical features like ZCR, speech envelope (ENV) for classifying filled pause (FP) and elongation (ELO) in Malay language [7]. Stuttered speech repetition detection algorithm based on MFCC and dynamic time warping (DTW) with accuracy of 83-90% is proposed in [8], [9].

Various stuttering events are classified in [10] using i-vector based KNN and LDA classification resulting in 80- 85% classification accuracy. In [11], similarity matrix image is computed using MFCC, PLP and filter bank energy feature sets. Dysfluent regions are detected using threshold based morphological image processing having an average classification accuracy of 82.5%. SVM based dysfluency classification method using a GMM supervector is introduced in [12], [13] with +96.10% accuracy. Repetition and prolongation classification using MFCC, LPC and perceptual linear predictive (PLP) and k-NN and SVM classifier is proposed in [14], [15] having classification rate of 96%.

A method using SVM classifier and fusion of prosodic (pitch and energy) and cepstral (MFCC) features is presented for stuttered speech classification with 97.80% accuracy in [16]. A deep belief network architecture is developed based on MFCC and LPCC features to classify stuttering speech signal having an accuracy of 85% in [17]. Computational intelligence approach based on ANN and SVM is developed to classify dysfluencies in stuttered speech signal in [18] with 85% accuracy rate. An objective methodology for dysfluency detection using six-level wavelet packet transform decomposition and features employing entropy features is presented in [19], [20]. Performance of the algorithm is evaluated using three distinct classifiers including k-NN, LDA and SVM classifiers resulting in classification accuracy of 96.67%. MFCC and LPCC based stuttered event classification approach is proposed in [21] using k-NN and LDA classifiers with 94% classification rate. Prolongation and repetition in stuttered speech classification technique using LPCC features and k-NN/LDA classifier is presented with 89.77% in [22].

In another study, [23], [24], same authors presented stuttered event detection approach using LPC, LPCC and WLPCC features with 97.78% classification accuracy. But the test segments taken were very small and it was observed that accuracy decreased for bigger test segments. MLP network architecture is presented in [25] to detect stop consonant repetitions with accuracy of 76.67%. This study presents a new approach based on MFCC and FBE matrix representation and feature extraction using GLCM and GLRLM descriptors. Convolutional Method (CNN) was used to classify different languages in [42]. The classification accuracy obtained is 97.86%.

The existing literature feature extraction approaches are primarily based on time-domain features extracted from the speech sample. The stuttering classification rate is limited between 87% and 94%. Additionally, the feature selection techniques are less explored in the existing literature hence limiting the classification accuracy. This article presents a new feature extraction algorithm based on MFCC and FBE matrix statistical features. The proposed feature extraction approach enhances the prolongation and repetition accuracy. Moreover, important features are selected using Laplacian score-based feature selection algorithm, thereby, reducing the computational complexity.

III. Proposed Method for Speech Dysfluencies Classification

This article presents prolongation and repetition classification using MFCC/FBE, two different types of texture descriptors and ELM classifier. The proposed scheme is presented in this section. MFCC and filter bank energy computation is explained next along with its importance in the stuttering classification process. GLCM and GLRLM texture features are investigated and discussed in detail. Laplacian score-based feature selection is employed in this study along with its brief introduction. Finally, extreme learning machine classifier that is employed in this work and the merits are discussed.

A. Architecture of MFCC and FBE based Dysfluencies Classification

The framework of the stuttering classification scheme is depicted in Fig. 1. It is the architecture used for stuttering classification using MFCC and texture descriptors. The sample voice is analyzed before taking it as an input from a person. At various stages, the input speech signal is manipulated and undergoes operations of Pre-processing, converting into frames, filtering and Windowing, and complementing with the uttered word. This speech algorithm has two major stages: training and testing stages and the process is shown in Fig. 2.

After pre-processing the input speech sample, MFCC and FBE matrix is obtained. GLCM and GLRLM descriptors are extracted from these two matrices. In order to reduce feature vector dimensionality, Laplacian score-based filter type feature selection is used. Finally, ELM is trained using the training database. In our experiments, 70% of the speech specimens are used for training stage and remaining 30% samples for testing.

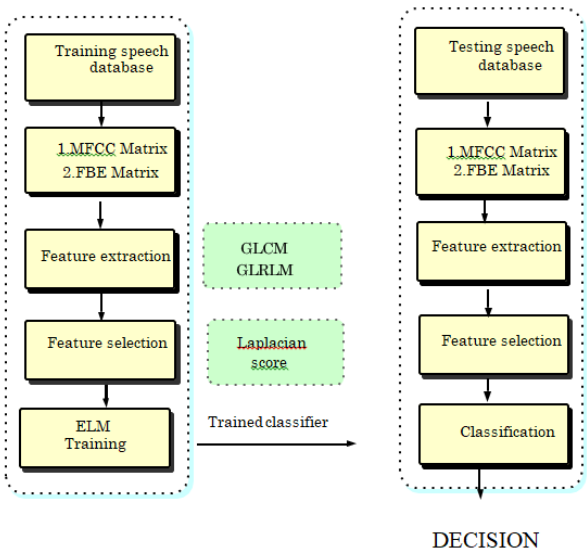

Fig. 1. Architecture of Stuttering Classification using MFCC and Texture Descriptor.

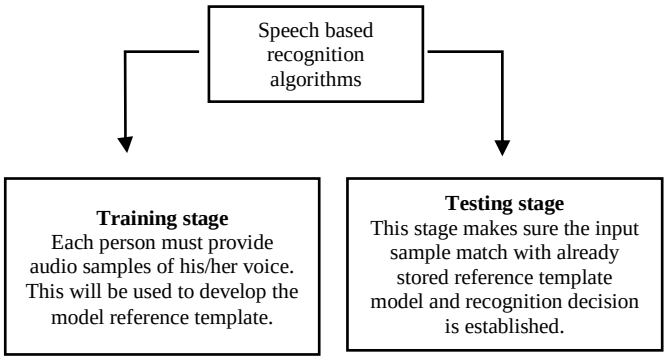

Fig. 2. Training and Testing of Voice Recognition Algorithms.

B. Mel-Frequency Cepstral Coefficients (MFCCs)

MFCC represents set of Discrete Cosine Transform decorrelated variables that are evaluated using transmutation of the energies (output from filter) that are compressed logarithmically. These are obtained from a sharply spaced triangular filter bank that precedes the Discrete Fourier Transformed audio signal. The extracted features represent parametric characterization of audio signals that plays important role to enhance the performance of the recognition approach. MFCCs is widely and commonly adopted feature extraction algorithm in variety of audio/speech/music processing algorithms [26]-[30].

MFCC describes short time cepstral features and uses Mel scale with linear separation below 1000 Hz and logarithmic spacing above 1 kHz. The value of Mel for any frequency f (Hz) is computed as:

$$\text{Mel}(f) = 2595 \times \log10(1 + f/700) \quad (1)$$

where M is the quantity of triangular filters, L represents the total Mel scale coefficients and Ek is energy of the filter bank (log) output. Filter bank approach characterizes the speech samples efficiently. A set of triangular band-pass filter is designed, and nonlinear Mel-frequency scale is employed considering human perceptual capabilities with specific frequency spacing. Intensity from each band is computed by multiplying Mel filter bank and magnitude spectrum of speech signal. We observed that, filter bank energy spectrum varies based on the input speech sample (prolongation and repetition). This dissimilarity is exploited in this study for stuttering event classification. The overall architecture and process of generating Mel frequency cepstral coefficients is shown in Fig. 3 [6], [7]:

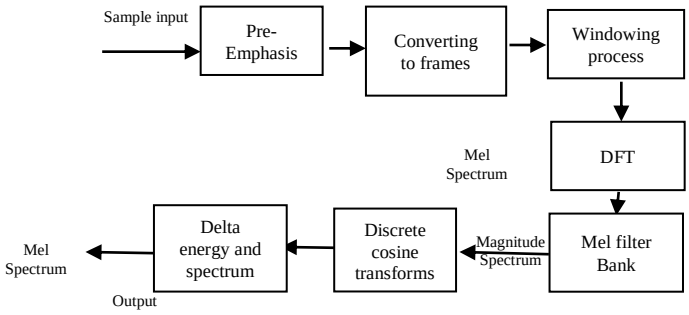

Fig. 3. MFCC Flow.

MFCC constitutes of seven major stages. Every stage has its own mathematical processes and functions described in the following steps:

Step 1: Pre–emphasis: This stage helps in escalating the signal energy at greater frequency range by allowing the signal to pass through a filter that prioritizes higher frequencies.

$$Y[x] = M[x] - aM[x - 1 \quad (2)$$

$$Y[x] = M[x] - 0.96M[x - 1] \quad (3)$$

Let us consider 'a' to have a value 0.96, which means it is assumed that there is 96% chance of a sample to regenerate from the previous sample.

Step 2: Converting to frames: Framing refers to segmentation of the voice samples into small framework with distance between 20 to 40 ms. The speech samples are derived from the analog to digital convertor. The input audio signal is segmented into N sample frames. Nearby frames are segregated by Y (Y < M). Y = 100 and M = 256 are the most typical values used.

Taking into account the succeeding step in feature extraction stage, it amalgamates all the immediate frequency bands. If the window is given as H(x); where x = count of samples contained in each frame, B(x) = signal output, A(x) = signal input, H(x) = window. The, the output of hamming window is:

$$B(x) = A(x) \times H(x) \quad (4)$$

$$h(x) = 0.54 - 0.46 \cos \Sigma 2\pi x;\ 0 \le x \le X - 1 \quad (5)$$

Step 4: Fast Fourier Transform: It transforms each framework of X samples that are in time domain to corresponding frequency domain. FT transforms the convolution of pulse in glottis tt[n] and impulse response I[n] of the vocal tract present in the time domain which is shown in equation stated below:

$$B(x) = \text{FFT}[I(t) * A(t) = I(x) * A(x)] \quad (6)$$

If A(x), I(x) and B(x) are the FT of A(t), I(t) and B(t) respectively.

Step 5: Filter Bank Conversion: The FFT range has high frequency and is broad and the audio signal is non-linear. Fig. 4 shown above describes a set of triangular filters to enumerate the weighted sum of all filter spectral samples so that the output is made to approach the Mel scale. Every filter has triangular magnitude frequency response with unit value at the center frequency and it gradually reduces linearly to zero at the Centre frequency of adjoining filters [7], [8]. Output of each filter is the filtered sum of its spectral components. Equation stated below is then used to calculate the Mel for any frequency f (HZ) as:

$$\text{Mel}(f) = 2595 \times \log10(1 + f/700) \quad (7)$$

Step 6: DCT: Log Mel spectrum is converted into time domain using Discrete Cosine Transform and this result in the formation of MFCC. MFC coefficients are also called the acoustic vectors. Hence, each input speech sample is converted into a chain of acoustic vector.

Step 7: Delta Energy and Delta Spectrum: The audio speech signal and the frameworks vary in accordance to the formant slope at its changeovers. Hence, features that relates to the variations in cepstral parameters over time have to be included. 13 delta parameters that include 12 cepstral features and one energy feature, and 39 double delta features are included. The energy E of a signal 'a' in a window frame from time duration t11 to time sample t12, is given by the following equation:

$$E = A^2t \quad (8)$$

Each of the thirteen delta variables constitutes the variation happening between frames corresponding to the energy parameter. On the other hand, 39 double delta features depict the variations among frames in the corresponding delta features as,

$$r(t) = [s(t + 1) - s(t - 1)]/2 \quad (9)$$

In short, the MFCC computation comprises of the framing stage where the input pre-processed speech sample is divided into several frames with overlap. After framing the signal, hamming window attenuates the framed signal to null at the beginning and end of the frame. The windowed signal is converted to frequency domain by applying Fast Fourier transform (FFT). The FFT spectrum is passed through a set of triangular band-pass filter to obtain the logarithm energy spectrum.

The placement of these filters is based of Mel frequency scale, which is proportional to logarithm of linear frequency scale, reflecting human perceptual capabilities. In the last step, discrete cosine transform (DCT) is applied on logarithm energy to extract L Mel scale cepstral coefficients using the energy compaction property and is obtained as,

$$C(n) = \Sigma\, Ek \times \cos(n \times (k - 0.5) \times \pi/40 \quad (10)$$

Fig. 4 and 5 shows filter bank energy spectrum for prolongation and repetition samples from UCLASS database respectively. It is clearly seen that for prolongation samples, (Fig. 4) the filter bank energy of the frames for prolongation utterances are equal. Whereas, in case of repetition (Fig. 5), filter bank frame energies are distributed more evenly as compared to prolongation frame energies. Moreover, central coefficient energy distribution is higher in Fig. 5 compared to Fig. 4. These differences are exploited for the classification in this article.

C. Gray Level Co-occurrence Matrix (GLCM)

Feature extraction technique is mainly used to make simpler the number of features that can accurately describe a large set of data. While analyzing complex data, large number of variables involves more difficulties. Huge number of variables traditionally requires more memory and computational power. Else it requires a classification algorithm which can fit the entire training sample but that result in poor generalization of new samples. Feature extraction refers to methods used for establishing fusions of the features while still describing the data without compromising on the accuracy. It is mainly used in applications that describes and retains the texture kinesthetic or visual attributes of a surface.

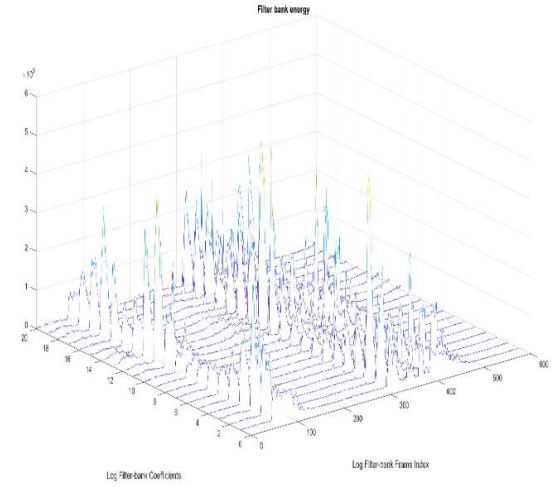

Fig. 4. Filter Bank Energy Spectrum for Prolongation Samples.

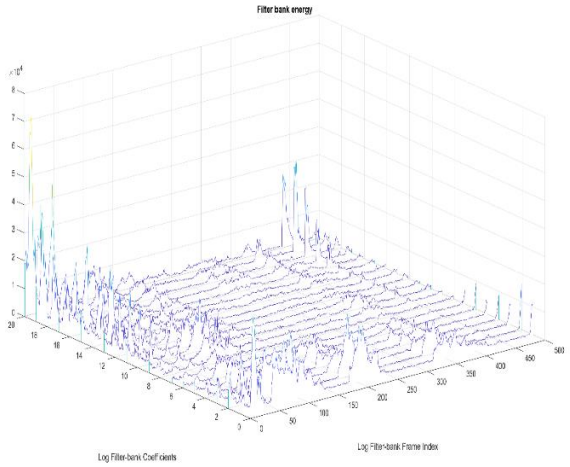

Fig. 5. Filter Bank Energies for Repetition Samples.

Texture analysis helps to find a distinctive way of illustrating the underlying/hidden characteristics of texture and personify them in an effortless and distinct form. This helps in robust, accurate classification and segmentation of samples. Although textural representation contributes a major role in image study and pattern recognition, only a few architectures implement the idea of onboard textural feature extraction method. Gray level co-occurrence matrix helps to obtain qualitative/statistical texture features. Hence GLCM is a numerical analysis method used for observing the texture that contemplates the spatial correlation between pixels [31]. GLCM is one of the most widely used texture descriptor to compute statistical features of the image based on gray level intensities and employed in different image processing applications like image segmentation, image retrieval, image classification and object recognition as discussed in [41].

The main advantage of the co-occurrence matrix computation is that, while considering the relation between two pixels at any instant of time, pixel pairs that coincide can be topologically matched in various inclinations in accordance to the distance and spatial-based angular relationships. This apparently exhibits the combination of grey levels of image

matrix and their positions. Matrix relationships are defined by changing the directions with different angles and displacement vectors. In this paper, twenty features are extracted from the MFCC and FBE matrix [32].

The count of rows and number of columns in a GLCM is the count of gray levels, H, present in the image. The matrix component A (a, b δp, δq) is the frequentness at which two pixels, divided by an interval (δp, δq), transpire within a given vicinity, one with potency 'a' and the other with potency 'b'. The component A (a, b δp, δq) has got the values of second order statistical probability for corresponding variations among the gray levels 'a' and 'b' at a specific displacement length l and at a specific angle (θ).

GLC Matrices are very delicate to the dimension of the texture sample on which they are computed because of their large dimensionality. Hence, the reduction in the number of gray levels is of utmost importance. In most of the cases, a reference pixel and its quick neighbor is contemplated. Usage of larger offset is feasible if the window is large enough. The top most cell at the left will contain the frequency of occurrence of combination 0,0. That means, it will contain the information about the total number of times a neighbor pixel having 0 gray level gets placed to the right of reference pixel with 0 gray level, within the image area.

D. Gray Level Run Length Matrix (GLRLM)

This matrix is another popularly used higher order texture descriptor useful in feature extraction. It is a textural representation model that helps in extracting the spatial plane features of each pixel relative to the higher order statistics [33]. A 2- dimensional feature matrix is obtained at the end of the process, exploiting the spatial variations because of the prolongation and repetitions. GLRL matrix is not just limited to 00 direction. It can also be used in other directions with θ = 450, θ = 900 and θ = 1350.

GLRL matrix gives us few textural parameters that can be extracted from it. It is observed that five texture features can be extracted from this GLRL matrix, namely: Shot Runs Emphasis (SRE), Long Runs Emphasis (LRE), Non-uniformity Gray Level (GLN), Non-uniformity Run Length (RLN), and Percentage of Run (RP). Later on, two more features called the Low Gray Level Run Emphasis (LGRE) and High Gray Level Run Emphasis (HGRE) were found to be extracted from this matrix. This parameter makes use of sequential gray level of pixels and then discriminates the texture that has equal values for Shot Runs Emphasis and Long Runs Emphasis with minor variations in the gray level distribution.

After those four more features were found to be extracted from the matrix, namely: Low Short Run Gray-Level Emphasis (SRLGE), High Short Run Gray Level Emphasis (SRHGE), Low Long Run Gray Level Emphasis (LRLGE), and High Long Run Gray Level Emphasis (LRHGE). Same intensity adjacent pixels in certain direction is termed as run length. Each element in the GLRLM characterizes the total gray level occurrences in the given direction. For a single MFCC matrix, it is possible to compute many different run- length matrices f (i, j θ) one for each chosen direction θ. Thus, given a direction, for each acceptable gray measure value, this matrix measures the total run times. GLRLM is parameterized by three different pixel features: intensity, length and direction of a run from a reference pixel. Total of 11 features per direction are extracted from the MFCC and FBE matrix [34]-[36].

E. Laplacian Score based Feature Selection

Feature selection plays important role as the preprocessing step in machine learning to select optimum features from the large input feature set. Feature selection techniques can be classified into: (a) filter and (2) wrapper techniques [37]. Filter methods are independent of the learning algorithm and faster, whereas, wrapper approaches produce higher accuracy and it needs learning algorithm. In this article, Laplacian score- based filter approach is used for feature selection [38]. As the name suggests, for every parameter, its Laplacian score is evaluated and calculated separately to reveal its locality preserving power.

Laplacian score approach is based on the reflection that two data points are probably related to the same point if they are near to each other. Generally, in all the learning tasks like classification, the local geometric structure is more important than the global structure of the given feature space. Hence, a nearest neighbor graph is designed to construct the local structure, and Laplacian score aspires those specific parameters that obey this graph model.

Laplacian score (LS) is based on the concepts of 'Laplacian Eigenmaps' and 'Locality Preserving Projection' and is used to identify importance of individual features. Locality preserving power is computed using this LS for each feature and the features are inferred to be similar if they produce very low LS. Based on the graph, structure is defined using the nearest neighbor and the geometric structure of the descriptor is evaluated. As LS is a ranking filter approach for feature selection, a threshold T is used to select number of features for classification.

F. Extreme Learning Machine (ELM) Classifier

Extreme learning machine algorithm is a contemporary state-of-the art machine learning algorithm with sole-hidden layer feed-forward neural network (SLFNs). ELM is fast; it has better generalization performance and enhances the training speed by assigning the weights randomly. ELM requires only two parameters: (1) hidden layer neural units and (2) their transfer function [39] and [43]. ELM algorithm is used in data classification and regression applications. The optimal values must be chosen for ELM training parameters to enhance the accuracy. However, while designing the classifier using ELM, the number of hidden nodes to be used for handling different problems remains a trial and error [40].

A major drawback of ELM is that the classifying borderline for the learning features of this algorithm may not be an adequate one. This is because the learning features of hidden nodes are arbitrarily allocated while they remain uninterrupted in the training stage [17]. Hence, few features might be miscategorized by the algorithm, mainly for those samples that are close to the classifying border line. Another observation made is that, in many cases, this algorithm might need additional hidden neurons compared to the already available traditional tuning-based algorithms [18]. Few researchers have

proposed that the above-mentioned shortcomings of ELM can be overcome by introducing several variants of ELM, such as incremental ELM [9], pruning ELM [12], error-minimized ELM [19], dual-step ELM [20], sequential online ELM [21], evolutionary ELM [18], voting-based ELM [17], ordinal and fully complex ELM [23], and balanced (symmetric) ELM.

IV. Simulation Results

Proposed stuttering event classification algorithm is evaluated using speech samples from UCLASS database [3]. The database includes 43 speakers recording generating 107 audio samples.

In this article, 39 speech samples are selected for classification similar to the settings used in [21]. During MFCC and FBE computation, the analysis frame duration is set to 25 ms with overlap of 10 ms. The pre-emphasis coefficient is set to 0.97 with 20 filter bank channels and 12 cepstral coefficient extractions. Lower frequency limit is set to 300 Hz, whereas 3700 Hz is the high frequency limit.

The GLCM features are extracted using one direction only, as during the experimentation we found that one direction is sufficient to generate satisfactory classification rate. GLCM descriptors are extracted from both MFCC and FBE matrix representation, generating 20-D feature vector for each. In addition to GLCM, GLRLM textural features are also extracted from these two matrices, thereby generating 24-D feature vector for MFCC and FBE matrix individually. Out of the total speech samples, 70% are used to train the ELM and enduring 30% are employed for testing. ELM is implemented using 300 neurons, which is set experimentally with sigmoidal transfer function. Finally, each stuttering speech sample is represented using 84-D feature vector.

Table I shows prolongation and repetition classification accuracy for individual (GLCM and GLRLM separately) and combined feature sets (GLCM+GLRLM). From Table I, it is observed that, GLCM has poor discrimination capability with classification accuracy of only 79.84%. Compared to GLCM features, GLRLM descriptors are more powerful during the classification. Finally, as expected, combined feature set (GLCM+GLRLM) resulted in highest accuracy of 92.64%. It is also evident that, feature fusion enhances the classification rate notably in the stuttering event discrimination. In order to demonstrate the effect of Laplacian score feature selection, additional experiments are performed. Table II depicts prolongation and repetition classification accuracy for individual (GLCM and GLRLM separately) and combined feature set using Laplacian score feature selection approach. Significant improvement in the classification accuracy can be observed (see Table II) by applying the feature selection technique. Combined (GLCM+GLRLM) feature set accuracy obtained was 96.36% using only 25 features. Thus, Laplacian score approach not only enhances the classification rate but decreases the number of features also (60% decrease in total number of features).

As this approach is ranking based approach, threshold T is used to select number of important features from the large input feature set. Fig. 6 shows the classification accuracy obtained using different threshold values. Highest accuracy was obtained at threshold T = 0.2, we choose final feature set with this threshold (resulting in final 25-dimensional relevant features only). As started above, GLCM descriptors can be evaluated using four different directions. Table III illustrates GLCM detection accuracy using different directions employing LS feature selection and without LS feature selection. As evident, feature selection improves the detection rate. It is also worth mentioning that, combining all four directions enhances the detection rate of the proposed technique. The present work utilizes ELM classifier with 300 hidden neurons. Tables IV and V shows the number of hidden neurons and corresponding obtained accuracy using GLCM and GLRLM features, respectively. It was observed that the highest classification rate is achieved using 300 neurons.

TABLE I. Prolongation and Repetition Classification Accuracy for Individual and Combined Feature Set

Features	Classification Accuracy (%)
GLCM	79.84
GLRLM	84.6
Combined	92.64

TABLE II. Prolongation and Repetition Classification Accuracy for Individual and Combined Feature Set using LS feature Selection

Features	Classification Accuracy (%)
GLCM	81.74
GLRLM	87.24
Combined	96.36

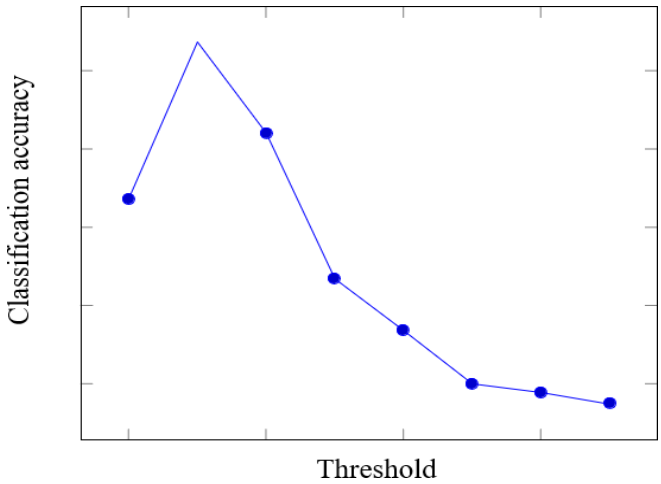

Fig. 6. Classification Accuracy vs Threshold Values using Laplacian Score-based Feature Selection for Stuttering Event Classification.

TABLE III. GLCM Detection Accuracy using Different Directions

Direction	Accuracy without FS	Direction	Accuracy with FS
00	79.84	00	81.74
00 + 450	78.12	00 +450	81.24
00+450+900	78.05	00+450+900	80.71
00+450+900+1350	77.69	00+450+900+1350	79.93

TABLE IV. NUMBER OF HIDDEN NEURONS AND ACCURACY USING GLCM FEATURES

Number of hidden neurons	Classification Accuracy (%)
100	75.29
150	76.35
200	75.85
250	78.16
300	79.84
350	78.97

TABLE V. NUMBER OF HIDDEN NEURONS AND ACCURACY USING GLRLM FEATURES

Number of hidden neurons	Classification Accuracy (%)
100	79.20
150	80.93
200	81.21
250	83.79
300	84.60
350	83.64

V. DISCUSSION

The proposed MFCC and FBE based textural feature approach is compared with existing stuttering event classification algorithms. Table VI depicts comparison of proposed method with already existing state-of- the art methods using different features and classification accuracy rates. It can be seen that the proposed technique performs better compared to all the traditional algorithms.

TABLE VI. COMPARISON OF PROPOSED METHOD WITH EXISTING METHODS USING DIFFERENT FEATURES AND CLASSIFICATION RATE

Method	Features	Classification Accuracy (%)
[4]	Acoustic and pitch	87.39
[6]	LH-MFCC	94.98
[8]	MFCC-DTW	90
[9]	MFCC-DTW	89
[14]	MFCC, LPC	95
[15]	MFCC, LPC, PLP	96
[21]	MFCC, LPCC	94
Proposed	MFCC, FBE	96.36

The prime objective of this article is to present a new statistical feature approach based on MFCC and FBE matrix to enhance stuttering event classification using UCLASS database. Prolongation and repetition event are distinguished using GLCM and GLRLM features extracted from MFCC and FBE matrix and Extreme learning machine classification. Laplacian score-based feature selection algorithm is employed to remove irrelevant features resulting in improvement in the classification accuracy rate. Experiments show that GLRLM outperforms GLCM descriptors during the classification stage. On selecting the best feature set of 25 features (T = 0.2), highest accuracy of 96.36% is obtained. And it can be observed from the results and tables that the performance of the proposed algorithm is better compared to other existing methods. Besides, this article also emphasizes the use of feature selection technique to reduce the computational complexity of the algorithm.

VI. CONCLUSION

This article presents stuttering event classification approach based on MFCC and FBE using UCLASS database. Prolongation and repetition event are discriminated using GLCM and GLRLM features extracted from MFCC and FBE matrix and ELM classification. Laplacian score-based feature selection algorithm is employed to discard irrelevant features resulting in improvement in the classification rate. Experimental results show that, GLRLM outperforms GLCM descriptors during the classification stage. After selecting best feature set of 25 features (T = 0.2), highest accuracy of 96.36% is achieved. In future works, experiments can be performed with large speech samples with different feature extraction approaches and classifiers to improve the classification rate further.

***Abstract*—One of the main problems of small companies is not knowing how to properly manage investments, resources, strategies, tools and responsibilities to be more competitive, the research objective is the development of management and innovation processes required by the new company for its permanence in the market and decision making to be carried out every day; small companies face the competitiveness of new products that emerge. Today there are a great variety of products, which are globally interconnected, therefore it is required to implement a structural equation model for its management, so that the company continuously improves and optimizes the available resources, therefore as a result is the management, focused on greater effectiveness of resources; so it is necessary that small businesses need to manage a model of investments, resources, tools and responsibilities to obtain support from the competitiveness of the market; which would allow it to be oriented to a sustainable development and be one step ahead of the competition.**

Keywords*—Competitiveness; continuous improvement; management; optimization; strategies

I. Introduction

Currently innovation has taken great importance in the small business sector to be sustainable in the market must have an analysis of the variables that determine the operation of a process in the execution of actions of the main factors that allow to achieve the goals, objectives and effectively complete the assignment tasks for which they were programmed, to achieve this should be considered to control complex processes with the help of different components for continuous improvement and have business success in a competitive environment [1].

In order to be competitive in the market, productivity must be increased and the quality of the products must be improved to achieve this, the implementation of technology and innovation that allows greater speed and optimal production is applied companies that work with various tools, devices and process control equipment must maintain the controls in operation for it is necessary to apply reliable and efficient tools [2].

For the role of innovation, it is necessary for the company to apply knowledge management, in order to obtain a higher level of commitment to achieve added value and be more competitive to achieve this, efficient and appropriate tools are needed to allow immediate solutions to problems, process control helps us to identify a system of continuous improvement for decision making in the company and optimize resources and goods, so as to ensure the effectiveness and efficiency in the process centers, opting for a mechanism for sustainable development, which was designed as a factor of organizational competitiveness [3].

A new work scheme allows to improve the processes and activities in a way to acquire a sustainable development from the point of view of the industry this has widely developed models of continuous improvement that allow to define the processes dedicated to the engineering components and where the most used technique is applied to break down the vision of the business in the strategic objectives, the establishment of different control panels allows to apply a model of development of techniques to manage the system, mainly of the processes of programming models and perform the analysis of the levels of innovation, the main results indicate that innovation has taken importance in identifying the factors of competitiveness, which affects the momentum of activities and generates value in the growth and development of economic sectors of companies that is becoming increasingly competitive [4].

II. Literature Review

Identified the wide variety of aspects that affect the organization of the company, such as planning and production control determining the anticipated way to raise objectives and scenarios that allow to organize and intend to achieve the established programs, to verify the work process or management in an organized and fast way, this control arises from the need to monitor the operations of productive process as the operation of different activities of the quality of products and services obtained [5].

The author in [6] raised a system that allows research to search, check and establish the objectives outlined, innovation generates competitive advantage to seek strategy that will enhance the sector of a not too distant future to develop the quality of resources and have the strategic management that leads organizations to be one step ahead of competitors [7].

The author in [8] manifests a research plan to analyze the state of available activities and resources and innovate performance in the relationship of obtaining competitive ability [9]. The internal control system of innovation processes allows to implement the improvement of business management of the sector [10]. The tool to achieve a better development of this internal control of research and innovation, establishes

activities that ensure safeguarding the identity assets of the information of the result records, to take indispensable action in the continuous improvement of the company, so that it identifies the activities that generate greater added value and be more competitive [11].

The author in [12] indicated, the entrepreneurial capacity of the productive sector has become the main essential element of the sustainable competitiveness of the sector, so the ability to innovate has allowed to achieve sustainable development, which is a major factor of a new environment to know better methods that is to innovate and improve these establishing ways that cause changes in products, processes and organizational systems, for such reasons companies must become aware in innovation that allows to generate competitive advantage [13] (Fig. 1).

A. *Competitiveness and Innovation in the Perspective of Business Development*

The author in [14] indicates the application, is oriented in developing and implementing standard controls with features applicable to the environment that interact the activities or processes in strategic plans.

The author in [15] mentioned that innovation is increasingly relevant in the agenda of entrepreneurs, the organizational model has been articulated from the control of production that allows to seek precisely the strategy for decision making in planning and innovate and be more competitive, in a changing world it has become a commonplace that innovation is key in the competitive construction in companies and sectors to continuous growth in innovation aspect, which allows to generate research and development centers or productive dynamics to realize and determine the main systemic approach [16].

The author in [17] stated to product or service innovation that allows the high degree of improvement with respect to the characteristics of implementing appropriate and technological methods in production, distribution or service with respect to enterprise resource planning that automates business practices in operational or productive aspect of the company, allowing to implement a new method of organizations applying business practice [18].

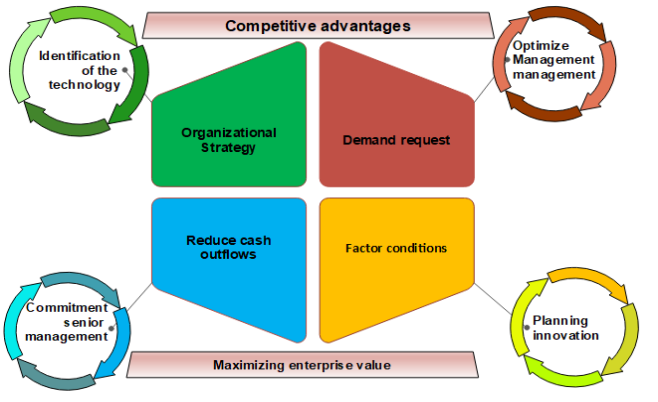

Fig. 1. Key Factors to Generate Competitive Advantage.

The author in [19], pointed out, the emergence of new marketing channels, has enabled the revolution of the application of technology and driven the change of market behavior that allows to obtain the business strategy, in achieving competitive advantage in innovation to learn the right mechanisms and put them into practice, the value of the premise that allows differentiation and positioning against the competition. Definitely [20]. Aspects allow to intervene in business development to have a more accessible notion and obtain results that bring benefits for research and knowledge to facilitate innovation in the generation of new ideas, novel and competitive products [21]. Therefore, it is shown in Fig. 1, competitive advantages, such as technology identification, optimization, and innovation are to obtain favorable results.

Translated with www.DeepL.com/Translator (free version), the author in [22] mentions the innovation of the entrepreneur as an engine of sustainable development, a key factor of the continuous growth model and the application of technology for the introduction of market goods, methods and generation of new raw materials allows to create from an idea, invention or recognition of a need for product development. The successful introduction in the market of new products or management and organizational techniques allows to innovate or create added value, new and significant [23].

The author in [24] focused on innovate, allows to create new value in the market on the premise of competitiveness that depends on the ability to innovate and improve to achieve competitive advantage, through technological innovation in the implementation of ideas, generate value to the product, consumer satisfaction and economic growth [25].

The author in [26] defines an open model of innovating and planning management systems, in which to implement a new commercial market, allows to improve product design in the presentation and development in an appropriate manner in the formulation of the response that allows to route the successful implementation of concrete result, there are factors that condition the economic environment by globalization, which arises the new competitiveness that surrounds us in the company and unstoppable in the growth of technological development [27].

B. *Challenges of Innovation for Sustainable Business Development*

The author in [28] stated, investigating the capabilities that allows companies to drive to be more competitive in innovation to become a strategic level, which we can group into two maneuvers that allow to improve productivity through cost reduction and highly innovative products.

Defined the environment of the company with economic growth of technological development and innovation, which forces companies to be more competitive, in innovation should consider the need to ensure business sustainability to productivity to maintain and improve competitiveness based on innovation, allows to design strategies of plans in differentiation to realize current new product designs and seek the new attributes of requirements and services requested by users [29].

The author in [30] proposed to investigate and invest the mechanism of adaptation of customer need that allows to create and develop a brand image to take of reference of the value chain of the company, the different elements that integrate allow to innovate and reorient the market modeling with the business objective, we can innovate periodically performing new designs of the products by investing in research, infrastructure, equipment and technology to implement the comprehensive development of a new competitive corporate culture.

The author in [31] mentioned that organizational research allows to determine the concentration and establish an innovative culture of different type of scope, in that way to reach and determine tools that help in the capabilities to create and innovate in the organizational method, allowing the resolution of the problem to synthesize and process information about certain instance; the challenge or problems in a visual way allows the exploration of innovative solutions [32].

The author in [33] details in the method of solving questions lightly that we must determine, the process of approaching each participant in assigning the premise on what we raise to create the reality to explore all possible variables, with the achievement of specific objectives that allows to know different scenarios to enrich the structure and identify and solve problems; in which to discover the implicit or explicit needs of the user to present alternatives and solve problems by generating a series of solutions through innovative prototypes.

The author in [34] proposed to provide information opportunities to generate new ideas through innovative thinking, and show the method of generating a business model, which allows to organize the development of an innovative and viable product model consisting of the methodology to assist in improving efficiency and to visualize the effectiveness of sustainable development.

As shown in Fig. 2, the structure of linear thinking allows to apply areas of thinking, observe and identify the innovative idea that comes from the search for opportunities in the environment of the ability to perceive the needs of the organization in concentrating a design to collect optimal service with innovative thinking to understand and focus on providing solutions to problems and provide opportunities to concentrate on the activity of discovering and getting more information [35].

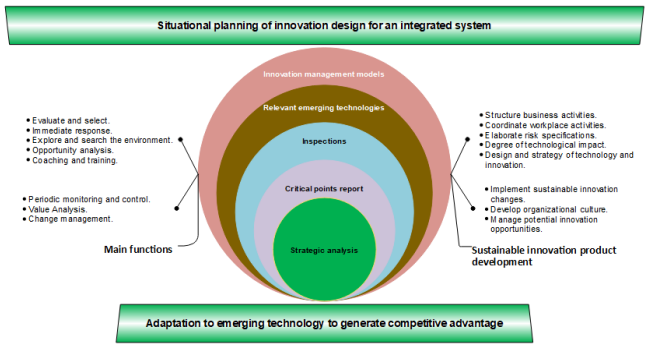

Fig. 2. Parameters of Technological Innovation Management.

The author in [36] detailed to the scheme that allows to demonstrate competitive advantage, constitute the key to improvement and sustainability that provides the perspective based on the importance of product innovation processes, productivity and sustainable development in competitive sectors and segments of companies that have the ability to improve and innovate to create and maintain capacity in a new approach to how to compete, in which it is to detect and discover segment of product and process characteristics to expand and refine the source of competitive [37].

The author in [38] manifests the dynamics of the innovative system of the first instance, promotes sustained investments as the best mechanism to circumvent the differences in productivity generated with a focus on gaining a competitive advantage, which allows to emerge the adversity of change and innovation of variables or key factors to achieve business success with a focus to be able to compete in the market, which lies in the ability of the company to innovate and maintain a competitive advantage [39].

III. Methodology

The present research encompasses a descriptive type design study of methodological approach that collects data from different aspects of the innovation system as a source of market competitiveness for small businesses, allows to perform a measurement analysis of improvements to implement and describe the behavior of the study variables, Therefore, a design is required to expose the thorough form in the studies to manifest the knowledge from the point to implement through structural equations for business development, this study aims to make a development for decision making through research that allows building elements that help identify the characteristics of analysis and diagnosis of all the factors of innovation to generate greater competitiveness [40].

The research presents a quantitative and non-experimental approach to collect data and information on small enterprises in Metropolitan Lima, allowing an analysis and diagnosis, thus concentrating on factors and variables that allow research and innovation to improve competitiveness. The units of analysis are determined in the diagnostic systems in order to propose immediate solutions that help to fulfill the functions for which they have been acquired, by prioritizing them [41].

During the research process, the redesign of the competitiveness process should be considered for continuous improvement through sustainable business development, allowing to determine and establish control parameters for this improvement, knowing any event that affects the performance of the markets to reduce the risks involved in taking measures to minimize possible losses and incorporate best practices for the implementation of methods, methodology, procedures for continuous improvement to improve the business economic development that will enable the most effective and efficient use in the available production that will allow obtaining the greatest possible amount of goods and services at a lower cost [42]. Establishing research and innovation actions to determine and minimize risks in operations, allows to establish the management to expand, optimize productivity and sustainable development of the company, in the research proposed in this document optimal decisions are made to expand capabilities in

business development that evaluates the management in a comprehensive, systematic way, taking advantage of the opportunities presented by the company [43].

The degree of competitiveness of the company is a key factor in the development for making decisions in an efficient and timely manner that allows to evaluate different areas of the company, thus being able to develop the proposed management model and the priority importance of evaluating the situation of the company to detect existing problems, establish priorities that allow to know the strengths and weaknesses and measure the productive performance of its economic activity.

IV. Results

The data analysis according to the structural methodology of the elaboration of structural equations proposed in the research methodology; starts with the reliability analysis of the instrument, evaluation of the factorial analysis, exploratory factorial analysis, confirmatory factorial analysis and elaboration of the structural equations model that performs the descriptive research of factors that obtains in carrying out the hypothesis testing ending with the results obtained. To obtain the Cronbach's Alpha with a coefficient 0.924, allows measuring the reliability of a measurement scale for the 39 items and a Cronbach's Alpha based on standardized items with a value of 0.924, by which, it indicates that there is an excellent level of internal consistency of instrument scale that exceeds the value of 0.9, explained in methodology of the present research can be observed in Table I.

TABLE I. Reliability Analysis and Diagnosis of the Instrument

Reliability statistics		
Alfa de Cronbach	Cronbach's alpha based on standardized items	N of elements
.924	.924	39

A. Item Reliability Analysis of Independent Variable

For the case of the independent variable innovation management model, the Cronbach's Alpha coefficient was obtained based on the standardized elements with a value of 0.918 higher than 0.9, obtaining an excellent coefficient in the indicators, as shown in Table II.

TABLE II. Analysis and Diagnosis of the Reliability of the Indicators of the Innovation Management Model

Reliability statistics		
Alfa de Cronbach	Alfa de Cronbach based on standardized items	N elements
.918	.918	20

B. Dependent Variable Item Reliability Analysis

It will allow to determine the degree of relationship between them, it is advisable to perform an individual analysis, for each variable and the dimension detailing the results obtained, by means of SPSS software version 25. For the case of the dependent variable source of business competitiveness of the Industrial SMEs, the Cronbach's Alpha coefficient based on the standardized elements 0.885 higher than 0.8 has been obtained, obtaining a good level coefficient in the indicators, which can be observed in Table III.

TABLE III. Analysis and Reliability Diagnosis of the Indicators of the Source of Business Competitiveness of Industrial SMEs

Reliability statistics		
Alfa de Cronbach	Alfa de Cronbach based on standardized items	N elements
.885	.885	19

C. Bartlett's Test of Sphericity Contrast Test

In the overall sufficiency analysis of the innovation management model as a source of business competitiveness of Industrial SMEs of the data evaluated with the data taken, by SPSS software version 25. With the KMO index of 0.906 given is considered an excellent value as seen in Table IV.

TABLE IV. KMO and Bartlett's Test for Integral Results

KMO and Bartlett's test		
Kaiser-Meyer-Olkin measure of sampling adequacy		
Bartlett sphericity test	Chi-square approximation	14186.893
	gl.	741
	Sig.	.000

D. Total Variance Explained

Considering the eight factors obtained in the explained variance table that should consider the existence of factors that are evidently that could not contribute the large extent of the structural equation model, for which, the use of exploratory result is required to be able to start the confirmatory analysis that could contribute to the theory of the research can be observed in Table V.

As can be seen in Fig. 3, the standardized confirmatory factor analysis values can be considered as the number of standard deviations by which the adjusted residuals differ from the zero-valued residuals, which will be associated with a perfect fit model.

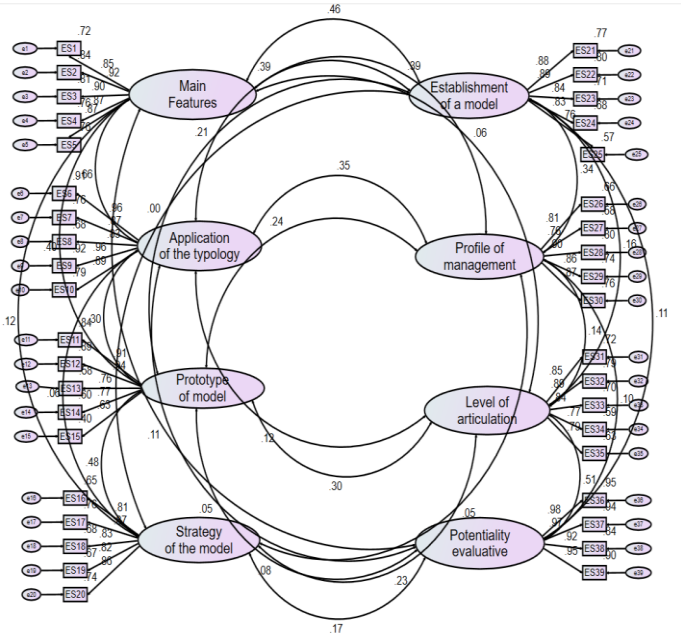

Fig. 3. Standardized Confirmatory Factor Analysis.

TABLE V. INTEGRAL EXPLAINED VARIANCE

Total, variance explained									
	Initial eigenvalues			Sums of loads squared by extraction			Sums of loads squared by rotation		
Component	Total	% of variance	% accumulated	Total	% of variance	% Accumulated	Total	% of variance	% accumulated
1	10.558	27.073	27.073	10.558	27.073	27.073	4.305	11.039	11.039

9	.654	1.677	81.808						
10	.512	1.312	83.120						
Extraction method: principal component analysis									

The results of the measurement scale adjustments of the confirmatory factor analysis model, the variables of the present research, it can be verified that most of them comply with a good adjustment of the model, specifically CFI=0.950, IFI= 0.950, TLI=0.945, NFI = 0.906 all complying with the norms with values higher than 0.90 and RMSEA= 0.053 lower than 0.08 complying with the specification of X^2 can be seen in Table VI.

The results of the fit measures of the confirmatory factor analysis model are detailed for the construction of the model and the results of the loadings of the unstandardized estimators of the structural equation model are also shown.

Fig. 4 shows the diagram of the values of the unstandardized loadings, it can be seen that it has a value greater than 0.5 from the latent variable to the observed variable; therefore, it presents an acceptable factorial loading.

TABLE VI. INDICATORS OF MODEL FIT MEASUREMENT

Statistics of model fit measurement indicators		
Absolute Adjustment Measures		
X^2	Chi-square and significance level (p)	1379.236
GFI	Goodness of Fit index	0.838
RMSEA	Root mean square error of approximation	0.053
NCP	Nocenttrality Parameter	705.236
RFI	Relative fit index	0.897
ECVI	Expected cross-validation index	4.278
RMR	Root mean square residual	0.043
Incremetal Adjustment Measures		
AGFI	GFI adjusted goodness of fit index	0.812
CFI	Comparative fit index	0.950
IFI	Incremental fit index	0.950
TLI	Tucker Lewis index	0.945
NFI	Normed fit index	0.906
Parsimony adjustment measures		
X^2	Normalizada X^2 / d.f.	2.046
PNFI	Parsimony normed fit index	0.824
PGFI	Parsimony goodnee of fit index	0.724
Others		
AGFI	Corrected goodness-of-fit index	0.812

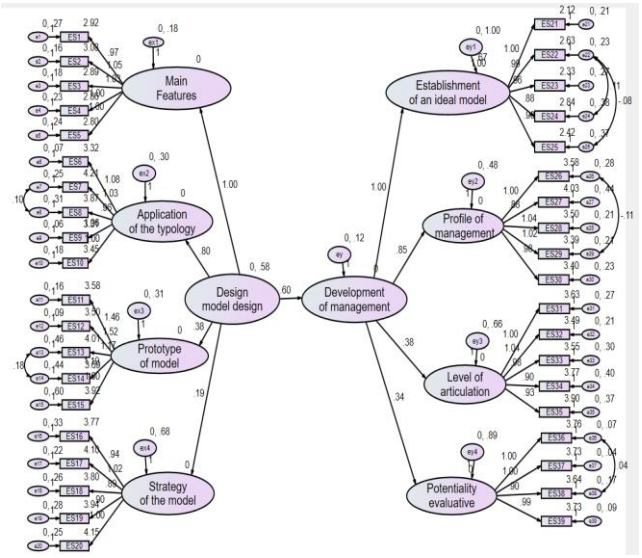

Fig. 4. Diagram of Non-Standardized Load Values.

The model with the correlations created in the described errors, by suggestion shows 693 degrees of freedom, which is obtained from a different number of parameter equal to 780 and a different number to parameter to estimate 87 obtaining 693 of difference (780-87=693), the changes that were made in this model in a definitive way, the structure equation that shows the values of adjustment measures, the results of the adjustment measures of the model of the structural equations of the variables of the present investigation are obtained, it will be possible to verify that it fulfills the majority in good adjustment of model that specifies CFI= 0. 951, IFI= 0.951, TLI=0.947, NFI=0.907, all complying with the norm of being equal to or higher than 0.9 and including X^2 = 2.003, which has a value between 2 and 5, by which, the model allows to obtain a good quality can be appreciated in Table VII.

Fig. 5 shows the diagram of improved specific values with unstandardized loadings. It can be seen that it has a value greater than 0.5, from the latent variable to the observed variable, therefore, it presents an acceptable factorial loading.

TABLE VIII. STATISTICS OF MODEL FIT MEASUREMENT INDICATORS

Statistics of model fit measurement indicators		
Absolute adjustment measures		
X^2	Chi cuadrado y nivel de significancia (p)	1376.142
GFI	Goodness of Fit index	0.840
RMSEA	Root mean square error of Appoximation	0.052
NCP	Nocenttrality Parameter	689.142
RFI	Relative fit index	0.899
ECVI	Expected cross-validation index	4.199
RMR	Root mean square residual	0.096
Incremental adjustment measures		
AGFI	GFI Adjusted goodness of fit index	0.818
CFI	Comparative fit index	0.951
IFI	Incremental fit index	0.951
TLI	Tucker Lewis index	0.947
NFI	Normed fit index	0.907
Parsimony adjustment measures		
X^2	Normalizada X^2 / d.f.	2.003
PNFI	Parsimony normed fit index	0.841

AGFI	Índice de bondad de ajuste corregido	0.818

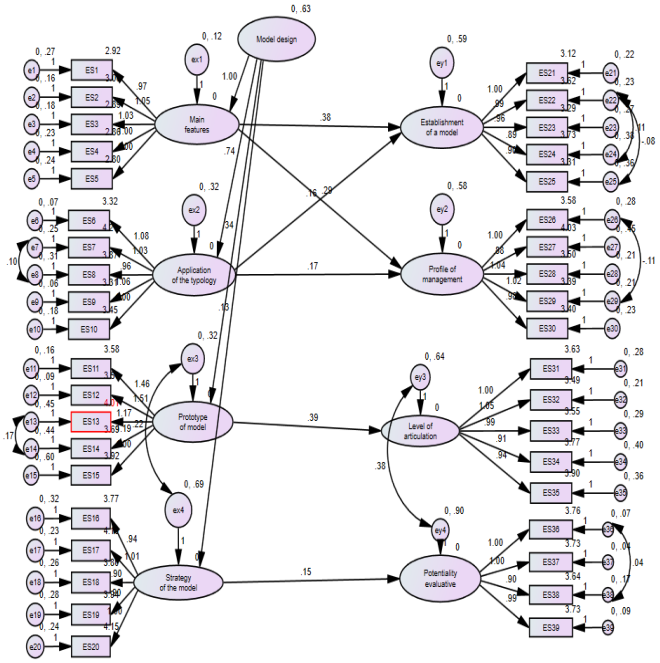

Fig. 5. Data Taken by AMOS software Version 24.

The detail of structural equations of the specific model considering X1: Main characteristics of the business management of industrial SMEs; X2: Generate the typology of industrial SMEs; X3: Prototype of integral system model; X4: Strategy of the proposed integral model through its business application; Y1: Establishment of an ideal model; Y2: Profile of business management; Y3: Level of articulation of variables and cause-effect relationships; Y4: Evaluative potentiality of its parameters in an exact manner, can be seen in Table VIII.

TABLE IX. SPECIFIC EQUATION MODEL

Integral system model plan indicators
X1 = 0.917 (X) + 0.119
X2 = 0.721 (X) + 0.323
X3 = 0.429 (X) + 0.321
X4 = 0.120 (X) + 0.688
Y1 = 0.373 (X1) + 0.589
Y2 = 0.301 (X1) + 0.582
Y3 = 0.292 (X3) + 0.640
Y4 = 0.129 (X4) + 0.900

E. Specific Hypothesis

In the specific hypothesis test of the result base of the specific theoretical model of structured equations, in the research methodology allows to obtain the data for a better interpretation of the specific hypothesis test, it will be based on the equation of the research methodology of the equations of the following table, it can be observed in Table IX.

TABLE X. REGRESSION FOR HYPOTHESIS TESTING OF SPECIFIC STRUCTURAL EQUATION

Hip.	Y = λX + Error		**λ**	**C.R.**	**P**
	(λ Non-standardized)		**Standardized**		
H1	Y1 ← 0.353 (X1) + 0.340		0.051	6.677	***
H2	Y2 ← 0.173 (X2) + 0.165		0.050	3.302	***
H3	Y3 ← 0.246 (X3) + 0.331		0.075	4.413	***
H4	Y4 ← 0.180 (X4) + 0.210		0.062	3.37	***

From the results obtained from the regression line of the structural equation model H1, H2, H3 and H4, a positive standardized loading greater than 0 is observed, validating the base of the equation $p<\alpha$ (α=0.05) can be verified, for which, the hypothesis (H0) is rejected and the alternative hypothesis (Ha) is accepted. It allows specifying if there is influence between the independent and dependent variables.

V. CONCLUSION

The main contribution of the research allows building the design of the innovation management model as a source of business competitiveness of industrial SMEs, which is strictly related to the hypothesis in alignment with the objectives of the problems posed in this research.

a) H1 was tested, therefore, it can be stated that the main characteristics of the business management of industrial SMEs and the establishment of an ideal model there is a highly significant direct relationship between the variables.

b) H2 was tested, therefore, it can be stated that the application of the typology of industrial SMEs improves the

profile of business management. There is a highly significant direct relationship between the variables.

c) H3 was tested, therefore, it can be affirmed that the prototype of the integral system model improves the level of articulation of the variables of cause-effect relationships. There is a very significant direct relationship between the variables.

d) H4 was proved, therefore, it can be affirmed that the strategy of the proposed integral model through its business application improves in evaluative potentiality of its parameters in an exact way. There is a very significant direct relationship between the variables.

***Abstract*—The COVID-19 pandemic has remained a global health crisis following the declaration by the World Health Organization. As a result, a number of mechanisms to contain the pandemic have been devised. Popular among these are contact tracing to identify contacts and carry out tests on them in order to minimize the spread of the coronavirus. However, manual contact tracing is tedious and time consuming. Therefore, contact tracing based on mobile applications have been proposed in literature. In this paper, a cross platform contact tracing mobile application that uses deep neural networks to determine contacts in proximity is presented. The application uses Bluetooth Low Energy technologies to detect closeness to a Covid-19 positive case. The deep learning model has been evaluated against analytic models and machine learning models. The proposed deep learning model performed better than analytic and traditional machine learning models during testing.**

***Keywords*—Contact tracing mobile application; coronavirus; COVID-19; deep neural networks**

I. Introduction

In March 2020, the coronavirus disease (COVID-19) was declared a pandemic by the World Health Organization [1]. Since then, relentless efforts were put in place by several nations to understand the virus and how to contain the pandemic. One of the promising approaches is digital contact tracing [2]. Contact tracing has been used to follow the pattern of networks for an individual or population infected by an infectious disease. In the past, contact tracing has been used to combat sexually transmitted diseases, severe acute respiratory syndrome (SARS) and other invading pathogens [3]. Traditionally, there have been various contact tracing models including Individual-based simulation models; Pair approximation models; Models based on branching processes; and Phenomenological approaches [4]. These come with various challenges such as the inability for stochastic simulation-based models to be analysed analytically. Other challenges are associated with contact structure itself, backward- and forward tracing, identification of Super-spreaders, endemic equilibrium and efforts required for contact tracing [4]. The effectiveness of various contact tracing mechanisms has been presented by Klinkenberg et al [5].

In recent years, digital contract tracing has been championed to supplement the deficiencies introduced by traditional contact tracing. For example, a mobile contact tracing application was developed to trace and monitor Ebola epidemic in Northern Sierra Leone and proved to be effective [6]. Similarly, Sacks et al. developed a smartphone based mHealth application using CommCare and business intelligence software Tableau to assist in contact tracing of Ebola epidemic in Guinea [7]. Swanson et al. [8] gives details on the performance of contact tracing in Liberia during the 2014 to 2015 epidemic. Other uses of mobile phones in contact tracing have been used in tracing the spread of Tuberculosis (TB) [9]. Furthermore, the outbreak of COVID-19 and subsequent declaration as pandemic has seen a proliferation of mobile applications aimed at contact tracing to help combat COVID-19 [10] [11]. These applications have proved effective in tracing contacts in order to contain the pandemic [2].

In early days of COVID-19 pandemic, Singapore developed a COVID-19 contact tracing mobile app called "TraceTogether" [12]. This app uses Bluetooth technology to facilitate contact tracing. The app further uses the received signal strength indicator (RSSI) values detected from other mobile devices for distance estimation. The detected RSSI values are then compared against calibrated RSSI values to determine distance between mobile devices. The app notifies users when they are exposed to COVID-19 and are in close contact to other users who are using the same app. It also allows users to access their COVID-19 health status. The app uses a BlueTrace protocol to preserve privacy. The reference

implementation of the BlueTrace is referred to as OpenTrace [13]. Through the Ministry of Health, the app provides guidelines on how to avoid getting infected. In case one tests positive for COVID-19, the data is then shared with Ministry of Health. The Bluetooth data is kept on the phone no longer than 25 days. Despite being useful, the application has been criticised for the potential in being exploited in undertaking criminal investigations by the police.

Similarly, a National Health Service COVID-19 app was developed in England and Wales [14]. The app gave an option to users to enable contact tracing. It was reported that the effectiveness of the app towards reducing infections was dependent on the number of users. Bluetooth RSSI values were used to estimate distance between two close devices. Several RSSI values were taken and then used to determine the distance. Another contact tracing app called Immuni was developed in Italy by the Ministries of Health and Technological Innovation in 2020 [15]. The app used Bluetooth technology to facilitate contact tracing. The distinguishing functionality of the app was the absence of a centralized database to manage contact tracing. For users willing to use the app, they would download the data to support contact tracing in their smartphones and a decision made locally in case the users were exposed. Privacy concerns were also addressed in the development of the app in line with the national laws.

A contact tracing app called "Radar Covid" was developed in Spain in 2020 [16]. Users of the app received notifications when they were in close contact with a COVID-19 positive person. The app used Bluetooth low energy technology to detect if the user is in close proximity to a positive case. The app was voluntary and addressed the privacy and security concerns of users. When the user test positive, the user is presented with an anonymous code that can be entered into the app voluntarily. This in turn facilitated the notification of other users in case they had been in contact with a positive case. Despite being useful the app had a vulnerability that allowed attackers to use fake identities.

In 2020 Apple and Google joined forces to develop application programming interfaces (APIs) to facilitate contact tracing [17]. The technology adopted was Bluetooth owing to its availability in virtually every mobile device. The APIs are used to detect contacts typically within two meters for a period exceeding 15 minutes [18]. As pointed out in [17], the APIs have addressed privacy concerns by preventing access to user profiles by health authorities.

Other technology-based contact tracing mechanisms to fight COVID-19 has been employed previously. For example, a combination of machine learning classification algorithm and data obtained from Wi-Fi signals from users was proposed to determine when two users sharing the same physical space can inform exposure [19]. In [20], a framework based on IoT was proposed for contact tracing. They incorporated symptom-based detection ignored in other tracing models to confirm COVID-19 cases. The work proposed by Sahraoui et al used online social network to trace COVID-19 infections [21].

Despite the many works presented on contact tracing, there is more to be done for digital contact tracing to be appreciated in future. One challenging issue is privacy and protection of user data. In this paper, we present a cross platform contact tracing application that uses Bluetooth Low Energy Generic Attribute Profile (GATT) framework and deep neural network to determine and inform users of exposure to COVID-19. GATT framework is used to mitigate the many concerns regarding data privacy and protection. The data exchanged between Bluetooth devices embedded with GATT framework is encapsulated thereby authorizing only intended recipient. The deep neural network is applied to predict the distance between communicating devices. Using GATT framework to encapsulate packets exchanged between devices and deep neural network to predict distance has not been presented in literature. Hence the proposed approach presents novelty and contribution of this paper.

The rest of the paper is structured as follows. In Section II we review the literature related to this work. Section III presents the Received Signal Strength Indicator (RSSI) obtained from Bluetooth Low Energy (BLE) devices. In Section IV, a logarithmic distance path loss model applied in this work is presented. A decision tree is presented in Section V. The proposed deep neural network model that uses the RSSI is reported in Section VI. A comparison of performances of models is presented in Section VII. Section VIII reports the development of a cross-platform contact-tracing mobile application. The conclusion appears in Section IX.

II. Related Work

In order to aid with the digital contact-tracing process, a number of mobile applications have been developed worldwide [11]. These applications have proved effective in tracing contacts in order to contain the pandemic [2]. However, despite being useful a number of challenges still remain [22]. These include security and privacy concerns by users sharing the data, transparency, the effectiveness of the tracing application, social and cultural issues, legal and ethical issues and many more [23]. Megnin-Viggars et al. [24] identifies other barriers and factors to engaging in contact tracing during an infectious pandemic such as COVID-19. To mitigate some of the challenges and barriers to digital contact tracing, researchers have proposed various solutions. For instance, blockchain technology has been proposed to preserve privacy during contact tracing for COVID-19 pandemic to gain trust by users [25][26][27]. According to [26], it was reported that blockchain technology was able to detect unknown cases of COVID-19. The application was also capable of enabling individuals to use the mobile application to predict the probabilities of being infected. The study paved way for the use of blockchain technology to contain the spread of the epidemic as well as early detection of unknown infections.

The works in [28], proposed a smart contact tracing mobile application that uses Bluetooth Low Energy (BLE) and machine learning techniques. The application determined whether the user was at risk or not depending on whom they came into contact with. An analytic proximity estimation model based on RSSI was particularly used to determine the distance between two devices. Five machine learning classifiers were considered in the estimation of distance

between devices. These were Support Vector Machine, Decision Tree, Naïve Bayes, Linear Discriminant Analysis and K-Nearest Neighbors. It was reported that the Decision Tree classifier yielded the best accuracy compared to other classifiers.

In [29], authors presented a contact tracing application for wearable devices that employs machine learning. The application used BLE for distance estimation whereas machine learning was applied to categorize the risk of possible exposure. Additionally, an appropriate signature protocol was used to guarantee infected user anonymity. The authors studied four supervised-learning classifiers namely Decision Tree, Linear Discriminant Analysis, Naïve Bayes and K-Nearest Neighbours. It was reported that the classifiers performed well and yielded good precision and recall values. The Decision Tree classifier was reported to yield the best performance in terms of precision, recall, accuracy among others.

In [30] authors proposed a BLE application that monitors location patterns of old people indoors. The system relied on RSSI to estimate the positions of these elderly people. To achieve this, BLE beacons were either attached to a person's clothes or worn on wrists. Further the users could also place the beacons in their pockets. The beacons were periodically sending broadcasts. These broadcasts were detected by a number of BLE enabled Raspberry Pi devices that were stationed at fixed known locations. The broadcasts carried the RSSI among others. Each Raspberry Pi then relayed the received data to a server for additional processing. The server ran a machine-learning classifier to determine the location of the person. A path-loss model was used for estimation of distance from RSSI. Further a number of classifiers were used and these are Naïve Bayes, Random Forest, BayesNet, Sequential Minimal Optimization and J48. In overall the performances of classifiers were good for indoor localization.

A dependence of RSSIs on distance for iOS and Android mobile devices was reported in [31]. According to [31], the iOS device was used in that study, the RSSI reached an asymptotic value (where the RSSI appears not to change) earlier than the Android device. It was further reported that the RSSI detected on the Android phone used decreased gradually compared to the iOS device. In terms of temporal RSSI variations, the Android device exhibited more variations compared to iOS. Therefore, according to the study [31], the dependence of RSSI on distance varies between iOS and Android devices.

In a related work [32], an evaluation of a contact tracing mobile application in Norway based on the Google Apple Exposure Notification (GAEN) system was reported. The authors observed variations in Bluetooth attenuation levels, when alerts are generated among others between iOS and Android mobile devices. The Android device was reported to exhibit high variabilities compared to iOS devices. In another related study [33], a number of data mining models have been applied to reveal hidden patterns in patients' data in Zambia. The models include J48 decision classifier, Naïve Bayes, Multilayer Perceptron among others. These models were shown to exhibit good performance compared to baseline results. The COVID-19 cases in Zambia are reported by the Ministry of Health through the Zambia National Public Institute [34]. The contact tracing process used in Zambia prior to this work was manual and time consuming.

It is clear from the works reported above that contact-tracing apps have found their application in mitigating the spread of COVID-19 pandemic. In terms of distance estimation, a number of models have been reported in the literature. These include simplistic path loss models as well as several machine learning models. Nevertheless, no work has considered GATT framework to encapsulate user data in order to mitigate the concerns regarding data privacy and protection. Furthermore, no work has used deep neural network to predict the distance between communicating devices. Thus, in this paper we propose deep learning methods to estimate distance between the devices and the GATT framework to encapsulate the data between communicating devices in order to secure user data. The proposed deep learning model is compared against some models reported in the literature. The deep learning model is further converted to models suitable for use in a contact tracing mobile application. We further developed a cross-platform contact-tracing app for use in Zambia that incorporates these models.

III. Received Signal Strength Indicator

The Received Signal Strength Indicator (RSSI) is a measure of the signal strength detected by a receiving device [35]. The RSSI is manufacturer dependent and can vary even at a fixed separation between the sending and receiving Bluetooth Low Energy (BLE) devices [35]. Factors such as multipath propagation, scattering, shadowing, refraction among others affect BLE signals and this has implications for applications that rely on BLE such as those for contact tracing [36]. The RSSI can be reasonably mapped to a distance from the sending device on iOS devices. However, the quality of RSSI on Android devices varies significantly due to presence of several chip manufacturers [35]. Nevertheless, a variation of this quantity with distance from a sending device can be used as a distance measure [35].

In this work, we relied on BLE RSSI to determine distance between two devices. Measurements were initially taken at several separations between two devices. It was observed that even when the distance was fixed, the RSSI reading was changing as reported in [35]. Measurements were taken at several distances between two devices beginning with an initial separation of 4 m to a final separation of 0.1 m in steps of 0.1m. At each distance, several RSSI measurements were repeated (twenty in this case) and the mean determined. Fig. 1 shows the dependence of the mean RSSI in decibels on actual distance separating two devices in meters. The signal originated from an iOS device (iPhone 7 Plus) and the RSSI was detected on an Android device (Infinix Smart HD). As can be seen from Fig. 1, the mean RSSI follows a particular trend despite the fluctuations as the distance between devices changes.

Similar measurements were undertaken for signals originating from an iOS device (iPhone 11) and detected on another iOS device (iPhone 7 Plus). Measurements were also undertaken for signals originating from an Android device and detected on an iOS device (iPhone 7 Plus). It was observed that

RSSI values decrease in general as the distance increased in all cases. However, variations of RSSI on distance were different for each case. The calibration results of mean RSSI at 2m separation for various devices has been reported for TraceTogether contact tracing app as used in OpenTrace [13]. The results shown in Fig. 1 at a separation distance of 2 m are in agreement with OpenTrace calibration results.

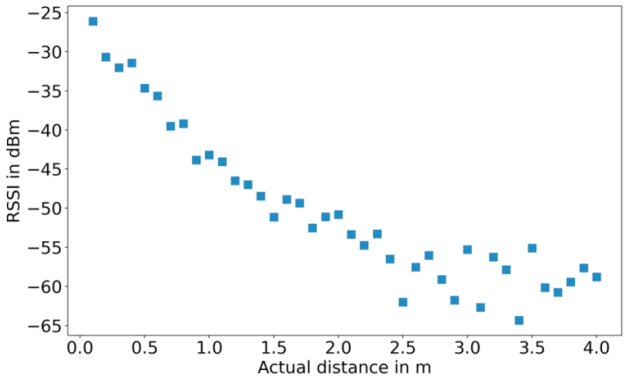

Fig. 1. Dependence of Mean RSSI in dBm on Actual Distance between Two Devices in Metres. The Signal Originated from an iOS Device (iPhone 7 Plus) and Detected on Android Device (Infinix Smart HD).

IV. Logarithmic Distance Path Loss Model

One of the simplest models relating RSSI to distance is the logarithmic distance path loss model [37]. This model is expressed as:

$$RSSI = - 10n \log(d/d_0) + A + X_\sigma \quad (1)$$

where n is an environment dependent path loss parameter, d is the distance from the sending device to the receiving device, d_0 is a distance where the RSSI takes the value A. X_σ is a random variable that follows a Gaussian-distribution. X_σ has zero mean and a variance of σ^2.

Taking the mean of equation (1), one obtains

$$RSSI_{mean} = -10n \log(d/d_0) + A_{mean} \quad (2)$$

where $RSSI_{mean}$ represents the mean RSSI. A_{mean} is the mean RSSI at distance d_0.

According to equation (2) the distance between two devices is then given by

$$d = d_0 10^{(Amean - RSSImean)/(10n)} \quad (3)$$

A. Optimization of Logarithmic Distance Path Loss Model

In order to apply the logarithmic distance path loss model to predict the distance between devices given the mean RSSI, suitable values of A, d_0 and n appearing in equation (3) were needed. A model function was created in python that returned the predicted distance given the mean RSSI, the values A, n and d_0 according to equation 3. As mentioned in Section III, various values of RSSI for measured actual distances were recorded. Some of these values and associated measured actual distances served as a data set to fit the model as shown in equation 3.

A built-in function called curve_fit in the python scipy module was used to fit the model appearing in equation (3). The curve_fit function uses nonlinear squares to fit the model to the data. The inputs to the curve_fit function were the model function as described before, the mean RSSI data, and the corresponding measured actual distances and the parameters d_0, A and n. The curve_fit function then returned the optimized values of n, A and d_0. The optimized values where latter used in the model to predict the distance between two devices.

V. Decision Tree

Decision Trees are a popular supervised learning method that can be applied in classification and regression problems [38]. They are capable of learning decision rules from the training dataset. These rules are usually expressed in form of if-then statements. When used in regression the decision tree model is piecewise smooth. According to [38], a Decision Tree can be set to have a certain maximum depth. However, as the depth increases, the tree rules tend to be complicated and such a tree is prone to overfitting.

In this work a Decision Tree was trained using various RSSI values in order to predict the distance between devices. The scikit-learn library [38] was used to implement the Decision Tree. The original dataset was first split into training and test sets. The training set comprised 80% of the original data whereas the test set comprised 20%. The training features were the RSSI values whereas the training labels were the actual distance between devices. A fit was then done on the training dataset. The fit was undertaken for models with varying maximum depth. It was observed that fitting was poor for models with small maximum depth, typically less than 5. A model with a maximum depth of 5 was therefore chosen. This model was then used to make predictions on the test dataset. It was observed that the larger the maximum depth model, the better the model fits the training dataset. However, models with larger maximum depths could not perform well when applied on the test set.

VI. Deep Neural Network Model

Deep learning is a subset of machine learning that is applied in several fields [39]. As pointed out in [39], in deep learning an artificial neural network consisting of multiple layers is used to model a problem. Among the layers are an input layer, a number of hidden layers and an output layer [39].

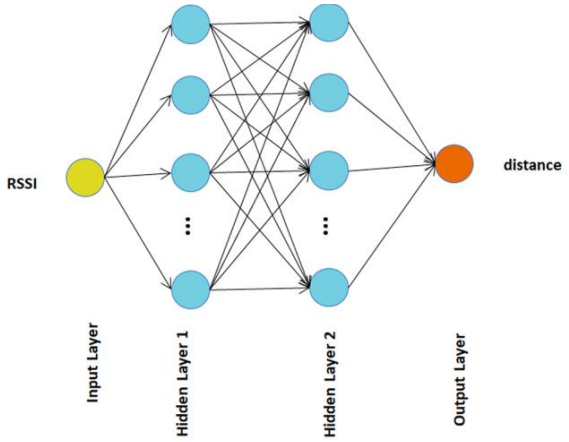

Fig. 2. Deep Neural Network Architecture for Predicting Distance between Two Devices.

In this work we propose a deep neural network (DNN) model to determine the distance between two devices using RSSI levels. Fig. 2 shows the deep neural network architecture for determining the distance between two devices. The input layer comprised one artificial neuron representing the RSSI signal which was subsequently normalized. For normalization, two quantities were first computed from the dataset. These are the mean and standard deviation. The normalized RSSI values were then computed by subtracting the mean from the original values and dividing the obtained result by the standard deviation. Two fully connected hidden layers were used in this study. The output layer predicted the distance between two devices. The programming language used to implement the model was python. The particular library used was tensorflow [40] and keras [41] as the application programming interface. The Rectified Linear Unit was used as the activation function. The Adaptive Moment Estimation (Adam) optimizer was chosen for this work. The learning rate was set to 0.01 as this was found to be appropriate. The loss function considered was the mean squared error. The original dataset for each platform was split into training and test sets where the training set comprised 80 percent of the original dataset. During training using keras, 10% of the training data was used for validation and the number of epochs was set to 200.

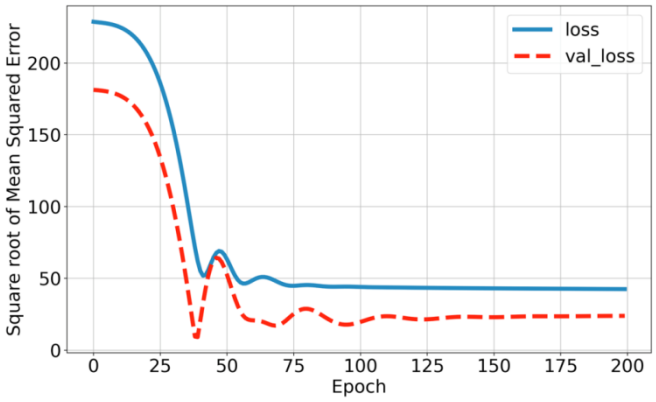

Fig. 3. Dependence of Square Root of Mean Squared Error on Epochs on Training Set (Loss) and Cross-Validation Sets (val_loss).

Fig. 3 shows the dependence of square root of mean squared error loss function on epochs. The loss functions on training set (loss) and cross-validation sets (val_loss) are shown in the Fig. 3.

The deep neural network model for each operating system was later converted to a model to be incorporated in a mobile application. For the iOS operating system, the model was converted to a coreml model using coremltools [42]. For the Android operating system, the model was converted to a tensorflow lite model according to [43]. As reported in [35], the RSSI is manufacturer dependent, therefore even for the same operating system, it varies from a device from one manufacturer to another.

VII. Comparison of Deep Neural Network, Decision Tree and Logarithmic Distance Path Loss Models

The accuracy of the deep neural network (DNN) model predictions was compared with the decision tree and logarithmic distance path loss model (LDPL). The root mean square deviation (RMSD), computed as the square root of the mean squared error (MSE) was used for the comparison. Equation 4 shows how the MSE is computed.

$$MSE = (1/(N-1))\ \Sigma_i\ (y_{predicted,i} - y_{true,i})^2 \quad (4)$$

In equation 4, $y_{predicted}$ represents the estimated target values, y_{true} represents the ground truth (correct) target values and N is the number of elements in the population. The MSE was determined using the mean_squared_error builtin function in a python sklearn.metrics module [44].

The root mean square deviation (RMSD) was then obtained according to equation 5.

$$RMSD = (MSE)^{1/2} \quad (5)$$

Fig. 4 shows the predictions of the deep neural network, decision tree as well as logarithmic distance path loss models for the iOS device. The maximum depth of the decision tree was set to 5. Also plotted is the training dataset. The trained models appear to reasonably fit the training dataset.

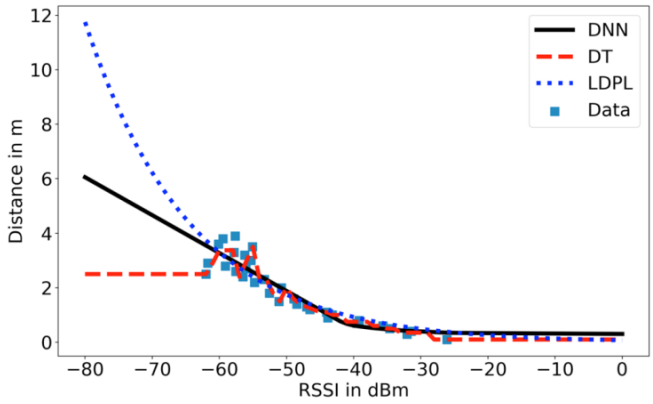

Fig. 4. Comparison of Actual Measured Data against Deep Neural Network (DNN), Decision tree (DT) and Logarithmic Distance Path loss (LDPL) Models Predictions during Training for the iOS Device.

Table I reports the RMSD computed according to equation (5) during training and testing of models. As reported in Table I, the DNN model performed better than the LDPL model during training and testing. However, the DT performed better than the DNN during training but the DNN performed better than DT during testing. This is attributed to overfitting by DT during training. Now, according to [28], it was reported that the DT performed better that the simplistic distance path loss model. This is also in agreement with the results reported in Table I.

TABLE I. Root Mean Square Deviation (RMSD) Calculation for Training and Testing the Deep Neural Network (DNN), Decision Tree (DT) and Logarithmic Distance Path Loss (LDPL) Models

RMSD on training the models in m			**RMSD on testing the models in m**		
DNN	***DT***	***LDPL***	***DNN***	***DT***	***LDPL***
0.41	0.15	0.46	0.44	0.49	0.57

The total processor (CPU) time to make model predictions on the entire training and test datasets used in Table I was

compared for the three models. Table II reports the total CPU time taken by the models in seconds.

TABLE II. TOTAL CPU TIME TAKEN TO MAKE MODEL PREDICTIONS ON THE DATASETS USED IN TABLE I.

CPU time taken during training in s			**CPU time taken during testing in s**		
DNN	***DT***	***LDPL***	***DNN***	***DT***	***LDPL***
0.091	0.00084	0.0008	0.095	0.00047	0.00098

According to Table II, the DT model took the least total CPU time to make predictions on the test dataset compared to LDPL and DNN models. However, as reported in Table I, the DNN model performed better than the DT and LDPL models in terms of predictions on the test dataset.

Owing to the fluctuation nature of the RSSI, a more accurate model for predictions is preferred despite the tradeoff in the CPU time taken to make predictions. As shown in Table II, the reported CPU times are all at sub-second level.

The processing power of mobile devices is generally lower than those of conventional desktop machines. It is worth mentioning that the DNN models have been further optimized to efficiently run on mobile devices as reported in [42] for iOS devices and [43] for Android devices. The DNN model was therefore adopted for prediction of distance between two devices.

VIII. DEVELOPMENT OF CROSS-PLATFORM CONTACT-TRACING MOBILE APPLICATION

In this work, a cross platform contact-tracing mobile application was developed. The targeted operating systems were iOS and Android. The application was developed in C# using Xamarin, a free, open source, cross-platform for building applications targeted at iOS and Android operating systems among others [45].

A number of features to be incorporated in the contact-tracing application were identified. These include the ability to detect the presence of another person running the same application on their device within an accepted range and notifying the users. The capability to notify a user if they have been exposed to a reported positive COVID-19 case in the past fourteen days was also included. In order to achieve this, the system used an already existing repository of COVID-19 patient data that contained unique diagnosis identifiers for patients. Furthermore, in case the user tested positive for COVID-19, the system was expected to provide an option to share their diagnosis identifier. This was an important feature that the application uses to notify others that they have come into contact with a positive case. A self-service feature where the user could query the application whether they have been in contact with a positive case was also included.

In order to meet these requirements, suitable technologies were identified. Bluetooth Low Energy (BLE) [46] was ideal for detecting when one user was closer to another. The Bluetooth LE Received Signal Strength Indicator (RSSI) levels described earlier were used to determine whether users were close to each other, within 2 metres for a period exceeding 15 minutes [18]. The deep neural network models described in Section VI were used to predict the distance between two users. The Global Positioning System (GPS) [47] / Cell Tower Triangulation [48] were used to determine the location in form of Latitude and Longitude coordinates. The location information was used for predicting COVID-19 hotspots.

To facilitate the contact tracing process, each mobile application user was assigned a unique random identifier that was later securely shared with another user who is in close proximity as determined by the deep neural network model. The Bluetooth Low Energy Generic Attribute Profile (GATT) framework was adopted in this case since it enables exchange of data between two devices [49]. According to GATT, the data is encapsulated in services where each service contains one or more characteristics.

The mobile application had GATT client and server capabilities. As a GATT server, the application was able to advertise services. To distinguish a mobile device running the contact tracing application from others, a unique service identifier following a universally unique identifier (UUID) format was generated for each device. Encapsulated in this service was a characteristic whose identifier was in universally unique identifier (UUID) format. The characteristic identifier was unique to the application and was used for contact tracing purposes. As a GATT client, the application was able to scan for a unique service associated with the contact tracing application and read the associated characteristics.

To implement the GATT capabilities in the application, a cross platform framework named Shiny was adopted [50]. Shiny supports BLE client and hosting among several features. This framework was also found to be convenient in that in supports backgrounding which allows an application to continue running even when sent to the background.

Fig. 5 is a top-level algorithm used to scan for BLE services, characteristics, RSSI and sending device manufacturer data among others. As shown in Fig. 5, the mobile application keeps scanning for devices and scan results are kept in a list. For every element of the list, the RSSI, manufacturer data as well as whether the device is connectable are obtained. With the obtained RSSI and sending device manufacturer data, an appropriate deep neural network (DNN) model is invoked to predict distance. In case the device is connectable, a connection was made to the device to discover offered services. The application checked for a particular service unique for contact tracing. If this service was available, the associated characteristics were obtained. The characteristics are used for contact tracing.

```
while scanning for devices:
    store scan results in a list
    for each result in a list:
        obtain RSSI, manufacturer data, IsConnectable value, and others from advertisement
        call appropriate DNN model to predict distance
        if IsConnectable value is true:
            connect to the device
            obtain discovered services
            if serviceUUID matches application UUID:

```

Fig. 5. Top-Level Algorithm for Scanning for BLE Services, Characteristics and RSSI.

The predicted distance was used in further processing such as alerting the user in case the devices were too close. Datetime information was also captured in addition to Latitude/ Longitude coordinates. This information, together with the predicted distance from RSSI, sending device manufacturer data, characteristic UUID and contact time was stored in a local database in the user's mobile device.

After collecting this information, the contact tracing mobile application then securely transmitted this information to a central database of COVID-19 cases. An application programming interface (API) using DotNet core WebAPI development framework was written that allows for data to be shared from the mobile application to the database server using JavaScript Object Notation (JSON) as an exchange data format and HyperText Transfer Protocol (HTTP) protocol as a transport medium.

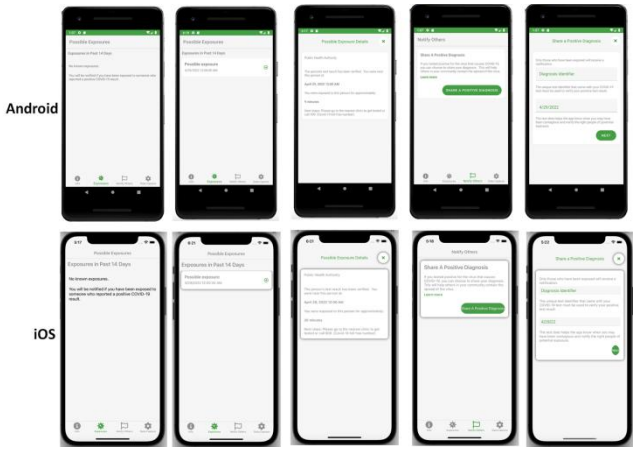

Fig. 6. Some Features of the Contact Tracing Mobile Application as Shown in Android (Top Row) and iOS (Bottom Row) Operating Systems.

A feature was also available that enables a user to determine in real-time whether they have been in contact with a positive COVID-19 case. The stored local contact tracing details for the last fourteen (14) days were then securely sent to the server and a Covid-19 database queried. If one of the contacts was recorded as a positive case in the COVID-19 database, the user was then alerted without revealing further details. To support this feature, the COVID-19 server offered a web service that was accessed through relational state transfer (REST) application programming interfaces (API).

Fig. 6 illustrates some features of the contact-tracing application. The mobile application provides real-time exposure alerts. The application also had a manual contact tracing feature to allow for positive diagnosed individuals to manually input the phone numbers of the contacts they have had met. In order to avoid abuse, a phone number verification feature was added. The application also incorporated location based services to get encrypted coordinates to be used in prediction of epicentres.

Furthermore, the Latitude, Longitude and date time information from contact-tracing applications was sent securely to the Ministry of Health databases. This data can be displayed in real-time in a map for identification of possible hotspots as shown in Fig. 7.

In this section it has been shown how the GATT framework was used to encapsulate and exchange data between Bluetooth devices embedded with GATT framework. Furthermore, the implementation of the deep neural network model in order to predict distance between communicating devices has been reported.

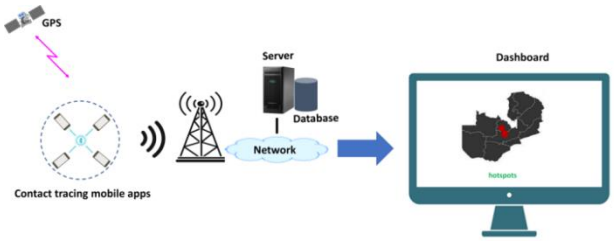

Fig. 7. Using Location and Datetime Information from Contact-Tracing Applications for Identification of Hotspots.

IX. Conclusion

A number of digital contact tracing applications have been applied world-over to facilitate the contact-tracing process. In this work, a cross platform contact tracing application that uses deep neural network models and Bluetooth Low Energy Generic Attribute Profile framework to determine and inform users of exposure to COVID-19 has been developed. The performance of deep neural network models has been evaluated against other models. The reported results show that the deep learning model performs well during testing.

The proposed deep learning model appears to learn the nonlinear relationship between distance and RSSI values better compared to analytic and decision tree models. The analytic model had four parameters according to equation 3. This suggests that the analytic model overlooked some parameters that are useful in determining the distance between communicating devices. As regards to decision trees, a major limitation is their likelihood to overfit the data on the training set as the maximum depth increases. The smaller the maximum depth, the less is the generalizing ability. On the other hand the larger the maximum depth, the larger the likelihood of overfitting on the training set resulting in less accuracy on the test set.

The developed contact-tracing application can be beneficial not only to COVID-19 prediction but also to other pandemics.

A Hybrid 1D-CNN-Bi-LSTM based Model with Spatial Dropout for Multiple Fault Diagnosis of Roller Bearing

Gangavva Choudakkanavar, J. Alamelu Mangai
Department of Computer Science and Engineering
Presidency University, Bangalore, India

***Abstract*—Fault diagnosis of roller bearings is a crucial and challenging task to ensure the smooth functioning of modern industrial machinery under varying load conditions. Traditional fault diagnosis methods involve preprocessing of the vibration signals and manual feature extraction. This requires domain expertise and experience in extracting relevant features to accurately detect the fault. Hence, it is of great significance to implement an intelligent fault diagnosis method that involves appropriate automatic feature learning and fault identification. Recent research has shown that deep learning is an effective technique for fault diagnosis. In this paper, a hybrid model based on 1D-CNN (One-Dimensional Convolution Neural Networks) with Bi-LSTM (Bi-directional Long-Short Term Memory) is proposed to classify 12 different fault types. Firstly, vibration signals are given as input to 1D-CNN to extract intrinsic features from the input signals. Then, the extracted features are fed into a Bi-LSTM model to identify the faults. The performance of the proposed method is enhanced by applying Softsign activation function in the Bi-LSTM layer and Spatial Dropout in the neural network. To analyze the effectiveness of the proposed method, Case Western Reserve University (CWRU) bearing data is considered for experimentation. The results demonstrated that the proposed model has attained an accuracy of 99.84% in classifying the various faults. The superiority of the proposed method is verified by comparing the predictive accuracy of the proposed method with the existing fault diagnosis methods.**

***Keywords*—Fault diagnosis; roller bearing; deep learning; 1D-CNN; Bi-LSTM; spatial dropout**

I. Introduction

Roller Bearing (RB) is a key component of any rotating machinery where rotation is involved. It is widely used in various industries such as transportation, agriculture, aerospace, medical domain and so on. RB is more susceptible to damage due to its continuous rotation with varying loads and pressure. Due to which there's a break-down of the entire machine which results in magnificent economic loss and severe safety accidents [1]. Therefore, it is very much essential to diagnose the roller bearing fault accurately because each fault type exhibits distinct characteristics and the fault may exist in any of the components such as Inner Race (IR), Outer Race (OR) and Ball.

Traditional vibration-based bearing fault diagnosis methods involved mainly three steps as data pre-processing, feature extraction, and fault classification. The vibration signals collected from sensors represents the information about bearing condition. In order to classify and detect the faults, many signal processing techniques have been discussed through analysis of signal characteristics in various domains such as time, frequency and time-frequency domain [2]. Due to the non-stationary nature of vibration signal, various feature extraction techniques such as Short-Time Fourier Transform (STFT), Wavelet Analysis (WA), Empirical Mode Decomposition (EMD), etc. were applied to extract the features [3]. Once the features are extracted and selected then those features are fed into the network model for classification.

Recently, Deep Learning (DL) technology has gained more importance in various domains such as image processing, natural language processing, speech recognition and so on. It uses multiple layers of the network to learn and extract relevant features from raw data and identifies the pattern for classification or recognition problems. Roller bearing's vibration data has similar dimensionality as that of image or speech. Hence, DL architecture can be used to diagnose roller bearing fault by transforming vibration signal into the framework of pattern recognition problem. DL model has an ability in automatic feature learning and classification that involves automatic feature extraction and identification of the faults accurately [4-5].

In this research, a hybrid method based on 1D-CNN-Bi-LSTM with Spatial Dropout is proposed for multiple fault diagnosis of roller bearing. Initially, one-dimensional raw vibration signal is collected and input into CNN model. Then, CNN extracts feature information from the signals and these extracted features are provided to Bi-LSTM network model to acquire the failure information to identify 12 types of bearing faults. For experimentation, CWRU dataset is being used to analyze the effectiveness of the method.

The rest of this paper is organized as follows: In Section II related work is discussed; Section III describes proposed methodology architecture which includes one-dimensional CNN and Bi-LSTM models. Section IV illustrates an experimental setup of bearing data collection; and Section V shows the discussion of results and its analysis.

II. Related Work

Many researchers have applied various deep learning models for fault diagnosis such as Deep Neural Networks [6], Long Short-Term Memory [7], Deep Belief Networks [8], Deep Auto-encoders [9], Gated Recurrent Unit Networks [10],

and Convolutional Neural Networks [11] and so on. Among these, CNN has received more importance in the study of roller bearing defect diagnosis. Abed et al. [12] proposed a robust approach for fault diagnosis of Brushless DC Motors through feature extraction and reduction using discrete wavelet transform (DWT) and orthogonal fuzzy neighborhood discriminant analysis (OFNDA) from vibration and current signals and RNN model was used for classification of faults. P. Zou et al. [13] focused on empirical mode decomposition (EMD) method which was combined with LSTM to obtain kurtosis value by extracting intrinsic mode functions (IMF) components and long-term dependencies from vibration signals to monitor the health status of an electrical machine. Cao, Lixiao et al. [14] constructed a fault diagnosis framework by extracting ten time-domain statistical features from vibration signals under varying load conditions and these features were fed into deep Bi-directional LSTM to identify the faults of Wind Turbine Gearbox. In [15], Mel Frequency Cepstral Coefficient features are obtained from vibration signals and given these features as input to Random Forest and eXtreme Gradient Boosting algorithms for diagnosis of roller bearing fault.

Zheng Wang et al. [16] discussed an architecture to obtain unsupervised H-statistic value from sensor time-series data based on deep LSTM and CNN for performance degradation valuation of roller bearing. Shichao and Haibin proposed a bearing fault diagnosis model in which 1D-CNN with LSTM is implemented, which adaptively extracted potential features from the original vibration signal and ensured the validity of the features through merging of pooling layers of max and average values to down sample the features. Then, LSTM was employed to acquire the dependencies among features of time-domain signals to perform fault classification [17]. Zhe Yuan et al. [18] presented a fault recognition approach for roller bearing using Multiscale CNN and Gated Recurrent Unit Network (GRUN) by providing multiple time scaled vibration data into the CNN to train the model and added the gated recurrent unit network to make the model predictive with an attention mechanism. In [19], the proposed adaptive anti-noise neural network architecture employed random sampling approach and boosted CNN with the exponential linear activation function to enhance the adaptability of the network without manual feature selection. GRUN was implemented to learn the features processed by CNN and classify the faults. This approach solved the problem of bearing fault diagnosis under changing load conditions and heavy noise.

Wenbing Yu et al. [20] discussed an intelligent fault diagnosis method for identifying ten different bearing faults based on lightweight MobileNet CNN by considering Western Reserve University dataset for evaluating the model and also computed average precision, recall and F1 score which resulted into 96%, 82% and 88%, respectively. Kai Gu et al. [21] discussed a novel diagnostic method to accurately identify the fault status of bearing based on LSTM and DWT for multi-sensors by obtaining fault details in both frequency and time scales through DWT and LSTM algorithm was used to characterize the long-term dependency information hidden in the time series data of a signal. In [22], a combined wavelet regional correlation threshold denoising (WRCTD) algorithm with CNN-LSTM was proposed for fault detection. WRCTD algorithm utilized the regional association of the wavelet decomposition coefficients and 3σ criterion to reduce noise in the raw sensor data and CNN-LSTM model reduced the hidden features of the pre-processed signal data to identify the fault type of the harmonic reducer under multiple working conditions. A novel fault diagnosis method was presented through application of sliding window processing to integrate the feature and time delay information from multivariate time series samples and then, the samples obtained were fed into the CNN-LSTM model to perform feature learning and capture time delay information to diagnose the fault of Tennessee Eastman chemical process [23]. A robust approach was proposed in [24] to predict the Remaining Useful Life (RUL) of roller bearing with combination of Density-Based Spatial Clustering of Applications with Noise (DBSCAN) and LSTM to detect the damage state and identify the abnormal state of bearing to estimate the RUL through feature extraction from signals. A new convolution-based bidirectional long and short-term memory network method was proposed to predict RUL, in which CNN was used to obtain feature information and BI-LSTM to acquire time-frequency information from the signals to construct health indicators (HI) and the experiments conducted on the PRONOSTIA bearing dataset showed that the proposed method performed better compared to other methods [25].

This work uses deep learning technique for fault diagnosis and it's motivated by the fact that deep learning involve automatic feature extraction whereas Machine learning needs manual feature extraction, in which prior domain knowledge and expertise is required.

III. Proposed Methodology

In this research, a multi-class fault diagnosis method is proposed based on 1D-CNN with Bi-LSTM to classify various faults. The advantage of CNN lies in automatic feature extraction and Bi-LSTM in handling gradient loss and explosion. The main goal is to diagnose the 12 different fault types using 1D-CNN with Bi-LSTM model by collecting vibration signals from CWRU dataset which contains set of ball bearings having localized faults. The proposed 1D-CNN-Bi-LSTM model consists of four convolutional and pooling layers, a Bi-LSTM layer, a LSTM layer and one fully connected layer as shown in Fig. 1.

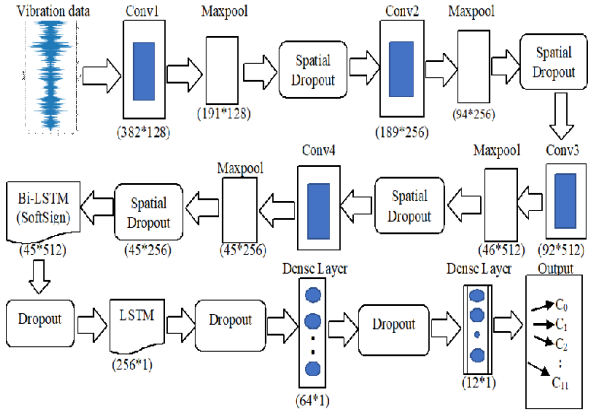

Fig. 1. Block Diagram of the Multi-class Fault Diagnosis Method.

Firstly, the raw input signals are input to the model, then convolution layers and pooling layers helps in automatic feature extraction. Next, these features are passed to Bi-LSTM and LSTM layers to highlight the features and finally, dense layer is used to classify the various faults. Bi-LSTM layer uses softsign activation function to improve the performance of the model. For verifying the effective performance of the proposed method, publicly available bearing dataset is considered [26]. The vibration data is measured for four operational conditions such as:

1) Normal Bearing- No fault, sampling frequency of 12kHz with 1797rpm (rotations/min).

2) Fault in Outer race - Sampling frequency of 12kHz with 1797rpm.

3) Fault in Inner race - Sampling frequency of 12kHz with

4) 1797rpm.

5) Ball fault- Sampling frequency of 12kHz with 1797rpm.

Details of each layer used in the proposed method is explained in the following subsections.

A. 1D-CNN

CNN is a deep learning algorithm which was originally proposed for processing of visual data. It is more effective in identifying image patterns in a stratified way from simple to complex features because of the two important properties such as weight sharing and spatial pooling. CNN consists of 3 layers namely convolutional layer, pooling layer, and fully connected layer. The convolution layer converts the input data into smaller feature maps through convolutional kernels by performing a summation of multiplications between the vectors of input data and weight coefficients [27]. In this paper, 1D-CNN is constructed, whose convolutional kernels and feature maps are all one-dimensional because of the one-dimensional characteristics of mechanical vibration signals.

Suppose 'x' is an input to 1D-CNN, then the output of the convolutional layer is computed as given in (1):

$$y_{i,\,j,\,k} = f\left(\sum_{i=1}^{m} x_{i,\,k} * w_{j,\,i} + b_i\right) \quad (1)$$

In equation (1), 'f' represents an activation function, which is typically a hyperbolic tangent, ReLu (Rectified Linear Unit), or sigmoid function; 'm' is number of samples ($1 \le i \le m$); 'p' is length of the convolutional kernels ($1 \le j \le p$); 'n' is length of the input data ($1 \le k \le n$); * represents convolution operation; $w_{j,i}$ is the weight and b_i is the bias.

The pooling layer is the sub-sampling layer to compress the size of feature maps. Down sampling is performed to minimize the dimensionality of the output from the previous convolution layer by moving the filter window from starting point to the end of feature map. Then a maximum or average of each part of the feature map is considered to represent each corresponding area. The role of pooling layer is to reduce the number of parameters and the computation in the network, so that it prevents overfitting and improves the generalization ability of the model. Max pooling is frequently used in the pooling layer which is computed as maximum of the previous feature maps. It is expressed as given in (2).

$$z_{i,\,j,\,k} = \max\left(x_{2i-1,\,j,\,k}, x_{2i,\,j,\,k}\right) \quad (2)$$

where, $1 \le l \le m/2$

Fully connected or Dense layer plays the role of classifier in CNN. For a multi-class classification problem, usually softmax is applied in the dense layer to ensure the range of output value lies between 0 and 1, and sum equals to 1. The predicted output represents the probability and value with the highest probability is considered as the final predicted result. The output of 1D-CNN is an input to the Bi-LSTM model to reduce variance in time series.

B. Batch Normalization

It is a regularization technique, which avoids model overfitting. In the training process of the deep neural networks, the distribution of inputs to the layers deep in the network which keeps changing for each mini batch as the weights are updated. This problem is known as "internal covariate shift". It delays the network to converge during the training phase. To avoid this problem, Batch normalization standardizes the input to each layer after every mini-batch and hence accelerates the network training. It is usually applied either before or after the activation functions of each hidden layer.

The process of batch normalization is shown in Fig. 2 [28]. It shifts the values of the input distribution to a hidden layer, such that the mean of these values is zero (zero centered) and then normalizes the inputs. It creates two parameter vectors for each layer, one with the scaled values and the second vector with the shifted values of the inputs to the layers.

The output scale vector 'γ' and the output offset vector 'β' are learnt through backpropagation. The final input mean vector 'μ' and the final input standard deviation vector 'σ' are estimated using exponential moving average during training.

C. Dropout

In a fully connected neural network, the probability of co-adaptation among the neurons is likely higher. As a result, the features extracted by the neurons for learning is more or less similar. This co-adaptation makes the model to overfit the training data and generalize poorly on unseen test data. Dropout is a technique to overcome this problem. It chooses a specified percentage of neurons randomly to be dropped during training by making their connection weights to zeros. Repeated application of this technique creates an ensemble of network architecture with a different set of neurons and their weights are dropped in each architecture as shown in Fig. 3(a) and (b) [29].

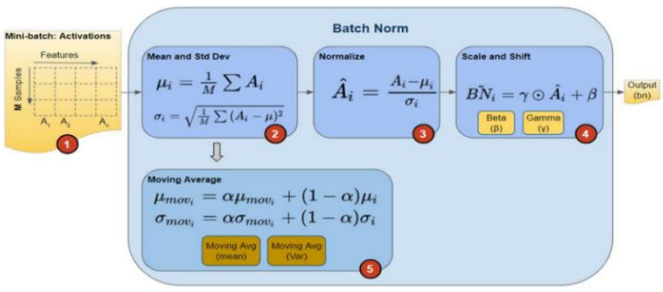

Fig. 2. Batch Normalization.

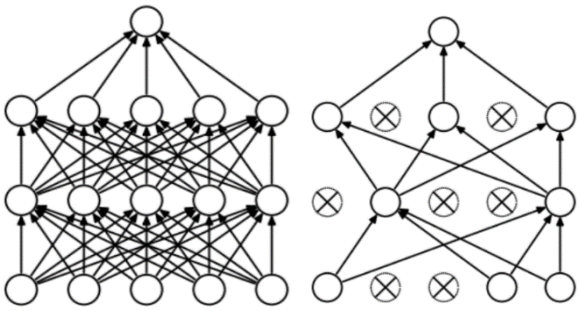


(a) (b)

Fig. 3. (a). Standard Neural Network. (b). Neural Networ with Dropouts.

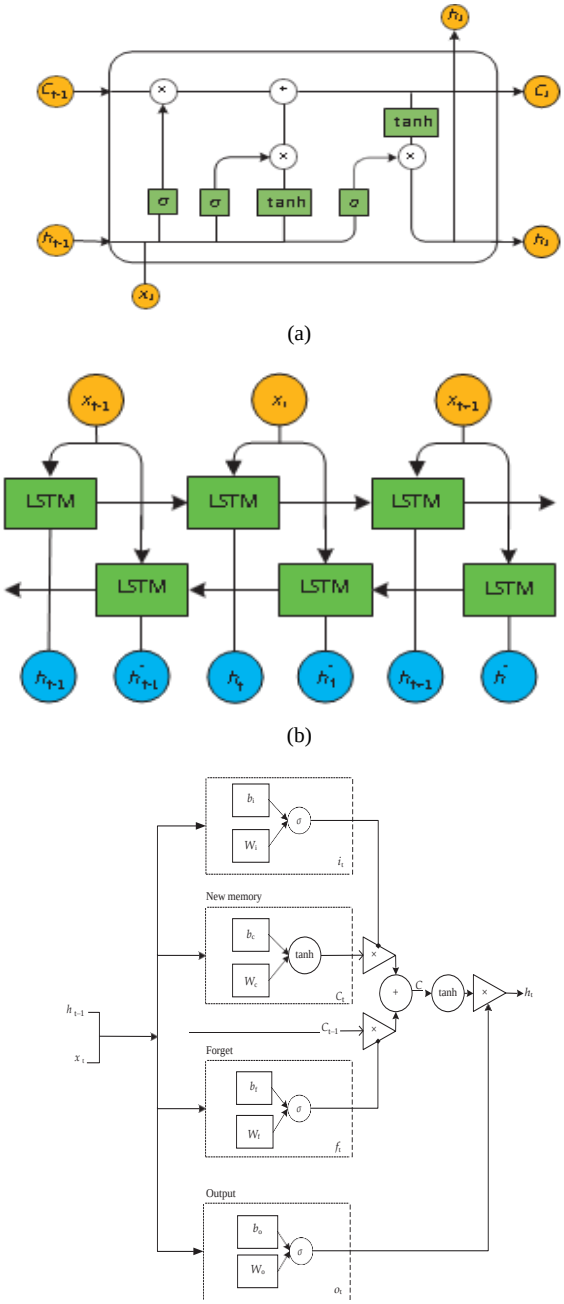
The weights of these dropped neurons are not updated during backpropagation. When some of the neurons are dropped, the other neurons take the responsibility of propagating the features to the subsequent layers of the network in the forward pass. Hence it prevents a sort of co-adaptation among the neurons and makes the network less reliable to the learning units, their weights and existence. All these factors help to generalize the model well on the test samples. Dropouts in convolutional layers are applied to the individual cells of the feature map/kernel and are called spatial dropouts. Dropouts applied to the hidden layers are regular dropouts.

D. Bi-LSTM (Bi-Directional Long-Short Term Memory)

Bi-Directional Long-Short Term Memory is a type of Recurrent Neural Network (RNN), which is a deep learning technique that is used to categorize and regress timeseries data such as audio, text forecasting and so on. Bi-LSTM combines LSTM layers from both directions. Hence, it captures long-term dependencies between signal patterns by making the flow of information in both forward and backward directions. There are 3 components in LSTM, namely i) forget gate, ii) update gate, and iii) output gate. The forget gate eliminates the irrelevant information which is received from the preceding unit. The update gate performs addition of information to the cell state, and the output gate selects the relevant information from the present cell state and gives the output [30]. The LSTM gating structure manages the information by enabling the memory cells to preserve long-term dependencies through selective passage. It avoids the problems of gradient loss and gradient explosion by strengthening the weight of relevant information and weakening the weight of irrelevant ones. The structure of the LSTM cell is shown in Fig. 4(a).

The LSTM network cannot make use of the full data while processing the time series signals because it processes the data only in one direction. Hence, the Bi-LSTM network is implemented, which contains LSTM layers overlaid on each other in reverse direction. It improves the performance by enabling the model to make efficient use of the main features. The unit structure of the Bi-LSTM network is shown in Fig. 4(b).

The internal processing of the LSTM cell is shown in Fig. 4(c).



(a)

(b)

(c)

Fig. 4. (a). LSTM Cell Structure, (b). Bi-LSTM Unit Structure, (c). The Internal Process of the LSTM Cell.

The inputs W_i, W_o, W_f, W_c represents weights and b_i, b_o, b_f, b_C represents bias vectors of input gate, output gate, forget gate and cell state respectively. The input of current state and output of the previous state is represented as x_t and h_{t-1}. The input value C_t' at moment 't' is calculated by applying the tanh activation function on the result obtained by computing the matrix product of vector $[h_{t-1}, x_t]$ with W_c and b_c as given in (3).

$$C_t^{'} = \tanh\left(W_c \cdot \left[h_{t-1}, x_t\right] + b_c\right) \quad (3)$$

The parametric value for each gate i.e., f_t-forget gate, i_t-input gate, and o_t-output gate at moment 't' is calculated by applying the activation function as shown in (4), (5) and (6).

$$f_t = \sigma\left(W_f \cdot \left[h_t\text{-}1, x_t\right] + b_f\right) \quad (4)$$

$$i_t = \sigma\left(W_i \cdot \left[h_t\text{-}1, x_t\right] + b_i\right) \quad (5)$$

$$o_t = \sigma\left(W_o \cdot \left[h_t\text{-}1, x_t\right]\right) + bo \quad (6)$$

An element-wise product of '*ft'* with the last cell state 'C_{t-1}' determines the info that is to be forgotten and remembered by realizing the control on C_{t-1} and the element-wise product of 'i_t' with the current input cell state C_t' determines the info in C_t' that needs to be stored and used. The state value 'C_t' of the hidden node at time '*t'* is calculated as given in (7).

$$C_t = f_t * C_{t-1} + i_t * C_t' \quad (7)$$

The output value 'h_t' at time '*t'* is computed as product of tanh function applied on unit state C_t, and output gate o_t, as given in (8).

$$h_t = o_t * \tanh(C_t) \quad (8)$$

E. Softsign Activation Function

The softsign function squishes its input to a range of -1 to +1 as like tanh. The function and its derivative are defined as given in (9) and (10).

$$\text{softsign } f(x) = \frac{x}{1+|x|} \quad (9)$$

$$f'(x) = \frac{1}{(1+|x|)^2} \quad (10)$$

Unlike tanh, this function has a flatter curve, its derivative descends slowly, and is less saturated. Functions that are more saturated, have their gradients vanishing quickly before reaching the initial layers of the network during backpropagation [31]. Hence, softsign solves this vanishing gradient problem better than tanh. Softsign converges in polynomial time whereas tanh converges in exponential time. Since softsign transforms the inputs between -1 to +1, the negative values enable the LSTM gates to delete the information when required.

IV. Experimental Setup

As the benchmark study, CWRU bearing dataset has been widely considered by many researchers for condition monitoring and fault diagnosis. An experimental setup of CWRU is shown in Fig. 5. It consists of a 2- hp (horsepower) motor, encoder, torque transducer, dynamometer, electric motor and so on. The deep groove ball bearing was mounted on the drive end of the motor to support the shaft which needs to be tested. An accelerometer was positioned above the bearing base of the drive end to measure the vibration signals. The load considered was about 1HP with 1772 rpm, and sampling rate of 12 kHz. Fault was induced in each component of rolling bearing by electro discharge with varying diameters of 0.007, 0.014, and 0.021 inches (1 inch = 25.4 mm).

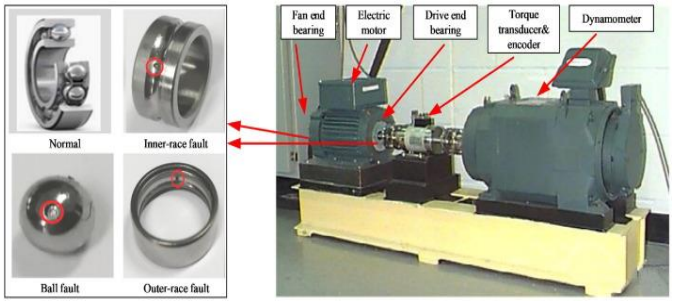


Fig. 5. Experimental Set-up of CWRU Data Collection.

In total, 12 bearing fault types with respect to BF, IR, OR and normal bearing were considered in this work as given in Table I. To label the fault types, One-Hot coding technique was used. In this experiment, to confirm adequate training size, 80% of the data was randomly chosen as training set and 20% as test set. For validation of the model, 10% of the training set was selected randomly to adjust model parameters.

V. Results and Discussion

In this proposed work, the vibration data is collected for 12 different bearing conditions that is provided by CWRU. The description of various fault types and count of samples considered for each fault class from the experimental setup is given in Table I.

Time-domain features for normal and faulty bearings are shown in Fig. 6(a)-(d).

The proposed hybrid model is implemented using the Python's deep learning modules i.e. Tensorflow and Keras [32].

TABLE I. Summary of 12 Drive End Fault Data of CWRU

Class	Types of Bearing Faults	No. of samples	Data description
C0	0.007-Ball	319	Ball fault level =0.007
C1	0.007-InnerRace	315	Inner Race fault level=0.007
C2	0.007-OuterRace12	318	Outer Race fault level at 12'o clock position = 0.007
C3	0.014-Ball	317	Ball fault level =0.014
C4	0.014-InnerRace	317	Inner Race fault level=0.014
C5	0.014-OuterRace6	317	Outer Race fault level at 6'o clock position = 0.014
C6	0.021-Ball	317	Ball fault level =0.021
C7	0.021-InnerRace	318	Inner Race fault level=0.021
C8	0.021-OuterRace12	317	Outer Race fault level at 12'o clock position = 0.021
C9	0.028-Ball	314	Ball fault level =0.028
C10	0.028-InnerRace	314	Inner Race fault level=0.028
C11	Normal	634	Normal Bearing

F. Parameter Settings for CNN-Bi-LSTM Model

The summary of the model's parameters set for the proposed hybrid CNN-Bi-LSTM architecture is shown in Fig. 7.

The first four convolutional layers used batch normalization and spatial dropout with a value of 0.25, which could effectively improve the performance of the network by preventing the overfitting problem. Softsign activation function was used as a classifier in Bi-LSTM with filter size of 256 and Adam optimizer for compilation. The loss function categorical cross-entropy and batch size of 32 was set to identify the fault state by setting a short time of 100 epochs.

The trainable parameters are those which are learnt by the model during the feature learning from the classification layers namely convolution, LSTM, and the fully connected layers. The non-trainable parameters are learnt by the model from the batch normalization layers.

Layer (type)	Output Shape	Param #
conv1d_4 (Conv1D)	(None, 382, 128)	512
leaky_re_lu_7 (LeakyReLU)	(None, 382, 128)	0
max_pooling1d_4 (MaxPooling 1D)	(None, 191, 128)	0
batch_normalization_7 (Batc hNormalization)	(None, 191, 128)	512
spatial_dropout1d_4 (Spatia lDropout1D)	(None, 191, 128)	0
conv1d_5 (Conv1D)	(None, 189, 256)	98560
leaky_re_lu_8 (LeakyReLU)	(None, 189, 256)	0
max_pooling1d_5 (MaxPooling 1D)	(None, 94, 256)	0
batch_normalization_8 (Batc hNormalization)	(None, 94, 256)	1024
spatial_dropout1d_5 (Spatia lDropout1D)	(None, 94, 256)	0
conv1d_6 (Conv1D)	(None, 92, 512)	393728

Total params: 2,618,444
Trainable params: 2,614,476
Non-trainable params: 3,968

Fig. 7. Summary of Model's Parameters.

G. Confusion Matrix

The confusion matrix is the representation of matching degree between the actual and predicted labels in the form of matrix. The confusion matrix for the proposed 1DCNN-Bi-LSTM model is shown in Fig. 8. The model has correctly classified 4111 samples out of 4118 by demonstrating an accuracy of 99.84%.

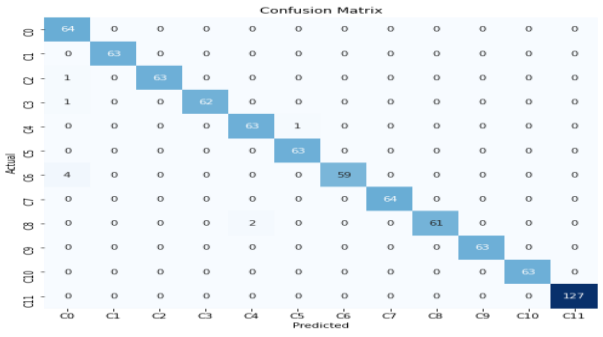

Fig. 8. Confusion Matrix.

H. Learning Curve

A learning curve is a plot of model's learning performance over experience or time. The model is evaluated during training phase after each update based on the training and validation dataset. It gives an idea of how well the model is learning and generalizing. The learning curve for the proposed method is shown in Fig. 9. It demonstrates the training and validation accuracy versus number of epochs.

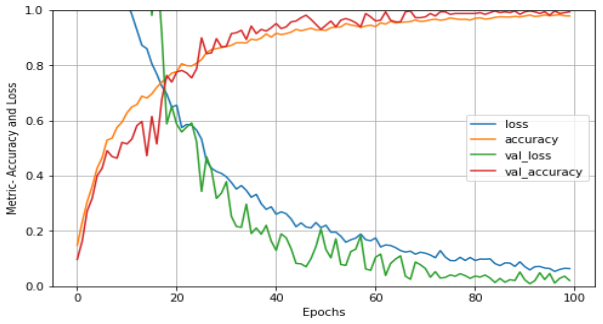

Fig. 9. Learning Curve for Hybrid CNN-Bi-LSTM Model.

A comparative analysis of the proposed hybrid model is made with other existing DL models as shown in Table II. The performance indicates that the proposed model accomplishes better results in classifying multiple faults as compared to other models.

TABLE II. COMPARATIVE ANALYSIS OF THE PROPOSED METHOD WITH OTHER DL MODELS

Model	Training Accuracy	Test Accuracy	Validation Accuracy
1D-CNN only	98.18	95.99	95.45
1D-CNN with LSTM	98.18	99.51	99.09
1D-CNN-Bi-LSTM	98.01	98.78	99.09
1D-CNN-Bi-LSTM (Softsign and Spatial Dropout)	99.84	98.17	99.69

VI. CONCLUSION

In this research, A Hybrid 1D-CNN-Bi-LSTM model with Spatial Dropout for Multiple Fault Diagnosis of Roller Bearing is proposed. Usage of Spatial Dropout technique and Softsign activation function in the proposed hybrid fault diagnosis method has shown an improvement in the accuracy by performing automatic feature extraction and preventing the problem of overfitting. 1D-CNN extracts the features from the raw signal and Bi-LSTM layer fuses the feature information to enhance stability of the model and classify the faults. The efficiency of the proposed model is analysed by considering CWRU bearing vibration data for experimentation. A comparative analysis of the proposed method is made with other existing models. The model has shown the performance accuracy of 99.84% in classifying 12 different fault types. Therefore, the proposed hybrid 1D-CNN-Bi-LSTM (Softsign and Spatial Dropout) is an effective multi-class fault diagnosis method with the prevention of model overfitting problem.

Building and Testing Fine-Grained Dataset of COVID-19 Tweets for Worry Prediction

Tahani Soud Alharbi, Fethi Fkih
Department of Computer Science, College of Computer
Qassim University, Buraydah 51452, Saudi Arabia

***Abstract*—The COVID-19 outbreak has resulted in the loss of human life worldwide and has increased worry concerning life, public health, the economy, and the future. With lockdown and social distancing measures in place, people turned to social media such as Twitter to share their feelings and concerns about the pandemic. Several studies have focused on analyzing Twitter users' sentiments and emotions. However, little work has focused on worry detection at a fine-grained level due to the lack of adequate datasets. Worry emotion is associated with notions such as anxiety, fear, and nervousness. In this study, we built a dataset for worry emotion classification called "WorryCov". It is a relatively large dataset derived from Twitter concerning worry about COVID-19. The data were annotated into three levels ("no-worry", "worry", and "high-worry"). Using the annotated dataset, we investigated the performance of different machine learning algorithms (ML), including multinomial Naïve Bayes (MNB), support vector machine (SVM), logistic regression (LR), and random forests (RF). The results show that LR was the optimal approach, with an accuracy of 75%. Furthermore, the results indicate that the proposed model could be used by psychologists and researchers to predict Twitter users' worry levels during COVID-19 or similar crises.**

***Keywords*—COVID-19; sentiment analysis; emotion analysis; worry dataset; concern analysis**

I. Introduction

At the end of the year 2019, China reported cases of pneumonia caused by an unknown virus in Wuhan City. Later, this pneumonia was defined by the World Health Organization (WHO) as the coronavirus disease 2019 (COVID-19)[1]. It was then declared a pandemic that has had multiple consequences, including the death and long-term effects of infected people. According to WHO, as of July 2022, the total number of reported COVID-19 cases was approximately 545 million, with a total of 6.3 million deaths[1]. The uncertainty and low predictability of COVID-19 threaten people's both physical and mental health, especially in terms of emotions and cognition [2]. The most challenging effects of the pandemic, especially during lockdowns, are depression, anxiety, and worries due to unemployment, losing loved ones, or being personally affected by the disease [3]. While there are several programs that psychologists and therapists carry out to enable recovery from these issues, there is an immense need to study worry using other sources [4]. Traditional methods of public health monitoring, like questionnaires and clinical tests, have certain limitations; for example, they only cover a limited number of participants and are restricted to the data collection period[5].

In contrast, social media are becoming a significant source of rich real-time information during crises, including disease outbreaks and natural disasters [6]. Twitter is a unique source of big data for public health researchers due to the real-time nature of the content and the ease of searching and accessing publicly available data [7]. In this vein, COVID-19-related behaviors and sentiments are available on social media. Twitter users continuously post about their feelings and worries regarding these unusual circumstances[8]. This situation drew the attention of computer scientists and researchers, leading to numerous studies on the understanding of the emotional states during current events, especially those related to the pandemic [9].

The research problem is related to the discrimination of the worry analysis studies. Most of the researchers have focused on discrete emotion theories, like Ekman's emotion classification schema [10], by annotating texts to the six basic emotions (i.e., anger, disgust, fear, happiness, sadness, and surprise) [11]. As the most dominant emotions during crises are worry and anxiety [12], [13], the existing methods for emotion detection are insufficient to capture the emotion of worry accurately [14].

Detecting worry is complex as people are either unwilling to disclose worries to medical personnel or prefer sharing their feelings on social media. Thus, there is a lack of datasets that could be used for worry analysis, as many studies depend on surveys and interviews [15], [16]. To the best of the authors' knowledge, this is the first study to build a to-date dataset about COVID-19-related worries that is to be applied to machine learning (ML) models. In the context of this paper, worry about COVID-19 is classified into three fine-grained levels: "no-worry", "worry", and "high-worry". The "no-worry" category includes people discussing the news and politics about the virus or content-containing statistics and figures. On the other hand, people expressing high levels of feelings such as panic or fear ("high worry" category) are distraught. Between these two categories ("worry" category), there are people expressing concern about the virus, who are considered stressed about the present and the future.

The contribution of this paper is two-fold. First, the WorryCov[2] dataset was built based on three classes: "no-worry", "worry", and "high-worry". It was built with experts

[1]https://covid19.who.int

[2]Dataset is available from the authors upon reasonable request.

in linguistics and followed an annotation scheme under strict quality control. Then, several ML classification models were used to test the dataset.

The paper is outlined as follows. The related works are discussed in Section 2. Section 3 introduces the proposed approach. Section 4 provides the results and discussion, while Section 5 concludes the paper.

II. Related Work

Worry analysis is considered one dimension of emotion analysis frequently studied in the literature. Therefore, this study focuses on concern, sentiment, and emotion analysis towards or during disasters or pandemics such as the COVID-19 pandemic.

Much previous research was carried out to determine the public health concerns toward disasters or epidemics based on sentiment analysis results. For example, the work in [17] aimed to analyze Twitter messages relating to Hurricane Irene and trained a dataset based on sentiment analysis classifiers to categorize tweets into levels of concern. They evaluated the impact of various tokenization strategies and feature choices like a bag of words (BOW) and lexicons on classification accuracy. With 84.27% accuracy, the best settings for the maximum entropy classifier were removing punctuation, converting the text to lowercase, removing stop words, and building a worry lexicon. The Epidemic Sentiment Monitoring System [5] provides visualization tools for Twitter posts responding to public concerns about different diseases. The degree of concern reported that multinomial Naïve Bayes (MNB) achieved the highest F1-score using term frequency-inverse document frequency (TF-IDF) features. To measure and monitor public health concerns about communicable diseases, a sentiment classification approach was applied to Twitter data by measuring different levels of concern [18]. The classifier was trained with a dataset automatically generated by a programming system using an emotion-oriented and clue-based method. Three ML classifiers were evaluated, with the NB classifier achieving the best accuracy for the epidemic-related dataset.

Regression is often used to detect public health concerns. For instance, in [19], a strategy to predict to what extent news about a public health issue can be disseminated was proposed using a data collection of microblog news posts. This ML method relies on the logistic regression (LR) algorithm that automatically categorized news posts into two classes: normal news or news posts that resonated with widespread public anxiety.

As for COVID-19, abundant works have already been published studying the effects of this pandemic on various aspects. For example, most research focused on analyzing Twitter data and finding the main critical topics that raise concerns for individuals regarding the COVID-19 pandemic. In [20], [21] used the topic modeling technique LDA (an unsupervised machine learning model) to identify the most common topics in the tweets and performed sentiment analysis. Furthermore, analyzing citizens' concerns during the COVID-19 epidemic has been studied in [22]. 30,000 COVID-19-related tweets were collected from March 14, 2020. Each tweet was labeled as very negative, negative, neutral, very positive, and positive by using the natural language processing (NLP) library. Then, the authors used sentiment analysis on pre-processed tweets to show the level of concern in various US states. They presented an approach for measuring citizens' concern levels through Twitter data by using the ratio of very negative and negative tweet counts over the total number of tweets in the dataset. As a result, school closing-related tweets cause the highest level of concern among citizens. Similarly, the study [23] presented a method to identify the COVID-19 topic's degree of concern through user conversations on Twitter based on two phases of the classification process. The first classification step is to separate tweets into two classes, namely COVID-19 and non-COVID-19. The second step is to classify the COVID-19 data into seven topics: donations, emotional support, warnings and suggestions, hoaxes, notification of information, seeking help, and criticism. Six pairs of combinations of word-level and character-level word embeddings, namely Word2Vec and fastText, with three deep learning models, CNN, RNN, and LSTM, were used to apply the text classification model. The best accuracy was achieved when fastText and LSTM were used together for both stages of classification, with 97.3% and 99.4%, respectively.

Significant research in public health has applied emotion analysis using social media-derived information to monitor public emotions during disease outbreaks. Emotions such as anxiety, anger, happiness, desire, disgust, fear, relaxation, and sadness have been widely studied. Emotions are often linked with topic modeling to identify the topics and their intensity level. For example, findings in [12] indicate that the longer texts gave insights into what people worry about during the pandemic: the economy and the family. In the SenWave system [8], seven fine-grained sentiment categories, namely, optimistic, thankful, empathetic, pessimistic, anxious, sad, annoyed, denial, official, and joking, are used to study the concern of Twitter users from different countries. The labeled tweets are used to train the deep learning language models such as XLNet, AraBert, and ERNIE, while over 105 million unlabeled tweets are used for the testing process. An XLNet pre-trained language model was used for English tweets. The classifier achieved an 80% accuracy, which proves the efficiency of the models. However, emotion analysis studies are minimal compared with sentiment research due to the lack of annotated data [24]. The EmoBERT model [24] was used to capture emotions related to emotional health (annoyed, anxious, empathetic, sad) to compare emotions expressed on social media before and during the COVID-19 epidemic. In comparison to BERT and XLNet, EmoBERT achieved better results.

Our review shows that little research has addressed worry detection. However, many studies address anxiety as an issue of mental health, for instance, this study [25]utilized personal narratives from Reddit to detect anxiety disorders and classified anxiety-related posts into a binary level of anxiety. Using various linguistic features, including vector-space representations (Word2Vec and Doc2Vec), topic (LDA) models, Linguistic Inquiry and Word Count (LIWC) dictionary, and n-gram language models. Overall, all features

that have been used succeeded in classifying the level of anxiety, for single-source features, using Neural Network with N-gram probabilities achieved slightly better accuracy (92%) compare with using SVM with word-vector embeddings (word2vec), and for combined features, Neural Network has produced the highest accuracy of 98% by aggregating LIWC with word2vec embeddings and by aggregating N-gram features with LIWC. Moreover, this paper [26] developed its own binary classification dataset for detecting anxiety and depression users on social media who have not yet been diagnosed with mental illness. The authors have presented a comparative experimental evaluation using the traditional linear model and pre-trained LMs (language models). Their results showed that LMs (BERT and ALBERT) performed relatively well with balanced training data. However, in unbalanced training sets, Support Vector Machine (SVM) with word embeddings and TF-IDF features performed slightly better overall, with 0.750 F1-score, 0.747 for accuracy, and 0.740 for precision.

To our knowledge, Verma et al.'s study [14] is the most relevant to the prediction of worry using Twitter data. Using crowdsourcing, they re-annotated an existing dataset that contains four emotions (joy, anger, fear, and sadness) [27] for worry classification. A wide range of machine learning and deep learning models were evaluated. For traditional ML approaches, Multinomial Naive Bayes (MNB), and Support Vector Machine (SVM) are implemented by using feature-based models. For deep learning based on word embeddings, they used Hierarchical Attention Network (HAN) and CNN-static with combined Glove emoji2vec embeddings. While deep learning approaches based on contextual embeddings were also applied like RoBERT and XLNet. The results showed that deep learning methods outperform as compared to the traditional models for worry identification with 0.61 F1-score.

The gap in the current studies is related to the lack of a large new dataset for worry level detection related to COVID-19 tweets. Despite the many works, most previous results focus on the sentiment classification of tweets as positive, negative, and natural.

III. Proposed Approach

The proposed approach is shown in Fig. 1. Due to the limited dataset related to worry identification from text, we built a dataset and chose the classification task. We decided to select some machine learning models to validate the credibility of the collected dataset. The approach first described the data collection and the annotation process into three levels of worry using COVID-19-related tweets. The dataset was then used to extract features, run ML models, and evaluate the results.

A. Building the Benchmark Dataset

1) Dataset collection and filtering: To build the benchmark dataset, tweets were collected, filtered, and annotated. Twitter is one of the most popular social media and has a wide range of content including rich text, emojis, and hashtags [14]. The tweets related to COVID-19 were collected using Tweepy, the Python Twitter API library [28]. Initially, we used unified query keywords (i.e., coronavirus, covid-19, #coronavirus, and #covid-19), previously used in other studies [29], to identify the tweets related to COVID-19. The tweets were collected over three periods to ensure that they covered significant milestones during the pandemic. The three periods are consistent with [30] and are the following:

- First period: from January 30 to February 28, 2020. During this period, the first COVID-19-induced death was reported in China, and WHO announced a public health emergency.
- Second period: from March 29 to April 29, 2020. During this period, WHO declared COVID-19 a worldwide pandemic, leading many governments to impose restrictions on citizens in an attempt to reduce the spread of the virus.
- Third period: from May 10 to June 30, 2020. During this period, COVID-19 had spread globally, with an increased number of confirmed cases and deaths.

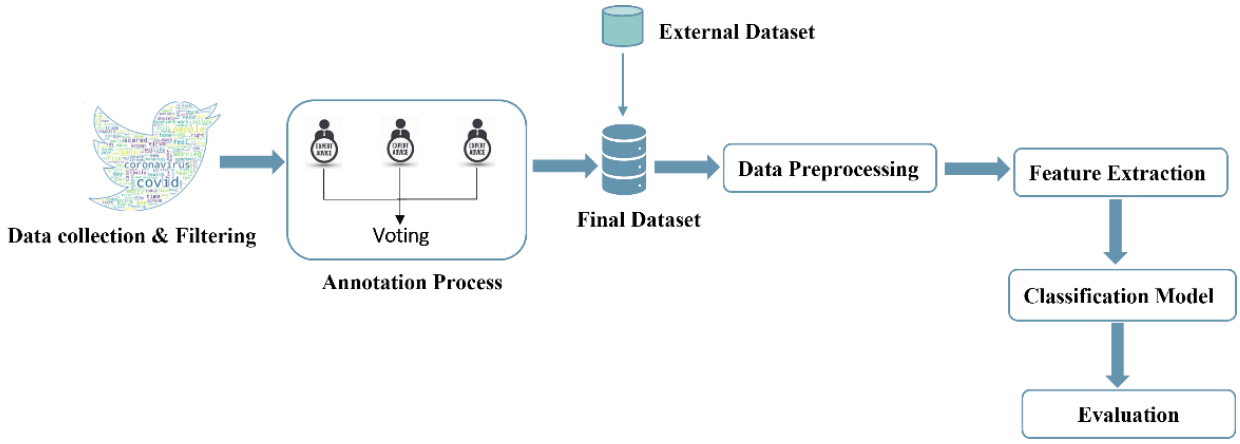

Fig. 1. Proposed Approach.

Following these periods and using the aforementioned keywords, 270,000 tweets were collected. Each tweet had 24 columns, including data and time, username, tweet text, and location. Since we wanted to detect feelings of worry at the tweet level, we removed the rest of the columns and only retained the text column. However, a large proportion of COVID-19-related tweets were probably not associated with one emotion; thus, annotating them would be costly and ineffective [31], [32]. To meet our objective, we focused solely on the worry emotion and used worry-related keywords to create a dataset of tweets representing this emotion. Following [33], we selected keywords (terms) to filter the collected data. The terms were extracted from Thesaurus.com by finding synonyms and terms related to worry; the dictionary is one of the trusted, free online dictionaries. The synonym keywords are shown in Table I.

Often, datasets contain noise and irrelevant text. Therefore, the following rules were applied to reduce the dataset to more concise and related tweets: (1) deleting duplicate tweets (i.e., retweeted by other users), (2) deleting non-English language tweets, and (3) deleting all tweets less than 40 characters (short tweet).

TABLE I. KEYWORDS USED FOR FILTERING TWEETS (EXTRACTED FROM THE ONLINE THESAURUS.COM DICTIONARY)

worry	anxiety	concern	apprehension	fear	afraid
worried	anxious	panic	stress	tension	terrify
worries	distress	nervous	uncertain	tense	terrified
scary	confusion	restless	doubt	horrible	terror
scared	confuse	pressure	uptight	horror	paranoid
discomfort	troubled	pain	upset	dread	alarm

2) Annotation process: Manual labeling of social media data is challenging and requires dedicated time from domain experts (time-consuming). However, it is a critical part of the data preparation process in supervised learning. We annotated the data for not just coarse classes (such as worry or no-worry) but also for fine-grained levels indicating the intensity or degrees of emotion. However, annotating instances for degrees of emotions is a more difficult task to ensure annotation consistency [33]. Therefore, this study followed a set of rules to overcome this challenge: (1) tweets were annotated to three classes only: "no-worry", "worry", and "high-worry",(2) Three English speakers with more than three years of experience in linguistics were employed; (3) the majority vote was used to annotate an individual tweet, and when the three experts disagreed, the tweet was considered irrelevant and was removed from the dataset; moreover, a newly developed website application was used to help the annotators accomplish their work; and (4) each annotator got the same number of tweets (2,700) for each month of the three periods (8,100 tweets in total). This process was slow but ensured results in accordance with the following guidelines to classify each tweet:

- "No-worry" class:
  - News or politics (i.e., conspiration theories, China-related discussion where the Chinese are blamed for the virus, US politics, critics of Donald Trump, etc.) and facts (e.g., numbers, statistics).

    Example: "China's outbreak is serious. But flu killed *5000 Americans* in the 1st 2wks of 2020 coronavirus infected 6, killed 0. Not sure what info you have that CDC director doesn't "The immediate risk to the US public is low." Our US readers deserve to know they don't need to panic."
  - Other diseases (i.e., tweets comparing COVID with other diseases, discussing symptoms and mortality rates).

    Example: "Aids is a killer disease Cancer is a killer disease Ebola is a killer disease Swine flu is a killer disease The only thing that divides Coronavirus to this other diseases is the fact that it is just the latest, stop with the panic and take care of yourself! #coronavirus."
  - Expressing some other emotions (i.e., tweets denying the existence of the virus or expressing any optimistic/positive attitude toward it).

    Example: "markets are full of pads soap Dettol, etc. People are not freaking out as they know there's enough. They aren't crazy buying. Let's hope the panic ends soon all over the world and we live happily again #covid-19."
- "Worry" class:
  - Expressing general concern (i.e., mentioning being worried/stressed/concerned about the present and future of COVID-19).

    Example: "Also, I'm young and healthy and unlikely to die from covid-19, so no reason to be afraid at all for me. I'm nervous about infecting those who are less likely to survive though, so I will do my best to prevent that of at all possible if I get infected."
- "High-worry" class:
  - Expressing concern (i.e. tweets expressing feelings of panic, fear, etc.).

    Example: "i'm tired of crying. i'm tired of the anxiety, and panic attacks. i want to go outside again. please - STAY HOME. #COVID-19 #COVID19Ontario."
  - Frequent use of intensifiers (e.g., extremely, so, very) and featuring content related to (fear of) death.

    Example: "So much stress, so much anxiety, AND I'M PREGNANT. Headaches all day, puking many times a day, quarantined. People are dying, this is not cool. #coronavirus"

The annotation resulted in 7,861 instances corresponding to the three classes. The "no-worry" class included 3,158 instances, the "worry" class had 3,127 instances, and the "high-worry" class included 1,576 instances. The remaining 239 tweets were eliminated as the annotators disagreed with their classification (not sure). However, we noticed that the WorryCov dataset is imbalanced. So, it should be solved to reduce skewness and increase the performance of ML models [34]. Therefore, we decided to expand the dataset using other external datasets. To our knowledge, no dataset focuses on only worry emotion. Therefore, we selected the intensity of anxiety based on [11] since it was considered a synonym for worry. Anxiety levels in [11] ranged from 1 to 9, where 1 was considered the lowest and 9 the highest. Considering this range, we chose the intensity levels 7, 8, and 9 as descriptive of the "high-worry" class, resulting in a total of 3,127 instances in the "high-worry" class.

B. Prediction of Worry Levels

The balanced benchmark dataset was used to evaluate the performance of different ML models. In this section, the data preprocessing, feature extraction, classification, and evaluation steps of this dataset are discussed.

1) Data preprocessing: Preprocessing generally improves the data quality by extracting meaningful fragments from a given text excluding the noise [35], [36]. Preprocessing steps include text cleaning such as URL, digit, punctuation removal, etc., and lemmatization.

In the cleaning step, we removed URLs, user mentions, and hashtags. Previous research on sample datasets shows that these items do not provide any evidence of the level of worry in tweets or useful information [37]. Next, each tweet was converted to lowercase to avoid considering the exact words as unique features, such as "HELP", "Help", or "help" will be converted to "help" [38]. Then, the contractions (i.e., "I'm" instead of "I am") were replaced by the original phrase as described in [37]. Next, digits, punctuation marks, and extra spaces that do not provide any semantic information to the text were removed. NLP classification tasks often involve removing stop words to improve performance metrics [39]. However, in this dataset, worry feelings were frequently expressed as ideas about oneself, leading to the use of the "I" and "my" pronouns. Therefore, stop words were not removed to retain the linguistic characteristics of worried users. Finally, each word was lemmatized using Wordnet Lemmatizer available in the natural language toolkit (NLTK) library [40].

2) Feature extraction: Often called a features vector [37], this step refers to transforming raw data into numerical data that machines can understand. Term frequency-inverse document frequency (TF-IDF) is a popular text vectorization technique to generate vector representations of a text [41] and was employed in this experiment. The TF-IDF weighting scheme is based on two parts: term frequency (TF) and inverse document frequency (IDF). TF-IDF is mathematically formulated in the following (1) [42]:

$$\text{TF} - \text{IDF}(t, d) = \text{TF}(t, d) \times \text{IDF}(t) \quad (1)$$

where t denotes a term and d denotes a document.

TF is the frequency of any term within a given document and is calculated by dividing the number of mentions of a given word by the total number of words in the document [37], TF is defined by (2) [43]:

$$\text{TF}(t, d) = \text{Number of times the term } t \text{ appears in the document / Total number of terms in the document} \quad (2)$$

IDF represents the importance of a term in the corpus of the text. It is a technique that combined with TF reduces the impact of common words. There are some words, like "the", "is", "and", etc., that occur frequently but are void of information. IDF is defined by Eq. (3) [44]:

$$\text{IDF}(t) = \log(\text{Number of documents / Documents containing the term t}) \quad (3)$$

C. ML-Based Classifiers

Four ML-based classifiers were used in the multi-classification task. These methods were multinomial NB (MNB), logistic regression (LR), Support Vector Machine (SVM), and Random Forest (RF). The default settings of these methods were taken from the scikit-learn library [45]. MNB is suitable for classifying discrete features or fractional counts such as TFIDF. LR calculates the likelihood of a target variable based on a collection of independent variables and a given dataset. SVM is a classification algorithm for two-group classification problems (in our case one-vs-rest scheme is used). Finally, the RF algorithm builds many random decision trees using bagging and feature randomness for each tree.

D. Evaluation Metrics

Each classifier was evaluated using the following performance measurements: accuracy, precision, recall, and F1-score. These standard metrics are defined as follows:

Accuracy is the ratio of the number of correct predictions to the overall number of predictions:

$$\text{Accuracy} = (TN + TP) / (TN + TP + FP + FN) \quad (4)$$

Precision is the ratio of the correctly predicted positive instances to the total positive instances:

$$\text{Precision (P)} = TP / (TP + FP) \quad (5)$$

Recall is the ratio of the correctly predicted positive instances to the total of all instances in the actual class:

$$\text{Recall (R)} = TP / (TP + FN) \quad (6)$$

F1-score is the harmonic average of precision and recall:

$$\text{F1-score} = (2 \times P \times R) / (P + R) \quad (7)$$

where TP, TN, FP, and FN denote true positive, true negative, false positive, and false negative, respectively.

IV. Results and Discussion

After filtering (see Section 3.1), we obtain 15,000 tweets. Fig. 2 presents the word cloud of the most commonly used words in the WorryCov dataset. The most frequent keywords are related to the COVID-19 pandemic, such as "Covid",

"corona", "coronavirus", and "scared". The distribution of tweets among the three worry levels is shown in Fig. 3. The figure demonstrates that the three classes are balanced. Fig. 4 includes tweets representative of the three levels of worry. The figure shows that the "high-worry" class shows fear and stress behavior. While the "worry" class indicates familiar people's behavior during any pandemic. In contrast, the "no-worry" indicates informative or news content or an optimistic feeling.

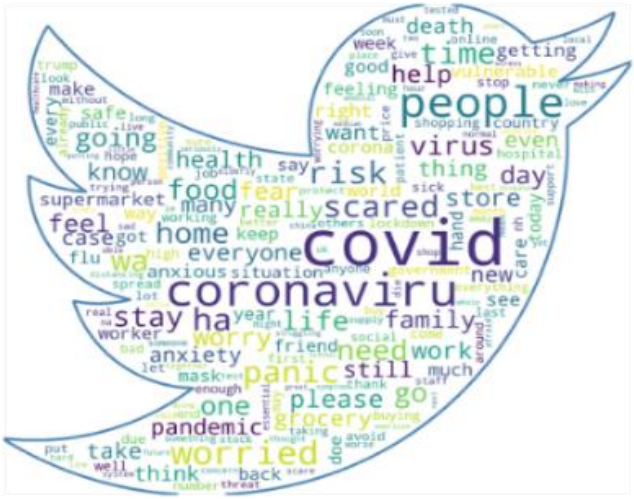

Fig. 2. The Word Cloud of the Collected Tweets.

Fig. 3. Distribution of the Tweets among the Three Worry Levels.

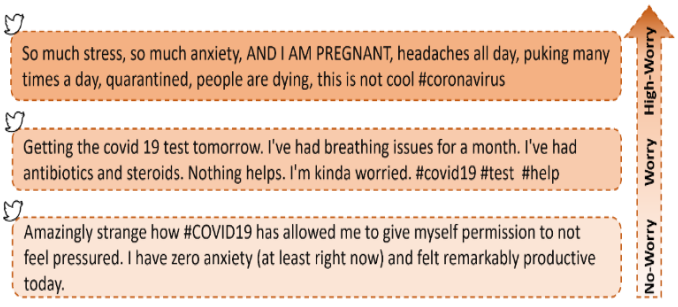

Fig. 4. A Sample of Tweets from the Benchmark Dataset Representing the Three Levels of Worry.

To predict the performance of the selected ML models, the dataset was split into 80% for training and 20% for testing. Next, data preprocessing and feature extraction (see Section 3.2) were employed to extract relevant features. Finally, the accuracy, precision, recall, and F1-score results were reported for the average class (Table II).

As shown in Table II, the classification performance of LR (reported in bold) performed better than the other models in terms of accuracy, precision, recall, and F1-score. It yielded the highest accuracy of 75%, a precision of 0.751, a recall of 0.747, and an F1-score of 0.748. On the contrary, RF acquired the lowest values with an accuracy of 68%, 0.683 for recall, 0.682 for precision, and F1-score of 0.682.

An investigation of the dataset shows that the LR algorithm was able to build features better than others because the training algorithm of LR uses the one-vs-rest scheme in the multiclass option and the cross-entropy loss. However, the results cannot be generalized as the absolute difference among the high-performing models in Table II is less than 4%.

Fig. 5, 6, and 7 show the precision, recall, and F1-score measurements, respectively, for all the applied algorithms according to the three worry levels. The results indicate that although the dataset was balanced, the TFIDF feature extraction method did not provide sufficient information to the classifiers. The feature sets did not detect the worry classes due to embedded semantic features within this textual class label, which TFIDF could not capture.

The "no-worry" class was the highest-performing class label, while the "worry" class was the lowest-performing class label. However, for the "no-worry" and "high-worry" classes, other information was available. For example, in the "no-worry" class, some terms related to blame, news, and politics are present. As for the "high-worry" class, intensifiers were present. These results indicate the possible usefulness of the TFIDF feature set.

TABLE II. RESULTS OF THE PROPOSED MACHINE LEARNING (ML) MODELS

Algorithm	Accuracy (%)	Precision	Recall	F1-score
Multinomial NB	71	0.729	0.711	0.714
SVM	74	0.748	0.741	0.743
Logistic Regression	**75**	**0.751**	**0.747**	**0.748**
Random Forest	68	0.683	0.682	0.682

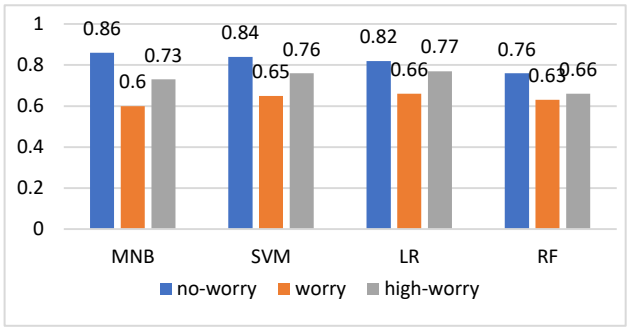

Fig. 5. Precision Results for the four ML Models per Worry Class.

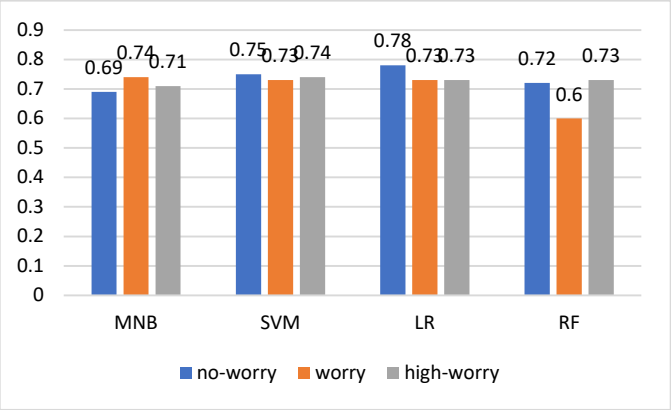

Fig. 6. Recall Results for the four ML Models per Worry Class.

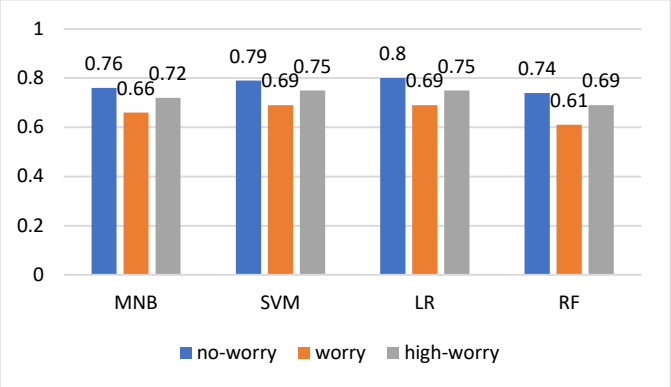

Fig. 7. F1-score Results for the Four ML Models per Worry Class.

In general, the current method, compared to Verma et al.'s study [14] is based on a new dataset. The new approach is also much more focused on the worry levels compared to 9 anxiety levels in [11], ranging from 1 to 9, where one was considered the lowest and nine the highest.

V. Conclusion

In this paper, we compiled a fine-grained benchmark dataset for the classification of worry levels concerning the COVID-19 pandemic. The dataset was collected from Twitter and was annotated using a majority vote among three experts. The WorryCov dataset was used to classify and predict the level of worry among Twitter users during the pandemic. Several experiments were conducted using the following ML algorithms: NB, LR, RF, and SVM. The optimal performance was achieved by LR, with an accuracy of 75%. It is recommended that the proposed approach be used for decision-making in healthcare entities to plan programs for the affected people. However, the current work has a few limitations. For example, the dataset is relatively small and was collected based on a short period from 2020–2021. Moreover, human behavior changes over time due to interaction with infected people, vaccination initiatives, and governments' health policies. Therefore, a new set of keywords that represent the new set of tweets might be needed to uncover the new trends in human worry levels. In the future, several deep learning models could be used to enhance the performance of the current approaches.

***Abstract*—Biometric authentication systems have always been a fascinating approach to meet personalized security. Among the major existing solutions fingerprint-biometrics have gained widespread attention; yet, guaranteeing scalability and reliability over real-time demands remains a challenge. Despite innovations, the recent COVID-19 pandemic has capped the efficacy of the existing touch-based two-dimensional fingerprint detection models. Though, touchless fingerprint detection is considered as a viable alternative; yet, the real-time data complexities like non-linear textural patterns, dusts, non-uniform local conditions like illumination, contrast, orientation make it complex for realization. Moreover, the likelihood of ridge discontinuity and spatio-temporal texture damages can limit its efficacy. Considering these complexities, here, we focused on improving the input image intrinsic feature characteristics. More specifically, applied normalization, ridge orientation estimation, ridge frequency estimation, ridge masking and Gabor filtering over the input touchless fingerprint images. The proposed model mainly focusses on reducing FPR & EER by dividing the input image in to blocks and classify each input block as recoverable and nonrecoverable image block. Finally, an image with higher recoverable blocks with sufficiently large intrinsic features were considered for feature extraction and classification. The Proposed method outperforms when compared with the existing state of the art methods by achieving an accuracy of 94.72%, precision of 98.84%, recall of 97.716%, F-Measure 0.9827, specificity of 95.38% and a reduced EER of about 0.084.**

***Keywords*—Ridge orientation; Gabor filtering; region masking; ridge frequency; contactless fingerprint**

I. INTRODUCTION

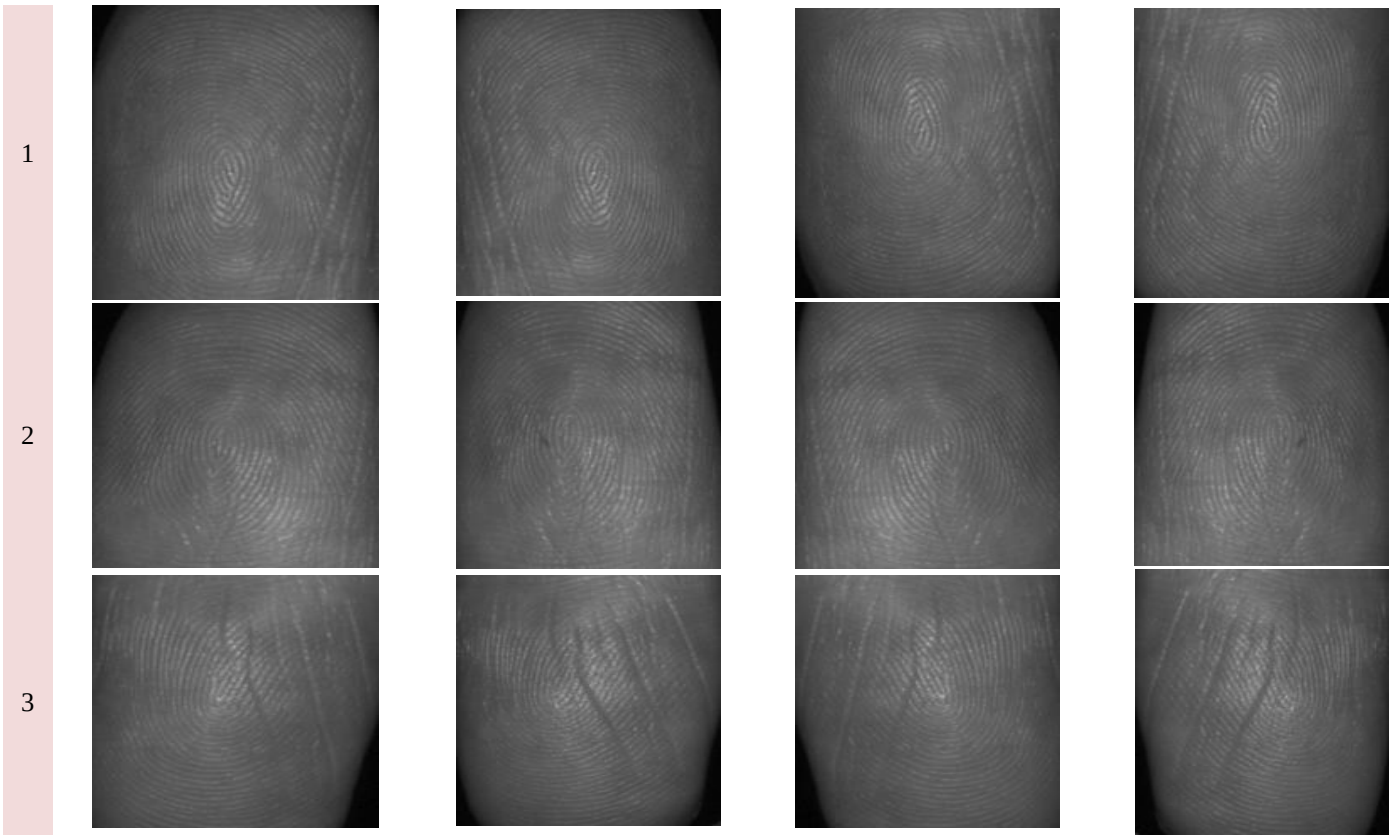
The last few decades have witnessed exponential rise in advanced technologies, including software computing, decentralized computing, smart intelligence, sensor and hardware systems. Despite significant innovation and technological horizon, personalized security or system security often remains a challenge under dynamic application environment [1]. Whether it is data, channel or infrastructure, guaranteeing security for these key systems has remained as an open challenge for academia-industries [2]. In the last few years, the rise in attack events too has increased significantly. The different attacks models have been developed on the basis of the exploiting user's or system access credentials like passwords, smart card attack loss, impersonation, Brute Force attacks etc. [1][2]. Most of these attacks have resulted huge data losses and breach, financial losses, system failure, and even the loss of life. Unlike cryptographic concepts, in the last few years biometric driven authentication systems have increased significantly [4][5] having superior potential with high scalability, interoperability and time-efficiency. Its efficacy can easily be visualized as Aadhar Card system by Unique Identification Authority of India (UIAI) [17]. Interestingly, more than a billion of population in India possesses a fingerprint driven Aadhar card for its verification. Though, Aadhar is a multi-modal system; however, evolved with fingerprint identification. In contemporary world whether it is corporate official attendance systems, entry or exit or even attendance systems in schools, fingerprint had remained a viable choice. In sync with such significances, a large number of efforts have been made by academia-industries; however, the recent pandemic of COVID-19 has limited the scope of the classical touch-based fingerprint authentication systems [6]. COVID-19 pandemic has almost limited the efficacy of the touch-based two-dimensional fingerprint driven modalities, as this pandemic was found exponentially spreading due to inter-personal infection through such frequently touching devices [14][15]. For instance, in certain offices, an executive could be seen trying his/her fingers many times to get system access. Fun, apart, but the severity of such frequent problems is high in real-world applications. The local conditions like sensor efficiency, optimality, sample distortion, scratches and humidity etc. often impact efficacy of the classical touch-based fingerprint techniques [3][7]. To alleviate such issues, improving feature modality in conjunction with contactless identification system seems to be the motivation for academia-industry for future efforts [8-12]. Noticeably, unlike touch-based two-dimensional feature learning environment, retrieving fingerprint feature under different orientation, lighting conditions is a complex problem. Moreover, suffer from the low accuracy and hence such system often undergoes false positive under varied local feature conditions and spatio-temporal complexities. Therefore, to cope up with touchless fingerprint identification system demands, researchers require improving local conditions, feature modalities as well as learning environment [13][16]. These key scopes are considered as the key driving forces behind this study.

In the last few years very few but significant efforts have been made towards touchless fingerprint detection methods. Jonietz et al. [3] recently tried to use depth camera and mobile

devices to perform touchless fingerprint detection. Despite RGB image and depth information combination, the key problem of non-uniform cues over feature space makes it limited towards realistic purposes. To alleviate such issues, Pang et al. [18] derived a three-dimensional feature model from input image that helped in improving ridge-valley information. To achieve it, authors at first employed least square method to fit a local paraboloid surface that helped estimating the local surface curvature and tensors curvature. Though, this approach helped in improving ridge-value orientation and depth information; however, at the cost of increased computation. Unlike previous works, Jonietz et al. [19] designed touchless finger detection model exploited aggregated channel features with RGB color space for finger segmentation that in conjunction with geometric shape helped estimating the fingertip for verification. Zaghetto et al. [20] too made effort to alleviate issues primarily caused due to orientational complexity and resulting spatio-temporal feature changes. To achieve it, authors applied Multiview scanner with multilayer neuro-computing. Despite their ability to address bad positioning problem, they could achieve the highest accuracy of 94%, which still needed to be improved. Though, Galbally et al. [8] made effort to improve accuracy by applying Laser sensing technique named 3D: FLARE. Yet, this approach was limited to yield a scalable solution for real-world purposes. Noticeably, these all approaches failed in providing a solution with scalability and efficacy towards real-world application. However, the depth assessment indicates that improving local input condition with superior feature segmentation and learning can yield superior performance.

Considering above stated key issues and allied scopes in this research, the emphasis was made on multi-dimensional optimization including pre-processing, feature extraction and eventual learning model. Being touchless approach, we considered normal three-dimensional RGB images as input, which is then processed for histogram equalization followed by contrast improvement and filtering. Recalling, non-linear ridge value patterns and local textural variations, we performed image normalization using Z-score method. Here, we performed block-wise normalization to improve contrast information. Subsequently, orientation image estimation was performed to improve local feature distribution. Moreover, it enabled frequency image estimation to make further spatio-temporal feature learning better. As post frequency image estimation, we performed ridge mask generation and Gabor filtering to ensure optimal local spatio-temporal textural feature (STTF) distribution for further minutiae detection. Unlike classical approaches, we performed three-dimensional minutiae projection and ridge mapping that improved overall feature space to achieve better spatio-temporal features for further learning. Finally, cropping the improved ridge mapping information, we performed deep-STTF feature extraction by applying Gray-level Co-occurrence Matrix (GLCM) followed by classification using random forest algorithm.

TABLE I. ILLUSTRATION OF 3D CONTACTLESS FINGERPRINT SAMPLES



II. METHODOLOGY

This section focuses on improving input data environment to ensure reliable fingerprint detection. In major touchless fingerprint detection models the viewing angle, image orientation, loss of ridges or damaged ridges and furrow structure, varying lighting or contrast etc. often impacts features, that eventually influences overall prediction accuracy. Considering this fact, in this paper, we focused on alleviating local data complexities. Moreover, we intend to guarantee intrinsic feature driven local conditioning so as to make optimal feature extraction without depending on the classical minutiae detection and segmentation. To achieve it, the proposed work encompasses data acquisition, Local Pre-conditioning and Image Quality Enhancement followed by feature extraction, classification and performance analysis.

A. Data Acquisition

In sync with the targeted contactless environment for fingerprint detection system, in this work we collected contactless three-dimensional sensor driven images to prepare datasets. The 3D touchless fingerprint datasets were collected in such a manner that it could enable effective learning under data heterogeneity and diversity to make it more efficient under realistic environment. Training over the large heterogeneous fingerprint patterns can make artificial intelligence driven models robust towards realistic purposes. Moreover, it can help achieving high reliability. We considered the 3D Fingerprint dataset comprising a large contactless fingerprint sample. Noticeably, for our case study we considered a total of 50 subjects and the samples collected were from the subjects aged in between 28 to 55 years. The subjects comprised a total of 40 man and 10 women that eventually contributed 160 and 40 fingerprint samples, correspondingly. The data considered had been collected under natural light conditions with standard illumination. Here, no specific light or illumination control measure was applied. To introduce diversity in reference to the viewing angle, illumination, contrast, orientation etc., subjects were instructed to stand in-front of the camera; and were instructed to move freely while keeping target fingers within camera vision range. Though, the similar dataset named 3D-FLRE-DB retrieves each fingerprint sample 15 times, where five different samples were obtained at a specific speed; we considered data retrieval at the random movement without any pre-calibrated speed definition. To introduce mode STTF feature heterogeneity the samples were not collected consecutively rather were captured at the different interval or gaps. To achieve it, once capturing one sample from a subject, the sample from another subject was captured, and this process was followed across the sample collection process over target subject volume. This approach was primarily done to introduce high spatial variability and textural heterogeneity to improve learning efficiency. A snippet of the data considered in this study is given in Table I.

1) Preliminary: Let, I be the input fingerprint image with $N \times N$ dimensional matrix, with $I(i,j)$ as the pixel intensity for the ith row and the jth column. In sync with touchless input, we hypothesize that the input images possess minimum resolution of 600 dots per inch, which is not difficult in contemporary high-definition camera. Thus, for the input images with aforesaid specification, the mean and the variance of the fingerprint image I in its gray-level form are derived as equation (1) and (2) respectively.

$$M(I) = \frac{1}{N^2}\sum_{i=0}^{N-1}\sum_{j=0}^{N-1} I(i,j) \tag{1}$$

$$Var(I) = \frac{1}{N^2}\sum_{i=0}^{N-1}\sum_{j=0}^{N-1} \left(I(i,j) - M(I)\right)^2 \tag{2}$$

B. Local Pre-conditioning and Image Quality Enhancement

The overall proposed local pre-conditioning model encompasses the following key processes:

- Image Normalization.
- Local Orientation Estimation.
- Local Frequency Estimation.
- Ridge Masking.
- Gabor Filtering and Smoothening.

The proposed model at first performed normalization in such a manner that it retains a pre-defined mean and variance characterized.

2) Image normalization: Consider $I(i,j)$ be the gray-level value for the input touchless fingerprint image where (i,j) be the corresponding pixel values. Moreover, let M and Var be the measured mean and variance of the input image I. In this case, the normalized gray-level image for the input $I(i,j)$ can be obtained as $G(i,j)$, which is mathematically derived as per equation (3).

$$G(i,j) = \begin{cases} M_0 + \sqrt{\frac{Var_0(I(i,j)-M)^2}{Var}}, & if\ I(i,j) > M \\ M_0 - \sqrt{\frac{Var_0(I(i,j)-M)^2}{Var}}, & Otherwise \end{cases} \tag{3}$$

In (3), M_0 and Var_0 represents the expected mean and the variance values, correspondingly. In the proposed model, normalization is performed as a pixel-wise function and therefore it retained the native image clarity, especially ridge-and-furrow structure for further feature extraction and learning. Here, the key motive was to minimize the variations in the gray -level values in the direction of ridges and furrows so as to enable further processes more efficient without losing any intrinsic information.

3) Ridge orientation estimation: In reference to the touchless fingerprint, where the input image can have spatio-temporal differences caused because of varying light conditions, change in orientation, spatial and temporal feature non-linearity. To ensure optimal feature learning, we focused on improving ridge STTF. To achieve improved ridge information and allied intrinsic values, we performed ridge orientation estimation. In this work, we designed a least-mean square image orientation estimation concept for orientation image estimation. The proposed Ridge Orientation Image Estimation model is accomplished in multiple sequential steps. A snippet of the involved algorithm and allied implementation is given as follows:

Step-1: Split the input Gray-level image in $w \times w$ dimension. Here, we considered 64×64 dimension to split input image into multiple grids.

Step-2: Estimate the gradient information in x and y directions for each pixel element (i,j). Here, the gradient in x and y directions were, $\delta_x(i,j)$ and $\delta_y(i,j)$, respectively for the input pixel elements (i,j). In this work, to ensure low computational overheads over a large input image, we applied Sobel operator method to perform gradient estimation.

Step-3: Measure the local orientation values for each input block, especially centered at the pixel element (i,j) by applying following mathematical formula.

$$V_x(i,j) = \sum_{u=i-\frac{w}{2}}^{i+\frac{w}{2}} \sum_{v=j-\frac{w}{2}}^{j+\frac{w}{2}} 2\delta_x(u,v)\delta_y(u,v) \quad (4)$$

$$V_y(i,j) = \sum_{u=i-\frac{w}{2}}^{i+\frac{w}{2}} \sum_{v=j-\frac{w}{2}}^{j+\frac{w}{2}} \left(\delta_x^2(u,v) - \delta_y^2(u,v)\right) \quad (5)$$

$$\theta(i,j) = \frac{1}{2} tan^{-1}\left(\frac{V_y(i,j)}{V_x(i,j)}\right) \quad (6)$$

In (6), $\theta(i,j)$ represents the LMS value of the local ridge orientation for the block centred at the pixel location (i,j). In fact, ridge orientation signifies the direction which is orthogonal to the dominant direction of the Fourier spectrum over $w \times w$ window.

Step-4: This is the matter of fact that unlike touch-based fingerprint detection models, touchless image driven approaches might undergo more noise, reflections, dust related problems. In addition, touchless images can have the likelihood of the more damaged or corrupted ridge values or orientation, which can also be given rise due to the change in orientation or light intensity, contrast etc. Non-uniform skin surfaces too can show different spatio-temporal distribution for the ridge and furrow values in touchless fingerprint images. In sync with such complexities and allied challenges, the estimated values of the local ridge orientation can become inaccurate as well at certain time. In reference to these issues, we recall a hypothesis stating that as the local ridge orientation values vary gradually in local vicinity, especially in those neighboring localities where there is no singular point takes place or appear. In this reference, the use of a low-pass filter can be employed to manipulate the incorrect local ridge estimation (6). Now, to achieve it the orientation image is converted into a continuous vector field (CVF), which is mathematically derived as per (7) and (8). In above (7) and (8), the variables Φ_x and Φ_y represent the x and y components of the vector fields, correspondingly.

$$\Phi_x(x,y) = cos\big(2\theta(i,j)\big) \quad (7)$$

$$\Phi_y(x,y) = sin\big(2\theta(i,j)\big) \quad (8)$$

Then performed LPF filtering by applying following mathematical approaches (9-10).

$$\Phi'_x(i,j) = \sum_{u=-\frac{w_\Phi}{2}}^{\frac{w_\Phi}{2}} \sum_{v=-\frac{w_\Phi}{2}}^{\frac{w_\Phi}{2}} W(u,v)\Phi_x(i-uw, j-vw) \quad (9)$$

$$\Phi'_y(i,j) = \sum_{u=-\frac{w_\Phi}{2}}^{\frac{w_\Phi}{2}} \sum_{v=-\frac{w_\Phi}{2}}^{\frac{w_\Phi}{2}} W(u,v)\Phi_y(i-uw, j-vw) \quad (10)$$

In (9-10), the parameter W represents the two-dimensional LPF possessing single integral where the size of the filter is considered as $w_\Phi \times w_\Phi$. We performed smoothing at the block level where the filter size was fixed as 5×5.

Step-5: Update the local ridge orientation at the pixel position (i,j) by using (11).

$$O(i,j) = \frac{1}{2} tan\left(\frac{\Phi'_y(i,j)}{\Phi'_x(i,j)}\right) \quad (11)$$

Thus, applying above stated approach of smoothening and allied orientation image estimation we obtained a uniformly oriented field image, which is consequently processed for frequency estimation.

4) Ridge frequency estimation: As stated in the previous sections, in case of touchless fingerprint images, especially when there are no minutiae in certain neighborhood, the gray-level values along ridges can be reconstructed as a sinusoidal wave. Noticeably, these sinusoidal-shaped waves are modelled towards the direction orthogonal to the local ridge orientation. Because of this reason, another key intrinsic feature from the input fingerprint images can be obtained in the form of local ridge frequency estimation. In other words, similar to the ridge orientation, ridge frequency can be modelled as an intrinsic feature for the touchless fingerprint images. In the proposed model, to estimate the ridge frequency information in a neighborhood we employed the pre-estimated measures like normalized image and the ridge orientation images. Let, G and O be the normalized and the orientation images, respectively. Then, with these values, we estimated ridge frequency using following sequential implementation approach.

Step-1: Split the input Gray-level image in 64×64 dimension.

Step-2: Estimate the orientation window with fixed size $l \times w$ (128×64) over each block, centred at the pixel information (i,j).

Step-3: In reference to the Step-2, estimate the $x-$signature $(X[0], X[1], \dots, X[l-1])$ of the ridges within the window, conditioned at:

$$X[k] = \frac{1}{w}\sum_{d=0}^{w-1} G(u,v), k = 0,1,\dots,l-1 \quad (12)$$

$$u = i + \left(d - \frac{w}{2}\right) cosO(i,j) + \left(k - \frac{l}{2}\right) sinO(i,j) \quad (13)$$

$$u = j + \left(d - \frac{w}{2}\right) sinO(i,j) + \left(\frac{l}{2} - k\right) cosO(i,j) \quad (14)$$

In case there exists no minutiae in the oriented window, the x-signature constitutes a discrete sinusoidal-shape wave, possessing the similar frequency as that of the ridges in oriented window. This as a result, enables estimation of the ridge frequency from x-signature. Consider that $T(i,j)$ be the mean pixel counts in between the two subsequent peaks in the x-signature, then the ridge frequency $\Omega(i,j)$ is measured as per (15).

$$\Omega(i,j) = \frac{1}{T(i,j)} \quad (15)$$

In case there is no consecutive peaks available in x-signature, then the frequency is assigned a fixed value -1 that helps in differentiating it from the genuine frequency values.

Step-4: In case, the fingerprint images are taken over a predefined and definite resolution, then the value of frequency of the ridges within certain vicinity remains within a definite range. In case of 600 dots per inch resolution (DPI) this range remains within the level of $\left[\frac{1}{3}, \frac{1}{25}\right]$. In this manner, in case the measured value of the frequency becomes higher than the above stated range, the frequency is assigned a value -1, signifying that no genuine frequency could be estimated or observed.

Step-5: In touchless fingerprint images and corresponding blocks where the minutiae or ridges are corrupted due to any local or personal regions, it doesn't constitute any well-structured sinusoidal wave. In this case, it becomes inevitable to interpolate those frequency values of those specific blocks from the frequency of the adjacent blocks possessing well-structured frequency. Here, we applied the following measures to perform interpolation, over each block centered at the pixel location (i,j).

$$\Omega'(i,j) = \begin{cases} \Omega(i,j) & if\ \Omega(i,j) \neq -1 \\ \frac{\sum_{u=w_{\Omega/2}}^{w_{\Omega/2}} \sum_{l=w_{\Omega/2}}^{w_{\Omega/2}} W_g(u,v)\mu(\Omega(i-uw.j-uw))}{\sum_{u=w_{\Omega/2}}^{w_{\Omega/2}} \sum_{l=w_{\Omega/2}}^{w_{\Omega/2}} W_g(u,v)\delta(\Omega(i-uw.j-uw)+1)} & Otherwise \end{cases} \quad (16)$$

Where, $\mu(x) = \begin{cases} 0, & if\ x \leq 0 \\ x, & Otherwise \end{cases}$

$$\delta(x) = \begin{cases} 0, & if\ x \leq 0 \\ 1, & Otherwise \end{cases} \quad (17)$$

In (16), W_g refers the discrete Gaussian kernel with mean and variance are assigned as 0 and 9, correspondingly. Here, the other components w_Ω be the size of kernels which was fixed at 7. In case there exists minimum one block possessing the frequency value of -1, then the value of Ω is swapped to Ω′, and the above stated process is repeated (Step-5).

Step-6: Considering the gradual change in the inter-ridge distance variation, the proposed model applies LPF to eliminate the outliers.

$$F(i,j) = \sum_{u=w_{\Omega/2}}^{w_{1/2}} \sum_{u=w_{\Omega/2}}^{w_{1/2}} W_t(u,v)\, \Omega'(i-uw, j-uw) \quad (18)$$

In (18), W_t represents the two-dimensional LPF with single integral, while $W_t = 7$ be the filter's size.

5) Ridge masking: As stated above, in real-time touchless fingerprint image a block or allied pixel can be either in non-recoverable or recoverable region. And therefore, classification of the blocks or pixels in above stated categories can be done on the basis of the wave's shape analysis. In this work, we employed three distinct features including amplitude (α),frequency (β) and variance (γ). Consider that, $X[1], X[2], \ldots, X[l]$ be the x-signature of a specific block centered at the pixel position (i,j), then the aforesaid three different features pertaining to that block are obtained as per the following approach.

Step-1: Assign the value of α as the mean height of the peak and the mean depth of the valley.

Step-2: Define β as $\frac{1}{T(i,j)}$, where $T(i,j)$ refers the number of pixels in between the two consecutive peaks (average value).

Step-3: Estimate the value of variance γ, as per (19).

$$\gamma = \frac{1}{l}\sum_{i=1}^{l}\left(X[i] - \left(\frac{1}{l}\sum_{i=1}^{l} X[i]\right)\right)^2 \quad (19)$$

Thus, applying this method we estimated a large number of three-dimensional patterns for each input image. Moreover, k-NN classifier was applied to classify each block of $w \times w$ dimension that classifies each input block as recoverable or non-recoverable so as to help identifying the most suitable set of feature blocks for feature extraction. In case a block was found recoverable, the corresponding region was estimated. In case, the fraction of the recoverable region was lower in comparison to a predefined threshold $(T_{Threshold} = 40)$, we dropped that image for further feature extraction and learning. Finally, an image with higher recoverable image with sufficiently large intrinsic features were considered for further feature extraction and learning, so as to improve fingerprint detection and classification. Here, we label the recoverable region $R(i,j)$ as 1, while non-recoverable region is labelled as 0. Now, once identifying the optimal set of intrinsically enriched images, we performed filtering to improve spatio-temporal feature distribution. The details of the filtering method applied is given in the subsequent section.

6) Gabor filtering and smoothening: This is the matter of fact that the structure of the parallel ridges in fingerprint image, especially possessing well-structured orientation and frequency can provide sufficiently large intrinsic information to drop irrelevant and noisy components. On the other hand, the sinusoid waves pertaining to the ridges too change gradually in the local fixed orientation. Because of this reason, a bandpass filter can be designed in such a manner that it would eliminate all unexpected or undesired noise components, while retaining the true ridge information for further learning. In reference to this scope, Gabor filter can be a viable solution as it possesses both orientation-selective characteristics as well as frequency-selective characteristics in both frequency as well as spatial domains. Considering this fact, we applied Gabor filter as the bandpass filter to eliminate noise components while preserving genuine ridge structures in fingerprint images. The Gabor filter can typically be presented as (20).

$$h(x,y:\phi,f) = exp\left\{\frac{1}{2}\left[\frac{(xcos\phi)^2}{\delta_x^2} + \frac{(ysin\phi)^2}{\delta_y^2}\right]\right\} cos(2\pi f cos\phi) \quad (20)$$

where ϕ refers the Gabor filter's orientation, while f represents the frequency of a sinusoidal wave. The components

δ_x and δ_y be the space constants pertaining to the Gaussian envelope towards x and y, correspondingly. Here, the modulation transfer function of the considered filter is stated as per (21).

$$H(u,v:\phi,f) = 2\pi\delta_x\delta_y\, exp\left\{-\frac{1}{2}\left[\frac{[(u-2\pi/f)sin\phi]^2}{\delta_u^2}+\frac{(ucos\phi)^2}{\delta_v^2}\right]\right\} + 2\pi\delta_x\delta_y\, exp\left\{-\frac{1}{2}\left[\frac{[(u-2\pi/f)sin\phi]^2}{\delta_u^2}+\frac{(ucos\phi)^2}{\delta_v^2}\right]\right\} \quad (21)$$

In (21), $\delta_u = 1/2\pi\delta_x$ and $\delta_v = 1/2\pi\delta_y$.

To implement Gabor filters over each input touchless fingerprint image, three different parameters including the frequency of the sinusoidal wave u_0, filter orientation and standard deviation of the Gaussian envelope in the different directions δ_x and δ_y are considered. Here, the frequency characteristics of the filter f is estimated by employing local ridge frequency and the ridge orientation values. In the proposed model, the selection of trade-off between δ_x and δ_y is maintained in such a manner that higher the trade-off, more noise tolerant. However, it might cause spurious ridge information. On the contrary, smaller the values, the lower the Gaussian envelope, δ_x and δ_y. However, it might be less effective towards noise elimination. In this work, δ_x and δ_y values were assigned as 4.0, each. Now, consider that the input gray-level input fingerprint image be G, O be the ridge orientation image, while F be the ridge frequency image, and R be the recoverable mask. Then, the improved fingerprint image ε is obtained using the following equation.

$$\varepsilon(i,j) = \begin{cases} 255, & if\ R(i,j)=0 \\ \sum_{u=-w_g/2}^{w_g/2}\sum_{v=-w_g/2}^{w_g/2} h(u,v:O(i,j),F(i,j)G(i-u,j-v), & Otherwise \end{cases} \quad (22)$$

Thus, the final local pre-conditioned and improved fingerprint images are processed further for the feature extraction and identification.

C. GLCM Driven STTF Textural Features Extraction and Classification

In this research work, GLCM functions as a descriptive statistical feature distribution model assessing the probability of the pixel's gray scale values over an input fingerprint image. Functionally, it extracts high-dimensional statistical features. In this work, the varied STTF features are distributed uniformly throughout the pre-processed input image. In this work, over each input fingerprint image we extracted the different STTF features, which were later combined together to yield a composite feature vector for learning and classification. In this method, the retrieved spatio-temporal textural features were derived in the form of a matrix representing pixel intensities $I(x,y)$, centered on the pixels (x,y). In this manner, we extracted different spatio-temporal textural features for each input pre-processed images, with distinct probability matrix $P_{i,j}$. Here, the above stated probability matrix signifies the differences of the intensity between the pixel elements i and j that later helps in detecting motion patterns. In GLCM gray-scale refers the pair association along a direction, and therefore retrieving the gray-scale values can yield a matrix representing the association matrix among the pixels towards the target direction. We obtained symmetric matrix S by amalgamating the gray-scale information along with the allied transpose values. It enables estimation of the cumulative relationship among pixels in one direction. We normalized the symmetric association matrix S using (23) to obtain the probability matrix $P_{i,j}$.

$$P_{i,j} = \frac{S_{i,j}}{\sum_{i,j=0}^{N-1} S_{i,j}} \quad (23)$$

With the extracted values of $P_{i,j}$, the different STTF features including Contrast, Energy, Homogeneity, Correlation, Mean, Standard deviation, Variance, Kurtosis and Skewness are obtained. As stated, a total of nine STTF features were obtained for further feature learning. Here, our predominant goal was to retain maximum possible and significant features for learning and classification so as to achieve higher accuracy.

Once extracting above stated nine different GLCM features, we performed horizontal concatenation to estimate a composite feature vector for further learning. The composite GLCM feature obtained is given in equation (24).

$$GLCM_{Feat} = Conc\begin{pmatrix} CONT, ENE, HOM, CORR, \\ Mean, Var, STD, Kur, Skw \end{pmatrix} \quad (24)$$

Now, once estimating the composite feature vector ($GLCM_{Feat}$), we projected it for feature learning and classification. As stated, in this work we intended to exploit maximum possible feature instances to ensure optimal learning by Random Forest learning method and hence classification accuracy.

III. Results and Discussion

As stated above, in this section we mainly focus on assessing efficacy of the proposed contactless fingerprint detection and classification model, qualitatively as well as quantitatively. In other words, here we examine whether the use of local pre-conditioned image improvement yields superior performance. Before discussing the simulation results quantitatively, a snippet of pre-conditioned and enhanced results is given as follows.

Fig. 1(a) presents a random input 3D touchless fingerprint image. Here, it can easily be visualized that the illumination at the image center and bottom is relatively higher in comparison to the top corners. Moreover, the ridge structures in lower right bottom are unclear with high level of ambiguity. Furthermore, the straight division lines on the left side (bottom to top) can easily be visualized in this sample image, which can disrupt the ridge continuity to make further feature segmentation or allied feature learning. Noticeably, there are numerous local conditions such as low temperature, salty water contact by which the ridge values get changed temporarily. Though, with touch-based classical methods while pressing finger over the sensor, such local deformations get suppressed; however, in touchless fingerprint detection it can have decisive impact on feature learning and hence classification. To alleviate such issues, we performed local pre-conditioning to improve the ridge quality for further feature extraction. As repeatedly stated in the previous sections, we intended to guarantee ridge continuity over the different local conditions while ensuring that the ridges contain sufficient intrinsic features. To achieve

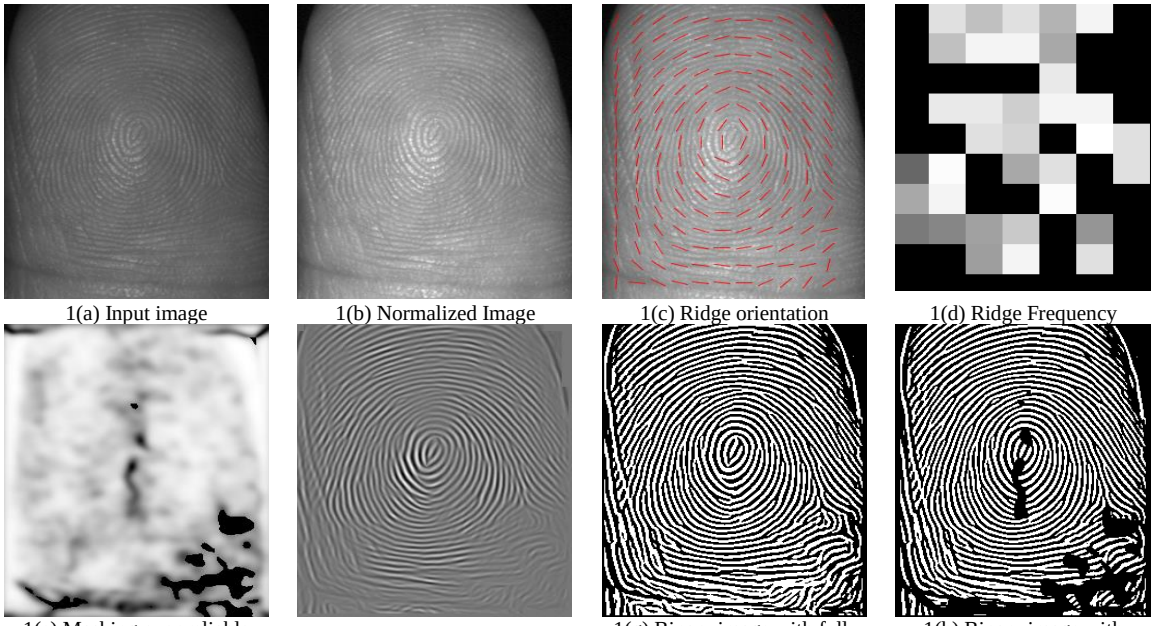
it, we applied the different pre-processing steps like image normalization, ridge orientation estimation, frequency estimation, ridge masking and filtering. Fig. 1(b) presents the normalized image output obtained from the original input image. Here, the impact of normalization can easily be visualized. Now, recalling the methodological intend where we intended to improve ridge structure continuity even over non-linear textural fingerprint surfaces, we performed ridge orientation estimation as shown in Fig. 1(c). The ridge frequency obtained over each grid is given in Fig. 1(d). In Fig. 1(e) presents the ridge masking results where the high frequent ridges are masked as 1, while the less frequent ridges are labelled as 0. Here, the key motive was to retain the ridge information carrying densely distributed features. The improved ridge structure is obtained by filtering (Fig. 1(f)). Here, observing the results it can easily be understood that the improved 3D touchless fingerprint image caries more uniform ridge's distribution with precisely perceptible structure, which can provide more efficient feature vectors for further learning and classification. The other images (Fig. 1(g) and Fig. 1(h)) represent the binary images, where 1(g) depicts the binarized image over the input (1(f)). Observing the bottom of the binarized image (Fig. 1(g)), it can be found that the bottom of the image carries ambiguities primarily because of ridge and furrow diversity, conjunction and non-linear bifurcation, random cuts etc. This as a result can impact STTF textural features and hence overall fingerprint detection accuracy. However, retaining a threshold driven approach can retain only feature intensive components to perform further feature and classification. Thus, observing the results in Fig. 1, it can be stated that the inclusion of the proposed model can yield superior feature vector for further learning and classification. Noticeably, in our proposed model to perform feature extraction we considered the improved ridge image (Fig. 1(f)) as input, which is hypothesized to yield superior performance.

The statistical performance outputs were measured by obtaining confusion matrix in terms of Accuracy, Precision, F-measure, Specificity, Recall and EER and are listed in Table II.

This is the matter of fact that a large number of studies have been done towards touch-based fingerprint detection systems; however, the efforts made towards touchless fingerprint detection are countable and very rare. Our depth literature assessment revealed that merely countable a dozen of efforts is made so far to introduce 3D touchless data for fingerprint detection. To assess relative performance, we have selected the recent methods like [8-12]. Ritesh and Ajay [9] developed a collaborative paradigm by exploiting ridge-valley minutiae information to perform contactless fingerprint detection. In their effort, authors mainly focused on improving minutiae under complex input data environment (like unclear ridge bifurcation, varied viewing angle and allied textural gradiance). Moreover, authors tried to suppress spurious minutiae information so as to improve accuracy and reliability.

TABLE II. PERFORMANCE ASSESSMENT

	Proposed method
Accuracy	94.72%
Precision	98.84%
Recall	97.71%
Specificity	95.38%
F-measure	0.9827
Equal Error Rate	0.084



1(a) Input image 1(b) Normalized Image 1(c) Ridge orientation 1(d) Ridge Frequency

1(e) Masking over reliable feature space 1(f) Improved Ridge structure 1(g) Binary image with full-scale input 1(h) Binary image with Threshold (Reliability >0.5)

Fig. 1. Pre-conditioned and Enhanced Results by the Proposed Method.

Authors applied the different datasets or fingerprint matchers like NBIS Biometric Image Software, MCC, and COTS (Commercial off-the-shelf), and therefore obtained the different performance over the different benchmark data. Interestingly, over the NBIS matcher they could achieve the EER of 13.33%. Noticeably, in comparison to their effort our proposed model exhibited EER of 0.084%. It shows superiority of our proposed model over the existing approach [9]. Recently, Galbally et al. [8] developed 3D-FLARE, a touchless fingerprint detection model; however. Despite the fact that their approach was quite complex in real-world realization, it exhibited EER of 10.03%. Though, to alleviate aforesaid data environment complexities, authors [8] made effort to segment yaw angle with fingerprint and fingertip separation etc., which was followed by hybrid feature extraction using local binary patterns (LBP) and Histograms of Oriented Gradient (HOG) features. Authors applied LBP+HOG features obtained from the segmented features to perform classification.

Authors could achieve the average EER of 10.03%, which is still higher than our proposed model. Kumar and Kwong [10] proposed a single camera driven touchless fingerprint detection model. In fact, it was a 3D minutia matching concept that made effort to recover extended 3D fingerprint features from the reconstructed 3D fingerprints. The EER performance by authors [10] was 1.02%, which is far more than our proposed model. An improved model by Lin and Kumar [11] applied deep learning driven multi-view touchless fingerprint detection model. This approach exploited multi-view deep representation to perform touchless fingerprint detection. Their proposed model [11] encompassed convolutional neural network where one fully convolutional network was applied to perform fingerprint segmentation, while three other layers were employed to learn 3D multi-view fingerprint feature representation. Undeniably, authors made effort to address at hand complexities with contactless fingerprint detection models that resulted into reduced EER value (0.64%). Zheng and Kumar [12] performed 3D fingerprint identification by exploiting recovered surface normal and albedo information. The key novelty of this approach was that it didn't require any surface reconstruction rather it employed different mathematical approaches to retrieve surface normal and albedo information, which was later used for learning and classification. The EER performed by this approach was 2.49%, which was higher than our proposed model. Thus, observing overall performance outcomes and allied inferences as shown in Fig. 2, it can be stated that the proposed touchless fingerprint detection model outperforms other state-of-the-art methods.

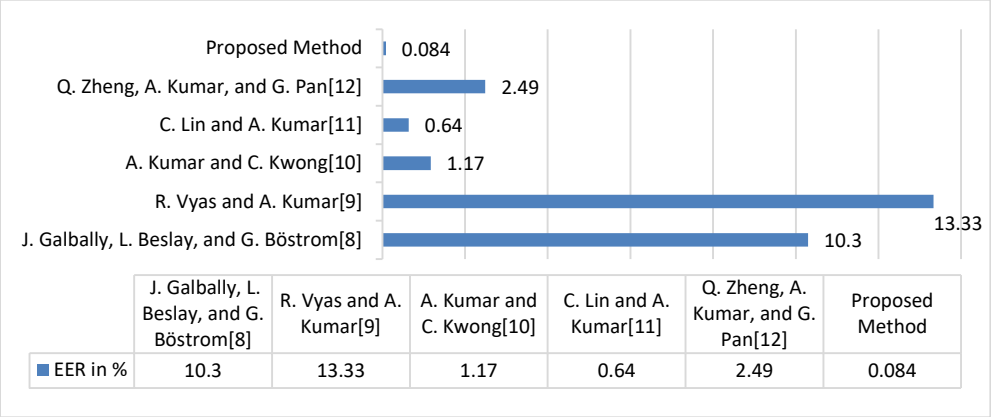


Fig. 2. Comparison of Equal Error rate of the Proposed Method with the Existing State-of-the-Art Methods.

IV. Conclusion

Since the inception, the fingerprint detection models have always been considered as a vital alternative of the classical cryptosystems. Undeniably, being fast in execution and diverse in spatio-temporal presentation, fingerprint-based systems turn out to be more efficient solution for personalized security and access control purposes. This efficacy makes fingerprint-based authentication system as one of the most used approaches for corporates, financial sectors, smart home and industrial monitoring and control. Despite robustness, being touch-based paradigm, its optimality has been challenges under different operating environment, especially in reference to the health and hygiene. During the recent pandemic of COVID-19, touch-based fingerprint models were found vulnerable due to touch-based infection probability. To alleviate such issues, contactless fingerprint detection method can be a viable solution; however, being touchless in nature such approaches might undergo different complexities like the impact of viewing angle, textural non-linearity, non-uniform illumination and contrast, ridge and furrow ambiguity, ridge discontinuity, etc. On the other hand, extracting structural features or other STTF features over aforesaid local adversaries can impact overall efficacy. In other words, training over a feature obtained from ambiguous or minimally distinct spatio-temporal feature space can give rise to the high false positive rate (FPR) and Equal Error Rate (EER). To alleviate such problems, it requires multiple optimization measures including local quality improvement or ridge improvement, and information-rich feature extraction. To achieve it, at first a local pre-conditioning concept was derived that mainly focused on improving ridge's orientation and spatial presentation so that the optimal features could be extracted. Recalling the fact that extracting features over the ambiguous ridges or furrows or even over detached ridges can lead false positive, the proposed pre-processing model helped in alleviating aforesaid complexities. This approach eventually retains only those feature-rich spatial components having clearly observable or distinctly distributed ridges for reliable feature extraction and

classification. As a future work we can experiment with the different feature extraction methods and learning algorithms to improve the accuracy of classification. Efforts can also be made in feature extraction stage like using Deep Neural Networks to reduce the Equal Error Rate and False Positive rate.

ACKNOWLEDGMENT

The Authors would like to thank the management, Principal and authorities of Malnad College of Engineering, Hassan for extending full support in carrying out this research work.

***Abstract*—In recent years, the availability of chatbot applications has increased substantially with the advancement of artificial intelligence techniques, and research efforts have been active in the English language, which presents state-of-the-art solutions. However, despite the popularity of the Arabic language, its research community is still in an immature stage. Therefore, the main objective of this systematic literature review is studying state-of-the-art research – for both the English and Arabic languages – to answer the proposed research questions regarding the development approaches, application domains, evaluation metrics, and development challenges of chatbot applications. The findings show that researchers have devoted more attention to the education domain using retrieval-based approaches while the generation-based approach has grown in popularity recently for providing new responses tasks. Whereas the hybrid approach for ranking multi-possible responses of combining both previous approaches shows a performance improvement. Besides, most metrics used to evaluate chatbot performance are human-based, followed by bilingual evaluation understudy and accuracy metrics. However, defining a common framework for evaluating chatbots remains a challenge. Finally, the open problems and future directions are highlighted to help in developing chatbots with minimal human interference to simulate natural conversations.**

***Keywords*—Chatbots; Arabic language; development approaches; domain applications; evaluation metrics**

I. Introduction

A chatbot is an example of a computer application based on artificial intelligence (AI) that aims to simulate human behavior by conducting a conversation with users using natural language data. The most well-known social applications, such as Telegram and Facebook Messenger, are supported by chatbots. Several organizational benefits of using chatbots include 24-hour availability, endless patience, increased sales, and reduced operational costs [1]. These benefits have led to an increasing demand for the development of chatbots using AI techniques. However, developing effective chatbots that can respond at the level of an actual human is challenging due to the requirement of understanding user inputs, generating appropriate responses, and perceiving the context of the conversation [2].

Over the past decade, a rapid development of chatbots based on English language has taken place in many application domains. In last two years, several *surveys* have been published about chatbots, mostly focused on the implementation approaches, such as those [3],[4],[5]. However , some of the previous research have been limited to specific domains, those researches reviewing the techniques, characteristics, and approaches used in the development used in the development of an intelligent tutoring chatbot applied to education [6], [7]. Moreover, the research in [8] examined previous articles which showed that the personalized learning framework of chatbots helped students improve in their studies. Although the surveys in [9],[10],[11],[12] were careful investigations, they have different aspects *than* this SLR. For example, the study in [11] used a different database and selection criteria. Also, the studies in [9] and [12] presented different research questions. In addition, the evaluation measures and challenges of implementation are not highlighted in [10].

Although developing a chatbot follows similar approaches regardless of which language is being used, for languages such as Arabic, chatbot implementation is challenged by the language's rich morphology, multiple dialects, and orthographic ambiguity [13][14]. However, according to findings obtained from this SLR, in the past three years, research about Arabic chatbots has substantially increased but still has insufficient resources such as available data sets, pretrained models, and tools [13]. Furthermore, to date, few surveys have been done about Arabic chatbots to identify the techniques, metrics, and data sets used. However, chatbots that existed till 2018 are used to process the data in the survey of [15] and did not address some of the same research questions investigated in this SLR [16]. In addition, the survey in [17] highlights one approach to develop a chatbot instead of covering all of the three approaches that will be covered in this SLR. Also, the study in [18] takes a different perspective on a number of applications involving the chatbot. Finally, the study in [19] investigates the characteristics of Arabic chatbots. Overall, the Arabic chatbot research community is still at an immature stage, so the English studies are included to present state-of-the-art solutions.

The objective of this SLR is to present a general overview of the English and Arabic developed chatbots by deeply investigating the current articles in this field. It addresses the domain applications, and approaches used to develop a chatbot and compare these addressed aspects to both languages, English and Arabic. The challenges and evaluation metrics also will be considered. Furthermore, after discussing the findings, the open research problems and future directions for research will be highlighted. The rest of this paper is organized as follows: Section II briefly overviews the chatbot technology. The methodology that follows in this SLR is provided in

Section III. The discussion of finding, open research problems and future research directions are presented in Section IV. Finally, Section V reports conclusion.

II. Chatbot Approaches and Techniques

A. Chatbot Approaches

The selected articles in this SLR generate their responses using different approaches. These approaches can be categorized based on the response generation into rule-based, corpus-based, and hybrid approaches [20]. Fig. 1 presents the approaches along with their common techniques in the selected articles.

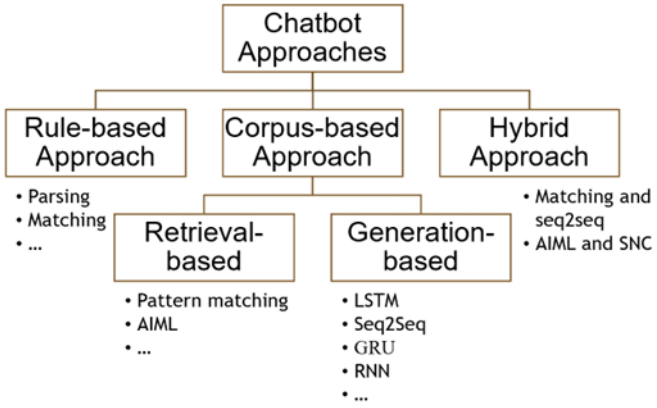

Fig. 1. The General Structure of Chatbot Approaches.

1) Rule-based approach is made up of a set of predefined human-made rules used in the hierarchy to convert user input into an output [20]. The rules break down the input into a sequence of tokens to find a pattern and generate a response rather than generating a new response. Although this approach can be considered easier in terms of implementing, it restricts responses to inputs *within* the predefined rules only and may provide inaccurate responses, leading to an unsatisfactory experience [1].

2) Corpus-based approach uses a knowledge base that contains a statistical language approach to select suitable responses instead of using predefined rules. Most chatbots in this approach produce their responses either two approaches:

- Retrieval-based approach uses information retrieval to get a candidate response from the corpus based on heuristics techniques rather than generating a new response [20]. This technique considers not just input but also the context by identifying keywords to offer the optimal response from a predefined responses (knowledge base) [21].
- Generation-based approach generates the responses based on the dialog context and does not require any predefined response. The chatbot attempts to generate a new response by considering the current and previous user interactions. It may require a large training set, which is potentially tricky to obtain. However, this approach has a high chance of response errors since generating in real-time.

3) Hybrid approach takes advantage of the combined strengths of the generation-based and retrieval-based approaches. Thus, the responses achieve more accurate results by capturing the informative pattern features. The researchers conducted *this* combination by ranking the response from generative and retrieval models or enhancing the informativeness and diversity retrieval responses by feeding them into a generation-based approach [1].

B. Chatbot Techniques

Several techniques are used in this SLR. The following subsections describe these techniques in detail:

1) Parsing. It converts text into meaningful representation string to determine the dependence relationship between its terms or its semantic structure. The parsing technique can be a lexical parsing that converts text into less complicated atomic terms to help extract information and simplify the manipulation. After applying lexical parsing, a syntactical parsing and a semantic parsing can be applied. These two parsing techniques determine a sentence's grammatical structure and extract a specific meaning by converting text to a machine-understandable representation of its meaning [21]. The parsing technique helps chatbots to understand text by identifying the main keywords in it [22]. For example, “set your eyes on my friend” and “could you see my friend” would both generate the same parsed “see my friend”. Moreover, this technique helps to identify the ambiguity in order to ask a user to rephrase his input [23]. For example, two possible ways to interpret the sentence “I saw my friend with my phone”: 1) did my phone help me see my friend; 2) did I see my friend holding my phone.

2) Pattern matching. Chatbots in this technique create a response with patterns where they are made manually, which is a non-trivial process [21]. Although it helps in response time reduction, the responses may be fully predictable and repeated, resulting in dull interactions that lack spontaneity and the human touch [24]. For example, the chatbot recognizes the input “where is the stickers?” and identifies keywords, here is “books”, where each keyword associates with an intent and response, here are “Office supplies” and “Different types of supplies in the office supplies aisle”, respectively.

3) AIML. Chatbots implement a syntax of the pattern matching technique through different technologies like the AIML to retrieve the most suitable response selection [25]. AIML is an open standard language derived from the Extensible Mark-up Language (XML). AIML comprises data objects consisting of two elements which are topics and categories. A topic is an optional top-level element with a set of categories related to that topic, while a category is a rule with a pattern and template matching for input and response, respectively. The objects are sorted in AIML files. Despite its readability, usefulness, and effective use of response time, it must provide a pattern for each conceivable response and update it on a regular basis, which cannot be done automatically [10].

4) RNNs. The RNNs allow the chatbot to handle sequential data and consider the current users' input. Due to the internal short memory, it memorizes the previous users' input. In other words, unlike a traditional Neural *Network*, RNN permits data to remain. The main idea of RNN is saving the output of a particular layer and feeding it as input to the next layer to predict the output [26]. Due to the vanishing or exploding gradient problem [27], the unmodified version of RNN is not appropriate for some applications. LSTM [28] and Gated Recurrent Units (GRU) [29],[30] are different solutions to this problem.

5) LSTM. The LSTM is a special kind of RNN [28]. LSTM is designed to handle long-term *dependencies* and solves the vanishing or exploding gradient problem in RNN. Thus, the gates are introduced in LSTM. Gates are the core component in LSTM, which decides which information that will be memorized. Additionally, the gates output the value between zero and one, where zero means do not memorize anything and one means let everything pass to the next state. Moreover, three kinds of gates are available in LSTM: input gates, forget gates, and output gates to control the flow of information. The input gate is responsible for the state update mechanism while the forget gates decide which information should be memorized. Additionally, the output gate determines the output from the hidden layer. The memory cell in LSTM comprises these three gates. Since the LSTM is created as the solution to short-term memory, it is capable of remembering aspects such as gender. Thus, depending on the previously remembered input, the chatbot can use "his/her". There exists a different architecture of LSTM, such as BiLSTM, which considers the input from the opposite direction as well [31]. Besides, the GRU is the main competitor of the LSTM and RNN [29],[30]. Due to its architecture, it is more popular and less complex than LSTM. The input and forget gate are combined to form a single "update gate".

6) Seq2Seq. Seq2Seq structure is the first architecture proposed to solve translation problems: their success bodes well for NLG. The seq2seq is trained end-to-end using different datasets and domains. Furthermore, due to its flexibility, simplicity, and generality, it is widely used to solve different NLP tasks, which makes seq2seq the industry-standard structure [32]. Technically, seq2seq is composed of two RNNs, namely, an Encoder and a Decoder. The Encoder processes the input of the user word-by-word while the Decoder generates the response word-by-word based on previous conversations. For building chatbots, rather than translating from one language to another, the problem was considered as translating the user input to the chatbot response. Additionally, the length of the input and response sequences can differ, which is one of the advantages of seq2seq structure over others.

III. Survey Methodology

The systematic method used in this SLR for reviewing chatbot articles are based on Kitchenham guideline [33]. This guideline consists of three stages which are planning, conducting, and reporting the review.

A. Planning

This subsection presents the research preparation of the SLR, search procedure and finally the inclusion and exclusion criteria.

1) Goals and research questions. The primary purpose of this SLR is focusing on analyzing the state-of-the-art English and Arabic chatbot articles, especially, with respect to their development approaches, application domains, evaluation metric and the main chatbot's development challenges. To achieve these objectives, four research questions are addressed. Table I presents the research questions and motivation.

TABLE I. List of the Research Questions

Number	***Research Question***	***Motivation***
RQ1	What are the main development approaches used for chatbot with regard to the user's generating appropriate response?	Identifying the state-of-the-art approaches and their techniques may be a significance for developers to provide more fit solutions by working and evolving the recent techniques trends
RQ2	What are the several domains used for building the chatbot?	Identifying the several application domains that most common used may help and enable researchers to address the current focus of domain of application as well as boost research in less contributed domains
RQ3	What are the commonly used metrics to evaluate the chatbots' performance?	Identifying the commonly used metric to evaluate the performance may help to improve and standardized the assess of chatbot, besides mitigate the difficult of comparing the performance of different chatbots
RQ4	What are the main challenges facing the implementation of Chatbot?	Open-research problem in development chatbot and the future directions are provided to continue developing the current issues.

2) Databases identification and search procedure. Six digital databases were *selected* which are: IEEE Xplore Digital Library, Springer, ScienceDirect, Google Scholar, Web of Science (ISI), and ACM. The search was done using 15 keywords as mentioned in [15], [9], [11] and presented in Fig. 2. The search procedure uses 15 keywords belonging to the computer science field in the predefined date ranges. There are 14 keywords for English and additional special keyword for Arabic search "Arabchat". For Arabic search, the same 14 keywords are used proceeding by adding "Arabic" term.

3) Inclusion and exclusion criteria. All criteria are applied manually after searching in the six databases. The inclusion criteria are based to the date and type of articles for both English and Arabic research. The selected articles of research work of the journals based on English chatbots started since 2018 till beginning 2022, period at which our actual SLR research study is done. However,due to the lack of Arabic research, the selected Arabic articles from journals and

conferences are starting from 2004 which is the publication year of one of the earliest Arabic articles till beginning 2022 [15]. Moreover, selected range of the earliest approach, rule-based approach, is extended because lately few recent research studies were utilizing this approach. Four inclusion criteria are: 1) Articles published in both English and Arabic Languages; 2) Articles published in specific ranges as mentioned previously; 3) Full text articles; 4) Articles that addressed the proposed research questions.

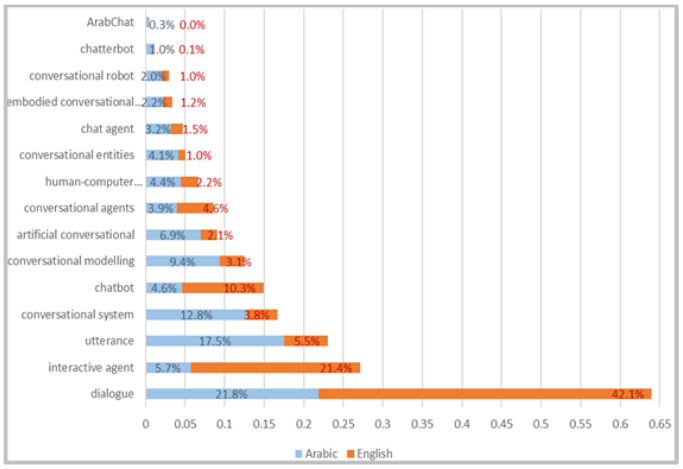

Fig. 2. Total Retrieved Articles for 15 Keywords.

After applying the inclusion criteria, four exclusion criteria are used. The first criterion discards any article that is not related to the chatbot depending on their titles and abstracts. Conspicuously the search in databases sometime returns a huge number of articles that cannot be processed manually. Thus, one ascension in this step is considered which is the returned articles in a database search engine are ordered relevantly to the keywords. Therefore, irrelevant investigated articles are followed by irrelevant articles as well. The second criterion is to remove the duplicate articles that appear in more than one database out of the searched six databases. The third criterion relates to the research questions and involves assessing the candidate articles under the quality assessment as will be discussed in the following subsection. The last criterion keeps journals for both languages and accepts Arabic articles from conferences, while books and theses are filters.

B. Conducting the Review

1) Article selection. The result of 15 keywords searching in all databases returns 59,169 articles. Fig. 2 presents the total number of returned articles for each keyword from all databases in ascending order. The most common keywords is “dialogue” for both English and Arabic chatbot research. Mostly, the greater number of words in each keyword, the smaller number of returned relevant articles, such as the two keywords "dialogue" and "human-computer conversational systems". Moreover, different searching strategies are used in digital databases for retrieving relevant articles. Some of them including in ACM and Google Scholar mostly return a large number of articles exceeding 250K which is caused to restrict the search in them to occur keywords only in the title of articles. Although of that, Google Scholar database still returns the largest number of relevant articles.

2) Data extraction. The result of applying manually exclusion criteria presents in Fig. 3. Firstly, removing irrelevant articles by analyzing their titles and abstracts remained 321 articles that were downloaded. Then 137 duplicated articles were removed. Next, the full texts of the remaining articles were investigated deeply, resulting therefore at filtering 56 articles not addressing the research questions or not passing the quality assessment. The 40 of articles are filtered involving books and theses. As a result, 50 and 38 English and Arabic articles, respectively, are relevant and investigated for the SLR.

3) Quality assessment. The assessment process was conducted in simultaneously with articles extraction. The process was performed for each candidate article individually where the various assessments is discussed until a consensus was achieved. The checklist of ten assessment questions are provided, where a candidate article was selected when at least it gets seven yes answered to the ten questions [34]: 1) Does the article present the objectives of the research clearly? 2) Does the article well-describe the proposed approaches and techniques? 3) Does the article attempt to address an existing issue with chatbot applications? 4) Does the design adhere to well-defined design concepts or principles? 5) Does the article describe the used dataset? 6) Does the article state the results? 7) Does the article state the process of performance evaluation? 8) Dose the article discusses one of domains in the chatbots application? 9) Does the article have a coherent reporting and understandable? 10) Does the article have an appropriate research method appropriate to address the aims of the research?

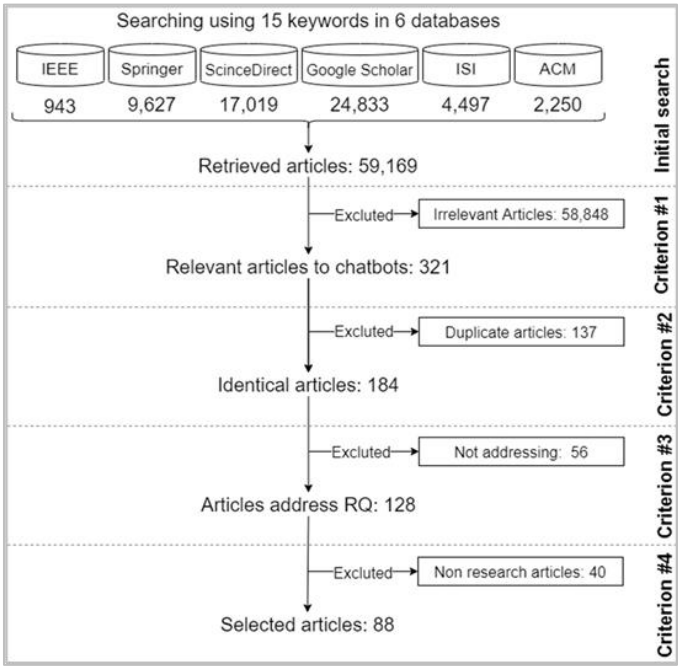

Fig. 3. Data Extraction Step.

C. Reporting the Review

1) Approaches. A detailed comparison of these works is offered in Table II. It is worth noting that no technique is the best selection for all problems. Hence, experimentations in the selected articles are used to compare these techniques. In addition, many chatbots have been developed using state-of-the-art platforms or programming languages for various purposes [5]. Table III presents publicly existing platforms in the selected articles to implement chatbots. The other research works done in [35],[36],[37],[38] develop chatbots using programming languages based on C# in Verbot 5.0, on Snatchbot, Microsoft Visual Studio linked to Google Translate API and the Twilio platform, respectively, as well as some libraries in python are used, such as ChatterBot and chatterbot_corpus.

2) Domains. The functionality of chatbots can be divided into two categories: task-oriented chatbots that interact to fulfill tasks, usually for a specific domain, and non-task-oriented chatbots that engage in open-domain interactions, usually for the sake of amusement. Depending on the selected articles, different domains are divided into two main categories: open domains and closed domains. Table IV analyzes English chatbots followed by Arabic chatbots ordered by their publication years from domain perspective.

3) Evaluation metrics. Human-based and automatic-based evaluation metrics are two main metrics to evaluate chatbots. Human evaluation involves having a group of people communicate with the chatbot and evaluating various aspects using evaluation frameworks or questionnaires. The other categories include different proposed evaluation frameworks, such as sensibleness and specificity average (SSA) and quasi-Turing test method [39][40]. Table V presents a summary and comparison of more than 20 types of evaluation metrics used in chatbot development over the selected articles. While more than 70 articles have detailed the evaluation of their works, about 15 different articles seem not to evaluate their chatbot at all, which were classified under the not available (NA) category. From the table, it can be observed the most common measure used for both languages is human evaluation, then the BLUE and Accuracy for English and Arabic, respectively.

TABLE II. APPROACHES AND TECHNIQUES USED IN IMPLEMENTING SELECTED ARTICLES

Approach	*Techniques/Structures*		*Description*	*Advantages*	*Disadvantages*	*Articles*
Rule-based	Rules and patterns matching		Set of predefined human-made rules	• Simple and lower cost implementation • Quick deploy • No overtime for learning user intent	• Cannot learn on their own. • Fail to response outside its preset understanding	[41],[42],[43]
	Parsing		Converting a text to be less complicated terms	• Providing dependency relationship between words or semantic structure of the text	• Same the rules and patterns matching disadvantages	[44],[45],[46]
Corpus-based: 1.Retrieval-based	Pattern matching		Matching inputs with predefined structures of responses	• Sufficient on simple tasks • Select informative responses from candidate responses • More flexible than the rule-based.	• Providing chatbots without reasoning and creation. • Limited capabilities and repeated responses.	[47],[48],[49],[50],[51], [52],[53],[54],[55],[56],[57], [58],[59],[60],[61],[62],[63], [64],[65],[66],[67]
	AIML		Represents the knowledge as objects which derived from XML	• Advantages of pattern matching • Powerful in designing conversational flow	• Building all the possible patterns manually • Difficult to scaling	[68],[69],[70],[71],[72],[73], [74],[75],[76],[77],[78]
2.Generation-based	LSTM	CNN	CNN usually used for learning features utomatically by utilizing convolution and pooling processes	• Accurate on a larger dataset • Suitable to remember longer sequences	• Uses large number of parameters • Required more memory size • Long execution time • More complex structure	[79],[80]
		CNN and GRU	GRU is a type of RNN technique related with LSTM.			[81]
		RGDDA based on gradient reinforcement learning	Generating responses by utilizing user-specific information			[40]
		Stacked LSTM	Stacked LSTM is comprised of multiple LSTM layers			[82]
		Stacked LSTM and BiLSTM	BiLSTM: Both directions is followed by the input.			[83]
		BiLSTM, HRED	HRED generates context and response			[84]

Approach	*Techniques/Structures*		*Description*	*Advantages*	*Disadvantages*	*Articles*
			embeddingusing three stacked RNNs			
		Attention	Attention is based on RNNs cell and improved technique of seq2seq learning			[85]
	seq2seq	Seq2seq learning based on encoder-decoder architecture	Mapping a sequence of input words to another representation of response sequence.	• Same advantages of tachniques that seq2seq depending on it • Support variable-length size of input and response	• Same disadvantages of tachniques that seq2seq depending on it	[39],[86],[87],[88],[89],[90], [91]
	GRU		In compression to LSTM, GRU required fewer parameters training and it not being required for an additional cell state	• Uses less training parameter • Uses less memory • Take less time in execution • Less complex structure	• Not suitable for large dataset • •Not suitable for long-distance relations	[92],[93]
	RNN	Attention mechanisms besides BiGRU	Attention mechanisms Improved technique of seq2seq learning based on RNNs cell. Resolve the problem of systems' incapability to remember a longer sequence	• Uses less training parameter • Uses less memory • Take less time in execution • Less complex structure	• Suffer from gradient exploding and vanishing problems. • Difficult to process very longer sequences • Not suitable for parallelizing or stacking up	[94]
		Enhancement of RNN-GRU	This technique is improved by adding three additional cells which are Refinement, Adjustment, and output cells			[95]
	Pre-trained model	GPT-2, DIALOGPT, BoB, aubmindlab, CakeChat, asafaya,	To map words to actual number vectors, a language modeling and feature extraction technique was used.			[96],[97],[98],[99], [100]
Hybrid	Combination of generation and retrieval-based approaches		XiaoIce: more popular example from Microsoft	• Easy to select the attributes (relevance) from ranked features list.	• If the hybridization technique is not complementary to each other, the performance quality may decrease.	[101]
			Proposed PS, GP, and PRF			[102]
			Develop matching method based on the seq2seq			[103]
			Develop a model using the Twitter LDA model and attention mechanism			[104]
			Integrate AIML technique with a SNC model			[105]
			Multi-strategy process including LSTM with an attention mechanism beside rule-based technique			[106]

TABLE III. PLATFORMS USED IN IMPLEMENTING SELECTED ARTICLES

Framework	*NLP features*	*API*	*Control conversation*	*Languages*	*Limitation*	*Articles*
Google's DialogFlow	Yes	Yes	Yes	More than 45 languages from Bengali to Vietnamese except Arabic	Limitation of understanding the synonyms and hyponyms besides the documentation isn't very good	[107],[108],[109],[110]
Pandorabots	Yes	Yes	No	Support many languages including Arabic	Limitations to dealing with Arabic spelling mistakes	[76],[77]
IBM Watson Conversation	Yes	Yes	NO	13 languages from Arabic to Spanish	Not support Enhanced intent detection and autocorrection fixes misspellings	[111],[112]
Microsoft Azure	Yes	Yes	Yes	Translating 100 languages from Afrikaans to Yucatec Maya	Replying using translation system which increase the error rate	[60]
Rasa	Yes	Yes	Yes	Can be trained on any languages	Not support Arabic predefined trained entities	[113],[114]
Facebook Bot Engine (Wit.ai)	Yes	Yes	Yes	More than 100 languages from Afrikaans to Zulu	Time consuming when training the chatbot to understand all the different forms of Arabic text	[115],[116],[117]
Chatfuel	NO	Yes	NO	Support many languages including Arabic	Inflexible in terms of conversation flows and multi-languages	[118]
OSCOVA	Yes	Yes	Yes	NA	Not appropriate for complex conversation	[119]
Recast.AI	Yes	Yes	Yes	More than 15 languages from Arabic to Swedish	Poor documentation	[120],[121]

TABLE IV. DOMAINS USED IN SELECTED ARTICLES

Domain	*Languages*	*Articles*
Religion	Classical Arabic	[73],[60],[72]
Education	English	[117],[86],[90],[108],[118],[107],[45],[112],[109],[122]
	Classical and MSA Arabic	[50],[51]
	MSA Arabic	[54],[58],[57],[55],[52],[53],[67],[66],[110],[63],[65]
	Arabic dialects: Saudi Arabic dialect and Jordanian	[77],[78]
Healthcare	English	[41],[44],[47],[70],[49],[71],[119]
	MSA Arabic	[74],[111]
	Arabic Dialects: Egyptian	[100]
Tourism and airline	English	[35],[43]
	MSA Arabic	[59],[75],[46],[113],[115]
Business and customer service	English	[87],[69],[121],[81],[84],[95],[83],[106],[120]
Empathy and personalization	English	[123],[101],[92],[124]
	MSA Arabic	[85],[125]
Open	English	[68],[89],[79],[40],[104],[99],[36],[102],[94],[39],[82],[48],[105],[88],[114],[98],[116]
	MSA Arabic	[64],[42],[61],[56],[80],[93],[38],[62]
	Arabic Dialects: Gulf Arabic and Egyptian	[91],[76]

TABLE V. METRICS USED IN SELECTED ARTICLES

Categorization	*Metrics*	*Articles*
Automatic based Metric	F1-Score	[89],[114],[106],[80],[62],[100]
	Precision	[105],[106],[80],[62]
	Recall	[105],[106],[80],[62]
	Accuracy	[92],[114],[126],[105],[124],[80],[93],[62],[100],[76],[56],[74]
	PPL	[89],[102],[94],[92],[98],[124],[126],[39],[101],[85]
	BLEU	[79],[83],[94],[81],[92],[95],[84],[126],[127],[86],[101],[49],[40],[40],[99],[85],[91]
	ROUGE	[79],[83],[84],[49]
	MAP, P@1 and MRR	[103],[104]
	SkipThoughts cosine similarity, embedding average cosine similarity, vector extrema cosine similarity, BOW and greedy matching scores	[79],[102],[94],[81],[84],[127],[88]
	Other	[87],[95],[84],[39],[116],[40],[99],[109],[43], [48], [79], [102], [127]
NA		[70],[41],[44], [107],[47], [68], [69], [108], [121],[38], [61], [67], [67], [73], [108], [113]
Human based Metric	H: User Satisfaction	[35], [45], [82], [84], [89], [118], [128],[36], [49], [98], [101], [117],[112], [119], [120], [122],[60], [77], [85], [90],[63], [78], [91], [110], [125],[46], [57], [59], [111], [115],[54], [55], [65], [66], [75],[42], [50]–[53], [58], [64], [72]

IV. Discussion

This SLR reviews 88 articles to address the four research questions. This section discusses findings, highlights challenges and open problems with providing future research directions that we expect would help in developing chatbots.

A. Finding

1) Approaches. Initially, no approach or technique is the best for all domain applications. Selecting one approach or another deeply depends on several considerations. With recent improvement in computational recourse, most articles use generation-based approach, which is increasingly important in the development of chatbots. The encoder-decoder architecture is used as the main learning method in chatbots. However, a large number of datasets and high amount of computation time is required. When it comes to selecting the appropriate response from the structured data to respond to the user's input, the retrieval-based approach is the best. There are different improvements for retrieved information in this approach as shown in [47],[65],[66],[69]. However, purely retrieval-based approaches do not perform reasoning, and therefore, they are only suitable for mirroring current knowledge. More recently, significant findings based on performance has been offered by the emergence of the various hybrid approaches. This improvement may be due to the advantages of combining previously mentioned approaches; retrieval-based and generation-based. Moreover, the rule-based approach is straightforward, easy to implement, understand and fast but is too fixed to predefined rules in the database. Thus, extraneous inputs cannot be answered. Thus, it is limited used in developing chatbots in comparison to other approaches.

Furthermore, the generation-based approach in English-language chatbots has more attention. However, overall, there is currently limited research on Arabic-language chatbots. Retrieval-based approach represents the vast majority of the selected approaches in Arabic chatbot research articles, whereas generation-based approach has started to attract attention in 2018 [80]. The most commonly used technique for Arabic-language chatbots is the pattern matching followed by AIML in retrieval-based approach. The LSTM technique is the most employed in developing Arabic chatbots followed by seq2seq and GRU in the generation-based approach.

Besides the three main approaches, some selected articles use publicly available platforms to create and launch their chatbots as presented in Table III. These platforms eliminate the required experience in coding to develop the chatbots from scratch. The platforms simplify development and standardize some implementation processes. Although some of these platforms have a well-described approach, such as Pandora's [129] that uses the retrieval-based approach, most hide the details of their systems. In addition, A closer inspection of the table shows that Google's DialogFlow, Facebook's Wit.ai, IBM Watson Conversation, and Microsoft Azure are cloud-based platforms that support different programming languages besides the natural languages. However, they differ significantly in other aspects [130].

2) Domains. The selected articles show most efforts was devoted to the education domain. A possible explanation might be because of several possible potential areas of education where chatbots can be utilized. According to Fig. 4, there is a significant difference in the published research between Arabic and English chatbots, especially in the business domain. Simultaneously, some of the Arabic chatbots are developed as religious chatbots, whereas English chatbots focus on other domains. Overall, the remaining domains are addressed almost equally in both languages. Furthermore, the research to date has tended to focus on MSA rather than Arabic dialects. This finding may be explained by the fact that MSA has a formal and clear format in written and expression, which helps with analyzing. However, due to the rise of social media platforms, few recently published articles focused on Arabic dialect chatbots, such as those in the Gulf Arabic dialect, Saudi dialect, Egyptian dialect and Jordanian dialect.

In addition, a relationship is observed between the domains and the approaches. Fig. 5 displays the distribution of the investigated approaches in 88 articles across seven domains. Obviously, for the education and health domains, the majority of chatbots seem to be developing using the retrieval-based approach. The possible explanation of this bias is that the chatbots in these domains are always prepared to fit a specific knowledge base. In contrast, most of the chatbots in business, emotions, and open domains are built using the generation-based approach. Thus, chatbots should be able to produce a new natural conversation with more appropriate responses.

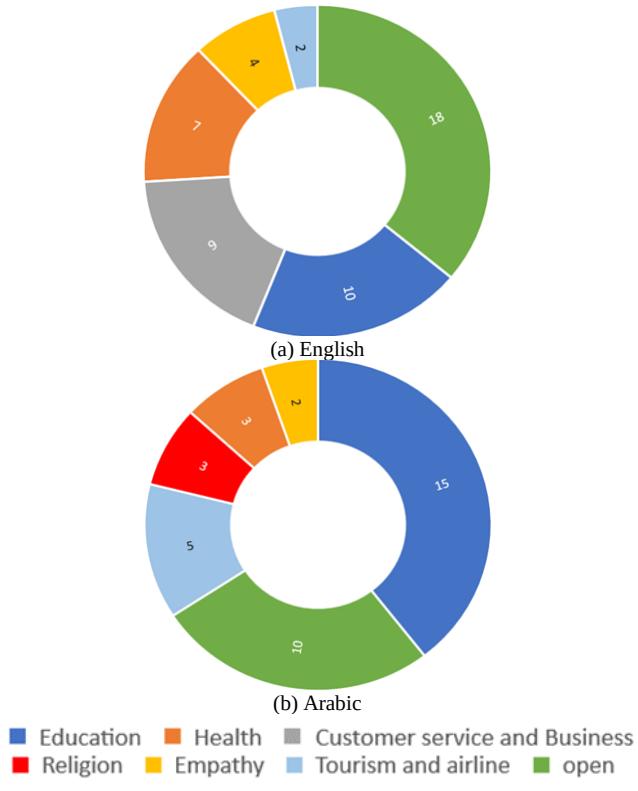

Fig. 4. Finding in Domains with Languages Perspective.

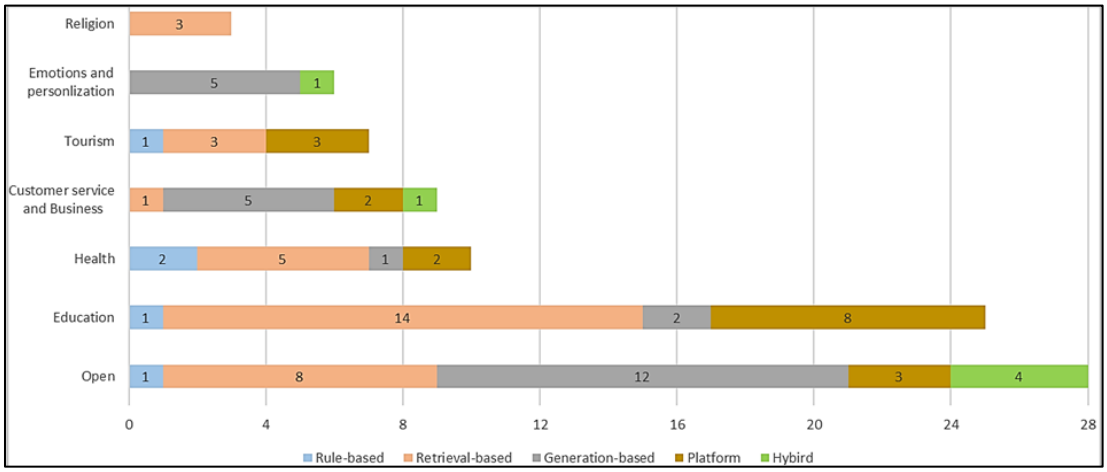

Fig. 5. Finding in Domains with Approaches Perspective.

3) Evaluation metrics. The vast majority of chatbot research uses the human-based metric, followed by BLUE and then accuracy, as presented in Fig. 6, where the most used types of the ROUGE metric are ROUGE-1 (unigram) and ROUGE-2 (bi-gram). Overall, no specific evaluation metric is more represented in articles due to the lack of gold standards of the evaluation. The evaluation of empathy, user satisfaction, and fluency are examples of the needed intervention of human evaluation. In terms of the time and resources, automated evaluation measures are more efficient than human ones. However, they appear to be incapable of accurately assessing the quality and efficacy of the entire conversation even they are easier to use and do not require manual work by human judges.

Moreover, several important differences are between the Arabic and English metrics. From Fig. 6, most of the Arabic articles focused on human evaluation whereas human evaluation and the BLEU metric are more popular in English articles. This may be due to several challenges of the Arabic language such as the lack of available data resources.

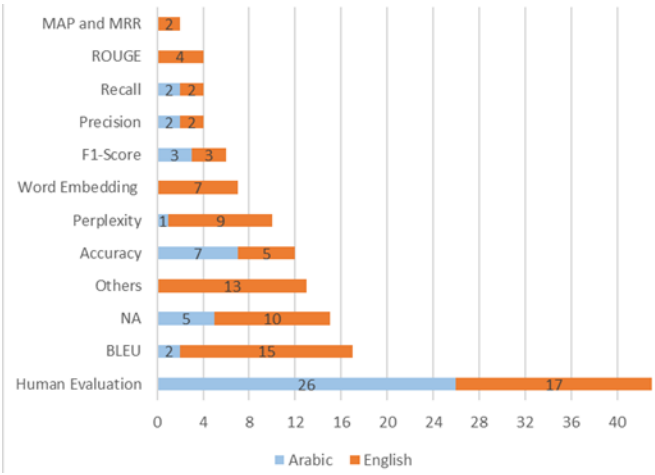

Fig. 6. Finding in Metrics Perspective.

B. Open Research Problems

Several challenges are in chatbots development, but for a comprehensive conversation experience, the development requires a balance between different directions.

1) Ambiguity in conversation. The simple meaning in natural language can be interpreted in more than one way. Therefore, simulating human conversation with a chatbot is quite challenging. Although deep learning has recently taken a lot of researcher attention, there is still a long way to go before chatbots can produce human-like conversation. Moreover, ambiguous word senses are a problem in the building of a semantic conversational AI.

2) Consistency in natural language interpretation. Inaccurate and unsuitable responses are given as a result of inconsistency in interpretation. Microsoft Tay chatbot is a popular example of natural language misinterpretation. It was originally released by Microsoft Corporation via Twitter on March 23, 2016 and was shut down after 16 hours of its launch due to inconsistencies in interpretation [131].

3) Detecting and maintaining conversation. The flow of the conversation is determined by the context of the conversation. Open-domain conversation is another challenge that required determining the topic and keeping track of the context besides detecting when the topic is changed. Despite the spectacular development of chatbots, they are occasionally unable to recognize the intent of users, which makes users frustrated.

4) Data efficiency and time. There is still a problem of little or no datasets being available in certain domains, especially clear in task-oriented systems, where gathering datasets would be costly and time-consuming for new domains. In English, several lexicons are built, such as SentiWordNet and WordNet [132]. By contrast, a lack of Arabic lexicons and resources affects the progress of Arabic chatbots.

5) Evaluation. No universal framework is to evaluate chatbots. There is a lack of unified definitions, metrics, and validated scales in evaluation [133]. The lack of a common

framework makes accurate testing and comparison of different models difficult. Although human evaluation offers qualitative estimation, it is subjective and time-consuming.

6) Privacy and security. Some chatbots are designed to rely on APIs to obtain information, which makes it important to secure the user's data. The kinds of data that the chatbot collects and provides can be used to supplement the support offered by different services, such as in the education domain. This will almost certainly improve the quality and efficiency of the resources available. Moreover, ethical issues of using chatbots are, either from the user side when they abuse the chatbot, or from the chatbot side, when they may save and use the user information for different purposes.

7) Lack of emotions. Some chatbots are developed with predefined conversations that limit their linguistic intelligence and make them mechanical and incapable of communicating in a natural manner. Involving these emotions in chatbots gives them human-like communicative behaviors, recognizing the different meaning possibilities of input and then producing more appropriate responses.

C. Open Research Problems

1) Datasets. Although many word sense disambiguation approaches have been developed [134], [135], they typically increase the computational complexity, which may not be a desirable solution. Moreover, most of the selected articles have built their own dataset, especially for the Arabic research, and others build Arabic corpora [136],[137], [138], whereas others used translation techniques [61],[72]. However, these solutions are limited, and there is still an open-domain problem that needs a lot of attention. In addition, a limitation of Arabic annotated data sets is another problem [136]. Thus, working on providing appropriate data sets and making them available for research can be considered a valuable contribution to chatbot research.

2) Evaluation framework. A new comprehensive framework of evaluation should be provided. Building this framework is not an easy task and may be affected by different factors, such as inputs having multiple semantic meanings and the length of the conversation that may be related to the task itself, for example, the flow of direct questions asked by students differs from entertainment conversations. The framework may also distinguish from different domains, for example, evaluating student understanding differs from completing booking tasks. Thus, the evaluation frameworks must assess providing these tasks to users, and research must define a robust evaluation framework that can mitigate the negative effects of these challenges.

3) Human-like conversation. The current research suffers from limitations in generating a natural conversation, resulting in a noneffective chatbot [10]. A number of factors may affect the behavior of chatbot conversation. First, ambiguous inputs need to be verified and detected to produce appropriate behaviors, such as asking to rephrase the input. Second, bi-linguistic, or multi-linguistic chatbots offer a wider variety of capabilities and provide more user trust. Third, leveraging emotional and contextual cues encourages a user to continue chatting, necessitating further investigation by the researcher into sentiment and emotional analysis. From the Arabic language side, many articles have been conducted on Arabic morphological analysis and generation using a range of methods. This applies in various levels of linguistic complexity, including stemmers [139],[140]. However, Arabic is a derivational and inflectional language that needs a lot of attention and improvement.

4) Extended and different perspectives. Although the selected articles critically survey the state-of-the-art solutions, they focus on specific research. Hence, other perspectives are not addressed in this SLR, and the challenges exposed in this SLR can inspire researchers to focus more on addressing them. Furthermore, due to access constraints, six databases are considered for selecting the articles. Thus, articles in the remaining databases may support or limit the findings in this SLR. Even so, this SLR can be considered as a contribution toward English and Arabic research for the taken criteria.

5) Empirical investigation. This SLR addresses the four research questions without empirical investigation. Involving empirical contributions in future works would give a broader analysis of chatbot development and usage.

V. Conclusion

Chatbot usage has become increasingly prevalent in recent years. One of the key goals of adopting chatbots is minimizing human involvement. The rapid technological advancements of AI aid in achieving this goal and help in the development of more flexible chatbots that are able to produce human-like conversation. This research provides a systematic review of the articles on the evolution of chatbots to investigate the four research questions. A systematic review protocol was used to analyze 50 and 38 articles for English and Arabic works, respectively, and to extract research from six well-known digital databases in computer science. The SLR analyzes the articles in terms of development techniques, domains, evaluation metrics and underlines some challenges and open problems of chatbot development. Furthermore, presenting future directions may assist researchers in identifying crucial aspects that require deep investigation and more development. The findings show that the research domain targeting education receives greater attention from researchers than other domains, and the retrieval-based approach is the most widely utilized approach in this domain. However, this approach is not able to generate a new response that is not predefined in the chatbot's knowledge base. In contrast, the generation-based approach is suitable for tasks that demand providing a new response. Hybrid approaches generally combine between these approaches and are most used for ranking the multiple possible responses when its performance may improve by using one approach rather than another one. However, they still require further developed.

This SLR concludes that current chatbots are still unable to simulate human conversation. Simultaneously, increasing research interest and rapid technological advancements could

evolve chatbot conversation and make chatbots more flexible, fluent, and human-like. Indeed, this SLR provides various recommendations for future articles, which creates a chance for researchers to continue to develop research on chatbots.

ACKNOWLEDGMENT

Lubna Alhenaki would like to thank the Deanship of Scientific Research at Majmaah University for supporting this work under Project No. R-2022-258.

Lima Perú

***Abstract*—The aim of this paper is to investigate the hypothetical duality of classical electrodynamics and quantum mechanics through the usage of Machine Learning principles. Thus, the Mitchell's criteria are used. Essentially this paper is focused on the radiated energy by a free electron inside an intense laser. The usage of mathematical strategies might be correct to some extent so that one expects that classical equation would contain a dual meaning. The concrete case of Compton scattering is analyzed. While at some quantum field theories might not be scrutinized by computer algorithms, contrary to this Quantum Electrodynamics would constitute a robust example.**

***Keywords*—Classical electrodynamics; quantum mechanics; machine learning principles; mitchell's criteria**

I. Introduction

The science of Machine Learning is been applying to a wide spectrum of disciplines in both basic sciences as well as engineering. Mainly the purpose of this application is the improvement of the functionalities of systems. This is often linked to a kind of optimization of the critic variables of systems. Thus to get the best scenario for each system one needs firstly to identify the relevant pieces that would play a critic role in the chain of processes. Clearly one here would argue that Machine Learning is actually applicable to all those input-output systems whose black-box might be unknown. In this manner emerges the necessity of differentiating the one-way path that do not allows to come back at the beginning of the processes. Among the plethora of Machine Learning philosophies one finds the one invented by Tom Mitchell that establishes that system can learn from a triplet of postulates:

- All system has explicitly a concrete task that allow it to develop in a sustained manner.
- In order to accomplish the nominal task the system must to apply a coherent strategy based on a methodology that would have to exhibit a well-designed performance.
- Once the system has accomplished its task then it would analyze if the performance of the used strategies were the right ones against other alternatives. Only if the task was solved without to expends the system resources then one calculated the efficiency of the involved processes. When this is high enough the one can say that the system has enough learning to be applied successively.

Motivated by the Mitchell's criteria, in this paper the energy radiated by a free electron inside an external super intense laser is treated with these criteria. In essence the study is centered in the following question: Given a relativistic electron in a strong laser, under what conditions the classical physics is abandoned to pass a entire scenario governed by quantum mechanics.

These so-called hybrid theories that combines criteria from classical physics and quantum mechanics have been studied at an entire framework of quantum electrodynamics (QED in short) by R. P. Feynman [1]. Subsequently have appeared the works of Volkov [2], Narozhnyi [3], Vachaspati [4], Kibble [5], Reiss [6], Eberly [7] that have studied QED with infinite waves that can be seen as classical fields without quantization. For example consider the QED Lagrangian:

$$\mathcal{L} = -ie \int dx^4 \bar{\Psi} \gamma_\mu A^\mu \Psi \tag{1}$$

where the spinors $\bar{\Psi}$ and Ψ satisfy the Dirac equation and A^μ the external field expressed as an 4-dimension vector without any type of quantization in contrast with the Dirac spinors. As it is well-known in field theories, from Eq.1 one can extend it to others types of elementary interactions by which is usual to derive the well-known diagrams of Feynman.

This paper is entirely focused on the implications of the vectorial potential $\mathbf{A}$ inside classical electrodynamics that allows to estimate observables such as energy radiated as well as to make predictions at the generation of new sources of powerful light at the super-intense regime. Thus emerges the following questions:

- Under what conditions the energy radiated by an electron is quantized?
- There is an exact boundary that separates the quantum mechanics and classical description of radiation emitted by an relativistic electron?
- Is the interaction electron and external field a system that can be described by the principles of Machine Learning?

This paper explores the capabilities of Machine Learning [8] to measure the limits between classical electrodynamics and QED in the concrete case when a relativistic electron is inside a external super-intense laser. For this end the Mitchell criteria [9] are employed to distinguish the scenarios where a transition from the classical to quantum takes place. In second section the theoretical machinery is presented. In third section the implementation of Mitchell criteria at the classical formalism and its link to QED is presented and discussed. In last section the conclusion of paper is presented.

II. Theoretical Machinery

A. Classical Backscattering Radiation

An important example of the transition from classical to quantum dynamics of light is given by the classical Compton backscattering. Commonly the theory demands to employ the covariant notation given by ϕ=$k^{\mu}x_{\mu}$=$k\cdot x$ based from the definition x_{μ}=(x_0,$\vec{x}$). From this the 4-vector k^{μ}=(1,0,0,1) describes an incident field along the +z direction yielding ϕ=x_0-z. Thus the 4-vector $A_{\mu}\equiv$ (0,$\vec{\mathbf{A}}$) with $\vec{\mathbf{A}}$= $\mathbf{A}_x(\phi)$. For the concrete case of backscattered radiation the direction must be opposite to the incident field and written as -$\hat{k}$, which is means that the emitted radiation travels along the -z direction. With the definition of $\xi=\frac{e^2u_0^2\chi^2}{4\pi^2}$ one can write down:

$$\frac{d^2I(\omega,\mathbf{n}\Rightarrow -z)}{d\omega d\Omega}= \xi\left|\int_{-\infty}^{+\infty}A_x(\phi)\exp\left\{i\chi\left[\phi+\int_{-\infty}^{\phi'}\mathbf{A}^2(\psi)d\psi\right]d\phi\right\}\right|^2. \quad (2)$$

That is the backscattered radiation intensity derived in [10] with χ the shifted Doppler frequency that can be interpreted in classical electrodynamics as the harmonics of radiated energy and at the quantum mechanics language as the number of emitted laser photons. One can see that the quantity $|...|^2$ contains all the information of the processes of classical radiation. Although above nonlinear Compton scattering was derived from Eq. 2, then one can speculate about the possible quantum mechanics that it might contain. Now one can go through the integration of the exponential which is the focus of this paper. In the case of linear polarization the laser field which is assumed to be super-intense is defined as $\mathbf{A}(\psi)$=$a$sin$(\psi)\vec{i}$ then the integrand is written as $a^2\int_{-\infty}^{\phi'}\sin^2(\psi)d\psi$. The integration can be done in a straightforward manner yielding the product of three exponential:

$$\exp\left\{i\chi\left[\phi+\int_{-\infty}^{\phi'}\mathbf{A}^2(\psi)d\psi\right]d\phi\right\} = \exp(i\chi\phi)\exp(i\frac{i\chi a^2}{2}\phi')\exp(-i\frac{\chi a^2}{2}\sin 2\phi') \quad (3)$$

These changes have as objective to create infinite series using the basis of integer-order Bessel's functions guided by the formulation of Ritus and Nishikov [11] as follows:

$$\exp(i\chi\sin\phi)=\sum_{\ell}J_{\ell}(\chi)\exp(i\ell\phi) \quad (4)$$

$$\exp(i\frac{\chi a^2}{2}\sin\phi')=\sum_{m}J_m(\frac{\chi a^2}{2})\exp(im\phi') \quad (5)$$

$$\exp(-i\frac{\chi a^2}{2}\sin 2\phi')=\sum_{n}J_n(\frac{\chi a^2}{2})\exp(-in2\phi') \quad (6)$$

the usage of this technique that favorably ends in a kind of quantization of the intense field but working in a fully QED scenario given by the Volkov's states. Thus, with all these expansions and inserting them in Eq.3 and therefore inserting the result in Eq. 2 then one arrives to an important relation written below as:

$$\frac{d^2I(\omega,-z)}{d\omega d\Omega}=\xi\left|\int_{-\infty}^{+\infty}A_x(\phi)\sum_{\ell}J_{\ell}(\chi)\exp(i\ell\phi)\sum_{m}J_m(\frac{\chi a^2}{2})\exp(im\phi')\sum_{n}J_n(\frac{\chi a^2}{2})\exp(-in2\phi')d\phi\right|^2$$
$$=\xi\left|\int_{-\infty}^{+\infty}A_x(\phi)\sum_{\ell}\sum_{m}\sum_{n}J_{\ell}(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\exp(i\ell\phi)\exp(im\phi')\exp(-in2\phi')d\phi\right|^2. \quad (7)$$

It should be noted that Eq. 7 is a fully classical relation so that in a first instance it is impossible to link it to any fact done inside the quantum mechanics framework. In fact, one can see the it is pure emitted radiation done by a relativistic electron. Nevertheless the work of Ritus [12] it was proposed the connection between a semi-classical description a quantization of external light. In order to follow the Ritus's view the covariant quantities are explicitly written as $\phi'=k'_{\mu}x^{\mu}$ and $\phi=k_{\mu}x^{\mu}$. With this the argument of product of exponentials in Eq. 7 is written as: $i\ell k_{\mu}x^{\mu}+imk'_{\mu}x^{\mu}-2ink'_{\mu}x^{\mu}$. When it is conveniently ordered then one gets $i[\ell k_{\mu}-(2n-m)k'_{\mu}]x^{\mu}$. Clearly one has only information of light either emitted or absorbed despite the fact that the electron is the responsible of these processes. To homogenize the physics of this event it is also convenient to introduce the exponential exp$[i(p_{\mu}-p'_{\mu})x^{\mu}]$. To note that it is possible only if $p_{\mu}-p'_{\mu}\approx 0$ at the space-point x^{μ}. Logically the purpose of this is twofold:

- The conservation of 4-momentum.
- To force a kind of quantization of external field.

In this manner the argument of the resulting product can be written below as:

$$\text{Exp}\left[i(p_{\mu}+\ell k_{\mu}-(2n-m)k'_{\mu}-p'_{\mu}\right)x^{\mu}. \quad (8)$$

Thus one can easily to recognize that there is a pure conservation with the initial and final states of 4-momentum given by:

$$\mathbf{P}_{\text{IN}}=p_{\mu}+\ell k_{\mu}, \quad (9)$$

$$\mathbf{P}_{\text{FI}}=(2n-m)k'_{\mu}+p'_{\mu}. \quad (10)$$

As mentioned above the fact that emerge integer numbers it might not be directly linked to a case of quantization as noted by Ritus. Thus this kind of artificial quantization in a theoretical framework would have to be verified experimentally within a valid window of accuracy [13].

III. The Machine Learning Analysis

Although classical electrodynamics has been entirely developed as a robust branch of physics, the requirement of using advanced algorithms to minimize a biased interpretation of the equations might be seen as an advantage more than a disadvantage at the sense that one gets a kind of hybrid theory with a tuned interpretation. In the following the well-known Mitchell's criteria shall be used to provide a fair interpretation of Eq. 7. These criteria are classified and conceptualized as follows:

- The Task: any system might to have one or more tasks that justifies its existence.
- The Performance: once the task is identified, the system opts by a strategy that must to exhibit a well-defined performance.
- The Experience: depending on the performance and the completion of task, the system should be able to assess the experience along the chain of events. At the cases of an acceptable experience the system can claim that it was a kind of learning to be repeated in subsequent task.

Turning back to Eq. 7, then one can wonder if it requires to isolate a concrete task? And if it is required then for what? One can argue that the manner as Eq. 7 is written, then it represents already a **task** in the sense that one should figure out the best way to extract a reasonable interpretation through a rather clear procedure of integration without any ambiguity. With Eq. 9 and Eq. 10, Eq. 7 can now be written as:

$$\frac{d^2I(\omega,-z)}{d\omega d\Omega}=\xi\left|\int_{-\infty}^{+\infty}A_x(\phi)\sum_{\ell,m,n}J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\exp[-i(p_{\rm IN}-p_{\rm FI})_\mu x^\mu]d\phi\right|^2. \tag{11}$$

In addition, the task can also be seen as the demonstration that Eq. 7 is a hybrid formulation of radiated energy by a relativistic free electron. In other words, one can also wonder about the concrete capabilities of classical electrodynamics to exhibit a dual formulation of a fundamental process such as Compton scattering (or it can also be Thomson scattering [14] to some extent, for instance). From Eq. 11 one can wonder if it is quantum mechanics expression or it is needed to corroborate such hypothesis. By following the Mitchell's criteria it is desirable to define a clear route to argument that in fact Eq. 11 is a hybrid expression so that quantum mechanics laws apply. From Eq. 11 to demonstrate that it is a quantum mechanics description of process of interaction between a field and a relativistic free electron, the proposed **performance** requires only the verification at the energy or momentum. For the sake of simplicity the present analysis shall use the energy integration. This demands to employ $\phi = k^\mu x_\mu = \omega t$ that gives $d\phi$=$td\omega$ under the assumption that the photon 4-vector momentum is (1,0,0,0). Thus one arrives to:

$$i[\mathcal{E}+\ell\omega-(2n-m)\omega'-\mathcal{E}']t. \tag{12}$$

With Eq. 12 one clearly finds that its inclusion in Eq.11 turns out to be a Dirac-delta function in the sense that one gets:

$$\int\exp[i(\ell\omega+\mathcal{E}-(2n-m)\omega'-\mathcal{E}')t]\omega dt \\ \omega\delta(\ell\omega+\mathcal{E}-(2n-m)\omega'-\mathcal{E}'). \tag{13}$$

Eq. 13 is an important result in the sense that at least at the energy variable one finds conservation if only if the argument of Dirac-delta function is null. By inserting Eq. 13 into Eq. 11 one arrives to:

$$\frac{d^2I(\omega,-z)}{d\omega d\Omega}=\xi\omega^2a^2\left|\sum_{\ell,m,n}J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\delta[(\ell+1)\omega+\mathcal{E}-(2n-m)\omega'-\mathcal{E}']\right|^2. \tag{14}$$

Eq. 14 can be normalized to introduce into a scenario of probabilities. In this manner it is needed that:

$$N^2\frac{d^2I(\omega,-z)}{d\omega d\Omega}=1. \tag{15}$$

Therefore, the constant N can be explicitly written as:

$$N=\sqrt{\frac{1}{\xi\omega^2a^2\left|\sum_{\ell,m,n}J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\delta[(\ell+1)\omega+\mathcal{E}-(2n-m)\omega'-\mathcal{E}']\right|^2}}. \tag{16}$$

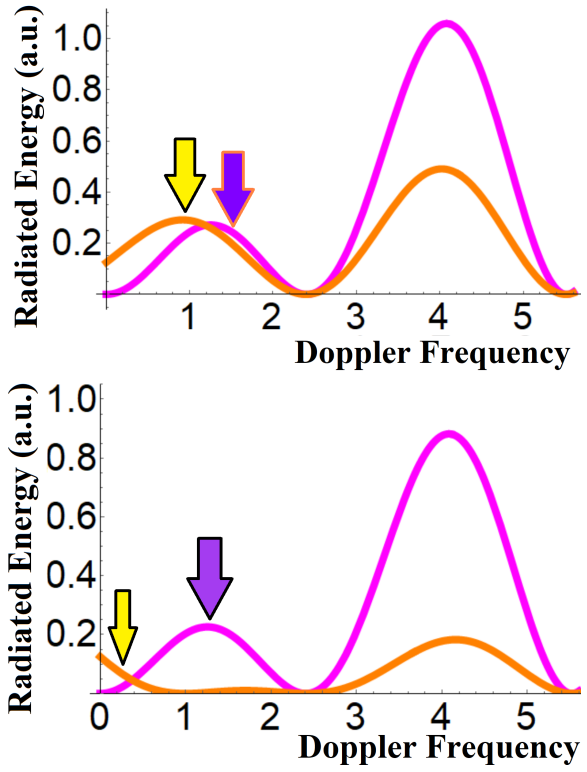

Fig. 1. Classical Distributions of Radiated Energy: Up: $|H(\chi,a)|^2$=0.16$|J_0(\chi)J_1\ (0.001\chi)\ J_0(0.001\chi)|^2$ (Magenta Color), and $|H(\chi,a)|^2$=0.5$|J_0(\chi+0.01)J_1\ (0.01\chi+0.01)\ J_0(0.01\chi+0.01)|^2$ (Orange Color). Down: $|H(\chi,a)|^2$ = 0.52×10^7 $J_0(\chi)\times J_1(0.001\chi)\times J_0(0.001\chi)$ (Orange Color) and $|H(\chi,a)|^2$ = 0.5×10^4 $J_0(\chi-0.01)\times J_1(0.01\chi-0.01)\times J_0(0.01\chi-0.01)$ (Magenta Color).

Once the constant N is calculated then the radiated energy can be estimated fom a procedure based entirely at the Mitchell criteria. Therefore, one can pass the classical electrodynamics concepts to one dictated by principles of Machine Learning.

IV. Interpretation by Mitchell's Criteria

In this way one gets that the applied **performance** has brought elements that play a concrete role at quantum electrodynamics (or QED in short). Thus Eq. 14 makes us to remind the well-known diagrams of Feynman's. In effect, the concordance with QED [15] as seen at the argument of Dirac-delta function has as central implication this pseudo quantization of electromagnetic field that although proposed initially as classically pure, now the interpretation of Feynman's rules [16] would suggest that in the initial state a free electron with initial energy $\mathcal{E}$ absorbs $[\ell+1]$ photons, whereas at the corresponding final state the electron has an energy $\mathcal{E}'$ and has emitted $[2n-m]$ photons. Actually, it is imminently nonlinear Compton scattering as observed by Bula [17]. Since Eq. 14 has been recognized as a potential expression that would play a role in QED, then one expects to arrive to a solid experience after the assumptions that the performance has demanded. In this way one can propose that Eq. 14 is a kind of square of sum of all allowed amplitudes that certainly it could to involve both linear as well as nonlinear contributions [18][19][20][21][22][23][24]. The case of simple Compton is of particular interest. Eq. 14 can be Compton scattering is $\ell=0$ and $2n-m=1$. However one can see that the crude assumption that these integer number would denote the number of photons fails because it is required that $n=m/2$ fact that is totally false in quantum mechanics. This reveals the "**bugs**" of algorithm to propose an effective strategy or performance. Thus simple Compton is restored with $\ell=n=0$ and $m=1$. When $H(\chi,a)$=$J_0(\chi)J_1(\frac{\chi a^2}{2})J_0(\frac{\chi a^2}{2})$ the classical radiated energy can be also interpreted as the measured quantum mechanics observable $\mathcal{O}(\chi,a)$, while $|H(\chi,a)|^2$ the square of all possible amplitudes. Therefore one can write down (where it is assumed after the integration of Dirac-delta function as commonly done in QED):

$$\frac{1}{\xi\omega^2a^2}\frac{d^2I(\omega,-z)}{d\omega d\Omega}=\mathcal{O}(\chi,a)$$
$$=|H_{m=1}(\chi,a)\delta[\omega+\mathcal{E}-\omega'-\mathcal{E}']|^2\approx|H_{m=1}(\chi,a)|^2 \quad (17)$$

A. Generation of Pseudo Amplitudes

In Fig. 1 (Up) one can see the plotting of $|H(1,0,0,\chi,a)|^2$=$|J_0(\chi)J_1(\frac{\chi a^2}{2})J_0(\frac{\chi a^2}{2})|^2$ for two cases: (i) the magenta-color line denoting simple Compton scattering with $\xi\omega^2a^2$=0.1610^7 and $a^2=0.002$ expressing the fact that the laser is not super-intense as initially assumed. (ii) the orange-color line is given by: $|H(1,0,0,\chi,a)|^2$=$|J_0(\chi+0.01)J_1(\frac{\chi a^2}{2}+0.01)J_0(\frac{\chi a^2}{2}+0.01)|^2$ resulting that the peak is shifted to the left-side with a rough coincidence to the value of argument of Bessel function. The added value 0.01 can be perceived as the error at the measurement of Doppler frequency. The reader can corroborate that the case of using -0.01 the negative case, the first peak or Compton peak is gone. In Fig. 1 (Down) the case of $|H(\chi,a)|^2$ = 0.52×10^7 $J_0(\chi)\times J_1(0.001\chi)\times J_0(0.001\chi)$ (orange color) and $|H(\chi,a)|^2$ = 0.5×10^4 $J_0(\chi-0.01)\times J_1(0.01\chi-0.01)\times J_0(0.01\chi-0.01)$ (magenta color) is plotted. While the magenta color distribution exhibits the fact that the central peak is shifted to right-side, the orange color distribution the incorporates errors at the order of 0.01 at the arguments of Bessel function given by: $0.01\chi-0.01$ one can perceive this as the degradation of radiation spectra due to quantum mechanics effects. The product of Bessel functions from above can be defined as a kind of pseudo amplitudes that can be written as:

$$H(m,n,\ell,\chi,a)=\left|J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\right|. \quad (18)$$

where $J_\ell(\chi)$ acts as a propagator whereas $J_m(\frac{\chi a^2}{2})$ and $J_n(\frac{\chi a^2}{2})$ can be understood as a kind of input and output states. In fact, the integer number given by the order of Bessel function, is expressing the fact that there is a kind of "classical" absorption as well as emission. From Eq. 17, the square $|H(m,n,\ell,\chi,a)|^2$ represents an observable that is related to radiated energy. This is of importance at the sense that Machine Learning can manage the best values of integer number in order to find the peaks of radiation that to some extent can be perceived as the peaks of X-rays [25][26][27].

In this manner one has below:

$$H(\chi,a)=\sum_{m,n,\ell}\left|J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\right|, \tag{19}$$

that emulates to some extent the sum of all possible possibilities for absorption and emission. Then, the intensity of radiated energy is the square of Eq. 19:

$$I(\chi,a)=\left|\sum_{m,n,\ell}J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\right|^2. \tag{20}$$

From Eq. 20 one can define the purity of emission at the sense that a detector can sense Compton photons accompanied of pile-up photons, all those that were created by parallel processes. Then this purity is written as:

$$P(\chi,a)=\frac{\left|\sum_{m,n,\ell}J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\right|^2}{\left|\sum_{m,n,\ell}J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\right|^2+\frac{d^2I_{\rm B}(\omega_{\rm B},a_{\rm B})}{d\omega_{\rm B}d\Omega}} \tag{21}$$

where $I_{\rm B}$, $\omega_{\rm B}$ and $a_{\rm B}$, the intensity, frequency and intensity of background field. In praxis one expects actually that the Compton photons have greater energy than their noise in order to be efficiently detected (see for example [28][29][30][31][32][33]). Thus one has below that:

$$\frac{\frac{d^2I_{\rm B}(\omega_{\rm B},a_{\rm B})}{d\omega_{\rm B}d\Omega}}{\left|\sum_{m,n,\ell}^{M,N,L}J_\ell(\chi)J_m(\frac{\chi a^2}{2})J_n(\frac{\chi a^2}{2})\right|^2}<<1. \tag{22}$$

In this manner, while the Machine Learning **task** would consist in the identification of Compton photons still at a classical scenario. Then, the **performance** would need to have a clear procedure to accomplish the identification of that photons (see for example [34][35][36][37][38]). Thus, it would consist in the searching of the best values of M,N,L to satisfy Eq. 22. Subsequently, the **experience** would be that of Eq. 21. The final Sigmoid function can be derived from Eq. 21 and Eq. 22 so that one arrives to:

$$S(\chi,a,M,N,L)=\frac{1}{1+{\rm Exp}\left[-\frac{\frac{d^2I_{\rm B}(\omega_{\rm B},a_{\rm B})}{d\omega_{\rm B}d\Omega}}{H(\chi,a)}\right]}. \tag{23}$$

The sign "-" in Eq. 23 emerges from the fact that $H(\chi,a)$ can acquire negative values due to the Bessel functions. A deeply analysis of Eq. 23 can be a window to investigate all those available values of classical radiation that might be encompassing quantum mechanics. In addition, the role of these integer number can also be correlated to the existence of a kind of entropy that would appear from the projection of classical observables in a quantum scenario, in the sense that Entropy = Log$[|H(\chi,a)|^{g(r)}]$ (see for example [39], Fig. 2).

V. Conclusion

In this paper, the derivation of quantum observables have been possible with the classical electrodynamics of Hartemann-Kerman equation. The radiated energy equation has been derived, and its relevance in quantum mechanics has been done through the criteria of Tom Mitchell. Along rhis document, integer number have been obtained in a fully analogy to the states of absorption and emission of photons of a relativistic electron in a laser field. Thus, the resulting spectra are strongly dependent on the integer-order Bessel functions. Therefore, the integer number are exploited at the sense that them allow to design a strategy inside the territory of Machine Learning. Finally a Sigmoid function was derived. This clearly demonstrates that classical electrodynamics appears to exhibit a certain flexibility to be adapted to new concepts of computing in physics theoretical as well as experimental.

Approximate TSV-based 3D Stacked Integrated Circuits by Inexact Interconnects

Mahmoud S. Masadeh
Computer Engineering Department
Yarmouk University
Irbid 21163, Jordan

***Abstract*—Three-Dimensional Stacked Integrated Circuit (3D-SICs) based on Through-Silicon Vias (TSVs) provide a high-density integration technology. However, integrating pre-tested dies requires post-bond interconnect testing, which is complex and costly. An imperfect TSV-based interconnect indicates a defective chip that should be rejected. Thus, it increases the yield loss and test cost. On the other hand, approximate computing (AC) is a promising design paradigm suitable for error-resilient applications, e.g., processing sensory-generated data, by judiciously sacrificing output accuracy. AC perform inexact operations and accepts inexact data. Thus, introducing AC into 3D-SICs will significantly ameliorate the efficiency of design approximation. Therefore, this work aims to *increase the yield and reduce the test cost by accepting 3D-SICs with defected interconnects as approximate 3D-SICs*. This work considers 3D-SICs, where the sensor is stacked on logic (CPU) which is stacked on memory (DRAM). Then, use the memory-based interconnect testing (MBIT) approach to detect and diagnose the faulty interconnect. Based on the detected fault location and type, and for a maximum allowed error, some sensory 3D-SICs with defected LSBs interconnects are accepted and used in error-resilient and data-intensive applications. Targeting data lines only, 50% of the defected interconnects, i.e., least significant bits (LSBs), were accepted as approximate. Thus, the proposed work was able to significantly increase the yield. Two applications, i.e., ECG signal compression and detecting of their R peaks, demonstrated the effectiveness of using a sensory device with a faulty data line in its least significant 8-bits. The approximate ECG signals have a compression rate higher than the exact with negligible (around 0.1%) reduced accuracy.**

Keywords*—Approximate computing; Three-Dimensional Integrated Circuit (3D IC); Through-Silicon Via (TSV); testing; approximate communications; approximate interconnect; yield; energy efficiency

I. Introduction

Three-Dimensional Stacked Integrated Circuit (3D-SICs) based on Through Silicon Vias (TSVs) are emerging among industry and research groups. 3D-SIC is a package with a vertical stack of naked dies which are interconnected utilizing Through-Silicon Vias (TSVs) [1]. TSVs are electrical nails that are etched into the back-side of a thinned-down die, which permit that die to be vertically interconnected to another die. TSVs provide short vertical connections with reduced latency, low capacitance, and low inductance compared to wire-bonds. Thus, TSVs allow for more interconnects between dies with high speed and low power dissipation [2].

The feature-size scaling is becoming difficult and expensive. Moreover, the semiconductor industry is continuously demanding more functionality, bandwidth, and performance at smaller sizes, power dissipation, and cost. Thus, TSV-based 3D-SICs are the promising solution for such requirements [3]. 3D-SICs is a continuation of Moore's Law, which is called *more than Moore's law*. This design paradigm delivers various benefits such as reduced power consumption, reduced footprint, high bandwidth communication, low latency between dies, high transistor density per volume unit, and heterogeneous (e.g., logic, memory, radio frequency (RF) circuits, analog circuits, and sensors) integration [4].

The TSV-based 3D-SICs are promising products for various applications, e.g., the Internet of Things (IoT) and Bio-Medical applications [5]. These applications encompass a tremendous number of mobile and sensory devices, which continuously generate a tremendous quantity of data with redundant and noisy parts. Thus, these data can be processed approximately due to their intrinsic error-resiliency. Similarly, the data could be generated approximately.

Approximate Computing (AC) [6] is an emerging computing paradigm, among both industry and academia, that utilizes the intrinsic resiliency property of Recognition, Mining and Synthesis (RMS) applications. AC provides various benefits such as reducing computation speed, power consumption, and storage space, while achieving an acceptable output quality for various error-resilient applications [7]. Numerous approximation techniques, e.g., voltage over-scaling, approximate arithmetic units, approximate memory, and approximate communication, gained significant interest. However, AC is still immature research direction and does not have standards yet.

Similar to 2D ICs, those TSV-based 3D-SICs require manufacturing testing to meet the expected customer quality. The test operation is executed once at the beginning of the field operation of the IC. Thus, assuming the dies are fault-free, a faulty TSV that could represent a data line, address line, or control line, mandates discarding the whole 3D-SIC. Moreover, workload features could change for an operating IC. Thus, dynamic faults such as Electromigration (EM) should be considered during the operational lifetime. Therefore, to increase the yield and void rejecting an IC with a defected interconnect, *this work proposes accepting TSV-based 3D-SICs with defected interconnects and considering it as an approximate 3D-SICs*. Moreover, extra TSVs could be used to replace the defected interconnects that represent the most significant bits (MSB) of the data and address lines. On the other hand, the error that is caused by the least significant bits (LSB) of the data and address lines can be tolerated without TSV replacement. Extra TSVs are not targeted in this work due to their extra overhead.

The goals while manufacturing DRAM chips differ from those of logic chips, where DRAM designers target reduced area and refresh needs while logic designers target high performance with reduced energy. For best performance, DRAM and logic chips are manufactured individually based on different technology before integration. Thus, wide-IO memory-on-logic are realized as stacked-die applications.

This paper considers 3D-SICs, where the sensor is stacked on memory (DRAM) which is stacked on logic (CPU). Then, use the well-known memory-based interconnect testing (MBIT) approach to detect and diagnose the faulty interconnect. Based on fault location and type, and for a maximum application-dependent acceptable error, some defected 3D-SICs are accepted as approximate. Then, used in error-resilient and data-intensive applications, which tremendously increase the yield rate and reduce test cost.

The rest of this paper is arranged as follows. Section II explains near-sensor computing with various forms of integration. Section III demonstrates TSV fabrication steps, their possible defects and faults, as well as their fault models. The most relevant related work is explained in Section IV. Our proposed methodology is highlighted in Section V. In Section VI, as a case study on ECG signal, we evaluate the proposed methodology and then accept a 3D-SIC with an inexact TSV-based data line. Section VII highlights some of the future directions and concludes the paper.

II. Near-Sensor Computing

The number of sensory devices is expected to reach 75 billion by 2025 and 125 billion by 2030 [8]. They generate a huge amount of repetitious and unformed data. Usually, sensing and processing nodes have different functional requirements and varied manufacturing technology. Moreover, for data sensing, a noisy analog domain is utilized while the data is processed digitally on *von Neumann* computing devices. Thus, sensed data should be transferred from the sensing to the processing node. Therefore, various issues related to response time, data storage, data security, communication bandwidth, and energy consumption should be considered.

There are various forms of integration technologies for near-sensor computing including 3D monolithic, planer SoC, 3D heterogeneous, and 2.5D chiplet integration [9]. In a 3D monolithic integration, the system typically combines various functional layers of sensor, memory and processors in a 3D stacked structure via interlayer vias. For a planer SoC integration, the functional units are integrated with a planar wire connection. However, in 3D heterogeneous integration, different functional units are fabricated individually on different wafers. Then, integrated with advanced packaging technologies, such as TSVs, die-to-die, die-to-wafer and wafer-to-wafer interconnects. This work targets TSVs-based interconnects. For 2.5D integration, the chiplets with specific functions are connected through an interposer, which is a compromise between 2D and 3D packaging integration.

The unprecedented explosion of sensory-generated data and its usage in real-time applications mandates adopting a data-centric approach instead of a computing-centric approach. This enables a system with high performance and energy efficiency. Near-Sensor computing is the solution to provide efficient processing of sensory data with minimal data movement or transformation. In near-sensor computing, the operations of data generation, collection, and processing are performed closed to the sensory devices. The *conventional processing* of sensory-generated data includes data sensing, conversion from analog to digital, storing in memory, transmitting data to the processing unit, then data processing. These steps cause high latency and power consumption. However, the processing units in near-sensor computing reside beside sensors and process data at sensor nodes. Thus, the combination of sensing and computing functions reduces data movement. The sensory computing system performs data processing at two different levels of abstraction, i.e., low and high levels, as described next.

Low-Level Near-Sensor Processing: It removes the undesirable noise from the raw sensory-generated data and includes data filtering, noise suppression and feature enhancement, which are local operations. Such processing ameliorates the computational workload and improves the efficiency of high-level processing. It aims to optimize the features of the raw data. Usually, low-level filtering utilizes circuits located between the sensing devices and high-level processing units.

High-Level Near-Sensor Processing: It comprises the cognitive process that enables the identification of the input signals. It includes recognition, classification and localization. The authors of [10] presented a near-sensor CNN accelerator for image recognition where data processing is close to the sensors. With a near-sensor design, the energy consumption and speed of operation are 60X and 30X, more efficient, respectively, compared to related work. In [11], the authors showed that utilizing 3D stacked ICs (rather than 2D) for near-sensor NN accelerators provides high bandwidth, reduced energy consumption, and low latency of data transfer. Thus, this work targets 3D stacked ICs with inexact TSV-based interconnects.

Near-sensor computing is more complicated than near-memory computing because it includes a huge sensory-generated data of various types. Planer integration of sensors and processing units on a limited area reduces the reserved footprint for sensors. Thus, 3D integration, where sensors are mounted on the top layer while processing units are arranged on the bottom layers, will provide complete exposure for high fill factor. The short distance between the sensing and processing units delivers a high communication bandwidth and low latency. Thus, this work focuses on 3D-SICs by TSV.

III. Interconnect Fault Models

For TSV-based interconnects, this section explains the main used terminology, the basic stages of TSV fabrication, their possible defects, faults, and their fault models.

A. Terminology

Here, we explain various keywords that are used in the rest of the paper. A *defect* is an unintended difference between the implemented hardware and the intended design, emerged from the manufacturing process, e.g., open and bridge defects. The probability of defects in ICs grows with reduced feature size. *Failures* are the physical manifestation of the defect. Defects are generally modeled at a higher conception level

by *faults*, e.g., Stuck-at-Zero (SA0) and Stuck-at-One (SA1). Various defects may be represented with the same fault. A collection of faults with identical properties are grouped in a *fault model*, which should accurately reflect the behavior of defects; as they are used for generating and evaluating test patterns [12]. Faults can be detected by applying a series of *test vectors*; the obtained test responses are compared with golden fault-free responses. The fraction of detectable faults which is called *fault coverage* (FC) indicates the quality of the test.

B. TSV Fabrication Steps

The main manufacturing steps for TSVs, which are cylindrical copper nails, are shown in Fig. 1. These main steps are (*1*) etching of TSV holes: It should be vertical and uniform with a high aspect ratio, (*2*) oxidation: deposition of oxide to isolate the etch from the surrounding semiconductor, (*3*) barrier seed: a barrier layer of metals is deposited before filling the etch with copper. It will prevent the diffusion of the metal into the oxide, (*4*) plating: use copper or tungsten for filling which should be void-free, where the operation of filling should produce minimal stress to avoid warpage, and (*5*) chemical mechanical polishing (CMP): remove the extra layer on the top of the filling. Then, the TSV is ready.

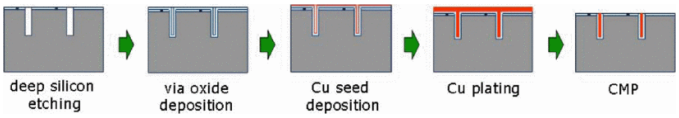

Fig. 1. TSV Fabrication Steps

TSVs can be organized into three classes, based on their fabrication time, during the IC manufacturing process: (*1*) via-first: TSV is fabricated before the front-end logic (FELO, transistor). However, it is more suitable for wafer handing rather than die and it requires adding constraints on design rules of transistor scaling, (*2*) via-middle: TSV is fabricated after the front-end logic (FELO) and before the Back-end of the line (BEOL), which is metal layers deposition, thinning, dicing, and assembly, and (*3*) via-last: TSV is fabricated after the IC fabrication process and before dicing and assembly. It has the lowest TSV fabrication process while being applicable for die and wafer stacking. However, during the manufacturing process, various reasons could cause a defect in the TSV, which are described next.

C. Interconnect Defects, Faults and Fault Models

The various manufacturing steps of TSVs are inherent sources of interconnects defects. There are various defects related to TSV including incomplete fill, pinhole, cracks, TSV misalignment with μ-bumps, TSVs Pinch-off, missing contacts between TSVs and the transistors, and Crosstalk between various TSVs [13].

Fig. 2 shows a general classification of interconnect fault models, which can be static or dynamic. Moreover, a defect can cause a single line or a multi-line fault. SA0 and SA1 are single-line static faults. However, wired-AND and wired-OR are multi-line static faults. Path delay fault (PDF) and path open fault (POF) are single-line dynamic faults. Whenever

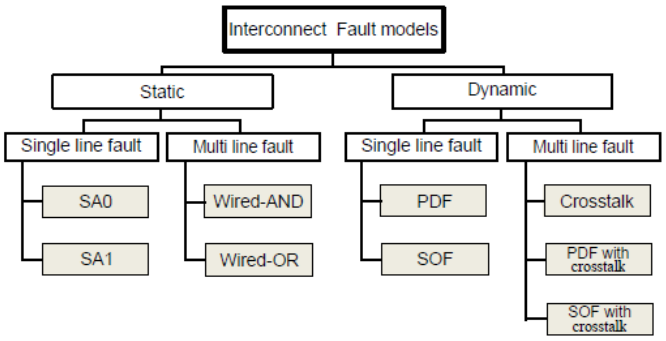

Fig. 2. Classification of Interconnect Fault Models [14]

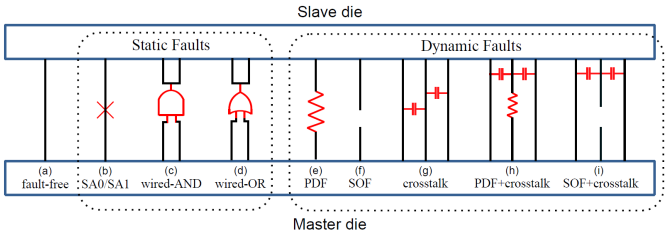

Fig. 3. Static and Dynamic Interconnect Faults [14]

crosstalk is introduced, we will have a multi-line dynamic faults. The interconnect faults are depicted in Fig. 3, including:

1) Stuck-at-Fault (SAF): Has two types which are stuck-at-0 (SA0) and stuck-at-1 (SA1) as depicted in Fig.3(b).

2) Bridge Fault: Simple bridge faults include wired-AND and wired-OR faults. Complex bridge faults also exist, such as (A dominate-AND B) where wire A is fault-free and wire B takes the value A $\cap$ B.

3) Path Delay Fault (PDF): A partial open line defect increases the line delay, e.g., rising or falling delay time (Fig.3(e)).

4) Stuck Open Fault (SOF): This is caused by a completely open line defect (Fig.3(f)).

5) Crosstalk Fault: As shown in Fig.3(g), faults on victim lines are caused by crosstalk from aggressive neighbours. Several crosstalk faults exist as described by the Maximum Aggressor (MA) fault models such as (1) glitch-up, (2) glitch-down, (3) falling delay, and (4) rising delay. Each fault has a specific behavior, while it represents the same phenomena.

6) Path Delay Fault (PDF) with Crosstalk: As shown in Fig.3(h), this is a compound fault where faults due to partial resistive opens are affected by crosstalk from neighbors.

7) Stuck Open Fault (SOF) with Crosstalk: As shown in Fig.3(i), this is a compound fault where faults due to complete open lines are affected by crosstalk from neighbors.

We will show the effects of these faults on TSV-based interconnect and the 3D-SIC as a whole.

IV. Related Work

There is a considerable number of publications that investigate approximate computing, IC testing, and 3D stacked

ICs. However, the portion of the research in approximate computing and hardware design that considers interconnects is scarce. Next, we introduce the most relevant work regarding approximate communication and approximate TSVs.

Recently, researchers investigating various techniques of *approximate communication* for approximate computing. They target network-on-chip (NoCs), aiming for reduced power consumption and latency. The proposed techniques rely on: 1) *lossy compression*: compress each packet and reduce its quality before transmission in order to reduce traffic intensity [15], 2) *value-prediction*: forecast data based on its locality to reduced the transmitted data [16], and 3) *protection-based*: approximate data by protecting the critical part to lower the cost of error correction [17]. These techniques significantly enhance performance and energy consumption. However, controlling the quality of communication is still a significant point. In [18], the authors proposed a hardware-based quality management framework for approximate communication to minimize the time needed for the approximation level calculation. Thus, they presented a new NoC design that observes the application error and adjusts the data approximation level accordingly.

Data transmission across chip interconnects requires a significant amount of time and energy. Thus, the authors of [15] proposed a framework for approximate bus architecture, which is conscious of approximable data. The proposed framework utilizes a light compression technique. For 0.5% quality loss at the application level, the proposed framework achieved a 29% performance improvement. In [19], the authors proposed a framework to reduce power consumption and communication latency of NoCs by incorporating a quality control method and data approximation to reduce packet size. For that, error-resilient variables are identified by analyzing the source code. When transmitting error-resilient variables, a lightweight lossy compression technique is utilized to significantly reduce packet size. In a closely-related work, the same authors explored, in another work, the possibility of using Reinforcement Learning (RL) to manage data quality [20].

The authors of [21], confirmed that the energy consumption of manycore is influenced by data movement, which demands energy-efficient and high-bandwidth interconnects. Towards this direction, they declared that *integrated optics* is an encouraging solution to control the bandwidth limitations of electrical interconnect. However, integrated optics with low-efficiency lasers have high power overhead. Thus, the authors of [21] proposed using *low-power optical signals* to transmit the least significant bits of floating-point numbers. Accordingly, their proposed design has 42% laser power reduction for image processing applications. Similarly, the authors of [22] presented a technique to design scalable *approximate nanophotonic interconnects*. Thus, enhance the interconnect energy efficiency by adjusting the transmission robustness to the application requirements. They achieved a 53% power reduction for output errors of 8%.

The authors of [23] proposed a runtime dynamic Built-In Self-Repair (BISR) technique to improve runtime reliability. For that, they used a test scheme to identify runtime and manufacturing defects. Then, replace defective TSVs with neighbour fault-free TSVs. However, each TSV has its test circuit which causes a large area and power overhead. The authors of [24] showed that testing of 3D-SICs is a challenge due to their complex structure. After stacking, the power and ground TSVs are connected to a grid that makes their testing a challenging task. Thus, they proposed a built-in self-test (BIST) architecture for power and ground TSVs. The proposed BIST enhances reliability by testing for full-open, pin-hole, and bridge faults. However, the proposed BIST introduces hardware overhead with low test coverage.

Previously, various works proposed approximate ICs by designing exact ICs and accepting the defective with minimal fault coverage as approximate ICs [25]. Others proposed designing approximate ICs, and accepting a defective approximate IC if the manufacturing error is within the acceptable approximation error [4]. However, the proposed chips were 2D, not 3D and the approximation is for the logic while considering the interconnect as fault-free. To the authors' knowledge, none of the previous works proposed using ICs with *defective interconnects* as approximate ICs nor targeted designing approximate 3D-SICs, which we propose here. This work mainly targets the communication interconnect itself, i.e., the TSV, as a hardware component. Our proposed idea is a simply different and efficient way. We test and diagnose the faulty TSV-based interconnect with zero area overhead, the ability to detect static and dynamic faults with at-speed testing, and a short test execution time. Then, the output quality of the defected 3D-SIC with defected interconnects is analyzed for a given quality metric. Based on that, some defected 3D-SICs are accepted as approximate ones. Thus, the yield is increased.

V. Proposed Methodology

In this section, we provide a detailed explanation of the proposed methodology. First, we explain Interconnect's built-in self-repair (IBISR). Then, revise memory-based interconnect testing (MBIT). Consequently, the assumed TSV layout is explained because multi-line faults are position-dependent. Next, how a faulty TSV-based data line could be considered approximate is explained.

A. Interconnect Built-In Self-Repair (IBISR)

The researcher of [26] proposed architecture of test and repair of a defect of TSV in 3D-IC, where BIST structure detects a defective TSV. Then, neighbours of the proposed BISR structure isolate and repair the defective TSV. This enhances the yield with an area overhead. The authors of [27] introduced a novel approach for repairing the deficient TSVs in 3D-ICs where interconnect built-in self-test (IBIST) is utilized. Then, the obtained results from IBIST provoke the repairing of defective TSV based on the given BISR structure. They employ repetitious TSV and the time-division multiplexing access (TDMA) in the case of multi defective TSV. However, the high fault rates and TSV footprint make the spare-based repair solutions inadequate [28]. In this work, to keep zero area overhead, we will not introduce interconnect repair. However, it is under investigation for closely related future work.

B. Memory based Interconnect Test (MBIT)

The authors of [14] proposed a Memory Based Interconnect Test (MBIT) approach for 3D-SICs where memory is stacked on logic by testing interconnects through memory read and write operations. MBIT solution can complete at-speed testing

and *diagnosis* and is able to detect all static and dynamic faults. Moreover, MBIT has zero area overhead and allows flexible patterns to be applied. The required test time is much lower than traditional based solutions such as Boundary Scan, but is three times slower than hardwired BIST solutions. However, BIST solutions have a large area overhead and cannot apply flexible patterns. Utilizing MBIT, the minimum set of test patterns required to detect all static and dynamic faults are the patterns to detect *PDF with crosstalk* and *SOP with crosstalk*. We assume a single fault at a time where the number of data lines is L_d = 16, and the number of address lines L_a = 16. We simulate memory test patterns, for a memory die stacked on a logic die that consists of a MIPS64 processor, by using the MIPS64 simulator in [29]. The simulator can handle a maximum of L_d = 64-bit data lines and L_a = 12-bit address lines (lowest 3 bits are byte offset).

C. TSV Layout

The TSV lines represent address, data, and control lines. Also, it include ground and power lines between stacked dies. Testing for multi-line dynamic faults requires knowing the exact layout of the address and data lines. For clarification, we assume a regular TSV array of size 4 × 4 to demonstrate how to generate test patterns for multi-line dynamic faults. Thus, knowing the exact layout is required to accurately analyze the 3D-SIC performance. We assume that a TSV victim is affected by the closest neighbour, i.e., 1^{st} aggressor model. Thus, as shown in Figure 4, a victim TSV (group 1) could be affected with a maximum of 8 aggressors (group 2, 3, and 4).

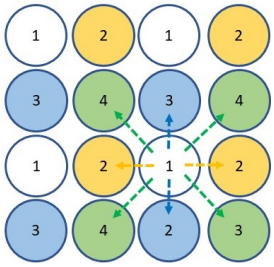

Fig. 4. TSV Layout and Grouping

The JEDEC Solid State Technology Association defends open standards for the microelectronics industry [31]. It provided a standard for stackable Wide-I/O Mobile DRAMs which describes the logic-memory interface for functional and mechanical characteristics, widening the conventional 32-bit DRAM interface to 512 bits. Figure 5 shows the interface for JEDEC Wide-I/O with 1200 connections, where each channel has 300 interconnections. Each channel consists of 6 rows by 50 columns. JEDEC's Wide-I/O interface includes four memory channels, each with 128 bi-directional data lines. Moreover, each channel has 51 control and address signals. Thus, the layout of the interconnections is given where a faulty TSV would be affected by the adjacent ones.

D. The Proposed Methodology

The authors of [32] designed and implemented back-illuminated CMOS image sensors (CIS) (BICIS) with TSV-based bonding between the 3 layers. The number of TSVs for connecting pixel substrate and DRAM substrate is about 15,000 and about 20,000 for connecting the DRAM substrate and the logic substrate. Thus, the fabrication of 35000 TSV could result in defective ones, which will reduce the yield. Therefore, we propose to accept defected TSVs that still provide accepted quality. Algorithm 1 shows the proposed methodology (as a list of steps) for accepting a 3D-SIC with defected TSV-based interconnects as *approximate 3D-SIC*.

Algorithm 1 The Proposed Methodology for Approximate TSV-Based 3D-SICs with Inexact Interconnects

Result: 3D-SIC with inexact interconnects
Manufacture Wafer#1 (CPU);
Manufacture Wafer#2 (DRAM);
Manufacture Wafer#3 (Sensor);
Test and Dice Wafer#1 (CPU);
Test and Dice Wafer#2 (DRAM);
Test and Dice Wafer#3 (Sensor);
Stack the 3 dies by TSVs;
Perform Interconnect Test and Diagnosis;
if *No fault in Address, Data, or Control lines* **then**
    3D-SIC is accepted as Exact; ▷ This is the main goal
else
    if *Control line if faulty* **then**
        3D-SIC is Rejected;
    end if
    if *Data line if faulty* **then**
        Analyze the effect of error based on a given error metric and fault model;
        if *The effect of error is acceptable* **then**
            3D-SIC is Accepted with Faulty Data line; ▷ Data line investigated in this work
        else
            3D-SIC is Rejected;
        end if
    end if
    if *Address line if faulty* **then**
        Analyze the effect of error based on a given error metric and fault model;
        if *The effect of error is acceptable* **then**
            3D-SIC is Accepted with Faulty Address line; ▷ Address line will be investigated in future work
        else
            3D-SIC is Rejected;
        end if
    end if
end if

The wafers of the CPU, DRAM, and Sensor are manufactured then diced. The CPU, DRAM, and Sensor chips are tested at the wafer level and at the die level. Dies stacking is performed through TSV fabrication between the dies. Then, we test the TSV-based interconnects, i.e., MBIT, which implies applying the full list of test patterns. It will detect all possible faults, i.e., various static and dynamic faults. If the obtained test response matches the expected fault-free response for all applied test patterns, the tested 3D-SIC is exact with 100% fault coverage. That represents the ideal case. However, when there is a mismatch between the obtained test response and the expected fault-free response, the tested 3D-SIC is defective, and it should be rejected.

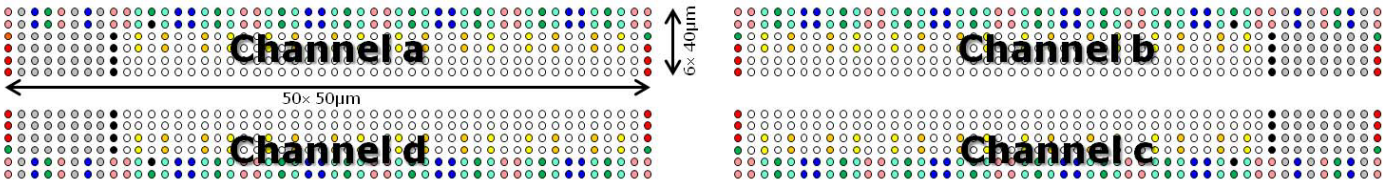

Fig. 5. The Interface for JEDEC Wide-I/O [30]

For a 3D-SIC with defected interconnect, *we perform interconnect diagnosis to identify the exact location and type of the defect*. Rather than discarding the defective 3D-SIC and reducing the yield, we propose to accept some defects based on its location and the used error metric. If a *control line* is identified to be faulty, the operation of the chip will be indeterministic, where it could perform read operation rather than write. Thus, we propose to reject the IC whenever a control line is defective. If a *data* is identified to be faulty, we evaluate its effect on the quality of the final results. If an *address line* is identified to be faulty, this is similar to a faulty address decoder, which is considered as a future work.

In approximate computing, the maximum acceptable error depends on the application, the applied inputs, and user preferences [33]. For that, different error metrics could be used for accuracy evaluation [34] [35], including: (1) Error Rate (ER): which is the percentage of erroneous outputs among all outputs, (2) Error Distance (ED): the arithmetic difference between the exact output and the approximate output for a given input, (3) Mean Error Distance (MED): the average of ED values for a set of outputs obtained by applying a set of inputs, and (4) Relative Error Distance (RED): which is the ratio of ED to the exact output. *Next, we explain how a 3D-SIC with a faulty TSV-based data line could be accepted as approximate IC based on various error metrics*.

E. Faulty Data Line

The number of data lines is L_d = 16 and a faulty data line will be denoted as D_n, for 0 $\leq$ n $\leq$ 15. We assume that the data lines have a normal distribution, where the probability of any line to have a value of 0 or 1 are equal, i.e., $P_{D_n}(0) = P_{D_n}(1)$ = 0.5. Under the assumption that a single fault could occur at a time [12], the error magnitude is 2^n for a faulty D_n data line. The acceptability of a 3D-SIC with a defected interconnect as an approximate one depends on the position of faulty *data line* and the used *accuracy metric*. Next, we explain different error metrics with various fault models:

1: Fault Model is SAF:

Error Metric is ED: For SA0 the data line is always 0, i.e., $P_{D_n}(0)$ = 1, and $P_{D_n}(1)$ = 0. Similarly, for SA1 the data line is always 1, i.e., $P_{D_n}(0)$ = 0, and $P_{D_n}(1)$ = 1. The error magnitude is 2^n for a faulty D_n data line with the assumption of a single fault at a time. Thus, we accept the 3D-SIC as approximate when $2^n >$ ED, and reject it when $2^n \leq$ ED. For large acceptable error, i.e., ED, more chips are accepted as approximate ones. Thus, the yield is increased. When the faulty data line (D_n) is located in the MSB of the design, e.g., 8 $\leq$ n $\leq$ 15, the error magnitude would be large. Thus, the defective chips are rejected, which reduces the yield. On the other hand, when the faulty data line (D_n) is located in the LSB of the design, e.g., 0 $\leq$ n $\leq$ 7, chips are accepted as approximate ones since their error magnitude is small, i.e., $2^7 >$ ED.

Error Metric is ER: The ER indicates the ratio of erroneous outputs among all outputs. A SAF data line, i.e., SA0 or SA1, will give the expected value for 50% of the time and an erroneous result for the rest of the time. Thus, the ER is 50% and the 3D-SIC with defected interconnect is accepted when the allowed ER $\leq$50% and rejected when the ER $>$ 50%.

Error Metric is MED: Under the assumption of one fault at a time the MED metric equals the ED. For multiple errors, MED is given by Equ. 1, where the average ED for a set of faulty data lines is evaluated. The ED for a single data line ranges from $2^{15} = 32K = 32768$ to $2^0 = 1$, based on its location.

$$MED = \frac{1}{16}\sum_{n=0}^{15} ED_n = \frac{1}{16}\sum_{n=0}^{15} 2^n \tag{1}$$

Error Metric is RED: Under the assumption of a single fault at a time the RED for a faulty data line is 1, while it is 0 for an exact interconnect.

2: Fault Model is Bridge Fault (Wired-AND, Wired-OR):

TABLE I. INTERCONNECT VALUE FOR BRIDGE FAULT (WIRED-AND, WIRED-OR)

Exact		A AND B		A OR B	
A	**B**	**A**	**B**	**A**	**B**
0	0	0	0	0	0
0	1	0	**0**	**1**	1
1	0	**0**	0	1	**1**
1	1	1	1	1	1

The bridge fault will give a final value based on: 1) its type; wired-AND or wired-OR, and 2) the value of its neighbour. As shown in Table I, faulty data line with wired-AND will give 0 for 75% of the time and 25% for the rest of the time. Similarly, a faulty data line with wired-OR will give 0 for 25% of the time and give 1 for the rest 75% of the time. Thus, we notice that the bridge fault is mapped to SAF with ER of 25%.

3: Fault Model is Path Delay Fault (PDF):

The dynamic fault of PDF for less than a clock cycle will not cause the circuit to fail. Thus, the data line will deliver an exact value.

4: Fault Model is Stuck Open Fault (SOF):

The SOF represents a completely open line. The floating data line is assumed to have a stable value of 0, a stable value of 1, or changes from 1 to 0. Thus, eventually, the SOF could be equivalent to SAF.

5: Fault Model is Crosstalk:

Figure 4 shows the physical layout of TSVs assuming the 1^{st} aggressor model, where the victim is affected only by the closest neighbour aggressors. Generally, any K^{th} aggressor model can be used, where *K* indicates the maximum TSV distance between victim and aggressors. The authors of [36] showed that restricting *K* to 1 is sufficient.

5.1: PDF with Crosstalk:

A transition at the victim, e.g., from 1 to 0, will be affected by the opposite transition, e.g., from 0 to 1, at the neighbours. Thus, the effect of crosstalk is similar to PDF.

5.2: SOF with Crosstalk:

Detecting SOF with crosstalk requires causing a transition on the victim while keeping the aggressors unchanged. The effect of this model is equivalent to SAF.

F. Possible Repair Scheme

Post-bond interconnect testing for memory stacked on logic requires special consideration since: 1) the stacked dies have different fabrication labs, 2) memory providers are unwilling to incorporate DFT such as JTAG for interconnect testing, and 3) the used DFT can not provide high coverage for dynamic faults. Generally, TSV repair depends on having extra TSVs. However, to avoid extra hardware we will not use extra TSVs nor perform TSV repair.

VI. Case Study

In this section, we evaluate the proposed methodology which accepts a 3D-SIC with an inexact TSV-based data line. Thus, consider it as approximate 3D-SIC, and utilize it in error-resilient applications where reduced accuracy is tolerated.

Biosignal is a human body variable that can be measured and monitored where it provides information on the health status of individuals. Wearable devices sense and process different crucial signs, e.g., electroencephalography (EEG), Electrocardiography (ECG), electrooculogram (EOG), and electromyography (EMG), and send the data to the cloud or to a smartphone. Various biomedical applications accept minor errors or small quality degradation in the values of the biosignal. Electrocardiogram (ECG) is a non-invasive examination that records and shows the electrical activities produced by heart muscle during a cardiac cycle. The ECG test is a standard clinical mechanism for analyzing abnormal heart rhythms and assessing the general condition of a heart. As shown in Figure 6, each ECG cycle consists of 5 waves called PQRST. A complete ECG is recorded using 10 electrodes capturing 12 leads (signals) to get a total picture of the heart. Next, we explain R-peaks detection of Electrocardiography (ECG) signals and its compression assuming the least significant 8-bits are faulty due to inexact TSV-based data line.

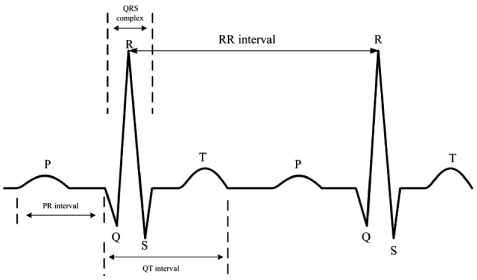

Fig. 6. Parts of an ECG Signal

A. Detecting R-Peaks of ECG Signal

ECG is one of the most critical diagnostic tools for different cardiac diseases. Fast automated detection of the P wave, QRS complex, and T wave is necessary for the early detection of cardiovascular diseases (CVDs). The detection of R-peak is important in all kinds of electrocardiogram (ECG) applications. Utilizing the approach proposed in [37], we performed R peak detection for 32 ECG recordings of the MIT-BIH arrhythmia [38]. For that, we use three parameters, i.e., true-positive (TP), false-negative (FN), and false-positive (FP). TP represents the number of correctly detected R peaks while FN is the number of missed R peaks. FP is the number of noise spikes erroneously classified as R peaks. Utilizing these parameters, we computed various statistical measures including Accuracy (Acc), Precision (positive predictability), Sensitivity/Recall (Se), and F1-Score, as given in the following equations.

$$Accuracy\ (Acc) = \frac{TP + TN}{TP + FP + TN + FN} \tag{2}$$

$$Precision\ (P) = \frac{TP}{TP + FP} \tag{3}$$

$$Recall/Sensitivity\ (Se) = \frac{TP}{TP + FN} \tag{4}$$

$$F1 - Score = 2 * \frac{Precision * Recall}{Precision + Recall} \tag{5}$$

Table II shows the various obtained accuracy metrics, which indicate the high performance of the R peak detection methodology. For the same ECG signals, we created an approximate version of it. For that, the various points of each ECG are approximated by randomly setting one of the least significant 8-bits to zero. This emulates the behaviour of a faulty data line (with SA0 fault) of a sensory device for recording ECG signals.

Stuck-at-0 fault at the least significant data bits did not change the number of total beats, i.e., TP + FN, since the R peak have a high magnitude value. R peak detection of approximate ECG signals missed 57 peaks and classified 123 noise spikes are R Peaks, i.e., FN=57 and FP=123. However, regardless of these false the *accuracy* decreased insignificantly from 99.88% to 99.74%. Similarly, prediction precision, recall, and F1-score reduced insignificantly with less than 0.1%. Thus, a faulty bit in the least significant 8-bits of data line will have

TABLE II. PERFORMANCE OF R PEAK DETECTION METHOD USING ECG EXACT AND APPROXIMATE DATA

	Total beats (TP+FN)	TP (beats)	FN (beats)	FP (beats)	Accuracy	Precision	Recall	F1-Score
Exact ECG	70453	70448	5	77	99.88	99.89	99.99	99.94
Approx ECG	70453	70396	57	123	99.74	99.82	99.91	99.86

reduced effect at application level. Various machine learning-based models could be used as a classifier to detect the QRS complex [39] [40], which are considered as future direction.

B. Compression of Biomedical Signals

Figure 7 shows the architecture for wearable ECG monitoring. The biosignals are acquired, filtered, digitized, *compressed*, and transmitted to the smartphone or cloud server for analysis. The distinct features are obtained, then the classification process detects anomalies. Reducing the amount of transmitted data, through discarding the least significant bits or/and data compression, extends the battery lifetime of mobile devices. Data compression helps to supply the required low-power wireless connection with a slightly large bandwidth.

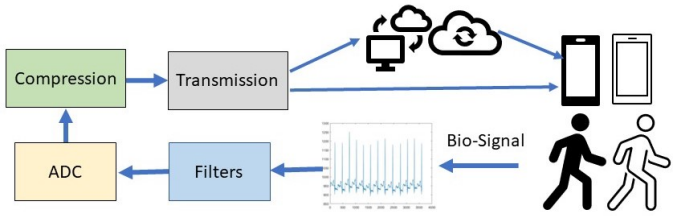

Fig. 7. IoT-Based Wearable ECG Monitoring System

MIT-BIH cardiac arrhythmia database is a widely used database in recent years [38]. MIT-BIH database was supplied by the Massachusetts Institute of Technology with 48 records each is 30 minutes in length. Utilizing the approach proposed in [41], we performed ECG compression for 32 ECG recordings of the MIT-BIH arrhythmia. Then, for the same ECG signals, formed an approximate version of it. Thus, the different points of each ECG are approximated by randomly setting one of the least significant 8-bits to one. This mimics the SA1 fault of a sensory device for recording ECG signals. To assess the ECG signal compression, various metrics are used such as:

Compression Rate (CR): measures the degree of data compression and expressed as given in Eq. 6. Thus, the highest is the best.

Root Mean Squared Error (RMSE): It is a metric for specifying the similarity between two sets, i.e., the original and compressed signal, as expressed in Equ. 7, where *y* is the original signal, *x* is the compressed signal, and *n* is the number of samples of the signal. Thus, the lowest is the best.

$$Compression\ Rate\ (CR) = \frac{Uncompressed\ Size}{Compressed\ Size} \quad (6)$$

$$RMSE = \sqrt{(\frac{1}{n})\sum_{i=1}^{n}(y_i - x_i)^2} \quad (7)$$

TABLE III. RESULTS OBTAINED FOR 32 MIT-BIH RECORDS

	CR	RMSE	Accuracy
Exact ECG	51.7	3.54	99.89
Approx ECG	53.8	6.21	97.91

As shown in Table III, the CR of the exact ECG signal is 51.7 and it is enhanced to 53.8 for the approximate ECG signals. Moreover, the RMSE is 3.54 for the exact ECG signal and it is increased to 6.21 for the approximate ECG which still very acceptable. This work aims to have a high-performance classifier on the compressed signal, both exact and approximate ECG. Thus, the decompressed ECG after lossy compression is classified and detected based on a supporting vector machine (SVM) classifier. The accuracy is 99.89 for the original signal which is reduced insignificantly to 97.91 for the approximate ECG signal. We notice the increase in the compression ratio while keeping the performance of classification of the compressed signal. Thus, a 3D-SIC with a sensory device where the least 8-bits of a data line are faulty can be easily accepted in various applications.

VII. CONCLUSION

Near-sensor computing is a well-known approach to designing efficient hardware for intelligent sensory processing. Data processing at sensory nodes provides a reduced area and time with efficient energy consumption. Thus, it is suitable for real-time and data-intensive applications. However, low-level and high-level near-sensor processing mandates new integration forms and processing algorithms utilizing emerging devices. Although near-senor processing is promising with a great future potential, most of the existing work is still in the development stage and confined to specific applications. This work proposes accepting 3D-SICs with defected TSV-based interconnects as *approximate 3D-SICs*. For this purpose, a sensory device is stacked on a memory die which is stacked on a logic die. To specify if the tested IC is acceptable, context-aware testing is required. Then, a faulty IC is investigated to detect its useability as an approximate one. To evaluate the effectiveness of using a sensory device with a faulty data line in its least significant 8-bits, we performed two applications on ECG signals. First, detecting R peaks of ECG signals then compressing the ECG signals. Both applications demonstrated the usability of the faulty data line in the LSBs of a sensory device. The obtained accuracy metrics, i.e., compression rate, root mean square error, accuracy, precision, recall, and F1-score, showed that a 3D-SIC with a sensory device where the least 8-bits of a data line are faulty can be easily accepted in various applications with enhanced yield.

***Abstract*—IoT-based robots can help people to a great extent. This work results in a low-cost posture recognizer robot that can detect posture signs from a disabled or virus-affected person and move accordingly. The robot can take images with the Raspberry Pi camera and process the image to identify the posture with our designed algorithm. In addition, it can also take instructions via Bluetooth from smartphone apps. The robot can move 360 degrees depending on the input posture or Bluetooth. This system can assist disabled people who can move a few organs only. Moreover, this system can assist virus-affected persons as they can instruct the robot without touching it. Finally, the robot can collect data from a distant place and send it to a cloud server without spreading the virus.**

***Keywords*—Internet of Things (IoT); Raspberry Pi; Pi camera; Pi robots; hospital robots; posture recognition robots**

I. Introduction

The Fourth Industrial Revolution (or Industry 4.0), a term coined by Klaus Schwab, refers to the industrial and manufacturing activities automation through using emerging technologies. Robotics as well as the Internet of Things (IoT) is a key element among such modern technologies. In recent times, robots and robotics is the part and parcel of modern science. Robots are working in lots of sectors including the dangerous, monotonous as well as restricted areas where there is a huge risk to human lives. It is a gift of modern artificial Intelligence. People implemented different types of robots for different works. IoT is an ecosystem where things have a unique identifier, embedded with sensors, and actuators, and can send or receive data over the internet. A fusion of both IoT and robotics or in individual manner, these advanced technologies are being used pervasively in many sectors, for example, smart home, agriculture- paddy cultivation [1], smart campus, smart city, environmental weather monitoring, industry automation-poultry farm automation [2], hotel management [3], health areas- patient management [4] as well as taking care of patient by providing nursing facilities [5], remote sensing and monitoring, virus affected and disabled people management [6]. However, the interaction between humans and robots is still a challenging task. Apart from verbal communication, humans use non-verbal signs like postures and gestures to communicate with each other. Non-verbal communication is an instinctive way of communication. It is done by facial expression, gestures/postures, gait, or head nods. It is noteworthy that there is a slight difference between gestures and postures. For example, hand gesture refers to a dynamic state of hand movements whereas hand posture refers to the static state of the hand. In this work, we have proposed an IoT-based system to command a robot with Bluetooth through mobile phone and hand postures, especially beneficial for physically challenged as well as virus-affected people. Apart from this, another system is integrated to measure the body temperature of the person through a contact-less IR temperature sensor and another sensor to measure the temperature and humidity of the room. The collected data will be stored in a secure thingspeak cloud server. Here, hand posture is used as an input to the robot and according to the input, the robot is designed to move towards 360 degrees of movement to left/right/forward/backward and to stop. This robot takes hand posture as input by a pi camera, then converts the posture into commands and performs accordingly.

The objectives of this work are as follows:

1) People can call the robot by hand postures and Bluetooth command to give the robot 360 degrees of movement. As this robot is controlled in two ways, namely, hand posture taken by a pi camera and also mobile Bluetooth, the system is reliable because if one type of controlling fails, the other type may work.
2) This robot may work in virus-affected areas with virus-affected people without making harm to healthy people eventually helping to stop community transmission.
3) The robot can collect data and send them to a cloud server for future monitoring.

The rest of the paper is arranged as follows: Section II discusses the related works associated with this paper, Section III

demonstrates the system model, algorithms, circuit diagrams and flowcharts of the work, Section IV shows the experiment results, comparisons of our work with some other works, limitations and finally Section V provides the concluding remarks and future scope of this work.

II. Literature Review

Researchers explored several approaches to detect hand postures in their works. In literature, the recognition systems are designed based on numerous methods such as deep-learning, 3D Model, depth, skeleton, motion, appearance as well as color [7]. Boyali et al. [8] proposed six different hand gesture and posture (1- Fist, 2- Hand Relax, 3- Fingers Spread, 4- Wave In, 5- Wave Out, 6-Double Tap) recognition system with an accuracy of 97% after receiving electromyography (EMG) signal which is acquired by eight myo armband attached to a person's arm. Here, sparse subspace clustering (SSC) and collaborative representation based classification (CRC) are used to train and recognize patterns. Nguyen et al. [9] demonstrated a hand posture recognition framework consisting of hand detection through traditional hand detector viola jone using haar-like and cascaded adaBoost, low level feature extraction on hand region through image conversion as well as pixel-based extraction, a combination of three kernel descriptors (KDES), namely, gradient, pixel value and texture KDES for hand representation on HSV, RGB, lab color channel and finally multi class support vector machine (SVM) for classification. They have reported an average of 97.3% accuracy on the NUS-2 data-set and 85% on their data-set within 1m to 3m distances. IoT based systems and robots are helping mankind in remote monitoring [10], remote sensing [11], disabled patient management [12], virus affected people management [13] and so on in all times [14] in secure way [15]. Embedded systems and IoT are helping hospitals [16], Agricultural Systems [17], energy generation [18], electronic voting [19] and bio-metric[20] security systems. Akhund et al. [6] reported a 97.9% success rate to recognize hand gestures of disabled as well as virus-affected people to operate the robot. They have developed a robotic agent consisting of an MPU6050 accelero-meter gyroscope sensor, Arduino nano, 433KHz radio wave receiver, L293D motor driver IC. The sensor is responsible for tracking the movement of the hand. Alam et al. [21] designed a hand gesture controlled robot which can recognize five different gestures (left, right, forward, backward, stop) with an accuracy rate of 93.8%. The system uses MPU 6050 module, Arduino nano, HT12E encoder IC, decoder chip HT12D, RF transmitter and receiver. Fakhrurroja et al. [22] developed a system to control electronic devices like fan, light, TV, AC of a smart home through the detection of hand gestures. In their study, kinect v2 sensor is used to track nine different hand state combinations along with raspberry pi and relay module. They have achieved 87% accuracy to detect the gestures. Chen et al. [23] investigated compact CNN named EMGNet to classify hand gestures after analyzing surface electromyography (sEMG) signals obtained through myo armband. The model is tested on Ninapro DB5 Dataset and validate on the myo Dataset. The model can identify 5 different hand gestures with 99.81% recognition accuracy. Maharani et al. [24] implemented two traditional machine learning algorithms namely SVM with directed acyclic graph and K means clustering for the classification of hand postures receiving through Kinect v2. The four gestures (forward, right, left and stop) are used to operate the bioloid premium robot consisting of IC 74LS241N, Arduino mega, kinect v2. They tested hand gesture recognition from the distance of 2, 3 and 4 meters where the range of the body slope was 45, 0 and 45 degrees. They have reported 95.15% accuracy in 10 ms and 77.42% accuracy in 4.45 ms using SVM and k-means clustering algorithm respectively. Meghana et al. [25] designed a system to move a robot towards forward, backward, right and left direction through identifying hand gesture as well as voice especially for the people who are unable to see or hear. The hardware used in the system is MPU6050, L293D driver, LCD, HC05 Bluetooth module, Arduino uno. Abed et al. [26] experimented with a vision-based hand gesture recognition system that can identify five different hand gestures to move a mobile robot towards forward, backward, left, right as well as stop. Raspberry Pi camera module is used to track hand gestures. The hardware that is used to process and provide commands to the robot along with a pi camera is Raspberry Pi 3 model B, L298N motor driver, power supply, camera board, 5 inches 800*480 resistive HD touch screen, rover 5 two-wheel drive platform. They have used Open cv library of python programming language to perform the task. The system showed 98% recognition accuracy. Su designed a 10 types of hand gestures recognition system based on depth vision and surface EMG signals. Here, leap motion controller collects depth vision data finally labeled by hierarchical K means clustering. In addition, myo armband is used to receive and transmit EMG signals. Then, preprocessing is done by a band-stop filter, and a band-pass filter. After feature extraction, finally, multiclass SVM is used to classify the signal. Adithya et al. [27] employed a deep CNN with rectified linear unit (Relu) activation function to automatically recognize hand gestures. They have trained and tested the model using 2 datasets namely the National University of Singapore (NUS) and the American fingerspelling dataset. The model showed 94.7 ± 0.80% accuracy, 94.96 ± 1.20% precision, 94.85 ± 1.30% recall, 94.26 ± 1.70% f1-score in case of NUS dataset and 99.96 ± 0.04% accuracy, 99.96 ± 0.04% precision, 99.96 ± 0.04% recall, 99.96 ± 0.04% f1-Score in case of American fingerspelling dataset. Chansri et al. [28] presented a skin color technique consisting of an RGB camera along with Raspberry Pi to control hand gestures. They have experimented on the American sign language dataset with 12 gestures and achieved 90.83% accuracy. Mondal at el. [29] developed a temperature detector product module for measuring the body temperature of covid 19 affected patients with 98% accuracy. The hardware part consists of LoLin NodeMCU V3 with ESP8266 module, DS18B20 temperature sensor probe, passive buzzer, LED and flat vibrator motor whereas programming is done in Arduino IDE. This system creates an alarm using a buzzer when the temperature exceeds 100.4°F or 38°C temperature. To store the data, they have used ThingSpeak cloud server. IoT based systems are helping people to make cheap irrigation systems [30], Seamless Microservice Execution [31], Big Data Processing [32] and blockchain technology [33]. IoT is helping lung cancer diagnosis [34]. Fog computing plays a vital role for augmenting resource utilization [35]. Cloud computing is helping to analyse people sentiment [36] and dynamic task scheduling algorithms can make it more efficient [37]. So, we should make proper use of IoT and robotics in medical science.

III. Methodology and System Model

A. Requirements

To implement the prototype we used Raspberry Pi 3B+, pi camera 5MP and python 3 programming language for the image processing part. The robot motion controlling part consists of a robotic chassis, breadboard DC gear motor, motor driver L298N, battery, wires, battery charger. Instead, the Arduino UNO Micro-controller, HC-05 Bluetooth Sensor, DHT11 sensor, IR temperature sensor MXL90614, Node MCU ESP8266, Wi-Fi, ThingSpeak cloud server and C++ programming language for Bluetooth controlling and data sending part.

B. System Model

The diagram of the system methodology of the robot movement is depicted in Figure 1. For recognising the posture with image processing we have used Raspberry Pi and Pi camera. The robot can be controlled via Bluetooth also. We could include Bluetooth module with the Raspberry Pi too but we have done it with Arduino uno to make the system more durable and easy. If Raspberry Pi fails any time to detect posture then Arduino will work with following the instructions from mobile.

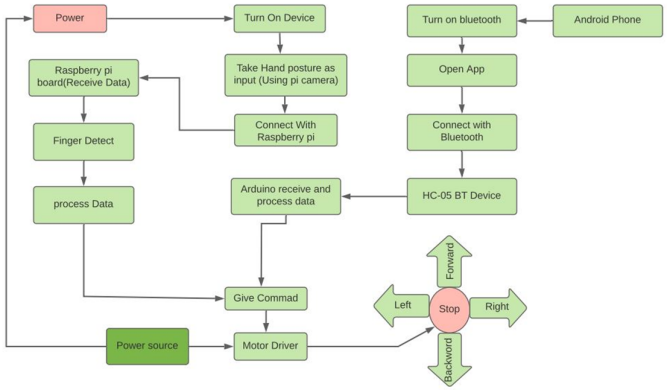

Fig. 1. System Methodology

1) Posture Detection Part: Posture detection is done with image processing using python programming language on Raspberry Pi 3 B+. Pycharm IDE community version was installed on Raspberry Pi. At first, we need to install two library function numpy and opencv. Before plugin library function we updated the pip version 2 to version 3. Then (while (cap.isOpened)) executes video capturing. We crop correct image size. Then we convert color in gray scale and create window for mapping the picture. After that conditions to find motion from the window will be executed with our image processing algorithm. If the motion found then motion pixel detect. We also plot detected motion in window map to simulate the detection in computer screen before applying it in Raspberry Pi and robot. Then the motion data and detected posture creates movement command for the robot to move 360 degrees. The movement commands goes to the GPIO ports of Raspberry Pi and send signal to the motor driver and the motor driver moves the 2 motor of the robot. Finally the robot moves by following the posture signal. If the motion not found then the robot will stop movement and again executes new video reading command. Algorithm for Movement controlling with posture recognition by Raspberry Pi and image processing is as mentioned in Algorithm 1.

Algorithm 1 Posture Recognition with Raspberry Pi and Image Processing

```
import: cv2; numpy ← np; math; cap = cv2.VideoCapture(0)
while (cap.isOpened()) do
    ret, img = cap.read()
    cv2.rectangle(img, (300, 300), (100, 100), (0, 255, 0), 0)
    crop_img = img[100 : 300, 100 : 300]
    grey = cv2.cvtColor(crop_img, cv2.COLOR_BGR2GRAY)
    value = (35, 35)

        cv2.imshow('Gesture', img)
        all.img = np.hstack((drawing, crop.img))
        cv2.imshow('Contours', all.img)
        k = cv2.waitKey(10)
    end if
    if k == 27 then
        break
    end if
end while
```

Flow chart of Hand posture recognition and finger detection is mentioned in Figure 2.

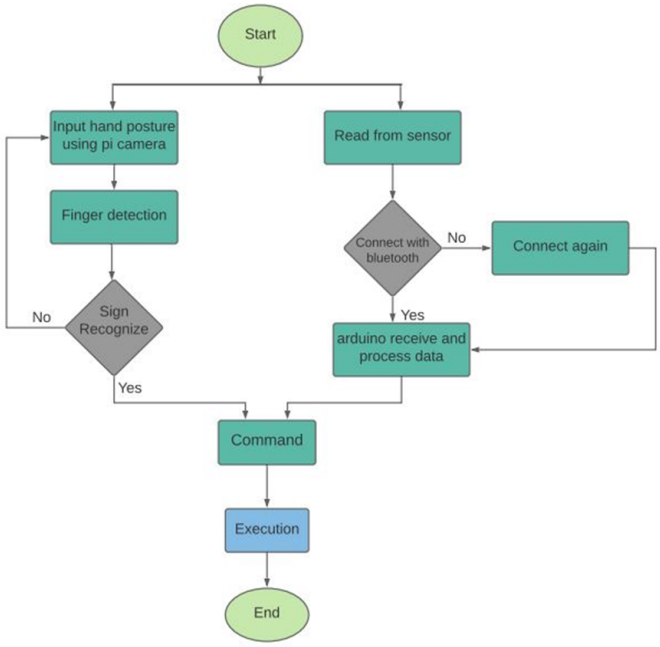

Fig. 2. Flow Chart of Hand Posture Recognition and Finger Detection

The circuit diagram of posture detection and robot controlling with Raspberry Pi is mentioned in Figure 3.

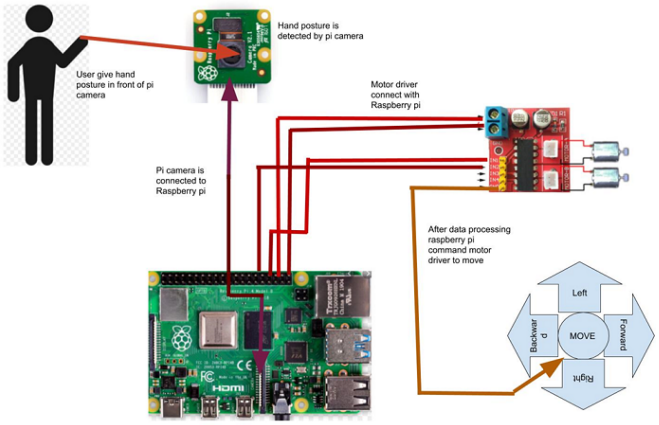

Fig. 3. Circuit Diagram of Posture Detection and Robot Controlling with Raspberry Pi

2) Bluetooth Sensing and Controlling Part: Movement with Bluetooth sensing from mobile phone is another part of this project. We used the Arduino IDE to write the C++ programming language for Arduino UNO Micro-controller. The Arduino will receive the signal sent from mobile phone with Bluetooth sensor HC-05. Android or IOS mobile phones can send any data via any Bluetooth data sender mobile app (we used Bluetooth RC controller available in app store and play store) to HC-05 after pairing. Arduino can receive that data with serial communication (Tx and Rx). After receiving the data in Arduino, conditions for 360 degrees movement will be executed. Then the signals for forward, backward, left, right and stop will be sent to the motor driver L298N. Then the motor driver will move the 2 DC motors of robot by following the commands. Algorithm for Movement Controlling with Bluetooth is mentioned in Algorithm 2.

The circuit diagram of robot controlling with Bluetooth is mentioned in Figure 4.

end while
```

3) Data Sensing and Sending Part: The system will be able to collect data from the patient with IR temperature sensor MXL90614 without touching people and collect the room temperature and humidity with DHT11 sensor. Then it will upload the collected data to a cloud server of ThingSpeak via Wi-Fi. The collected data will be shown in an Oled display and can be monitored from anywhere in the world with that cloud platform. The circuit concept of data sensing and sending part is shown in Figure 5. We used Node-MCU ESP8266 as micro-controller unit for this.

Algorithm for Data sensing and sending with NodeMCU is mentioned in 3.

IV. Results

We have got experimental result of this hand posture recognition robot. When it detects one finger it goes forward. When the pi camera detects two fingers of hand then it goes

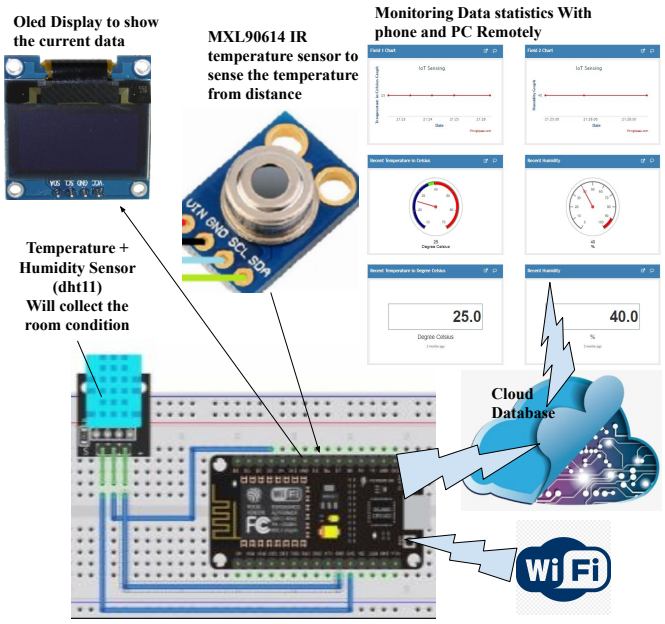

Fig. 5. Circuit Concept of Data Sensing and Sending Part

backward. According to the algorithm, when it detects three finger then the robot move to its right side and after detecting four fingers the robot moves to its left side. Finally when the camera detects five fingers of hand then the robot stops its movement. We use python programming language to detect fingers. Figure 6 shows detection of one finger simulation.

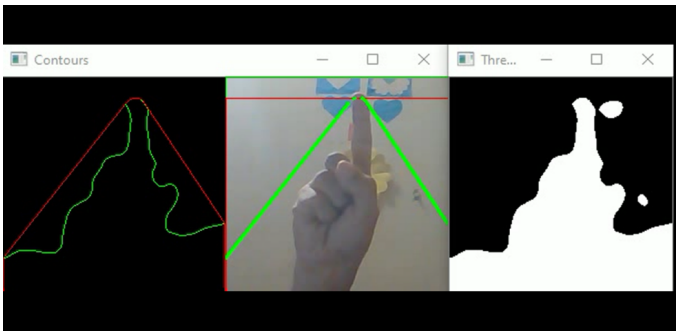

Fig. 6. Detect One Finger

The proposed system can detect two finger successfully. Figure 7 shows our system detect two fingers successfully.

Our system can detect two finger successfully. Figure 8 shows our system detect 3 fingers successfully.

The system can also detect two finger successfully. Figure 9 shows our system detect 4 fingers successfully.

Finally, our system detects five fingers form human hand. Figure 10 shows our system can detect 5 fingers accurately.

The system shows the collected data in the ThingSpeak server (Location: https://thingspeak.com/channels/739817). Figure 11 shows Collected data visualisation in cloud server.

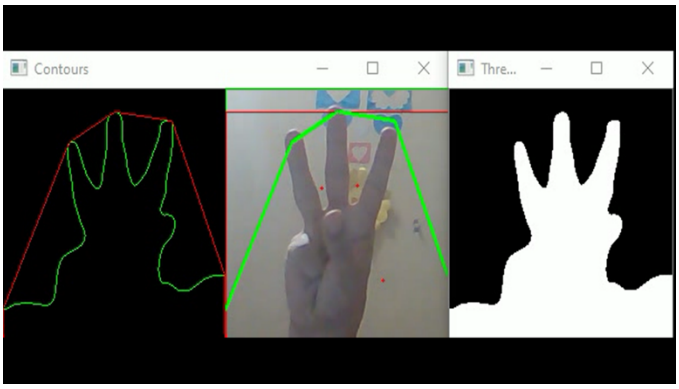

Fig. 8. Detect Three Finger

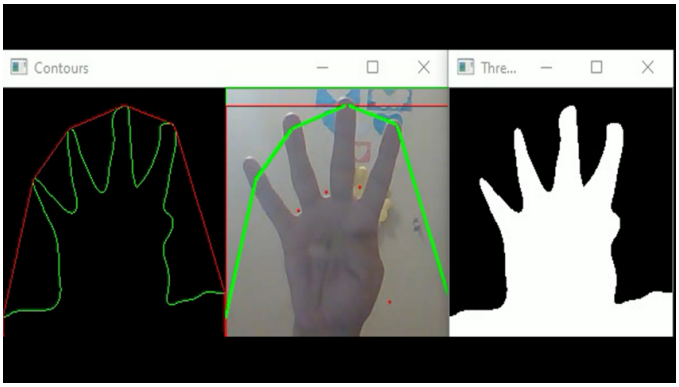

Fig. 9. Detect Four Finger

A. Prototype Output

Final view of the Prototype Robot is mentioned in Figure 12, Figure 13 and Figure 14.

B. Obtained Features and Results

We tested our system for posture detection, Bluetooth controlling and data sending to cloud server. We got desired results. The features obtained from the prototype are as follows:

1) The robot is able to recognize the posture and fingers of a patient and move towards the patient. It showed 95% success rate in 500 tests.

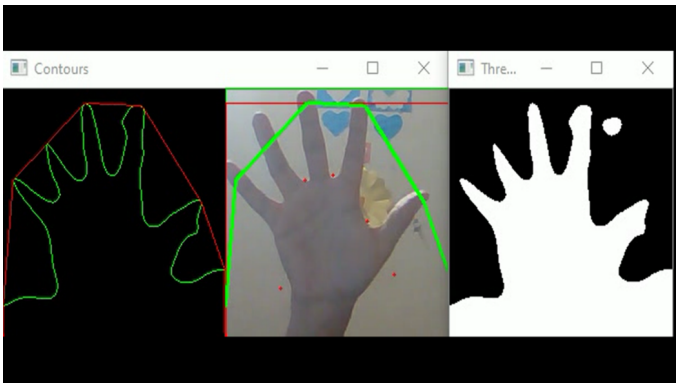

Fig. 10. Detect Five Finger

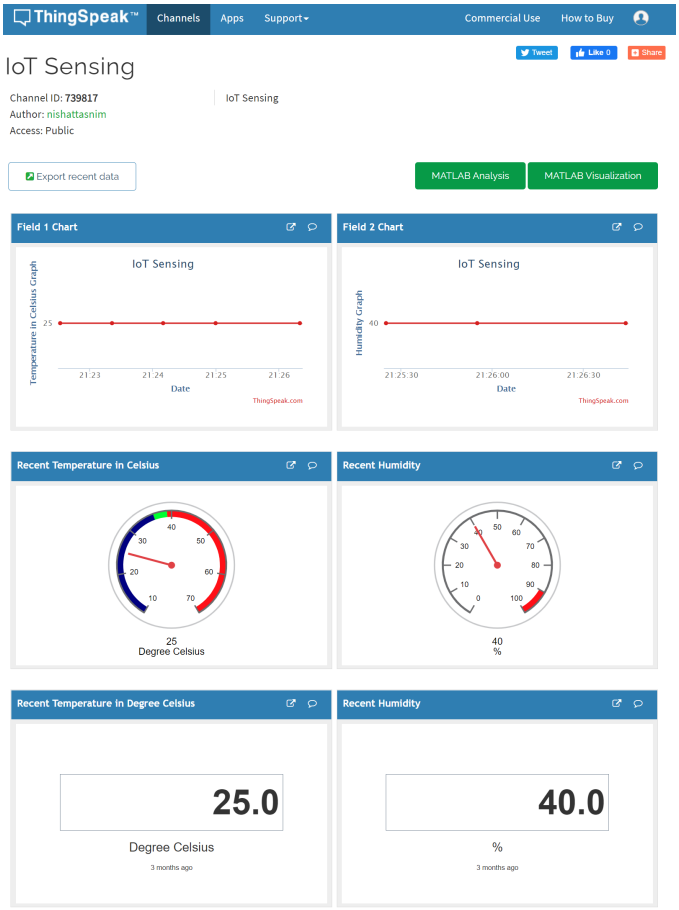

Fig. 11. Collected Data Visualisation in Cloud Server

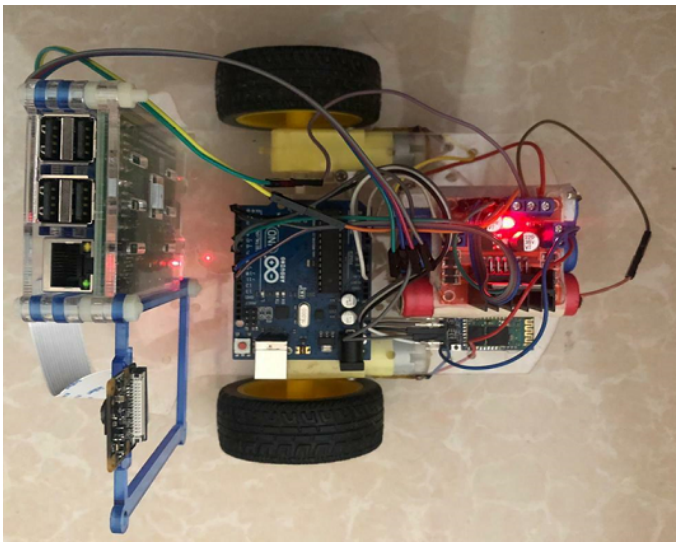

Fig. 12. Final Look (Side 1)

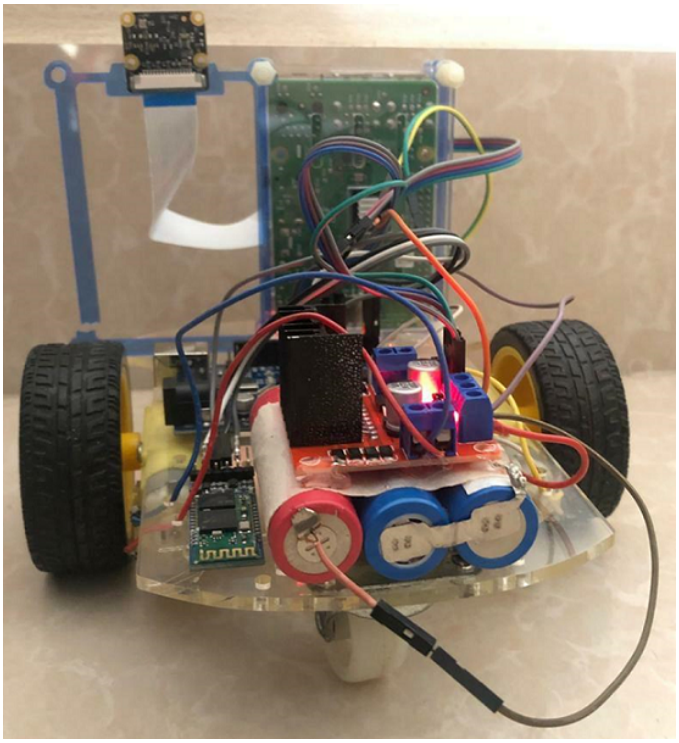

Fig. 13. Final Look (Side 2)

2) The robot can move 360 degree by following the instructions from posture. It showed 95% success rate in 500 tests.
3) The robot also works using Bluetooth sensor. It showed 98% success rate in 500 tests.
4) It can also make movement by the instructions from mobile phones via Bluetooth with 97% success rate in 500 tests.
5) The robot successfully collected temperature and humidity data from people and environment and showed in oled display with 96% success rate in 500 tests.
6) The robot successfully sent the collected data to cloud database with 94% success rate in 500 tests.
7) The system is cost effective. The prototype costs less than 100 USD. Where some existing systems may cost more than 500 USD without having all of the features obtained in this work.

C. Limitations

The system has some limitations also which can be mitigated in future development. The limitations we have found

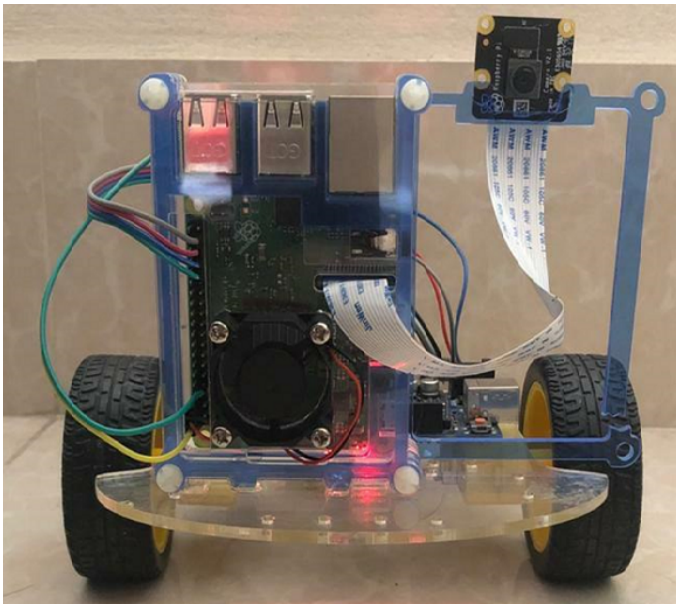

Fig. 14. Final Look (Side 3)

are as follows:

1) The system is not water proof. Water may damage the full or partial system.
2) For making the system low cost we used low cost sensors that may make incorrect results some time.
3) The robot should be maintained carefully. Otherwise it can be broken.

D. Discussion

The main objective of this paper is to operate a robot using hand gestures or a mobile phone through Bluetooth and after then, collect data and store them on a cloud server. The process of making hand gestures as input has been performed through an embedded pi camera, processed to recognize correctly as well as respond accordingly. The whole process takes on an average of 1500 milliseconds at the rate of 97% accuracy. Alam et al.[21] designed hand gesture-controlled robot using MPU 6050 gyroscope module and Arduino nano with an accuracy rate of 93.8%. Maharani et al.[24] performed 1080 number of tests in total by 6 different people with four gestures (forward, right, left, and stop), from three distances (2m, 3m, 4m), and at three slopes position (450, 00, -450). According to them, SVM showed superior results than K-means clustering with 95.15% recognition accuracy in 10ms. Hand gestures are used to control the home appliances[22] with the accuracy rate 87% in 3 meter distance. They utilized a Kinect sensor to take hand gestures with three-hand states(open, close, and lasso), and processing is performed through Raspberry Pi. Meanwhile, Xing et al.[38] achieved 83.23% accuracy using a little modified CNN to surface electromyographic signal for hand gestures recognition. Hence, it is evident that our proposed work provides superior the result compared to other existing methods summarised in table I.

Our robot also contains a non-contact temperature sensor MXL90614 which can detect Covid-19 affected patient's body temperature at a distance and send it to the cloud without wearing any devices in the body like the work of [29]. These above discussion shows the advantages of this work.

TABLE I. COMPARISON WITH STATE-OF-THE ART METHOD OF HAND POSTURE RECOGNITION

Method	Accuracy
Alam et al.[21]	93.8%
Fakhrurroja et al.[22]	87%
Nazzi et al.[38]	95.01%
Maharani et al.[24]	95.15%
Our Proposed Model	**97%**

V. CONCLUSION

In the modern era, robots are engaged in a lot of sectors. This work implemented an IoT-based posture recognizer remote sensing robot. Hospital patients can call the robot with hand posture and smartphone via Bluetooth; then the robot can go to the patient by following posture or Bluetooth command. Then it can collect data with sensors and send them to a cloud database. Therefore, any disabled or virus-affected person can control it and be monitored with this system remotely without affecting any healthy people. We got around 95-97% success rate among all the features. In future work machine learning features can be added to this robot to predict the patient and environmental conditions.

***Abstract*—In Deep Learning (DL), Generative Adversarial Networks (GAN) are a popular technique for generating synthetic images, which require extensive and balanced datasets to train. These Artificial Intelligence systems can produce synthetic images that seem authentic, known as Deep Fakes. At present, data-driven approaches to classifying medical images are prevalent. However, most medical data is inaccessible to general researchers due to standard consent forms that restrict research to medical journals or education. Our study focuses on GANs, which can create artificial fundus images that can be indistinguishable from actual fundus images. Before using these fake images, it is essential to investigate privacy concerns and hallucinations thoroughly. As well as, reviewing the current applications and limitations of GANs is very important. In this work, we present the Cycle-GAN framework, a new GAN network for medical imaging that focuses on the generation and segmentation of retinal fundus images.DRIVE retinal fundus image dataset is used to evaluate the proposed model's performance and achieved an accuracy of 98.19%.**

***Keywords*—DeepFakes; deep learning; retinal fundus image synthesis; segmentation; generative adversarial network (GAN); variational autoencoder (VAE)**

I. Introduction

An eye's retina is a sensitive membrane responsible for vision.As shown in Figure 1, three primary anatomical components are the Optic Disc, Macula, and Blood Vessels.

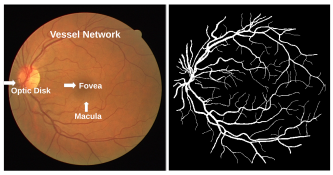

Fig. 1. Picture of the Retina on the Left; The Segmented Image on the Right.

To categorize the GAN's working capability, we divided them into seven categories: synthesis, segmentation, reconstruction, detection, de-noising, registration, and classification. The use of GANs has been studied across many different imaging modalities, including MRI (magnetic resonance imaging), CT (computed tomography), OCT (optical coherence tomography), chest X-rays, dermoscopy, ultrasound, PET, and microscopy.

A classic area of study in computer vision is image classification. A large, well-balanced dataset is frequently needed for training deep neural networks. However, because of the unbalanced dataset, most networks' performance will suffer while classifying medical images. Moreover, collecting pathological instances takes time in the domain of medical images. The ideal option is to create new, high-quality, diverse photographs of minority classes[1].

Artificial intelligence (AI) has gained popularity in recent years for use in medical imaging jobs [2]. However, even while medical data sets are more widely available, most of them only apply to certain medical diseases, and collecting data for machine learning methods is still tricky [3,4]. Some initiatives have focused on adding to the existing data to get beyond this obstacle. Numerous techniques for data augmentation have been proposed in this regard. Despite this, only minor adjustments, such as overfitting in learning processes or geometric modifications, have been made to meet the urgent requirement to provide data sets more meaningful [5,6]. However, considerable improvement has been accomplished by introducing synthetic data augmentation to extend training sets. For example, synthetic data can present novel photos to existing data sets. It might contribute to increased diversity within a dataset and, eventually, to more robust machine learning algorithms if such a strategy is adopted.

To achieve the mentioned improvements: 1) GANs exploit density ratio estimation in an indirect manner of supervision to maximize probability density over the data-generating distribution; 2) By discovering the latent distribution of high-dimensional data, GANs have improved the performance of visual feature extraction.

For all these Deepfakes comes into picture because Deepfakes have gained public attention for their sinister uses, but they have also investigated in several medical fields [7,8]. As ophthalmology has been at the forefront of the DL revolution, synthetic images can be used for various purposes, including fundus[9,10,11] and OCT. Several potential uses of GANs in ophthalmology have yet to be investigated, including how they can be applied to DL development and medical education [12,13] and the implications of their use for privacy regulations. This study had two goals:

- A GAN applied to synthetic images generated by using DRIVE database was tested to determine whether the machine could identify the authentic fundus images.
- In addition, GANs are being examined for their uses in ophthalmology, as well as their limitations.

The remaining portions of this paper take place in multiple sections—first, the related work regarding Image translation and Image synthesis is discussed in Section II Then, Sections III goes on with Materials & Methods for retinal image

generation. Next, the proposed network and its importance will discuss in Section IV Next, the experimentation findings take part in Section V where the segmentation's performance and execution time are concerned with existing techniques. Later on, concluding with a discussion in Section VI. Finally, Section VII contains a conclusion.

II. Related Work

Deep learning-based computer systems that assist in medical diagnostics are greatly interested. But because of restrictions on data access due to proprietary and privacy issues, these systems' development and improvement cannot be sped up by contributions from the general public [14]. For example, without the patient's consent, it might be challenging for medical personnel to publish most medical pictures [15]. Furthermore, the publicly accessible datasets frequently have an insufficient size and expert annotations, making them unsuitable for training data-hungry neural networks. As a result, only academics with access to private data can create these systems, which restricts the development and potential of this area of study.

A. GAN & VAE

In addition to GAN, Variational Autoencoder(VAE) is another family of deep generative models that should investigate for medical imaging tasks. Latent (random) vectors are the input for GAN. However, one must carefully modify the GAN output to create synthetic images with the required characteristics. To deal with this issue, VAE had introduced. An encoder and a decoder are the two components of a VAE. Utilizing multilayer convolutional neural networks, the encoder turns input images into latent vectors of random variables with corresponding mean and standard deviations.

VAE, unlike GAN, starts with samples selected from the latent vector associated with the input and then sends them to the decoder for reconstruction. Thus, we can manipulate VAE directly to create specific synthetic output images for clear input photos. However, due to the loss function of the mean square error, the output of the VAE could appear hazy. Combining the advantages of VAE and GAN creates an adversarial network for similarity measures to address this problem. The application of VAE in medical imaging is quite innovative [16,17] and needs further investigation to process retinal images.

B. Image-to-Image Translation

In picture-to-image translation, an altered version of an existing image is created synthetically. Therefore, a sizable dataset of matched instances is often needed when training a model for image-to-image translation. For which a paired sample dataset is traditionally required to prepare an image-to-image translation model. In other words, a sizable dataset with several examples of modified versions of the input image X that can be utilised as the intended output image Y. These datasets, particularly in the medical field, are time-consuming, expensive, and sometimes impossible to compile. The image-to-image translation framework can be applied to a variety of computer vision problems, including image super-resolution [18], image inpainting [19], and style transfer [20]. It is possible to employ both supervised and unsupervised methods [21,22,23].

C. Retinal Image Synthesis

Surgical simulations using an anatomic model of the eye and surrounding face were one of the first applications of retinal image synthesis. Nevertheless, the segmentation module's performance heavily influences the quality of the generated images. To reduce the requirement for annotated samples and to improve the representativeness (for example, the variability) of synthesized images [24], a generative adversarial approach is used in conjunction with a style transfer algorithm. Recent implementations like the retinal background and fovea have been modelled using a dictionary of small images without vessels [25]. In addition, it's an idea that training a segmentation network with authentic retinal images combined with synthesized ones leads to better segmentation results.

D. GAN's on Retinal Image Synthesis: Present Status

GANs have shown the ability to produce impressively realistic synthetic medical images. This section describes existing work on GANs for synthesising coloured retinal fundus images [26,27,28,29,30,31]. (Table I)

III. Materials & Methods

A. Dataset

The DRIVE dataset initially consisted of 40 photos, but we expanded it to 120 images, using 125 for training, 55 for validation, and 20 for testing. This image used with a field view of 45 degrees and a dimension of 565 x 584 pixels. It has 540 pixels in diameter and a FOV of 540 pixels. As seen in Fig 2, each image in the DRIVE dataset has a mask to aid in identifying the field of view (FOV) region.

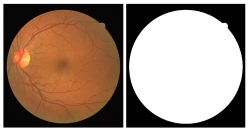

Fig. 2. DRIVE Database Sample (a) Original Image. (b) Mask Image.

B. Image Preparation

A black-and-white retinal vasculature map was created for each image using a U-Net trained on 154 photos from the DRIVE database [32].The unaided eye cannot detect pigmentation and choroidal blood vessel patterns on vessel maps, so information about them is removed. In addition, a circular mask with black background was placed on all retinal images with suitable vascular maps to create photos of the synthetic retinal fundus images.

C. Why GANs?

GANs are deployed and used for artificial data augmentation. GANs work through the creation of synthetic pictures while simultaneously learning to distinguish between them as actual pictures see Fig 3. In addition to their use in ophthalmology, GANs are helpful in molecular oncology imaging and generated positron emission tomography (PET) pictures [33]. Even though present radiology applications attempt to aid in the diagnosis, human perception has not yet been used in this situation to assess the quality of GAN created synthetic data. In several instances, using GAN improves medical imaging by creating fresh retinal pictures from data consisting of pairs of retinal vascular trees [34]. Generator loss function and Discriminator classification information about generated images are depicted as well as Convolutional neural networks (CNNs) are standard tools for categorizing images and returning a scalar to represent the realness of the input pictures.

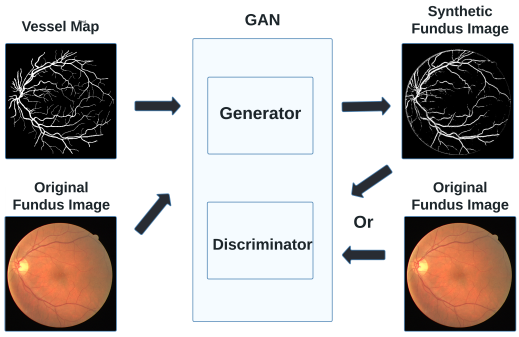

Fig. 3. Generative Adversarial Network Training, pix2pix.

D. U-Net

In order to generate a wider range of realistic images, we developed a pipeline instead of CNN based on this we trained a U-Net segmentation network with our synthetic data to generate a segmentation mask from a photorealistic medical image to assess the credibility of the data. The u-net design, explicitly created for biomedical images, is descended from the auto encoder architecture, which uses unsupervised learning for dimensionality reduction. The u-net is particularly helpful for biomedical applications because it lacks completely connected layers, has no restrictions on the size of input images and permits a substantially higher number of feature channels than a conventional CNN [35]. The decoding procedure also concatenates the receptive fields before and after convolution. By doing this, the network can use both the up-convolutional and initial properties. To determine the accuracy of the GAN, 4282 image pairs were trained for 200 epochs. Following this, synthetic retinal fundus images were created using all the retinal vascular maps from the test data. It is one of the key advantages of GANs that they can produce much larger datasets than the initial ones see Fig 4.

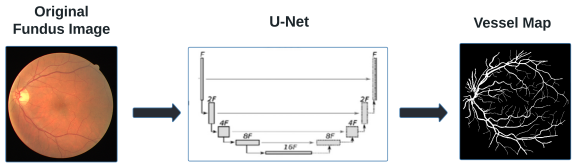

Fig. 4. U-Net Segmentation Network

E. Segmentation

Machine learning involves segmenting images into appropriate sections. Fundus pictures with low contrast, complicated, and compound characteristics must be meticulously segmented to separate retinal vessels from one another. Deep learning systems are capable of identifying vessels against backgrounds accurately. This method, however, did not factor in ambiguous vessels, resulting in inaccurate estimates of vascular calibre biomarkers, such as tortuosity, length-to-diameter ratios, branching angles, and fractal dimensions. The proposed architecture uses long and short skip connections along with U-Net to address the abovementioned problem. Segmenting retinal vessels and looking for anomalies in the retinal subspace requires an exact technique. In recent years, several supervised and unsupervised algorithms have been proposed to segment retinal vessels. However, manual feature extraction is necessary for training with supervised approaches for different applications [36], [37].In below we can see the workflow of supervised and unsupervised algorithms.

- A minimization function is used over the tuning process to determine which separation between the vascular and background classes is the most effective. Fig 5 displays a typical unsupervised learning algorithm workflow.

- In supervised approaches, the segmentation algorithm must learn the vessel segmentation rule by studying the images manually labelled by professionals. Fig 6 depicts the workflow of a typical supervised technique.

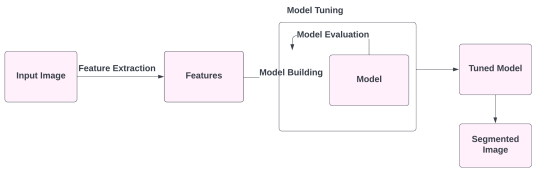

Fig. 5. Unsupervised Learning Algorithm Workflow.

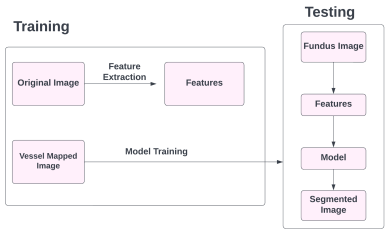

Fig. 6. Supervised Learning Algorithm Workflow.

For getting segmented image initially in the first set, 577,649 pixels (12.7 percent) are marked as vessels, while 556,532 pixels (12.3 percent) are marked as vessels in the testing set, which is segmented twice from the training set [38]. See Fig 7 and Fig 8 for detailed view of DRIVE dataset segmentation and masking. Our results are comparable to those achieved by state-of-the-art methods using U-Net implementation to Cycle-GAN Network.

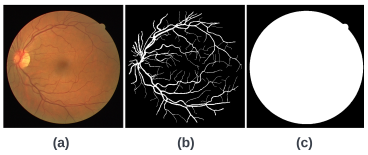

Fig. 7. A Sample from the DRIVE Dataset. (a) Training Image, (b) Vessel Segmented of the Training Image, and (c) Mask of the Image.

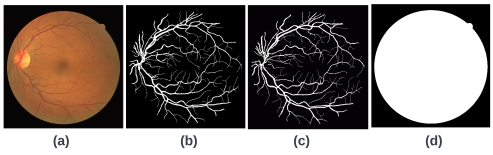

Fig. 8. (a) A Sample Test Image from the DRIVE Dataset. (b) The First Segmentation (c) The Second Segmentation (d) The Mask Image.

F. PreProcessing

During this stage, the retinal image quality is enhanced by separating vessels from the backdrop for achieving segmentation of vessels accuracy.The recommended network ensures that the retinal vascular tree can be segmented more effectively. Therefore, the trained model of the suggested network serves as the foundation for our method for retinal vascular segmentation, and its processing pipeline, as shown in Fig 9. It should note that using the DL network to segment a complete image may produce unreliable results. For the suggested neural network to focus, it is necessary to crop photos into patches.We will repeat this process in testing to produce segmented patches using the trained model. The segmented vessel tree is then produced by merging the segmented patches during the post-processing stage as shown in Fig 9.

IV. Proposed Work

A. Cycle-GAN: General Pipeline

Any model should be able to identify the underlying relationship between the two domains and extract distinctive features from each field for image transformation between them. Cycle-GAN is nominated to offer these guidelines[39]. The finding in (1) briefs a mapping between domain X and domain Y, and vice versa, the system essentially merges two GANs. A generator G: X Y trained by discriminator DY and a generator F: Y X trained by discriminator DX create a structure shown in Fig 10.

$$minmax(D,G) = E_x{-}Pdata(x)[logD(x)]{+}E_x{-}Py[1{-}D(G(y)))] \quad (1)$$

B. Loss Function

No paired data is available for CycleGAN training, so the input X and the target Y pair are not guaranteed to be meaningful. Thus, we propose the Cycle Consistency loss to ensure the network learns the correct mapping. Both discriminator loss and generator loss are similar to those used in pix2pix.

A cycle consistency refers to a close match between the input and the output. For Example, when we talk about NLP translations, the resulting sentence should be the same as the original sentence when translating from English to Telugu and then back to English. As a result of cycle consistency loss as specified in (2) and (3) :

- X image information is passed to generator G, which produces image Y1.
- A cycled image Y1 is generated by passing generated image F through generator X1.
- Between X and X1, we calculate the mean absolute error. In the Figure 11, generator G is responsible for converting image X into image Y. If you feed image Y to generator G, and the output would be the image Y itself or something close.

$$Forwardcycleloss : X \rightarrow G(X) \rightarrow F(G(X))\tilde{}X1 \quad (2)$$

$$Backwardcycleloss : Y \rightarrow F(Y) \rightarrow G(F(Y))\tilde{}Y1 \quad (3)$$

C. Image Generation

The validation dataset examined images created from retinal vessel maps manually after training the GAN for 100 epochs on 120 pairs of images.Using all vessel maps, produced a synthetic retinal fundus image from the test dataset, see Fig 12 how the synthetic image looks by using proposed network.

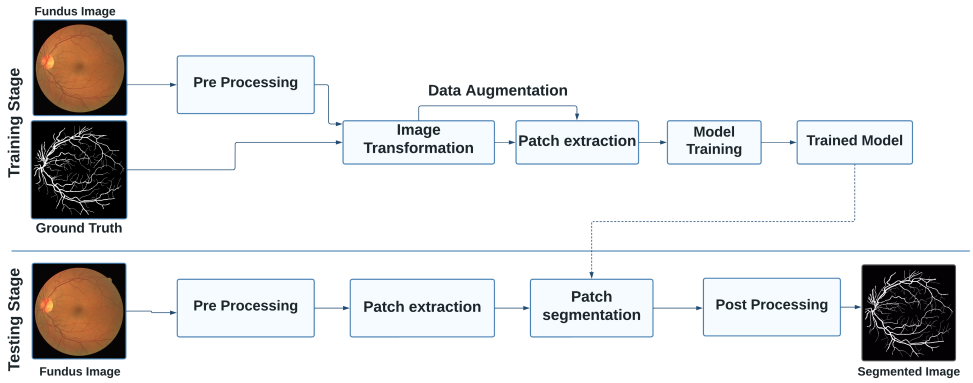

Fig. 9. Preprocess Functioning.

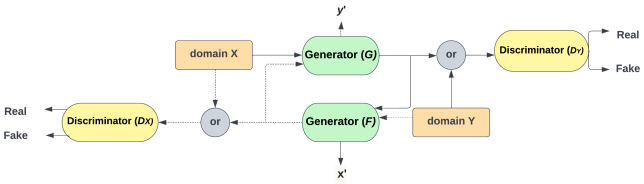

Fig. 10. Image Transformation using Cycle-GAN.

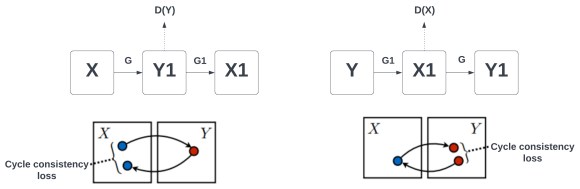

Fig. 11. Cycle Consistency Loss.

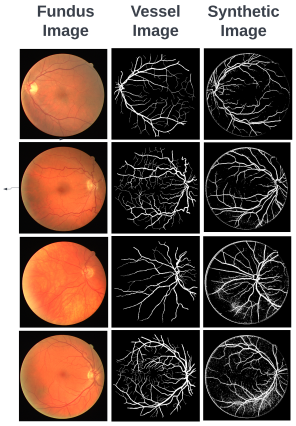

Fig. 12. A Trained U-Net is used to Segment Authentic Retinal Fundus Images (Left) into Associated Vessel Maps (Middle). In Order to Create the Artificial Retinal Fundus Images, We used pix2pixHD, a Newly Developed Implementation of a Generative Adversarial Network (GAN).

D. PostProcessing

A segmented blood vessel image is created by merging all segmented patches.As a result, the offered patches are gathered and reduced in size for cropping. These patches are then replicated in the appropriate order, depending on the image size for cropping[40]. To remove the white pixels surrounding the retina, the mask of the used picture is placed on the combined image. Then, noise is removed using the morphological transformation ”erosion” utilising an ellipse structural element of size 2*2.

V. Experiments and Analysis

In this section, it is explained about the Parameter Settings in Section A. Later on, the evaluation principle is described in Section B, where the method is configured and put into practice. Then, using a retinal image dataset, Image classification is provided in Section C. Finally, we will see execution time measures in Section D.

A. Parameter Setting

Segmentation performance is achieved by training the suggested network with parameters selected experimentally or by consulting recent works. Experimentally, we determine the learning rate, the optimizer algorithm, the weight initialization method, and the epoch number [41]. First, we train one model without changing the parameters. Next, we pick the value with the highest segmentation rate.

B. Evaluation Principle and Metrics

We advise comparing the segmentation findings with manual segmentation by a skilled medical professional. Each pixel is defined as True Positives (T_P), True Negatives (T_N), False Positives (F_P), or False Negatives for the evaluation (F_N). Pixels correctly identified as background or vessels are expressed as T_P and T_N, respectively. As opposed, F_P and F_N represent pixels incorrectly identified as background or boats. A segmentation performance measure consists of Accuracy, Sensitivity, Specificity, and F1-Score. These metrics are the ones that are used most often to evaluate segmentation results. To classify

pixels as vessels Accuracy performance is calculated, while Sensitivity and Specificity represent the ability to categorize pixels as vessels and backgrounds. The Precision parameter specifies the percentage of correctly classified background and vessel pixels among all correctly classified background and vessel pixels. As shown in Table II the suggested method employs the following performance metrics.

Table III provides the performance metrics on DRIVE dataset where our method achives 98.19% accuracy in detecting segmented images.The obtained ROC curves and plots representation for the performance metrics is shown in below Figure 13, Figure14.

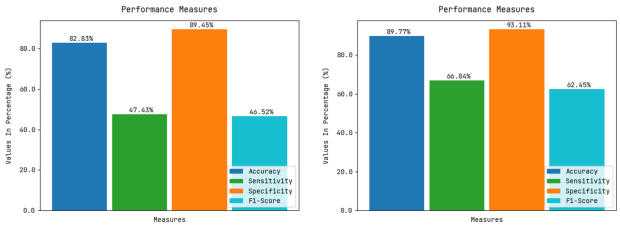

Fig. 13. Two Plots Measures for Test and Tain on DRIVE Dataset.

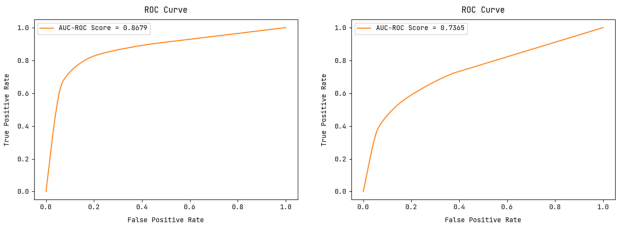

Fig. 14. Two Obtained ROC Curves on DRIVE Dataset.

TABLE II. PERFORMANCE METRICS

Metric	Elucidation
Accuracy	T_N+T_P/T_P+F_P+T_N+F_N
Sensitivity	T_P/(T_P+F_N)
Specificity	T_N/(T_N+F_P)
F1-Score	T_P/(T_P + F_P)

C. Image Classification

Using the high dimensional space, we can calculate the conditional probability, P(ai—aj), representing the similarity between two samples is shown in (4).

$$P(ai|aj) = \frac{exp\left(-\frac{-|ai-aj|^2}{2\sigma^2}\right)}{\Sigma_k \#1 exp\left(-\frac{-|ak-al|^2}{2\sigma^2}\right)} \quad (4)$$

50 actual and 50 synthetic photos with the same stage and illness distribution as the original dataset were uploaded, and runned ML programs to judge whether the photographs were natural or artificial. According to Figure 15 findings, most machine programs significantly distinguish between actual and artificial photographs.

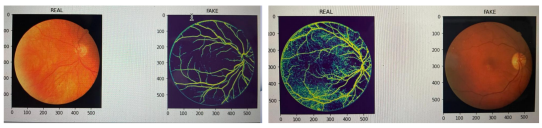

Fig. 15. Classfying Real and Fake Fundus Images.

D. Execution Time Measures

The proposed method is examined in this section for its processing performance. As shown in Table(IV),we propose calculating each image's execution period from the DRIVE dataset, respectively.Our analysis shows that despite the size of the image used, the computation values are too low for preprocessing, segmentation, and postprocessing.Then, we proposed evaluating the accuracy of the execution time compared to existing methods. Timing data is used in the evaluation for tarining the data. Because DRIVE is the most frequently used database, where values are provided in Table(V) , both metrics correspond to that database.

VI. DISCUSSION

In medical imaging, variations in illumination, noise, patterns, etc., result in a nonconvincing image produced by a GAN. A poorly defined vessel tree structure and dark spots show that the GAN can't distinguish complex systems. As a result, it can only identify colour, shape, and lighting features.There are many intricacies in medical images that must be accurately portrayed for the data to be useful for medical imaging. This lack of detail is unacceptable for medical image generation, as medical images contain many intricacies. By breaking down the complex task of generating medical ideas into hierarchical processes, our Cycle-GAN architecture improves the quality of synthetic images by using the below rules:

- In the first step of generating Images, GAN focuses on developing segmentation metrics by ignoring the realism of photos.
- Using this technique, in the second step, GAN concentrates only on generating the colour of an image, brightness of image, and texture of image based on the dimensions provided.

In addition, our proposed network generates more diverse photos than original dataset.With Fig 12, GAN is able to produce synthetic images by keeping general statistical classification of the real dataset.

The method of retinal image synthesis currently used for rebuilding the optic disc and fovea is quite adequate, but duplicate lesions with high fidelity is a challenge that requires further research. In addition, for quality validation, experts and ophthalmologists must assess the level of realism of generated images. As a result of this study, we were able to demonstrate the below points:

- That vessel maps of original retinal images obtained by ROP screening can yield realistic-appearing synthetic fundus images and

TABLE III. PERFORMANCE MEASURE VALIDATIONS ON DRIVE DATASET.

Database	No.of Epochs	Accuracy	Sensitivity	Specificity	F1-Score

- That most of machine programs can distinguish natural from synthetic retinal images.Annotated data can be used to create innovative methods for analyzing retinal images or to enrich information in existing databases to create synthetic images that look as authentic as possible. Additionally, due to GAN's adaptability, they can be used to synthesize medical images using approaches used for retinal synthesis.

VII. CONCLUSION

The synthesis of retinal pictures using GANs has recently attracted more interest, and GANs have significantly developed in recent years. These tools can overcome restrictions like the scarcity of sizable annotated datasets and overcome the expensive expense of collecting high-quality medical data. However, the findings of GAN applications in the realm of medical imaging are still far from being practically applicable. The unique anatomy of a colour retinal fundus image must also be taken into consideration when generating synthetic retinal images in order to learn about a patient's health.

In this study, we present the Cycle-GAN framework, a new generative adversarial network for medical imaging that focuses on the generation and segmentation of retinal artery images. As a result, these artificial visuals appear realistic. DRIVE retinal fundus image dataset is used to evaluate the proposed model's performance and achieved an accuracy of 98.19%. We must focus on investigating datasets of various biomedical images for interaction, domain adaptation tasks, and segmentation of medical images in the future.

ACKNOWLEDGMENT

We would like to thank VIT-AP university for facilitating the resources required for conducting this research.

***Abstract*—The world has seen road accident and its related societal and economical impact as one of the live, persisting problem in the last 2-3 decades and its prominence has been observed in the developing countries of the Asian subcontinent. With no exception, all major cities in India are facing the various challenges related to road accidents, mostly due to the large population density. Among the major cities in India, Bhubaneswar is a very fast growing city with aim to be the most livable city in Asia in the coming few years. With the city of Bhubaneswar as our study area, we address the issues related to road safety by determining the degree of severity of road accidents. We study the accident related data collected for the last decade using the spatial tools of Geographical Information System (GIS). Then using a GIS-map based analysis and a fuzzy-based model, we have found the spatio-temporal distribution of accident vulnerable locations with their degree of severity. Our experimental results show the accident hot-spots with values of selected contributing parameters such as timing, traffic density, vehicle speed, road intersections.**

***Keywords*—Road traffic management; accident vulnerability; GIS; fuzzy inference; fuzzy rules**

I. Introduction

Every year across the globe, the road accidents are increasing rapidly causing severe injuries and fatalities. As per the road accident data between 2004 to 2013, the accidental death is the 9th major reason of death and going to be 5th major by 2030, unless otherwise proper actions will not be taken [1]. As per [2], the global road accidental death has touched to 1.35 million in the year 2016. Hence, traffic safety is a prominent issue in the sustainable development of urban and semi-urban areas. To ensure traffic safety, road traffic accidents have been considered as one of defining components which contribute to the adverse impact on the economic growth in the developing countries, leading to social and economic concerns. In recent times death cases, severe injuries and property losses in road accidents are the major negative effects of transportation systems. The success of traffic safety programs relies on the analysis of reliable and accurate traffic accident data. Among few notable contributions towards traffic data analysis, in [3], using road accident data of UK between 2005 and 2019 for finding risk and predicting severity of accidental injuries, authors have used data analytics strategies. It can found in [4] that spatial pattern of accident distribution in a specific study area can be analyzed and accident hot spots are identified using GIS based spatial and statistical analysis tools. In [5], authors present the performance result of spatial analysis of accident prone traffic location classification using Multi-criteria Decision Making (MCDM) approach. The study in [6], proposes a detailed spatio-temporal analysis approach combining strategies such as emerging hot spot analysis, spatial autocorrelation analysis and time-space cube analysis to identify the accident hot spots and related traffic features.

This paper analyses the present state of traffic accident information on various arterial and sub-arterial roads in the selected study area that is the city of Bhubaneswar, in the eastern region of India. This paper also discuss the determination of highly accident prone locations using QGIS Software and safety deficient areas on the major roads of the city.

This paper examines the potential use of the Geographic Information Systems (GIS) technology in executing road accident analysis in the study area with the illustration of various point-pattern techniques. Since GIS can further extend the analytical and visualization features, its implementation in urban areas like Bhubaneswar would based more on comprehensive planning and management in data acquisition and integration. A comprehensive digital database on the road structures of Bhubaneswar with an coherent and organized naming conventions is the primary need for the analysis and management of road accidents using GIS development.

In the city map of Bhubaneswar, using GIS-based analysis, locations from the periphery are to be identified in every 500metres; For each location the probability of severity of accidents are to be measured on the basis of five context-specific parameters (described in subsequent discussions); While selecting each parameter in the input interface, a supplementary value is also selected with the parameter. That supplementary value represents the "degree of impact" of each selected parameter. Five possible concepts such as very high, high, normal, low and very low are considered to the context of "degree of impact". To control these fuzzy concepts, a fuzzy controller is used, based on Takagi-Sugeno's fuzzy approach.

Why Fuzzy Classifier: Models based on fuzzy classification are mainly based on processing of many ambiguous, vague, imprecise input information to get some certain inference by

producing various outputs. The input information is processed through a rule-base containing a set of fuzzy if-then-else rules. Depending upon the number and structure of rules in the rule-base, the complexity and quality of fuzzy-classifier is determined.

II. Related Works

P. B. Parmar et al. [7] identified blackspot (i.e. accident-prone locations) on some specific locations of S.P. ring road, Ahmedabad with heatmap plugin and analyzed using QGIS and also suggested remedial measures for the black spot such as to find the places where enforcement steps are needed and number of particular places where sign boards for speed restriction and traffic sign are needed.

J. Choudhary et al. [8] geocoded the accident locations for five years from 2009 to 2013 over the digitized map of the city of Varanasi. The authors also evaluated and analyzed the spatial densities and clustering of accidents using heat-map plugin. The accident hot-spots were isolated with the road stretches using the heat-map using Kernel Density Estimation.

Jerome Ballarta et al. [9] have identified accident hot spots in Katipunan Avenue, Quezon city using standard GIS geoprocessing techniques.

V. Prasannakumar et al. [10] did a comparative investigation on temporal and spatial aspects of road accidents in the city of Thiruvananthapuram. Then using cluster analysis and spatial data statistics, authors have described the temporal and spatial differences of the accident vulnerable locations from the nonvulnerable locations.

Sanjay Kumar Singh and Ashish Misra [11] in their study have analyzed the road accidents in Patna city using annual data in year 1996 to 2000. It provides a overview of road accident scenario in India and deals with existing transport system in Patna.

Deelesh Mandloi and Rajiv Gupta [12] have developed a GIS-based model for predicting the accident vulnerable locations using the road accident related parameters and have also given the remedial steps.

Yen Chen et al. [13] in their paper have discussed on application of geocoding technology for preparing spatial information to related to the traffic accidents and presented a method which accepts potential system reducing accidents as an index to identify the black spots. The association relates the features of road network elements with the black spots, based on the GIS data-storage.

Ela Ertung et al. [14] have carried out a GIS-based analysis of intersection road accidents by creating a database using fatal-injury traffic accident data at intersections in Antalya City Center, Turkey between years 2009 and 2010. They have also determined hot spots for intersection accidents and have conducted statistical evaluations of accidents.

Anik Vega and Dwi Cahyono [15] have used Multiple-Attribute Utility Theory (MAUT) strategy to map dense and accident-vulnerable traffic roads so as to analyze attribute and spatial data. This method helps in finding alternative new road to minimize the traffic density.

Michal Bil et al. [16] in their paper have evaluated and organized clusters of traffic accidents based on their significance. They have also suggested a better strategy for detecting cluster, based on standard Kernel Density Estimation (KDE), suitable to find the most hazardous spots by verifying the importance of the clusters and then ordering the most hazardous spots.

Hao Yu et al. [17] have conducted a comparative investigation of spatial analysis techniques for identifying hot-spots. They collected data from a 622.2-km section on the A1 highway in the UK. From 2001 to 2010, where 7930 crashes were found at the selected highway zones.

Gholam A. Shafabakhsh et al. [18] have conducted spatial analysis of traffic accidents for the city of Mashhad, Iran using GIS methods. Based on the spatial aspect, authors have given a detailed study on various types of road accidents, which is the first attempt in the Mashhad city corporation and also analyzed the accident types using spatial patterns in GIS tool. accidents.

A. Research Contributions

The followings are the list of our contributions in this paper:

1) To study the road accidents data in Odisha from the year 2010 to 2020.
2) To estimate the distribution and incidence of road accidents in the city of Bhubaneswar using GIS.
3) To design a fuzzy rule base with selected set of road accident parameters.
4) To identify the accident vulnerable locations using fuzzy classifier.

III. Study Area

Odisha has registered a sharp rise in road accident fatalities in the five years ending in 2020 against the target reduction in deaths by 50% during same period. A total of 107732 accidents occurred that led to 47884 fatalities. In the road accident statistics of the state of Odisha given in the Fig. 1, the major contributing city is Bhubaneswar, the capital of Odisha. It is seen that the year 2019 has the highest number of fatal accidents, a year which is taken as the starting of the "UN Decade of Action for Road Safety".

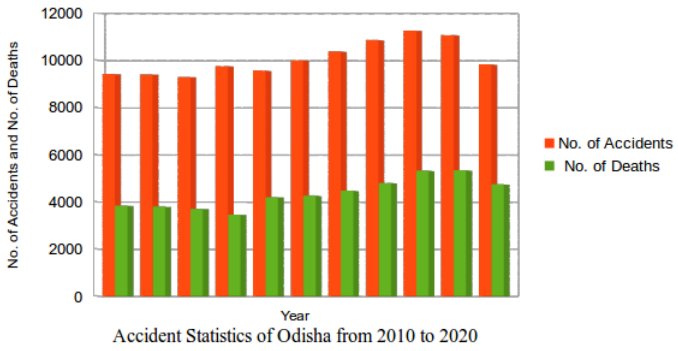

Fig. 1. Year-Wise Accident and Death Statistics of Odisha

Bhubaneswar, the capital of the state of Odisha and one of the popular tourist locations in India, is fast growing city which has organized various international events like International Mega Trade Fair, Men's Hockey Champions Trophy in 2014, Asian Athletics Championships in 2017, Men's Hockey World Cup in 2019, Men's FIH Hockey Junior World Cup in 2021 and also going to organized many more global events including Men's Hockey World Cup in 2023. It is on its way to be India's one of the most well-built cities and selected as a prominent city for the smart-city plan. Hence the crowd density is increasing alarmingly day-by-day leading to more accident cases. The objective of this paper is to evaluate and show hot-spots in Bhubaneswar using information modeling for identifying the statistical locations of accidents using GIS technology and a fuzzy classifier. Spatial-temporal analysis is needed for effective identification of hot spots and can be used to improve the safety of these spots.

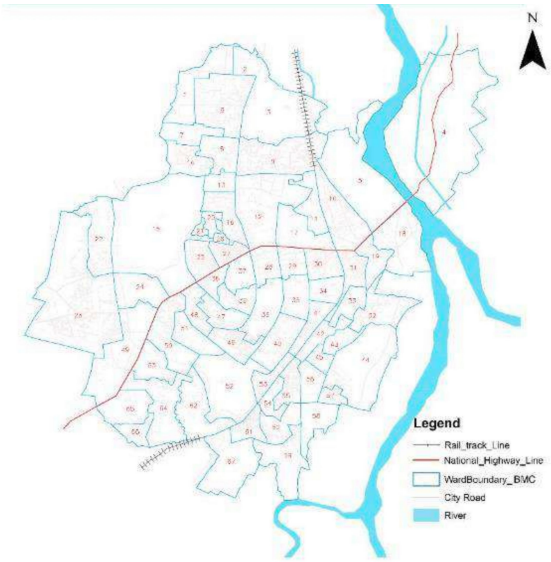

Fig. 2. Road Map of Bhubaneswar

Here Bhubaneswar is considered as the study area which is governed by Bhubaneswar Municipality Corporation. The city of Bhubaneswar sees rapid urbanization with both planned and unplanned way in all sides of the city such as towards Cuttack, Puri and Khurda. In the last three decades, Bhubaneswar has become the business as well as the educational hub of the state along with the best medical facilities available. As a result of which people from all corners of the state and the country as well, are coming to Bhubaneswar for their livelihood. It has a great impact to the population growth, urban environment and most importantly traffic congestion in the city. Nowadays, the traffic issues in the city has become a major concern. In Fig. 2, we have given the road map of Bhubaneswar prepared using QGIS, an open-source GIS software.

Over the years the Ministry of Road Transport and Highways (MoRTH) has been in the process of identifying the accident black spots on the National Highways passing through Bhubaneswar. Most of these spots located on NH-5 (now is NH-16) are mainly because of faulty road designs during ongoing of road projects. Inside the city of Bhubaneswar, Aiginia Chowk and Khandagiri Chowk are found to be two major black spots of NH-16 where 30 and 36 accidental death case occurred respectively between 2017 and 2020. Hence there is an immediate need of micro-level analysis of accident vulnerable locations in Bhubaneswar.

IV. Methodology Used for Identifying Accident Vulnerable Locations in Urban Traffic

Road traffic accidents are now considered as one of the major concerns in India. Authors in [19] mentioned that around 0.4 million accidents are occurring in India almost every year, hence leading to an ever-increasing accident rate. Since accidents are uncertain and unpredictable, hence there is high possibility that this increasing rate of accidents may sustain. Hence there is extreme need of identification of different accident-prone geographical locations and finding the different features related to accidents occurring at these locations which will monitor the different scenarios of road accidents.

In [20], authors suggested that to identify potential measures to prevent road accidents, there is a need for systematic correlation between frequency of accidents and attributes such as traffic information, road-side features, vehicle information, road structure. Lee et al. [21] suggested to use statistical models for analyzing road accidents to determine the correlation among the spatial features and road accident features.

However, [22] found certain demerits of using regular statistical methods for analyzing datasets with large dimensions In addition to problems like sparse data in large dimensional tables, statistical methods can also give some incorrect results mainly due to the assumptions based on the specific models. Hence some techniques based on artificial intelligence and data mining are adopted to handle the large datasets in road accidents.

In [23], authors described some specific data mining applications for road accident analysis, pavement analysis and roughness analysis of road. Authors in [24] narrated the potential data mining strategies like classification, clustering, association rule mining etc. for the effective analysis of road accident data.

As per authors in [25], for effective data analysis the accidents reports available in the police stations are not complete and sufficient for research. At the same time, these basic data can be used and analysed for some specific road segments with the help of statistical approaches, as described in [26], [27].

This paper uses fuzzy logic based classification technique to determine the high-frequency accident spots and subsequent analysis to identify various factors that affect road accidents at these spots. We first identify the parameters for the analysis of the accident vulnerable locations. Then using the fuzzy rule base, we compute the degree of vulnerability of the specific locations by correlating between the characteristics features of these locations and the various attributes in the accident data. Here our main focus is to interpret the results.

A. Proposed Model

The work is basically based on the classification and analysis of traffic data of the city of Bhubaneswar. The

proposed smart traffic management system is going to provide a systematic analysis of data. User has to give the required information like timing (early morning, morning, noon, afternoon, evening, night, late-night), road-condition (i.e. road-friction-density), level-of-road-intersections, existence of crowd-pulling-centers (such as school, bank, shopping mall, etc.) within 200metres periphery and traffic-calming-measures (such as speed-breakers, rumble-strips, bollards), etc. through selecting suitable icons given on the user-interface.

Then the sequence of selected attributes gets associated with values signifying the degree of intensity. The set of user information are then to be stored in a fuzzy rule base which is in the back-end of the system. The fuzzy rule base contains some generalized traffic information and more importantly a set of rules in the form of IF-THEN. In each of the rule the IF-part contains a set of premises which are nothing but the conditions required for finding the degree of accident vulnerability, and the THEN-part contains the response after vulnerability analysis. Hence the response selected by the user is now matched with the premises of the rules in a sequential manner. The rule, for which the inputs matched with all of its premises, will be selected. Then the result part of the selected rule is considered as the response to the user as the result of the vulnerability analysis.

An overview of the proposed system is shown in Fig. 3.

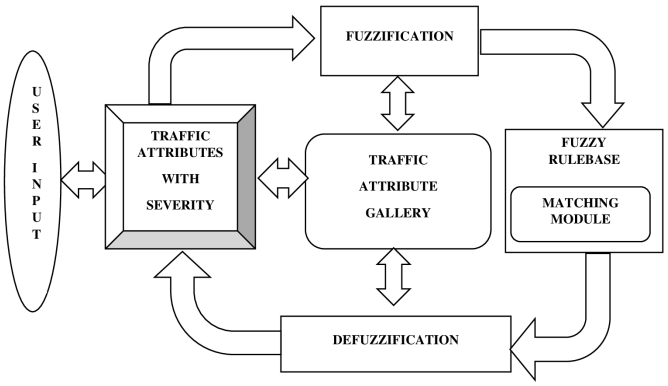

Fig. 3. Framework of Fuzzy-Based Accident-Vulnerability Location Identification

B. Rule-Based Fuzzy Inference System

A rule-base basically consists of the following components:

- a collection of knowledge, in the form of facts
- a set of rules-of-logic, in the form of "if-then", and
- an inference mechanism, which decides what rule is to be used and when.

The knowledge-base in the model consists of these if-then rules which represent conditional statements. Each rule has a premise (P) and a conclusion (C) in the form "if P then C". Based on these rules, the rule-base systems are broadly categorized into two types such as forward-chaining-system which is data-driven and backward-chaining-system which is goal-driven. A forward chaining system is based on first processing the initial data and the using the rules to form the valid conclusions based on the given initial data. A backward chaining system is based on first processing the goals and then searching for rules that can be used for getting the set goals.

C. Rule-based System

The working of the fuzzy controller is described with the following example: The reasoning method in a fuzzy-inference-model is based on the processing of a large set of if-then rules, leading to a knowledge-base. Each rule has a premise, that is the "if" part and a conclusion, that is the "then" part. The knowledge-base in the fuzzy-inference-system (FIS) consists of a large set rules of the form '$if x1 is P1 AND x2 is P2 AND ... xn is Pn then y is C$" where P1, P2, ..., Pn and C are linguistic variables that take fuzzy values from the interval [0,1], and x1, x2, ..., xn are the input parameters and y is the output parameter that is $y = f(x1, x2, ..., xn)$. There are two popular FIS such as Mamdani FIS and Takagi-Sugeno FIS.

In Mamdani-type FIS, the rule-base grows with the increase in parameters in the premise part which leads to difficulty in comprehending the co-relationships between the premises and consequences. In Sugeno-type FIS (or Takagi-Sugeno-Kang method), with fuzzy inputs and a crisp output, It is computationally suitable and efficient to work with adaptive and optimization methods, hence very effective for control problems. Takagi-Sugeno method gives a systematic way to produce fuzzy rules from a given data set. Mamdani-type FIS follows the technique of defuzzification of a fuzzy output where as Sugeno-type FIS follows the computation of crisp output using weighted average. Both the FIS have the same structure in the first two parts such as fuzzifying the inputs and execution of the fuzzy operator. The main difference is in the output membership functions of Sugeno FIS which are either constant or linear.

D. Input Parameters

Based on the data collected for road accidents in the study area, five input parameters are taken which are found to be potential parameters for the prediction of accident vulnerability. Input: $I_1, I_2, I_3, I_4, I_5, a_1, a_2, a_3, a_4, a_5$
where I_1, I_2, I_3, I_4, I_5 represent five parameters which affects vulnerability of locations towards accident, such as traffic density, vehicle speed, presence of crowd-gathering-centers, number of road intersections and timing. The inputs a_1, a_2, a_3, a_4, a_5 are described later in this section.

1) Traffic Density: (I_1) As per the Indian Road Congress (IRC), traffic density can be defined as the average number of vehicles that are present or available in one mile or one kilometer of a road segment, expressed in number of vehicles per kilometer or per mile. Then traffic density (I_1) is computed by:

$$trafficdensity = vehiclecount/segmentlength$$

The survey was conducted two times per hour on selected road portions.

The traffic density (I_1) is computed by the following formula: $I_1 = (1 * C_1 + 2 * C_2 + 3 * C_3 + 4 * C_4)/10$

where C_1, C_2, C_3 and C_4 represent the number of pedestrians, the number of two-wheelers, the number of four and six wheelers, the number of heavy vehicles, respectively.

2) Vehicle Speed: (I_2) Vehicle speed is one important parameter which has taken fuzzy values from [0,1] based on the range of speed.

3) Presence of Crowd Gathering-Centers: (I_3) This parameter is considered as it is including shopping malls, hospitals, educational centers which mainly responsible for crowd gathering and hence leading to accidents and congestions as well.

4) Road Intersections: (I_4) Road intersections can be several types such as 3-ways, 4-ways and multi-ways. Each intersection can affect differently based on the shape, structure, scope, use of channelization and other varieties of traffic-control-devices.

5) Timing: (I_5) Timing of road accidents is one of the most important parameters in the computation of degree of accident vulnerability of locations.

E. Degree of Intensity

We represent the degree of intensity of the accident by a numeric value in between 1 and 5 in the increasing order of the intensities that is from very low to very high. The value of the degree of intensity is based on the values of the input parameters I_1, I_2, I_3, I_4, I_5 and a_1, a_2, a_3, a_4, a_5 represent the degree of intensities of road accidents which are as follows:

- a_j = 5 for I_i = very high(VH), implies highly probable for severe accidents leading to death/fatal cases,
- a_j = 4 for I_i = high(H), implies probable for accidents leading to severe injuries,
- a_j = 3 for I_i = normal(N), implies for probable accidents leading to property loss,
- a_j = 2 for I_i = low(L), implies for probable accidents leading to minor injuries,
- a_j = 1 for I_i = very low(VL), implies for very low probability of accidents,

where $i = 1, ..., 5$ and $j = 1, ..., 5$. In Table I, the range of values for each input parameter is given with respect to their degree of intensities.

V. Experimental Results and Discussions

This section includes the result analysis of the different stages of the input parameter selection and the calculations of the fuzzy output of the rules.

A. Accident Dataset

To test the proposed model, traffic accident data are used which are collected from all districts of Odisha State with special focus on Bhubaneswar. The dataset, provided by the Department of Road Transportation, Odisha and Office of the Police Commissionerate, Bhubaneswar, contains 50,540 traffic accidents that occurred between the year 2011 to 2020. The dataset includes accidents that occurred on national highways such as NH16 and NH203, state highways in Bhubaneswar and its nearby rural areas. The attributes in the dataset include information about the accident timing, vehicle speed, road condition, nearby crowd-gathering centers and traffic density of the road during accident. In the dataset, some attributes are collected from the sensors deployed in the roads. Information, such as actual reason of the accident, light condition, visibility, and road conditions of the accident spot are collected from visibility sensors, traffic surveillance cameras, and tachographs. Hence, due to different modes of data collection, the dataset led to a very complex preprocessing of data. Here we have considered the severity of accident in terms of injury, loss of property, death cases as the dependent variable. Then we have translated these numerical variables into variables with ordinal values. We have considered records of 9640 accidents after preprocessing.

B. Fuzzy Rule-Base

The fuzziness add better and more accurate prediction to the whole system. While selecting value of each parameter as the input, a supplementary value is also selected with the input parameter. That supplementary value represents the "degree of intensity" of each selected parameter. Five possible concepts such as very low, low, normal, severe/high, very severe/very high are considered to the context of "degree of vulnerability". To control these fuzzy concepts, a fuzzy controller is used which is based on Takagi-Sugeno's fuzzy approach. The working of the fuzzy controller is described with the following example:

Input: $I_1, I_2, I_3, I_4, I_5, a_1, a_2, a_3, a_4, a_5$.

where I_1, I_2, I_3, I_4, I_5 represent five parameters, eg. five parameters which affects vulnerability of locations towards accident, eg. traffic density, vehicle speed, presence of crowd-gathering-centres, number of road intersections, timing., and a_1, a_2, a_3, a_4, a_5 represent the degree of intensity of road accidents.

Output: $y_i = f(I_1, I_2, I_3, I_4, I_5) = a_1 * I_1 + a_2 * I_2 + a_3 * I_3 + a_4 * I_4 + a_5 * I_5$

where y_i represents the degree of vulnerability based on the input parameters (I_is) and their degree of intensities (a_js).

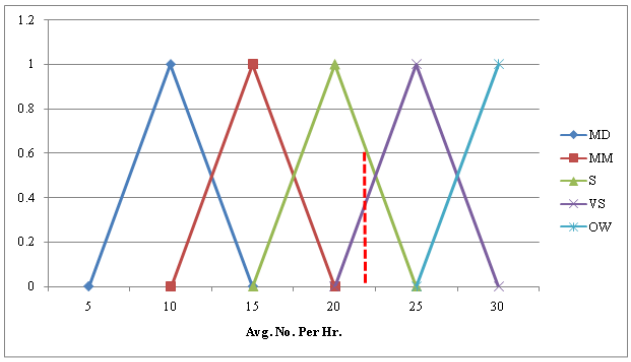

Fig. 4. I_1:Traffic Density

TABLE I. FACTORS OR PARAMETERS WHICH AFFECT VULNERABILITY OF LOCATIONS

Parameters	Very High(0.9-1.0)	High(0.7-0.8)	Normal(0.5-0.6)	Low(0.3-0.4)	Very Low(0.1-0.2)
traffic density	0.9-1.0	0.7-0.8	0.5-0.6	0.3-0.4	0.1-0.2
vehicle speed	> 80	60-80	40-60	20-40	0-20
road-intersections	> 6	6	5	4	3
crowd-gathering-centers	> 5	4	3	2	1
timing	15:00-21:00	9:00-15:00	6:00-9:00	3:00-6:00	00:00-3:00

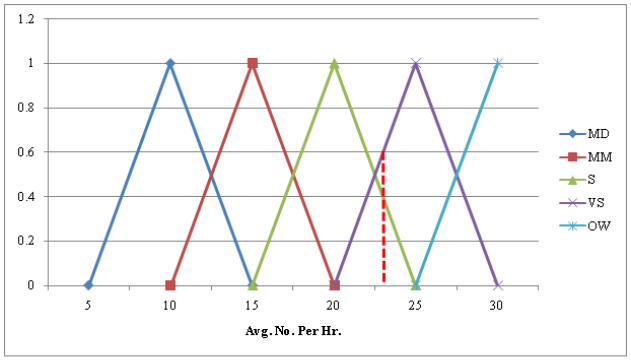

Fig. 5. I_2:Vehicle Speed

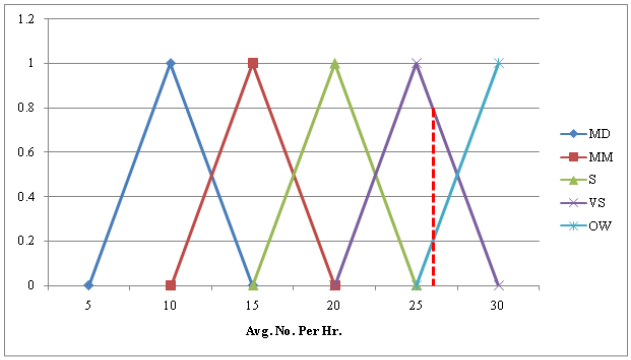

Fig. 7. I_4:Number of Road Intersections

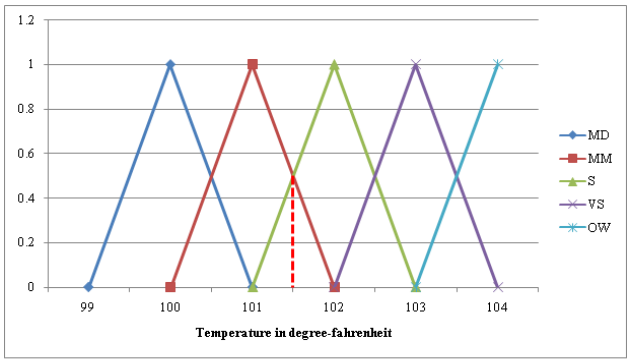

Fig. 6. I_3:Presence of Crowd-Gathering-Centres

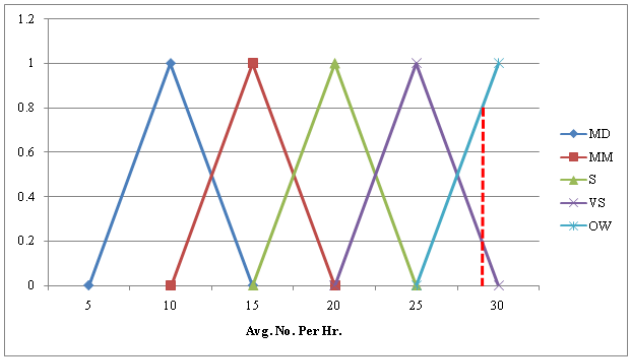

Fig. 8. $I_5$1:Accident Timing

We have taken an example scenario, which is as follows. Let $I_1 = 0.6$ per kilometer, from the Fig. 4 using triangle formula we get:

$$\mu_H(0.6) = 0.6$$
$$\mu_{VH}(0.6) = 0.4$$

Let $I_{82} = 82$ kilometers per hour, from the Fig. 5 using triangle formula we get:

$$\mu_H(82) = 0.7$$
$$\mu_{VH}(82) = 0.8$$

Let $I_3 = 3$ number of crowd-gathering-centre, from the Fig. 6 using triangle formula we get:

$$\mu_N(3) = 0.5$$
$$\mu_H(3) = 0.5$$

Let $I_4 = 4$ number of road intersections, from the Fig. 7 using triangle formula we get:

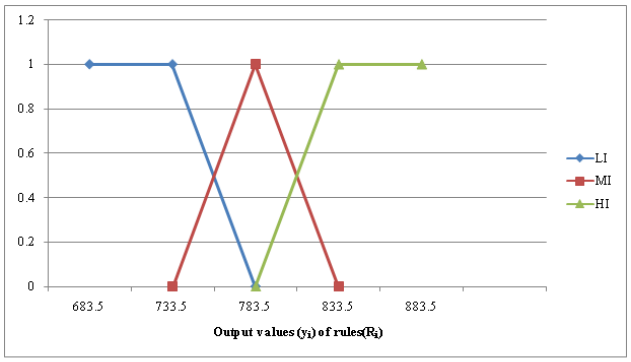

Fig. 9. Fuzzy Output of Rules

$\mu_H(4) = 0.8$
$\mu_{VH}(4) = 0.2$

Let $I_5 = 20$, from the Fig. 8 using triangle formula we get:

$\mu_{VH}(20) = 0.9$
$\mu_N(20) = 0.6$

From the above analysis, we get 32 numbers of rules. For each rule R_i, the corresponding y_i and ω_i (represents weight of rule R_i) value is computed as below:

Rule R_1: (I_1 is H)(I_2 is S)(I_3 is S)(I_4 is H)(I_5 is H)
$\omega_1 = \mu_H * \mu_S * \mu_S * \mu_H * \mu_H = 0.6 * 0.4 * 0.5 * 0.8 * 0.2 = 0.0192$
$y_1 = 4 * I_1 + 3 * I_2 + 3 * I_3 + 4 * I_4 + 4 * I_5 = 681.5$

Rule R_2: (I_1 is H)(I_2 is S)(I_3 is S)(I_4 is H)(I_5 is VH)
$\omega_2 = \mu_H * \mu_S * \mu_S * \mu_H * \mu_{VH} = 0.6 * 0.4 * 0.5 * 0.8 * 0.8 = 0.0768$
$y_2 = 4 * I_1 + 3 * I_2 + 3 * I_3 + 4 * I_4 + 5 * I_5 = 710.5$

Rule R_3: (I_1 is H)(I_2 is S)(I_3 is S)(I_4 is VH)(I_5 is H)
$\omega_3 = \mu_H * \mu_S * \mu_S * \mu_{VH} * \mu_H = 0.6 * 0.4 * 0.5 * 0.2 * 0.2 = 0.0048$
$y_3 = 4 * I_1 + 3 * I_2 + 3 * I_3 + 5 * I_4 + 4 * I_5 = 707.5$

Rule R_4: (I_1 is H)(I_2 is S)(I_3 is S)(I_4 is VH)(I_5 is VH)
$\omega_4 = \mu_H * \mu_S * \mu_S * \mu_{VH} * \mu_{VH} = 0.6 * 0.4 * 0.5 * 0.2 * 0.8 = 0.0192$
$y_4 = 4 * I_1 + 3 * I_2 + 3 * I_3 + 5 * I_4 + 5 * I_5 = 736.5$

Rule R_5: (I_1 is H)(I_2 is S)(I_3 is H)(I_4 is H)(I_5 is H)
$\omega_5 = \mu_H * \mu_S * \mu_H * \mu_H * \mu_H = 0.6 * 0.4 * 0.5 * 0.8 * 0.2 = 0.0192$
$y_5 = 4 * I_1 + 3 * I_2 + 4 * I_3 + 4 * I_4 + 4 * I_5 = 783.0$

Rule R_6: (I_1 is H)(I_2 is S)(I_3 is H)(I_4 is H)(I_5 is VH)
$\omega_6 = \mu_H * \mu_S * \mu_H * \mu_H * \mu_{VH} = 0.6 * 0.4 * 0.5 * 0.8 * 0.8 = 0.0768$
$y_6 = 4 * I_1 + 3 * I_2 + 4 * I_3 + 4 * I_4 + 5 * I_5 = 812.0$

Rule R_7: (I_1 is H)(I_2 is S)(I_3 is H)(I_4 is VH)(I_5 is H)
$\omega_7 = \mu_H * \mu_S * \mu_H * \mu_{VH} * \mu_H = 0.6 * 0.4 * 0.5 * 0.2 * 0.2 = 0.0048$
$y_7 = 4 * I_1 + 3 * I_2 + 4 * I_3 + 5 * I_4 + 4 * I_5 = 809.0$

Rule R_8: (I_1 is H)(I_2 is S)(I_3 is H)(I_4 is VH)(I_5 is VH)
$\omega_8 = \mu_H * \mu_S * \mu_H * \mu_{VH} * \mu_{VH} = 0.6 * 0.4 * 0.5 * 0.2 * 0.8 = 0.0192$
$y_8 = 4 * I_1 + 3 * I_2 + 4 * I_3 + 5 * I_4 + 5 * I_5 = 838.0$

Rule R_9: (I_1 is H)(I_2 is H)(I_3 is S)(I_4 is H)(I_5 is H)
$\omega_9 = \mu_H * \mu_H * \mu_S * \mu_H * \mu_H = 0.6 * 0.6 * 0.5 * 0.8 * 0.2 = 0.0288$
$y_9 = 4 * I_1 + 4 * I_2 + 3 * I_3 + 4 * I_4 + 4 * I_5 = 704.5$

Rule R_{10}: (I_1 is H)(I_2 is H)(I_3 is S)(I_4 is H)(I_5 is VH)
$\omega_{10} = \mu_H * \mu_H * \mu_S * \mu_H * \mu_{VH} = 0.6 * 0.6 * 0.5 * 0.8 * 0.8 = 0.1152$
$y_{10} = 4 * I_1 + 4 * I_2 + 3 * I_3 + 4 * I_4 + 5 * I_5 = 733.5$

Rule R_{11}: (I_1 is H)(I_2 is H)(I_3 is S)(I_4 is VH)(I_5 is H)
$\omega_{11} = \mu_H * \mu_H * \mu_S * \mu_{VH} * \mu_H = 0.6 * 0.6 * 0.5 * 0.2 * 0.2 = 0.0072$
$y_{11} = 4 * I_1 + 4 * I_2 + 3 * I_3 + 5 * I_4 + 4 * I_5 = 730.5$

Rule R_{12}: (I_1 is H)(I_2 is H)(I_3 is S)(I_4 is VH)(I_5 is VH)
$\omega_{12} = \mu_H * \mu_H * \mu_S * \mu_{VH} * \mu_{VH} = 0.6 * 0.6 * 0.5 * 0.2 * 0.8 = 0.0288$
$y_{12} = 4 * I_1 + 4 * I_2 + 3 * I_3 + 5 * I_4 + 5 * I_5 = 759.5$

Rule R_{13}: (I_1 is H)(I_2 is H)(I_3 is H)(I_4 is H)(I_5 is H)
$\omega_{13} = \mu_H * \mu_H * \mu_H * \mu_H * \mu_H = 0.6 * 0.6 * 0.5 * 0.8 * 0.2 = 0.0288$
$y_{13} = 4 * I_1 + 4 * I_2 + 4 * I_3 + 4 * I_4 + 4 * I_5 = 806.0$

Rule R_{14}: (I_1 is H)(I_2 is H)(I_3 is H)(I_4 is H)(I_5 is VH)
$\omega_{14} = \mu_H * \mu_H * \mu_H * \mu_H * \mu_{VH} = 0.6 * 0.6 * 0.5 * 0.8 * 0.8 = 0.1152$
$y_{14} = 4 * I_1 + 4 * I_2 + 4 * I_3 + 4 * I_4 + 5 * I_5 = 835.0$

Rule R_{15}: (I_1 is H)(I_2 is H)(I_3 is H)(I_4 is VH)(I_5 is H)
$\omega_{15} = \mu_H * \mu_H * \mu_H * \mu_{VH} * \mu_H = 0.6 * 0.6 * 0.5 * 0.2 * 0.2 = 0.0072$
$y_{15} = 4 * I_1 + 4 * I_2 + 4 * I_3 + 5 * I_4 + 4 * I_5 = 832.0$

Rule R_{16}: (I_1 is H)(I_2 is H)(I_3 is H)(I_4 is VH)(I_5 is VH)
$\omega_{16} = \mu_H * \mu_H * \mu_H * \mu_{VH} * \mu_{VH} = 0.6 * 0.6 * 0.5 * 0.2 * 0.8 = 0.0288$
$y_{16} = 4 * I_1 + 4 * I_2 + 4 * I_3 + 5 * I_4 + 5 * I_5 = 861.0$

Rule R_{17}: (I_1 is VH)(I_2 is S)(I_3 is S)(I_4 is H)(I_5 is H)
$\omega_{17} = \mu_{VH} * \mu_S * \mu_S * \mu_H * \mu_H = 0.4 * 0.4 * 0.5 * 0.8 * 0.2 = 0.0128$
$y_{17} = 5 * I_1 + 3 * I_2 + 3 * I_3 + 4 * I_4 + 4 * I_5 = 703.5$

Rule R_{18}: (I_1 is VH)(I_2 is S)(I_3 is S)(I_4 is H)(I_5 is

VH)
$\omega_{18} = \mu_{VH} * \mu_S * \mu_S * \mu_H * \mu_{VH} = 0.4 * 0.4 * 0.5 * 0.8 * 0.8 = 0.0512$
$y_{18} = 5 * I_1 + 3 * I_2 + 3 * I_3 + 4 * I_4 + 5 * I_5 = 732.5$

Rule R_{19}: (I_1 is VH)(I_2 is S)(I_3 is S)(I_4 is VH)(I_5 is H)
$\omega_{19} = \mu_{VH} * \mu_S * \mu_S * \mu_{VH} * \mu_H = 0.4 * 0.4 * 0.5 * 0.2 * 0.2 = 0.0032$
$y_{19} = 5 * I_1 + 3 * I_2 + 3 * I_3 + 5 * I_4 + 4 * I_5 = 729.5$

Rule R_{20}: (I_1 is VH)(I_2 is S)(I_3 is S)(I_4 is VH)(I_5 is VH)
$\omega_{20} = \mu_{VH} * \mu_S * \mu_S * \mu_{VH} * \mu_{VH} = 0.4 * 0.4 * 0.5 * 0.2 * 0.8 = 0.0128$
$y_{20} = 5 * I_1 + 3 * I_2 + 3 * I_3 + 5 * I_4 + 5 * I_5 = 758.5$

Rule R_{21}: (I_1 is VH)(I_2 is S)(I_3 is H)(I_4 is H)(I_5 is H)
$\omega_{21} = \mu_{VH} * \mu_S * \mu_H * \mu_H * \mu_H = 0.4 * 0.4 * 0.5 * 0.8 * 0.2 = 0.0128$
$y_{21} = 5 * I_1 + 3 * I_2 + 4 * I_3 + 4 * I_4 + 4 * I_5 = 805.0$

Rule R_{22}: (I_1 is VH)(I_2 is S)(I_3 is H)(I_4 is H)(I_5 is VH)
$\omega_{22} = \mu_{VH} * \mu_S * \mu_H * \mu_H * \mu_{VH} = 0.4 * 0.4 * 0.5 * 0.8 * 0.8 = 0.0512$
$y_{22} = 5 * I_1 + 3 * I_2 + 4 * I_3 + 4 * I_4 + 5 * I_5 = 834.0$

Rule R_{23}: (I_1 is VH)(I_2 is S)(I_3 is H)(I_4 is VH)(I_5 is H)
$\omega_{23} = \mu_{VH} * \mu_S * \mu_H * \mu_{VH} * \mu_H = 0.4 * 0.4 * 0.5 * 0.2 * 0.2 = 0.0032$
$y_{23} = 5 * I_1 + 3 * I_2 + 4 * I_3 + 5 * I_4 + 4 * I_5 = 831.0$

Rule R_{24}: (I_1 is VH)(I_2 is S)(I_3 is H)(I_4 is VH)(I_5 is VH)
$\omega_{24} = \mu_{VH} * \mu_S * \mu_H * \mu_{VH} * \mu_{VH} = 0.4 * 0.4 * 0.5 * 0.2 * 0.8 = 0.0128$
$y_{24} = 5 * I_1 + 3 * I_2 + 4 * I_3 + 5 * I_4 + 5 * I_5 = 860.0$

Rule R_{25}: (I_1 is VH)(I_2 is H)(I_3 is S)(I_4 is H)(I_5 is H)
$\omega_{25} = \mu_{VH} * \mu_H * \mu_S * \mu_H * \mu_H = 0.4 * 0.6 * 0.5 * 0.8 * 0.2 = 0.0192$
$y_{25} = 5 * I_1 + 4 * I_2 + 3 * I_3 + 4 * I_4 + 4 * I_5 = 726.5$

Rule R_{26}: (I_1 is VH)(I_2 is H)(I_3 is S)(I_4 is H)(I_5 is VH)
$\omega_{26} = \mu_{VH} * \mu_H * \mu_S * \mu_H * \mu_{VH} = 0.4 * 0.6 * 0.5 * 0.8 * 0.8 = 0.0768$
$y_{26} = 5 * I_1 + 4 * I_2 + 3 * I_3 + 4 * I_4 + 5 * I_5 = 755.5$

Rule R_{27}: (I_1 is VH)(I_2 is H)(I_3 is S)(I_4 is VH)(I_5 is H)
$\omega_{27} = \mu_{VH} * \mu_H * \mu_S * \mu_{VH} * \mu_H = 0.4 * 0.6 * 0.5 * 0.2 * 0.2 = 0.0048$
$y_{27} = 5 * I_1 + 4 * I_2 + 3 * I_3 + 5 * I_4 + 4 * I_5 = 752.5$

Rule R_{28}: (I_1 is VH)(I_2 is H)(I_3 is S)(I_4 is VH)(I_5 is VH)
$\omega_{28} = \mu_{VH} * \mu_H * \mu_S * \mu_{VH} * \mu_{VH} = 0.4 * 0.6 * 0.5 * 0.2 * 0.8 = 0.0192$
$y_{28} = 5 * I_1 + 4 * I_2 + 3 * I_3 + 5 * I_4 + 5 * I_5 = 781.5$

Rule R_{29}: (I_1 is VH)(I_2 is H)(I_3 is H)(I_4 is H)(I_5 is H)
$\omega_{29} = \mu_{VH} * \mu_H * \mu_H * \mu_H * \mu_H = 0.4 * 0.6 * 0.5 * 0.8 * 0.2 = 0.0192$
$y_{29} = 5 * I_1 + 4 * I_2 + 4 * I_3 + 4 * I_4 + 4 * I_5 = 828.0$

Rule R_{30}: (I_1 is VH)(I_2 is H)(I_3 is H)(I_4 is H)(I_5 is VH)
$\omega_{30} = \mu_{VH} * \mu_H * \mu_H * \mu_H * \mu_{VH} = 0.4 * 0.6 * 0.5 * 0.8 * 0.8 = 0.0768$
$y_{30} = 5 * I_1 + 4 * I_2 + 4 * I_3 + 4 * I_4 + 5 * I_5 = 857.0$

Rule R_{31}: (I_1 is VH)(I_2 is H)(I_3 is H)(I_4 is VH)(I_5 is H)
$\omega_{31} = \mu_{VH} * \mu_H * \mu_H * \mu_{VH} * \mu_H = 0.4 * 0.6 * 0.5 * 0.2 * 0.2 = 0.0048$
$y_{31} = 5 * I_1 + 4 * I_2 + 4 * I_3 + 5 * I_4 + 4 * I_5 = 854.0$

Rule R_{32}: (I_1 is VH)(I_2 is H)(I_3 is H)(I_4 is VH)(I_5 is VH)
$\omega_{32} = \mu_{VH} * \mu_H * \mu_H * \mu_{VH} * \mu_{VH} = 0.4 * 0.6 * 0.5 * 0.2 * 0.8 = 0.0192$
$y_{32} = 5 * I_1 + 4 * I_2 + 4 * I_3 + 5 * I_4 + 5 * I_5 = 883.0$

Now the combined action of all the rules can be obtained as follows:

$$y = \sum_{i=1}^{32} \omega_i y_i / \sum_{j=1}^{32} \omega_j = 783.25/1.0 = 783.25$$

Hence from the above computations we infer that: the rules (R_is) with output values (y_is) greater than the value of y are cases with high vulnerability and hence alertness is to be given in the output interface. The output of the fuzzy-controller, that is the degree of vulnerability is defined using fuzzy values as, given in the Fig. 9:

$$b_i(y_i) = \begin{cases} 1(LV) & \text{for} \quad y_i < 733.5 \\ 2(MV) & \text{for} \quad 733.5 \leq y_i \leq 833.5 \\ 3(HV) & \text{for} \quad y_i > 833.5 \end{cases}$$

Here LV, MV and HV represent low vulnerable, medium vulnerable and high vulnerable respectively. Hence, sequence of control is as follows:

parameters selected ⇒ for each input parameter, the degree of intensity selected ⇒ corresponding fuzzy ruled fired ⇒ with the output of the fuzzy rule, the degree of vulnerability notified.

Based on the values of the selected input parameters, the degree of vulnerabilities are computed for some specific locations in our study area. It is found that in addition to Khandagiri and Aiginia square, the other black spots identified includes Patrapada, Palasuni and Hanspal within the limits of our study area Bhubaneswar.

VI. Conclusion

Fuzzy Inference Systems have been reliable strategies for the analysis of accident data sets taken from various countries of the globe. In several attempts, different authors have used the Mamdani and Sugeno FIS for finding the causes of road accident severity. In this paper, we have taken an integrated

approach of GIS data modeling with fuzzy inference mechanism to analyze and identify the accident vulnerable locations withe their degree of vulnerability in the study area.

The present study have used fuzzy-based technique on different sections of accident locations. The rules generated for each section expressed the various reasons associated with road accidents in the specific locations. Each section may contain some similar rules, but they have different values for each group. The dataset for road accident and its analysis using fuzzy-based method shows that this method can be applied on other accident data having larger number of attributes to find more number of parameters linked with road accidents. It is observed that this fuzzy-based method has adequately found reasonable information from the given data set, with the outcomes produced at very general level because of some missing information such as the victim information, road surface condition, weather related information. The data with higher number of attributes can extract additional information using the present strategy.

***Abstract*—High-resolution images are highly in demand when they are utilized for different analysis purposes and obviously due to their quality aesthetic visual impact. The objective of image super-resolution (SR) is to reconstruct a high-resolution (HR) image from a low-resolution (LR)image. Storing, transferring and processing of high-resolution (HR) images have got many practical issues in big data domain. In the case of finger print images, the data is huge because of the huge number of populations. So instead of transferring or storing these finger print images in its original form (HR images), it cost very low if we choose its low-resolution form. By using sampling technique, we can easily generate LR images, but the main problem is to regenerate HR image from these LR images. So, this paper addresses this problem, a novel method for enhancing resolution of low-resolution fingerprint images of size 50 x 50 to a high-resolution image of size 400 x 400 using convolutional neural network (CNN) architecture followed by sub pixel convolution operation for up sampling with no loss of promising features available in low-resolution image has been proposed. The proposed model contains five convolutional layers, each of which has an appropriate number of filter channels, activation functions, and optimization functions. The proposed model was trained using three publicly accessible fingerprint datasets FVC 2004 DB1, DB2, and DB3 after being validation and testing were done using 10 percent of these fingerprint data sets. In terms of performance measures like Peak Signal to Noise Ratio (PSNR), Mean Squared Error (MSE), Structural Similarity Index (SSIM) and loss functions, the quantitative and qualitative results show that the proposed model greatly outperformed existing state-of-the-art techniques like Enhanced deep residual network (EDSR), wide activation for image and video SR (WDSR), Generative adversarial network(GAN) based models and Auto-encoder-based models.**

Keywords*—Single image super-resolution; convolution neural network; biometric; fingerprint images

I. Introduction

A biometric system is an effective tool used for personal identification in the fields of healthcare, insurance, forensics, security systems etc. In the modern computer age, among all other biometric systems, the fingerprint is one of the most widely used biometric systems. It is utilised for both personal identification and verification [1].

Now a days, in a fingerprint's rich details, such as pores and scars, can be captured using an optical fingerprint sensor at a resolution of 2000 dpi. Large scale bio metric systems are employed for personal identifications in nationally accepted identity cards and also in mobile based payment applications. For example, in India, nation-wide identity card like Aadhar, where each of the 1.3 billion citizens will have two iris pictures and all 10 of their fingerprints stored in huge database [2]. In big data system like this, it is a difficult task to meet hardware and software needed for this enormous storage and analysis for personal identification. It is challenging to compare an unknown fingerprint with this vast amount of data in personal identification. The potential of deep learning in big data allows for the analysis of very large and complex data, including images, videos or text, in the field of healthcare. Big data has security and privacy issues since acessability and process used to store, manipulate and retain data has increased [3]. In this scenario, a method for personal identification and analysis using fingerprint image with minimum computations and storage is highly in demand. Super-resolution techniques for enhancing low-resolution images in to high-resolution images with no loss of promising features used for identification is suitable in this situation, Here, we need to store low resolution images of size 50 x 50, but for fingerprint image analysis or verification, it is enhanced in to 8 times than input image so it will drastically reduce complexity involved in both hardware and software for storage as well as analysing huge volume of data.

While dealing with natural scenes and situations, the availability of high-resolution images is not always effortless. The major hurdles for the same are noise, blur, camera limitations, and limitations in acquisitions. The domains including medical diagnosis, digital surveillance, remote sensing and forensics analysis always require high-resolution images [4]. In forensics, biometric has prominent role and mostly fingerprint has vital role. For all those applications where personal identification and verification employed using fingerprint image, require high quality image and also image analysis of the same is to be performed with less space and computational complexity.

Super-Resolution (SR) is the means of reconstructing a high-quality image utilizing one or more low-quality image(s). Super-resolution techniques are divided into two categories: single image super-resolution (SISR) and multi-image super-resolution (MISR). SISR reconstructs the SR image from a low-resolution input image. SR models in the SISR and MISR categories have been constructed using either classical or deep learning methods. In the classical approach, Andrew Gilman et

al. [5] observed multiple algorithms for each super-resolution category and they are given as interpolation-based, learning-based, and reconstruction-based. Bi-linear, bi-cubic, and cubic spline are the most often used interpolation algorithms. These approaches used weighted average of neighbouring LR pixels to estimate unknown HR pixels. Ledig et al. [6] observed that interpolation-based approaches are quick and easy, but they muddy the image's details and make it difficult to establish the image's precision hence blurring of features and edges in a sample image is caused. Using an external image data-set, learning-based algorithms build a link between the LR and HR image. Nasrollahi, K., and Moeslund, T.B [7] observed that in reconstruction-based methods, the details of the HR image such as edge prior, gradient prior are recovered using some prior knowledge. In classical methods, images cannot be magnified beyond the image sample resolution without losing image quality. In recent years, deep learning-based super-resolution models have superior performance over classical methods in all applications in which image analysis is required.

In this paper a novel method for generating high-resolution fingerprint image from a low-resolution fingerprint image is proposed in which resolution enhanced eight times than input image using convolution neural network architecture and sub pixel convolution operation.

The paper is organized in such a way that the related work for SISR approaches is offered in Section II, the framework for the proposed model is explained in Section III, Experiment part is described in Section IV, results and evaluation metrics are reviewed in Section V, and the conclusion is presented in Section VI.

II. Related Work

Major approaches for super resolution of fingerprint images includes classical image processing techniques, Residual networks-based SR models, Auto-encoder based SR, Convolutional neural network-based SR and Generative adversarial network-based SR models as described below.

A. Classical Image Processing Techniques for SR

Ganchimeg G and Leopold H developed a model for fingerprint enhancement based on classical image processing techniques [8]. They employed filtering methods for noise removal followed by edge detection methods and thinning process for enhancement, but their result gets blurred for higher magnification orders. Nouf Saeed and Alotaibi [9] applied Gabor filter for denoising and after that deep boltzmann method is applied for ridge enhancement. Dinca Lazarescu Andreea-Monica et al.[10] applied convolutional layers for feature extraction and also for mapping low-resolution fingerprint image in to high-resolution images, but in their method, initially low-resolution image is enhanced using Laplacian filters and thereafter convolutional operations are employed. Major limitation of classical image processing techniques is artifacts or blurring occurs for large magnification orders.

B. Residual Network based SR Models

Zhenzhen Yang et al. [11] applied residual network for enhancing personal identifying features pores and ridges available in low resolution images. In their model, they applied 32 residual blocks in which each block contains 3 convolutional layers and relu activation functions. Finally resultant features extracted using residual blocks are combined with pixel shuffling blocks and regenerated output image. Since model is complex, it is computationally intensive. Seonjae K [12] employed two CNN (Convolutional neural network) based network for feature extraction and enhancement. First network employed for feature extraction of low-resolution images using dense layer with local skip connections. After that input image upscaled using interpolation technique and passed in to second network, which composed of many dense layers with local and global skip connections. Finally output from first and second network concatenated to regenerate enhanced image. Here, since second network performs feature extraction on interpolated image, computational requirement is considerably more and also dense network processing on features of interpolated image rather than original image. Yongliang Zhang et al. [13] employed convolutional residual network for fingerprint liveness detection.

C. Autoencoder based SR Models

Sandoval Veríssimo de Sousa Neto et al. [14] applied deep convolutional auto-encoder for feature extraction and applied Gabor filtering and Gaussian filtering for enhancement. But major limitation of auto-encoders is while encoding input image in to latent vectors, information loss may occur. Sergio Saponara et al. [15] applied convolutional auto-encoders for fingerprint image enhancement. In their model they employed convolutional layers for feature extraction, max-pooling layer used for down sampling and up sampling by deconvolution layer. Major drawback of auto-encoder based models are, while encoding input image, all promising features may not be represented in latent form hence during decoding and regenerating phase information loss takes place.

D. Convolutional Neural Network (CNN) based SR Models

Ajnas muhammed and Alwyn roshan [16] employed deep convolutional network (20 layers) for image enhancement. Since their network is deeper, it is computationally expensive. Ayushi Tamrakar and Neetesh Gupta [17] proposed SR model based on convolutional neural network (CNN) and long short-term memory (LSTM). In their model, they first applied CNN for both feature extraction and enhancement, thereafter LSTM applied on this feature map to classify images based on ridges in output image so that personal identification is employed using these ridges information. Fandong Zhang and Jufu Feng developed a model based on CNN and joint KNN-Triplet embedding. [18]

E. Generative Adversarial Network (GAN) based SR Model

Syeda Nyma Ferdous et al.[19] employed SRGAN for extracting features for detecting minutiae, ridge and pores to be enhanced so that personal identification is possible in all challenging situations but major hurdles of applying GAN model is computational complexity. Chi-En Huang et al. [20] employed residual GAN for enhancement. In their model, they employed residual network with attention module as generator and classification module will act as discriminator. Rafael Bouzaglo and Yosi Kellerc [22] developed generative

adversarial network with Resnet 50 as encoder, and convolutional decoder used for reconstruction. Masud An Nur Islam Fahim and Ho Yub Jungy [23] employed GAN based model for reconstructing good quality fingerprint image by applying skip connections on denoising auto-encoders and thereafter convolutional layers are appled for decoding. Amol S Joshi et al. [24] employed conditional GAN for deblurring input image followed by multiple discriminators. Gan based SR model requires training for both generator and discriminator separately and it takes longer time for reconstructing a better-quality image compared to other models, hence it is practically not feasible for employing to realtime applications. Mingzheng Hou et al.[25] employed GAN based network for generating good quality image. They applied SRResnet for upsampling the input image of appropriate size. Then, upsampled image was fed into an attention-based network for regenerating good quality image. Multiple discriminators were then applied to determine how well the regenerated image matched with ground-truth image. Since their model too complex, it is computationally expensive.

It is clear from the analysis of the previously mentioned SR models that there are a range of models for producing high-quality images from low-resolution data. All image processing applications require high-quality images in various scales to be supplied with less computations and minimal complexity in training and testing. Success rate of deep learning-based applications rely on learning strategy, availability of data-set, architecture of the model employed. Hence convolutional neural network architecture, a light weight neural network architecture with suitable number of layers, activation functions and optimizing functions is suitable to reconstruct images with higher PSNR and SSIM values with minimal training and testing computations.

III. Proposed Methodology

A. Model Architecture

In this model, initial step is pre-processing of input image (low-resolution image). In pre-processing stage, the gray scale finger print raw image is converted into unit 8 bit image. Then its pixel values are normalized to values between 0 and 1 by dividing pixel values by 255.

The preprocessed data is given to the deep learning model for training and testing. Architecture of proposed model shown in Fig. 1. In order to build a suitable model for enhancement of fingerprint images, we developed and tested 5 different behaviours of this architecture from scratch by changing number of filter (see Section V-A). Model details are explained in the Fig. 1. The input size of model is kept as 50×50 and the model predicted an output image of size 400×400. So, a resolution increasing factor of 8 times is achieved by this proposed system. The quality of generated HR image is verified and analysed using various standard techniques (see section V).

All five convolutional layers employed Relu as activation function and Adam as optimizing function with stride value as 1. After feature extraction and image reconstruction process, sub pixel convolution layer applied for up sampling LR image in to 8 times. Sub pixel convolution operates on 3 channels (3 sub pixels) of every pixel and combines 3 values for up sampling and regenerated image is very similar to ground truth image. Fig. 1 shows proposed SR model architecture with CNN and sub-pixel convolution operation.

B. Pixel Loss

During model training, the model weights are updated based on the custom pixel loss functions L_{pixel}. It is computed as per (1). In (1), GT represents ground truth image and SR image represents reconstructed image.

$$L_{pixel}(GT, SR) = \frac{1}{hcw}||GT - SR||_2^2 \tag{1}$$

Where h, c and w are the height, number of channels and width of the image.

IV. Experiment

A. Dataset

Proposed model trained from scratch using DIV2k data-set (https://data.vision.ee.ethz.ch/cv/DIV2K) and fine-tuned with publicly available standard fingerprint dataset - FVC2004 (http://bias.csr.unibo.it/fvc2004/databases.asp). This dataset is provided by the Biometric Systems Lab (University of Bologna), the Pattern Recognition and Image Processing Laboratory (Michigan State University) and the Biometric Test Center (San Jose State University). They provide three sets of finger print images with different resolutions and types. Table I shows the details of finger print dataset.

TABLE I. Dataset Details with Number of Images and Resolution

Data set	Number of images	Image size	Resolution
FVC 2004 DB1	240	640x480 (307K pixels)	500 dpi
FVC 2004 DB2	240	328x364 (11K pixels)	500 dpi
FVC 2004 DB3	240	300x480 (144K pixels)	500 dpi

B. Performance Evaluation

Well-known objective evaluation methods for measuring image quality include peak signal-to-noise ratio (PSNR), mean squared error (MSE), and structural similarity index (SSIM)[21]. This metric is defined as

$$MSE = \frac{1}{MN}\sum_{1}^{M}\sum_{1}^{N}(x_{i,j} - y_{i,j})^2 \tag{2}$$

Where $x_{(i,j)}$ represents original reference image and $y_{(i,j)}$ represents generated image and i and j are pixel positions of M N size image.

Peak signal-to-noise ratio (PSNR): PSNR is evaluated in decibels and is inversely proportional the Mean Squared Error. It is given as

$$PSNR = \frac{10log_{10}(2^n - 1)}{\sqrt{MSE}} \tag{3}$$

The higher values of PSNR denote the better quality of the reconstructed image.

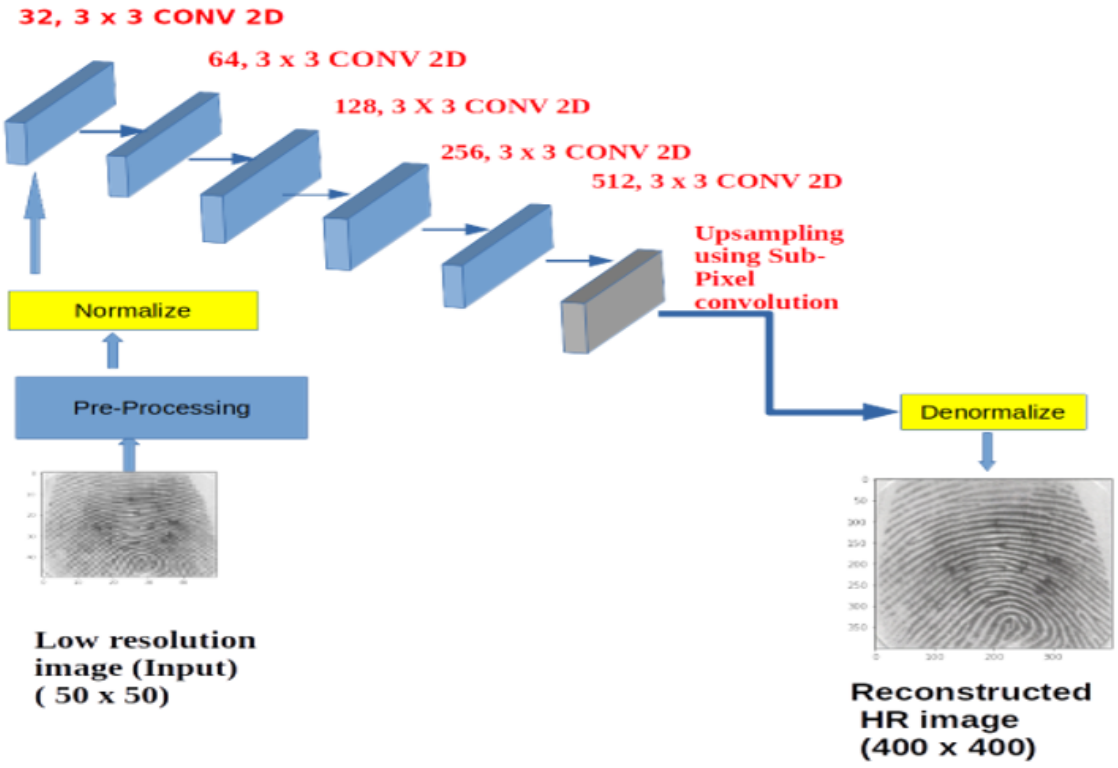

Fig. 1. Proposed Model Architecture.

TABLE II. MODEL BEHAVIOUR AND PERFORMANCE IN TERMS OF NUMBER OF TRAINABLE PARAMETERS, MODEL SIZE, PSNR, SSIM AND MSE VALUES, BY VARYING NUMBER OF FILTER CHANNELS & NUMBER OF CONVOLUTIONAL LAYERS

Case#	No of convolutional layers	Number of filter channels in each layer	Filter kernel size	Activation function applied	Optimizing function used	Mean PSNR, SSIM, MSE values	Number of trainable parameters and model size
1	5	Layer1 :8, Layer 2: 16 Layer 3: 32, Layer 4:64 Layer 5:128	3 x3	ReLu	Adam	PSNR: 8.4521 SSIM: 0.2475 MSE: 84.884	542,995 2.1 MB
2	5	Layer1 :16, Layer 2: 32 Layer 3: 64, Layer 4:128 Layer 5:256	3 x3	ReLu	Adam	PSNR: 19.45 SSIM: 0.687 MSE: 37.457	11,32,131 4.4 MB
3	5	Layer1: 32, Layer 2: 64 Layer 3: 128, Layer 4:256 Layer 5:512	3 x3	ReLu	Adam	PSNR :34.875 SSIM 0.9458 MSE: 22.04	2,897,923 11.13 MB
4	5	Layer1: 64, Layer: 128 Layer 3: 256, Layer 4:512 Layer 5:1024	3 x3	ReLu	Adam	PSNR: 35.788 SSIM : 0.9521 MSE: 18.967	87,795,87 33.5 MB
5	5	Layer1: 128, Layer 2: 256 Layer 3: 512 Layer 4:1024 Layer 5:2048	3 x3	ReLu	Adam	PSNR: 34.116 SSIM: 0.9501 MSE: 17.64	29,943,235 114.3 MB

Structural similarity index: SSIM measure similarity with greater accuracy and consistency than MSE and PSNR. It measures similarity between two images. It compares two images in terms of luminous, contrast and structure. The SSIM measure between two images x and y of size $N \times N$ is given as

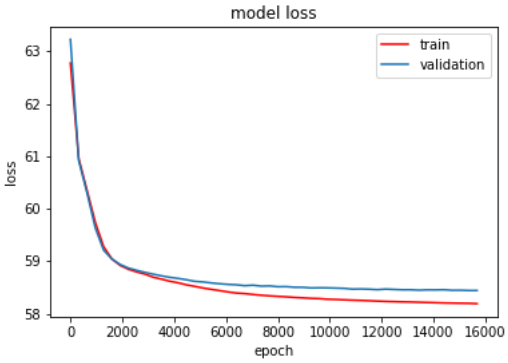

Fig. 2. Training and Validation Loss Curves.

TABLE III. PSNR VALUES OBTAINED DURING MODEL TESTING USING TEST SAMPLE IMAGES AND ITS COMPARISON WITH STATE OF ART METHODS EMPLOYED ON SAME DATA-SET

Image #	EDSR	WDSR	GAN Based model	Proposed Model
1	30.1	31.43	30.1	34.87
2	30.22	31.53	30.45	34.98
3	30.6	31.56	30.75	34.65
4	30.22	31.7	29.98	34.95

TABLE IV. MSE VALUES OBTAINED DURING MODEL TESTING USING TEST SAMPLE IMAGES AND ITS COMPARISON WITH STATE OF ART METHODS EMPLOYED ON SAME DATA-SET

Image #	EDSR	WDSR	GAN Based model	Proposed Model
1	25.36	27.73	29.87	22.05
2	25.55	27.43	29.1	22.1
3	25.22	27.1	29.43	21.98
4	25.62	26.98	29.1	22.01

$$SSIM(x_{(i,j)}, y_{(i,j)}) = \frac{(2\mu_x\mu_y + C_1) + (2\sigma_{xy} + C_2)}{(\mu_x^2 + \mu_y^2 + C_1)(\sigma_x^2 + \sigma_y^2 + C_2)} \quad (4)$$

Where C1, C2 are constants, μ_x and μ_y represents average of x and average of y. σ_x, σ_y represents standard deviation between ground-truth and regenerated images. SSIM values ranges between (-1,1).

In order to analyse the performance of the proposed model quantitatively we measured SSIM, PSNR and MSE values using reconstructed image with reference to the ground-truth image.

C. Training Strategies

The proposed model is trained and evaluated on a Nvidia Quadro T1000 4GB GPU based PC with 64-bits Windows Intel Xeon CPU at 2.60 GHz. Programs were written in Python language with Keras technology having TensorFlow as backend.

Input size is fixed as 50×50. Total there are 720 finger print images. We split the full dataset into train set and test data in the ratio of 9:1. So, 648 train data and 72 test data. Model is trained for 16000 epochs. During each epochs better model with lesser validation loss than previous is saved to hard disk using callback function of keras technology. So, after perfectly trained, best model with least validation loss is saved to hard disk for further testing and evaluations.

V. RESULTS AND DISCUSSIONS

Model trained for 16000 epochs, and got converged at 15680th epoch with validation loss of 58.4445. Fig. 2 shows the training and validation curves of model training stage.

Fig. 3 shows generated high resolution image of size 400×400 from low resolution input image of size 50×50. The generated HR image is visually compared with original ground truth image of size 400×400. In Fig. 3, generated images are visualized in a zoomed-in form just to visible the finger print patterns clearly. From the result figure, visually there is no any difference between the original ground truth image and generated HR image.

A. Research on Model Architecture

In order to build a suitable model for enhancement of fingerprint images, we developed and tested five different behaviours of this architecture from scratch by changing number of filter channels as shown in Table II. In each case we measured performance metrics quantitatively in terms of PSNR (Peak signal to noise ratio), SSIM (Structural similarity index), MSE (Mean squared error), Validation loss, Number of trainable parameters and Model size.

In first case, employed five convolutional layers and number of filter channel applied are 8, 32, 64, 128 and 256 accordingly. In this case, we obtained resultant image of poor quality in terms of different performance metrics mentioned above. In second case we adopted filter channels in each of the five convolutional layers are 16, 32, 64, 128 and 256 and obtained a result better than first case. In third case we employed convolutional layers with filter channels as 32, 64, 128, 256 and 512. In this case we obtained good quality image with significantly better value for performance metric like PSNR, SSIM, MSE, pixel-loss, number of trainable parameters and model size. In fourth case, we applied number of filter channels in each convolution layer as 64, 128, 256, 512, 1024. In this case, results obtained is slightly better than previous three cases except model size, which is a higher value. In last case, we adopted number of convolutional channels are 5 and number of filter channels employed are 128, 256, 512,1024, 2048. This case also we got better value in all performance metrics except model size and number of trainable parameters, which is a higher value than all other cases. From this comparison of five cases, we fixed third case as our proposed

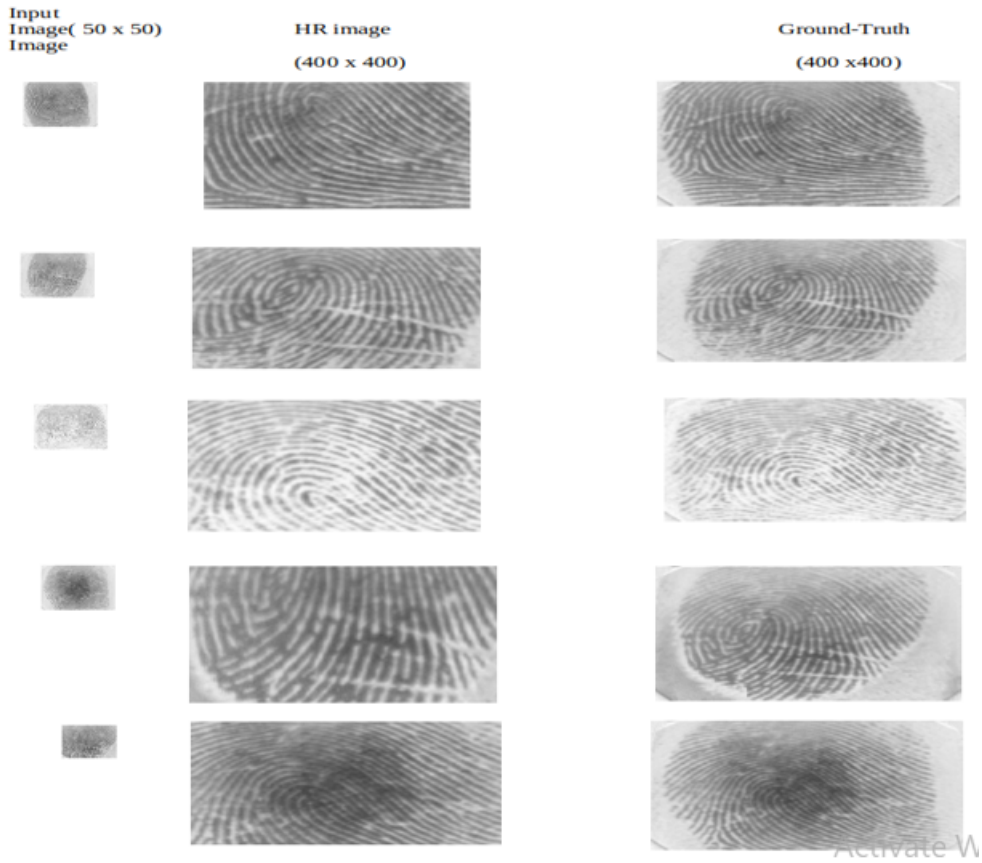

Fig. 3. Visualization of Some Input Images, Corresponding Generated Output Images and its Ground Truth Images.

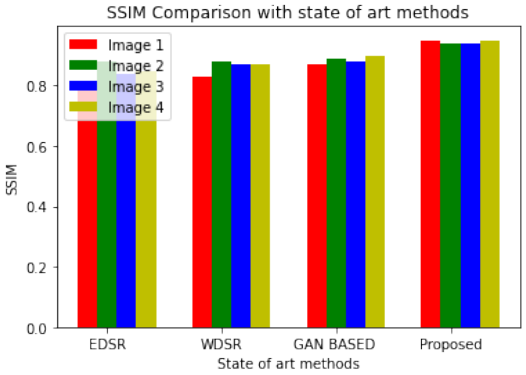

Fig. 4. SSIM Comparison with State-of-the-Art Methods.

model in which performance metrics like number of trainable parameters, model size and pixel loss are considerably less compared to other cases and PSNR, SSIM and MSE values are much better.

B. Comparison with State-of-the-Art Models

In order to analyse the performance of the proposed model quantitatively we measured SSIM, PSNR and MSE values using reconstructed image with reference to the ground-truth image.

Fig. 4 shows the comparison of SSIM index of proposed system with the state-of-the-art SR image generation techniques. For this comparison, we took four images and calculated SSIM values from the output values of other techniques like EDSR, WDSR, and GAN-Based technique. From this chart figure it is understood that proposed technique has got best performance than other technique in the perspective of SSIM index. Table III shows the comparison of proposed technique's PSNR with other techniques. Similarly Table IV shows the MSE values obtained during model testing using test sample images and its comparison with state of art methods employed on same data-set. From these two tables, it is understood that, proposed technique's performance is superior to other state-of-the-art methods.

VI. Conclusion

Fingerprints are used in many different applications like security control, law enforcement, smart phones, and criminal investigations. Over a lengthy period of time, the forensic community has used fingerprints as their most common biometric characteristic. Using a convolutional neural network, a light weight neural network for feature extraction and image reconstruction, followed by sub pixel convolution for upsampling, has been proposed as a novel architecture in this paper for resolution enhancement of low-resolution fingerprint images to high-resolution images. In this study, we looked at five different behaviours of this model, analysed model performance by altering the number of filter channels in each

of the five convolutional layers, and then fixed the model, which exhibits a notable improvement in performance metrics like PSNR, SSIM, MSE, model size, validation toss, and the number of trainable parameters when compared to other state of art methods. With no loss of the promising feature in the LR image, the proposed model enhanced the LR image eight times. Big data applications that analyse or compare fingerprint images for personal identification and verification confront significant challenges in meeting the necessary hardware and software requirements. In this case, the suggested model significantly contributes to improving the resolution of fingerprint images by taking a 50×50 input image and enhancing it eight times without losing any promising aspects, making it appropriate for real-time applications as well. Future work will build on this work by altering the model architecture through the use of a GAN-based network with perceptual loss while maintaining the computational viability of the model, making it appropriate for real-time applications as well.

Facultad de Ingeniería, Universidad Privada del Norte, Lima, Perú[5]

***Abstract*—In recent years, the development of mobile applications has been evolving and becoming more and more frequent. This event is positive, since it plays an important role in facing and mitigating the multiple adversities that appear in the different existing sectors, such as business. On the other hand, it was detected that a little known problem that many companies in the pharmaceutical industry experience is poor inventory management, which causes countless consequences, generally of a negative nature. For this reason, in this work it was decided to make a mobile application prototype to face this problem. In this regard, the RUP methodology was used, along with various computer tools, in order to elaborate the prototype. Besides, as a data collection technique, surveys were made, which were subjected to expert judgment, in order to qualify the prototype. Likewise, very satisfactory results were obtained, concluding that the mobile application prototype that was developed complies with all the necessary conditions to mitigate the inventory management problems of pharmaceutical industry companies.**

***Keywords*—Inventory management; mobile application; pharmaceutical industry; prototype; RUP methodology**

I. Introduction

In the context of the pandemic that we had to live through, no sector was spared from Covid-19. The health sector was also hit hard by said pandemic [1],[2].Currently, having good inventory control is very important for any company, regardless of its types and items. This action seeks to ensure that the elements that are needed, such as raw materials [3], supplies and spare parts, are available in a timely manner, in optimal conditions and in their respective locations.

It is necessary to keep in mind that in a review of studies it was mentioned that the organization's inventory management involves decisions that include financing, promotion, supply and acquisition management. All of them have high risks and have a direct impact on the financial framework [4]. Besides, proper inventory management ensures availability and minimizes investment when materials are needed.

In the case of the pharmaceutical industry, inventory management is also essential, both from a financial and operational perspective. Efficient inventory management reduces procurement and transportation costs. Likewise [5], it maintains an effective stock of products to meet the demands of customers and prescribers.

It cannot be denied that efficient inventory management is crucial for the future of any business, as it becomes a key factor for profitability thanks to its multiple benefits. Among them we have, for example, that it will allow the company to have a timely control of all its products [6], as well as knowing at the end of the period a reliable state of the economic situation.

On the other hand, efficient inventory management will also avoid causing problems that threaten the safety and health of patients. This is because the system will allow the proper management of products, thus preventing patients from acquiring expired, falsified [7], deficient and/or damaged medicines.

In this context, inventory management systems are very convenient. Implementing, consolidating and effectively applying an inventory control system helps in the progress of any business, as well as improves the efficiency of its activities [8]. If companies and organizations use an inventory system, they will obtain many benefits, since the correct inventory management will improve their decision making.

Based on everything mentioned above, it is justified that this work is very important, since it aims to contribute to all companies in the pharmaceutical industry that choose to implement the proposed mobile application. In the same way, the objective of the research is to design a mobile application prototype, using the Figma tool. This in order to improve inventory management in companies belonging to the pharmaceutical industry so that they achieve many benefits, such as the reduction of losses due to expiration dates and the improvement of customer service.

To all this, it is also worth mentioning the content of the next chapters that make up this work. In Section II, works related to the topic are shown together with an analysis; in Section III, the methodology used is indicated together with the tools that helped in the elaboration of the application prototype; in Section IV, the development of the work is detailed; in Section V, the results obtained are presented; in Section VI, the results obtained are explained and compared with prior knowledge on the topic; and finally, in Section VII, conclusions are drawn and ideas for future work are provided.

II. Literature Review

As it was well emphasized before, in the present work it was decided to address the issue of designing a mobile

application prototype to improve inventory management in companies belonging to the pharmaceutical industry, since it was evidenced that it is a common problem today. For this reason, it was decided to search for scientific productions that are useful and related to the topic, in order to collect information on their observations, results, conclusions and other relevant aspects and learn from them.

In the first instance, in a work carried out by the authors [9], it was proposed to design and implement a pharmacy management system with a stock alert system, in order to improve accuracy and improve safety and efficiency in the pharmaceutical store. About it, in its conclusions it is indicated that the developed software allows new prescriptions and refills to be processed more quickly and easily; at the same time, this makes the work of pharmacists automated, allowing them to have more time to advise clients and thus prevent them from making medication errors.

On the other hand, in a work carried out by the author [10], it was proposed to design a mobile application for inventory management in a minimart. In the process, Waterfall was the methodology used, with the stages of analysis, design, coding and implementation. Besides, in its conclusions it is indicated that among the many benefits of this application is that it allows the management of articles to be easier.

From another approach, in a work carried out by the authors [11], it was proposed to develop a system to accurately manage consumable goods in storage. In the process, Systems Development Life Cycle (SDLC) was the methodology used. Likewise, the mobile application was developed using the Android system. Besides, in its conclusions it is indicated that this system has proven capable of reducing inventory access time by 80% and accurately tracking inventory compared to manual stock counting.

Meanwhile, in a work carried out by the authors [12], it was proposed to develop an information system for the hotel industry, in order to facilitate the control of data and inventory, orders and acquisitions and guarantee the follow-up of the cleaning process and consumption of materials as a whole. In the process, Design Science Research (DSR) was the methodology used. Besides, in its conclusions it is indicated this system has multiple benefits, among which it is mentioned that it allows data control and analysis to be carried out very easily.

From another perspective, in a work carried out by the authors [13], it was proposed to develop a mobile application for inventory management with sales prediction. In the process, regression analysis, typical of data mining, was used. Likewise, the mobile application was developed using the Android system. Besides, in its conclusions it is indicated that this application helps companies achieve greater social empowerment and development.

Similar to the previous one, in a work carried out by the authors [14], it was proposed to develop an inventory management system using the Rule of Association, in order to ensure that stores properly maintain their records and update your items in stock. In the process, the association rule, typical of data mining, was used. Likewise, AngularJS was used for the implementation of the system; PHP (Hypertext Preprocessor) for the backend of system development and database management; HTML (HyperText Markup Language) and CSS (Cascading Style Sheets) for system interface design; and NoSQL as the database engine. Besides, in its conclusions it is indicated that this system was very useful, since it allowed creating transactions, updating items in stock, keeping records, generating reports for decision-making and making stores more effective.

Taking into account the previous works investigated, it can be seen that there is a limitation in the use of software development methodologies, since they only appear in some articles. In addition, it is also evident that there is a limitation in the exploration of different platforms that exist to develop mobile applications.

III. Methodology

Poor performance and unreliability of applications are common factors that drastically affect their acceptance. In this regard, measures must be taken in terms of quality. For this reason, in the development of this work, it was decided to use a software development methodology, together with various computer tools, in order to develop the prototype of the inventory management mobile application for pharmaceutical industry companies.

A. The RUP Methodology

RUP (Rational Unified Process) is a software development methodology that is object-oriented. It is responsible for establishing the bases, templates and examples for each of the aspects and phases of software development. Furthermore, it combines aspects of the development process (such as defined phases [15], techniques and practices) with other development components (such as documents, models and manuals) within a unified framework.

This methodology is one of the most widespread and well-known among software development companies. It is based on the Unified Modeling Language (UML) and is characterized by being iterative and incremental, focused on architecture and guided by use cases [16]. Likewise, the goal of this methodology is to develop high-quality software, capable of meeting the needs of customers, within the costs and schedules planned for the project [17].

Having mentioned all of the above, the scheme of the RUP methodology can be seen in Fig. 1.

B. Phases of the RUP Methodology

The RUP methodology consists of four development phases, within which several iterations are carried out in order to satisfy defined criteria before embarking on another phase. In other words, if we want to advance to the second phase of the RUP methodology, we first have to meet all the criteria established in its first phase.

1) Inception Phase: This first phase is very short and focuses on achieving the feasibility of the project. To do this, it is necessary to establish the scope, identify current and future risks, propose an overview of the software architecture and develop the plan for phases and subsequent iterations with customers or stakeholders.

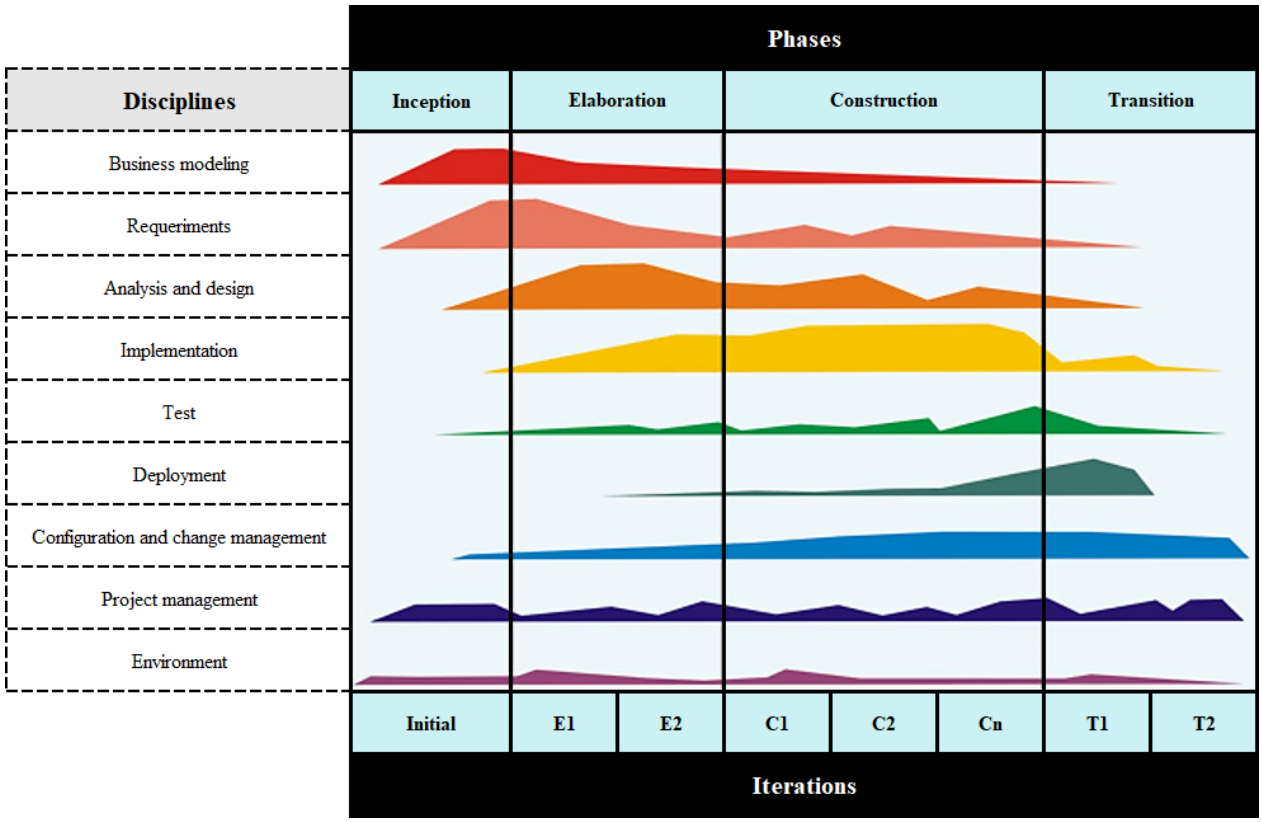

Fig. 1. Scheme of the RUP Methodology

2) Elaboration Phase: This second phase seeks to have a well-established base before moving on to the next. For this, it is necessary to select and elaborate the use cases [18], define the base architecture of the software, specify the selected use cases, develop the first analysis of the problem domain and design the preliminary solution.

3) Construction Phase: This third phase focuses on achieving the functionality of the software. For this, it is necessary to verify the pending requirements, manage the changes in relation to the evaluations made by the users and carry out the improvements.

4) Transition Phase: This fourth phase is the one that closes the project and seeks to ensure the availability of the software for end users. For this, it is necessary to carry out the final tests, adjust the errors and defects found, train users on the use of the software and provide the necessary technical support [18].

C. Elements of the RUP Methodology

A case apart from the four phases presented above, the RUP methodology is governed by four elements that work together and help to obtain the final result of the project.

1) Roles: It refers to the functions performed by each of the individuals or entities involved in the project. In this regard, it is worth mentioning that an involved party can play several roles, as well as the same role can be represented by several parties. In this sense, some roles [19], for example, could be that of a technical documenter, a software architect and a quality assurance.

2) Activities: It refers to the tasks that must be carried out by each of the individuals or entities involved in the project. In this regard, it is worth mentioning that each activity is assigned to a specific role. In this sense, some activities, for example, could be the elaboration of the use case diagram, the capture of software requirements and the performance of tests.

3) Artifacts: It refers to the products (in intermediate or final state) that originate during the various activities of the project and that are used to obtain the final result. In this regard, it is worth mentioning that the products capture information about the work carried out and transmit it. In this sense, some artifacts, for example, could be a document (such as the software architecture document), a model (such as the use case model) and an element belonging to a model (such as a class) [19].

4) Workflows: It refers to the sequence of activities that produce observable results of the project. In this regard, it is worth mentioning that all the roles, activities and artifacts that have been previously defined are integrated into the workflows. In this sense, some workflows [19], for example, could be a sequence diagram, a collaboration diagram and an activity diagram.

Having mentioned all of the above, the elements of the RUP methodology can be visualized in Fig. 2.

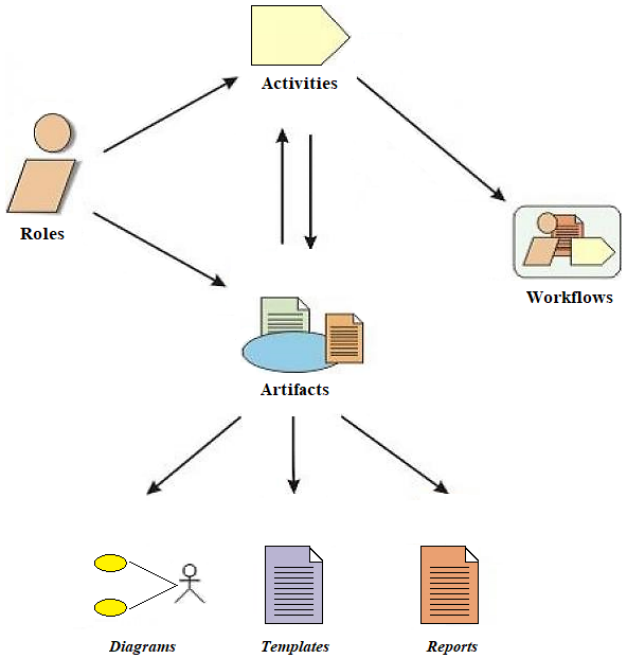

Fig. 2. Elements of the RUP Methodology

D. Technological Tools

1) Figma: It is used to create prototypes, through a development environment, which has an intuitive and easy-to-use interface. Figma allows designing user interfaces with excellent features in terms of design, prototype, collaboration, etc. In addition [20], it allows you to work collaboratively during the creation process and export the result in various formats such as PDF, PNG and JPG.

2) StarUML: It is an open source software modeling application based on UML standards [21]. It is flexible and easy to use.

3) Google Forms: It is a web-based application used to create forms for data collection purposes. Among its many benefits [22], its ease of handling when adding questions and answers stands out, as well as its ability to export the results in spreadsheets and statistical graphs.

IV. Study Case

During the development of the project, the activities of the phases of the RUP methodology that are most related to the development of the prototype of the mobile application for inventory management in a pharmaceutical industry company will be followed.

Based on the above, only the most necessary points of each of the phases of the RUP methodology were selected in order to achieve the final result that is the elaboration of the proposed prototype.

A. Phase 1: Inception

1) Scope of the Project: In this part, the scope of the project is established, which is related to its purpose. In other words, considering the purpose of this project, the need arose to raise some specific points, thus shaping the scope of the project. About it, the points that constitute the scope of the project are the following:

- Allow users to login.
- Register, modify and delete users.
- Register, modify, delete and query users.
- Register, modify, delete and consult providers.
- Register, modify, delete and consult products.
- Record sales.
- Generate sales reports.

2) Risks Associated with the Project: In this part, the risks associated with the project are identified to take them into account during the development of each of the activities because, as in any project, there are always situations that could occur and have a positive or negative impact on the final result. In this case, such uncertain events or conditions could be detrimental to scope and quality. About it, the risks associated with the project that were identified are the following:

- Inadequate choice of the technological tools to be used in the elaboration of the prototype.
- Ambiguous list of functional and non-functional requirements.
- Ambiguous definition of the roles of those involved in the project.
- Inaccurate rendering of Unified Modeling Language diagrams.
- Poor design of the prototype product of errors and details not considered.

3) Overview of Software Architecture: In this part, an overview of the mobile application architecture is proposed, which was done in order to provide a solid base to start modeling the system prototype. About it, the proposed architecture for this mobile application is presented in Fig. 3.

B. Phase 2: Elaboration

1) Software Requirements: In this part, the functional requirements and non-functional requirements of the system are defined. The functional requirements focus on the functionality of the system, since they are all those specific functions that the mobile application has. On the other hand, the non-functional requirements focus on the quality of the system, since they are all those specific attributes that the mobile application has. In this regard, these requirements are presented in Table I and Table II.

2) Business Use Cases: In this part, the business actors are established and the business use case diagram is designed. About it, these diagrams can be observed in Fig. 4 and Fig. 5.

3) Business Activities: In this part, the business activity diagram is elaborated. About it, this diagram can be observed in Fig. 6.

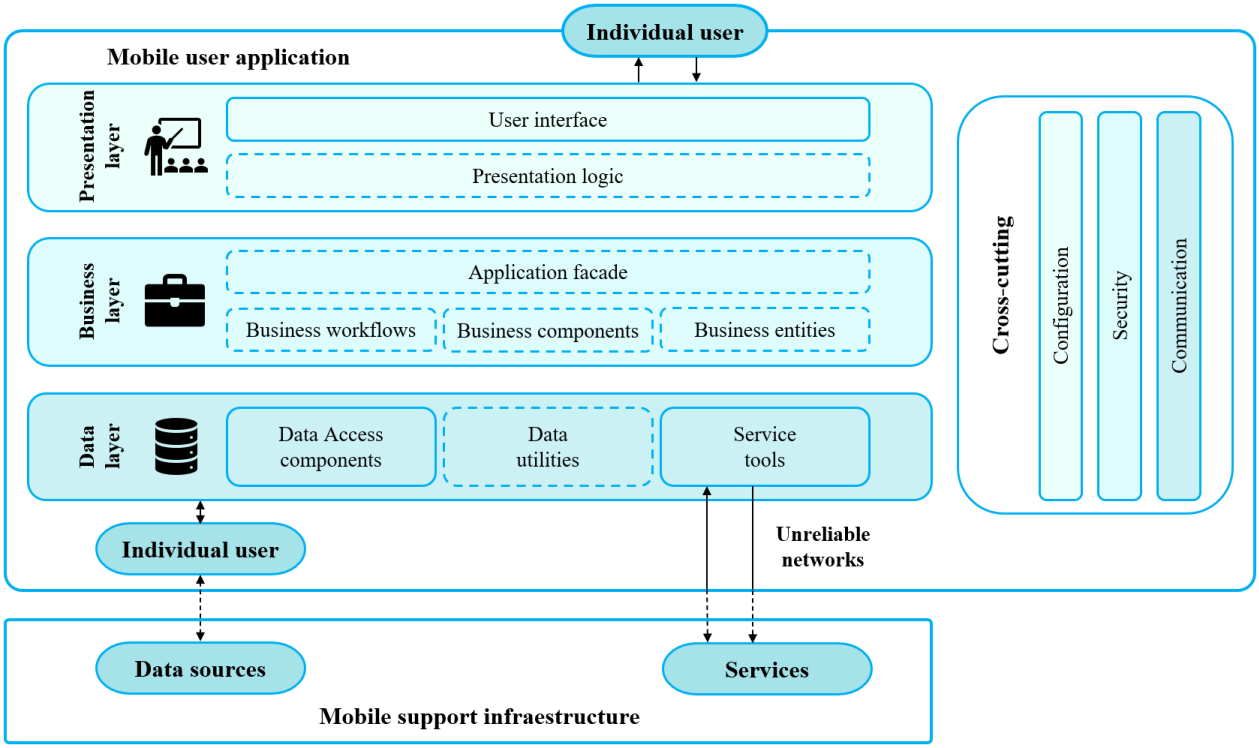

Fig. 3. Architecture of the Proposed Mobile Application

TABLE I. CAPTURE OF FUNCTIONAL REQUIREMENTS

Code	Description
FR01	The system will allow to validate the access of the users according to the entered data.
FR02	The system will allow to display a successful or failed login message
FR03	The system will allow to modify the login data of the users.
FR04	The system will allow to delete users.
FR05	The system will allow to register new users.
FR06	The system will allow to consult products.
FR07	The system will allow to modify of products data.
FR08	The system will allow to delete products.
FR09	The system will allow to register new products
FR10	The system will allow to consult providers.
FR11	The system will allow to modify of providers data.
FR12	The system will allow to delete providers.
FR13	The system will allow to register new providers
FR14	The system will allow to register the sale of products in real time.
FR15	The system will allow to generate sales reports.

TABLE II. CAPTURE OF NON-FUNCTIONAL REQUIREMENTS

Code	Description
NFR01	System learning time per user not exceeding 4 hours.
NFR02	Simple installation.
NFR03	Simple configuration.
NFR04	Disponibilidad de acceso 24/7 a todo el sistema.
NFR05	Safe and easy access.
NFR06	User authentication with a number of attempts not exceeding 3.
NFR07	Quick and easy navigation.
NFR08	Friendly and modern graphic interface.
NFR09	Ability to make changes and fixes.
NFR10	Ability to incorporate new functionalities.
NFR11	Compatibility with Android Studio and MySQL.
NFR12	Estándar de resolución 1440 x 2560: 560dpi.

4) System Use Cases: In this part, the system actors are established and the system use case diagram is designed. About it, these diagrams can be observed in Fig. 7 and Fig. 8.

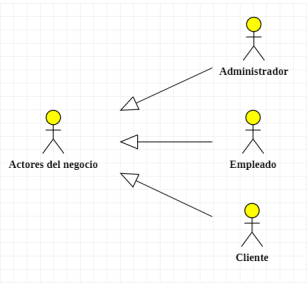

Fig. 4. Business Actors Diagram.

C. Phase 3: Construction

In this phase, the prototype of the mobile inventory management application is presented, which was developed with the Figma tool. This this application has two functionalities, these being the logistics area for employees and the sales area for customers. It is worth mentioning that the sales area was added as an added factor. Later, the most relevant interfaces of the application are shown.

In Fig. 9, it can be observed the charging interface, which appears when running the mobile application.

In Fig. 10, it can be observed the interface that appears after waiting for the application to load. This interface welcomes the

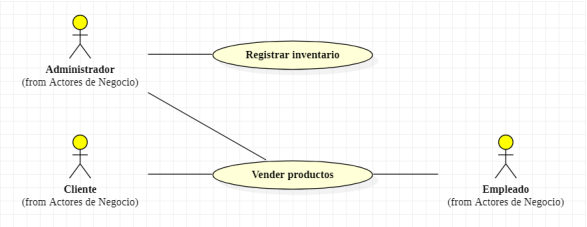

Fig. 5. Business Use Cases.

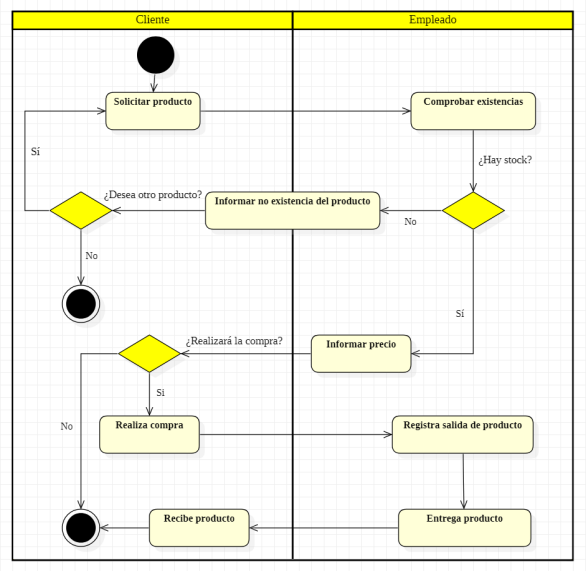

Fig. 6. Business Activity Diagram.

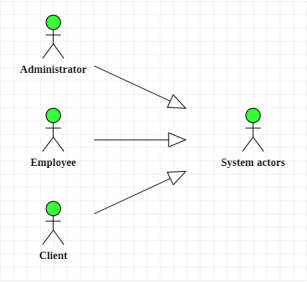

Fig. 7. System Actors Diagram.

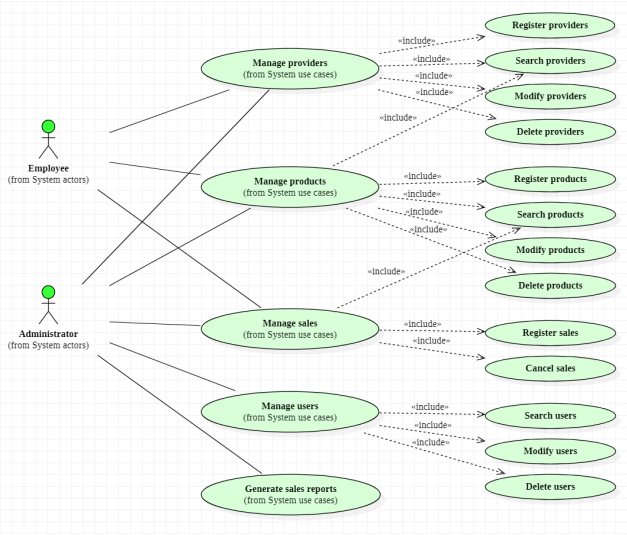

Fig. 8. System Use Cases.

user to the logistics area and asks him to enter his access data to enter. On the other hand, further down there is an option that directs the user to the entry interface to the sales area. The choice of which area to enter will depend on whether the user is an employee or a customer.

In Fig. 11, it can be observed the interface that appears after entering the access data. It shows the data of the employee who entered the system and gives the option to enter any of the windows you want.

In Fig. 12, it can be observed the interface that shows the providers part. It allows the user to contact them and register new ones.

In Fig. 13, two interfaces can be observed. The first interface allows you to register a new product. To do this, it will ask the user to enter their code and available stock. Also, it will ask the user to enter a comment about the product they are registering, as well as its expiration date. On the other hand, the second interface shows the list of products that are available.

In Fig. 14, it can be observed the interface that allows you to make sales reports, according to the date range that is entered. This interface shows the products sold, along with their respective units and prices. Also, it allows you to export the information.

In Fig. 15, it can be observed the interface that welcomes the user to the sales area. This interface shows the current products and offers. Also, it allows to search for products in the search engine.

In Fig. 16, it can be observed the interface showing the products part. In this interface the user can select any product he wants to buy.

In Fig. 17, it can be observed the payment interface, which allows you to make sales, asking if the payment method will be in cash or by card and if you want a bill or invoice. Also, this interface has the option to include an address for the delivery of the product.

D. Phase 4: Transition

It is important to validate that the elaborated prototype meets the necessary requirements of the end users and is free of errors and defects; otherwise, solutions will have to be found for the identified observations. For this reason, a validation of the prototype was carried out through expert judgment. Likewise, it is worth mentioning that the survey was prepared in Google Forms and contained fourteen (14) questions. About it, all this information can be observed in Table III.

On the other hand, it was sought that each expert, under their own criteria, qualify the proposed model. To do this, the survey responses were designed to be answered according to the Likert scale. Likewise, scores and percentages were

assigned. About it, all these data can be observed in Table IV.

V. Results

A. About the Case Study

In the inception phase, the scope of the project was established, focusing particularly on the operability of the system. Likewise, the risks associated with the project were identified, within which the prototype was tried to be free of errors and details not previously contemplated. Besides, an overview of the software architecture was proposed that served as a guide for the modeling of the system.

In the elaboration phase, the functional and non-functional requirements were captured. Likewise, five (5) UML diagrams were elaborated, these being the business actors, the business use cases, the business activities, the system actors and the system use cases.

In the construction phase, the prototype of the mobile

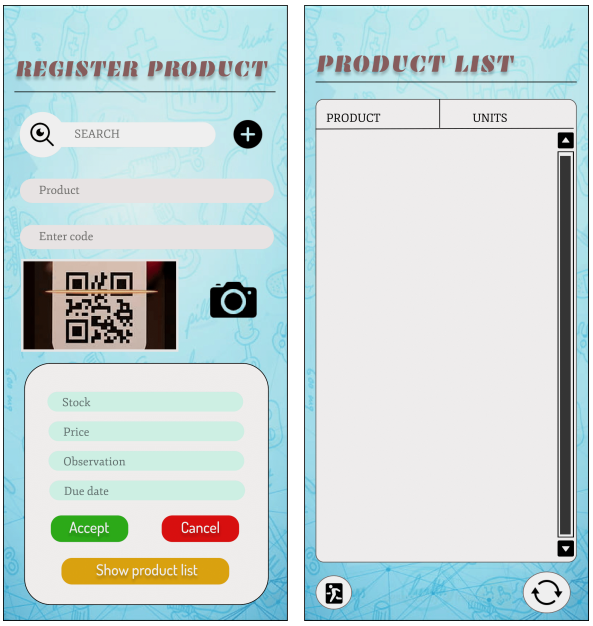

Fig. 13. Product Management Interfaces.

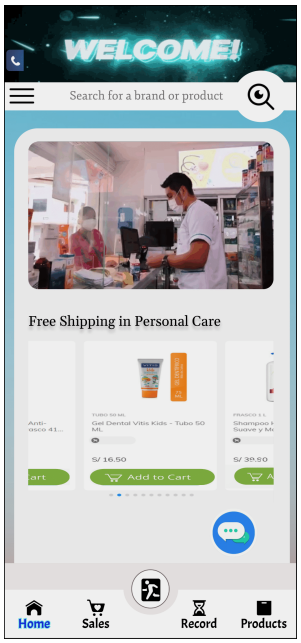

Fig. 15. Sales Area Interface.

Fig. 14. Sales Report Interface.

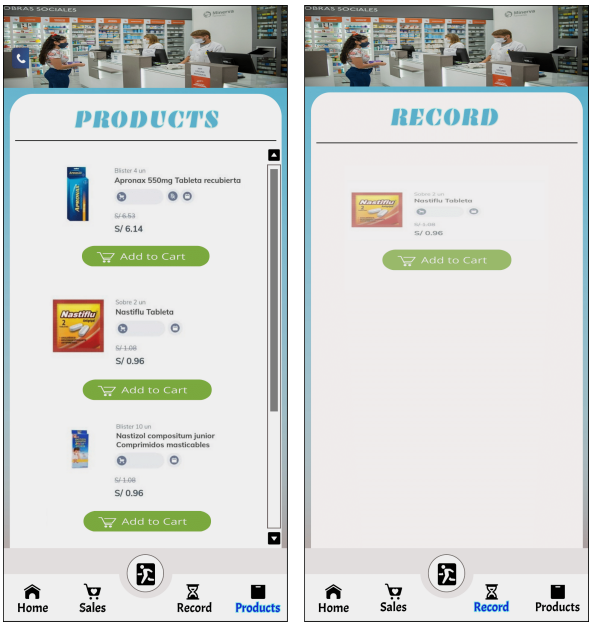

Fig. 16. Product Selection Interfaces.

inventory management application for the pharmaceutical industry was developed. About it, it is worth mentioning that the prototype consists of a wide variety of graphical interfaces, which allow users, products, suppliers and sales to be managed.

Finally, in the transition phase, surveys were carried out with the purpose of validating that the prototype is in optimal conditions and meets the needs of the user.

B. About the Survey

The survey model was elaborated with the Google Forms computer tool, which was very beneficial for the management of the data obtained.

Favorable results were obtained with respect to each of the survey criteria. About it, 96% of the total answers indicate that the respondents totally agree with the presentation of the application. Also, 92% of the total answers indicate that the respondents totally agree with the security, usability and functionality of the application. In short, all this shows that the application is optimal in terms of presentation, security, usability and functionality. For more details, all these data can be observed in Fig. 18.

Finally, it is necessary to mention that the survey

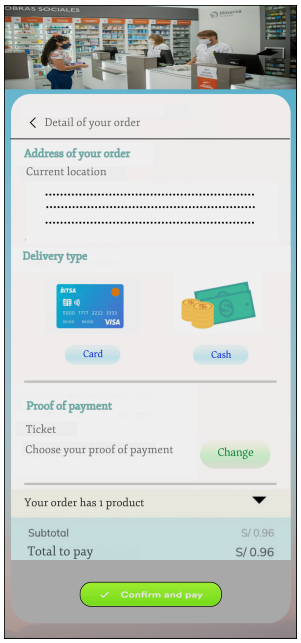

Fig. 17. Payment Method Interface.

TABLE III. SURVEY QUESTIONS

Criteria		Questions
Presentation	Q01	The interface of the application is modern.
	Q02	The interface of the application is friendly.
	Q03	The colors of the application stand out and contrast with each other.
	Q04	The graphics of the application pop and are timely.
	Q05	The windows of the application are well arranged.
	Q06	Indicate how much you agree with the presentation of the application.
Security	Q07	The access to the application is only for registered users.
	Q08	Indicate how much you agree with the security of the application.
Usability	Q09	The access to the application is easy.
	Q10	The navigation in the application is fast.
	Q11	Indicate how much you agree with the usability of the application.
Functionality	Q12	The application meets the needs of the user.
	Q13	The application will help improve inventory management.
	Q14	Indicate how much you agree with the functionality of the application.

application returned 93% in the final percentage. About it, all these data can be observed in Table V.

C. About the Methodology

As is well known, RUP is a methodology that focuses on planning and organizing a set of activities to turn user needs into software. The practices of this methodology are very common in large software projects; however, it is unknown what is the position of RUP compared to other software development methodologies. For this reason, a table was created to compare RUP with other software development

TABLE IV. ASSIGNMENT OF SCORES AND PERCENTAGES

Values	Scores	Percentages
Strongly disagree	1	20
Disagree	2	40
Neither agree nor disagree	3	60
Agree	4	80
Strongly agree	5	100

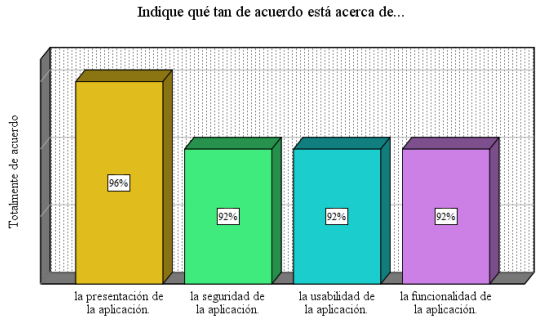

Fig. 18. Chart of Tables about the Opinion of the Respondents.

methodologies, in order to answer this question. About it, all this information can be observed in Table VI.

VI. DISCUSSIONS

During the literature review, works related to the development of mobile applications for inventory management were collected and analyzed. About it, it is worth mentioning that the works carried out by the authors [13] and [14] were very interesting. In both, data mining techniques were used in the methodological part and great results were obtained, demonstrating that there are other ways to develop software.

On the other hand, the literature review also allowed to compare the RUP methodology against other traditional software development methodologies, these being Waterfall and Incremental. Likewise, this comparison also involved some agile methodologies, these being Scrum, Kanban and Extreme Programming (XP). In this regard, it was identified that RUP is a very good methodology.

Now, regarding the surveys, it is worth mentioning that it is important that their application has yielded a high percentage of acceptance. This means that the prototype of the system is in optimal conditions and can be developed, since there is certainty that users will be highly satisfied with the application.

VII. CONCLUSIONS AND FUTURE WORKS

The prototype of the mobile inventory management application for the pharmaceutical industry developed meets the conditions of the users, given that the survey submitted to expert judgment was accepted by 93%. It was validated that the prototype has excellent presentation, security, usability and functionality. Therefore, it is concluded that there is certainty that the application will obtain great satisfaction from users and, therefore, can enter the development stage.

On the other hand, with respect to the case study, it is concluded that it was a good decision to use the RUP

TABLE VI. COMPARISON OF METHODOLOGIES OF SOFTWARE DEVELOPMENT

Criteria	Traditional methodologies			Agile methodologies		
	RUP	Waterfall	Incremental	Scrum	Kanban	XP
Proposals	It employs a set of activities necessary to transform user requirements into a system.	It linearly orders the different stages that must follow when developing the software.	It applies linear sequences in a staggered fashion as time progresses on the calendar.	It regularly applies a set of good practices to work collaboratively, as a team.	It applies a signaling system in which production tasks are displayed on demand by means of a series of cards.	It employs a set of techniques that provide agility, control, efficiency and flexibility in the development and management of the project.
Advantages	It allows early mitigation of high risks. It can be adapted and extended to meet the needs of any organization.	It provides the necessary tools to have clarity in the objectives from the beginning of the project. The costs and workload can be estimated at the beginning of the project.	It allows customers the opportunity to change requirements as components are added. It reduces the initial development time.	It allows to easily identify the objectives of each stage and the possible setbacks that may appear along the way. It manages the project in simpler and more manageable blocks, thus reducing the margins of error.	It allows variations in activities, thus ensuring that the product has the desired characteristics. It does not produce more than necessary, thus reducing waste.	It allows to save a lot of time and money. It has a very low error rate.
Disadvantages	The costs of the necessary team of professionals may not be covered on small projects. It may be unsuitable for use in small projects due to its high complexity.	It is difficult to go back and make changes. It delays tests until after completion.	It requires a lot of planning, both administrative and technical. It requires clear goals to know the status of the project.	It requires an exhaustive definition of the tasks and their deadlines. It requires that those who use it have a high qualification or training [23].	It is difficult to deliver on time on large projects. It is not implemented well in very long productive cycles.	It is difficult to keep track of what has been done. The commissions are very high in case of failure.

methodology, because it allowed the prototypes to be carried out in a systematic, orderly and coherent manner.

Finally, for future software development work, it is advisable to use other methodologies and other techniques related to data mining and technological trends.

***Abstract*—Thanks to its geographical and climatic advantages, Colombia has a historically strong fruit-growing tradition. To date, the basis of its food and economic development in a significant part of its territory is based on a wide range of fruits. One of the most important in the central and western regions of the country is the blackberry, which is rooted not only from the economic and food point of view but also culturally. For the departments of Casanare, Santander, and Cundinamarca, this fruit is one of the primary sources of income, rural employment, and food supply and income. However, small and medium farmers cultivate without access to technological production tools and with limited economic capacity. This process suffers from several problems that affect the whole plant, especially the fruit, which is strongly influenced by fungi, extreme ripening processes, or low temperatures. One of the main problems to be dealt with in its cultivation is the spread of pests, which are one of the causes of fruit rot. As a support strategy in producing this fruit, the development of an embedded system for visually diagnosing the fruit using a deep neural network is proposed. The article presents the training, tuning, and performance evaluation of this convolutional network to detect three possible fruit states, ripe, immature, and rotten, to facilitate the harvesting and marketing processes and reduce the impact on the healthy fruit and the quality of the final product. The model is built with a ResNet type network, which is trained with its dataset, which seeks to use images captured in their natural environment with as little manipulation as possible to reduce image analysis. This model achieves an accuracy of 70%, which indicates its high performance and validates its use in a stand-alone embedded system.**

***Keywords*—Automatic sorter; blackberry; deep neural network; fruit handling; image analysis**

I. Introduction

Colombia is a country that has been characterized by its great variety of fruits and fauna [1]. Its diversity and climatic stability, as well as its great cultural variety, have made it possible to define different foods that provide the necessary nutrients with an unparalleled flavor [2]. One of the most known and used fruits in daily life is the blackberry because it has an excellent flavor and an endless number of preparations [3], [4], [5].

Blackberry cultivation is mainly carried out by small family businesses without large investments in technology. These farmers strive to maintain the quality of the fruit [6], however, it is difficult to sustain it in planting with a size of approximately two hectares. Also, the process is further complicated by having to use chemicals to care for the plant, which always has an impact on the quality of the final product [7], [8].

An autonomous artificial sorting system can perform effective segmentation from images of blackberry in its different growth processes. Such a system, easy to use and very low cost, can support the production and commercialization of the fruit in its different stages [9], [10]. This type of system should consider a robust and low-cost portable design [11], [12], [13]. In this sense, the use of an identification algorithm capable of operating in real-time on low-cost embedded hardware is essential [14], [15], [16].

Annually Colombia produces 137,999 tons of blackberry. About 55% of the production stays in Colombia for fresh consumption (supermarkets and marketplaces) and less than 1% is exported [17]. Between 2015 and 2018, 12.8 tons of blackberry were exported, and it is known that the department of Cundinamarca is one of the largest producers, followed by Santander. These have an annual production of 26% and 17% respectively. Blackberry, despite its unique flavor, requires special processes to maintain its quality and avoid premature fermentation. Blackberry production costs are estimated at USD 2,410, which is divided into four main activities: land preparation, planting, harvesting, and inputs. However, for each ton of blackberry it is estimated that the value paid to the farmer is USD 400, which means that for every 14 million, a gross profit of USD 1,542 is obtained [18], [19].

Blackberry exports in Colombia are less than 1% [20]. However, this is one of the crops that generates the highest permanent income due to the domestic market [21]. Twenty percent of the product remains in the agro-industry for the production of juices, and jams, among others, while the remaining 55% remains for fresh consumption. This indicates that about 75% of the production remains for domestic trade, and is distributed in the largest distribution centers of agricultural products in the country. For example, Corabastos in the Colombian capital handles 36% of production, followed by the city of Bucaramanga with 20% in 2019. Its economic importance is reflected in the domestic market due to its great demand, and this, in turn, generates jobs and economic resources for the Colombian population. Therefore, it is estimated that 1,900 new hectares of blackberry crops are established annually. These crops can be affected by pests, which can end up destroying the entire crop if they are not properly cared for or do not have the necessary resources [22].

Since blackberry is a perishable food that grows in the field,

and its characteristic of food for pests such as flies, thrips, mites, and even the so-called fruit worms [23], it is essential to perform a quick and efficient characterization of the affected fruit to reduce possible damage and losses. These pests cause the fruit to be damaged, and this in turn is spreading throughout the crop, i.e., will produce losses to the farmer. For this reason, they implement various chemicals to eradicate them, which means that the blackberry has a large amount of them. An automatic grading system capable of being used by the farmers would increase their production capacity and product quality [24], [25].

The blackberry is a product with broad social roots that benefits the Colombian population from a nutritional and economic point of view. The blackberry industry provides employment in economically depressed areas, and at the same time has great nutritional value. Although it is not a product that brings income to the country as an export product, it is very important for the domestic economy in many regions of the country. It is a product that should be consumed fresh because it has a characteristic of rapid fermentation that considerably reduces its quality. Also, to maintain the quality of the crops, certain chemicals are used to eradicate pests, therefore it is necessary to invest in technology to facilitate and reduce production costs while ensuring the quality of the fruit [26], [27]. An automatic recognition system allows keeping control of the fruit throughout the production and commercialization process, which provides added value to the process and reduces costs [28].

In current fruit production processes, there is no equipment or tools similar to the one proposed in this research [29]. Previously, fruit inspection systems for harvesting have been implemented with shallow success, particularly for using traditional image processing strategies for sorting, which is very unreliable in actual field applications.

The paper is structured as follows. Section II describes the problem under study and the possible profile of the required solution. Section III presents the methodological development followed for the solution, giving details of each section of the system, from the input dataset and its manipulation to the desired output categories, including the architecture designed for the model. Section IV summarizes and discusses the results achieved by the model, using metrics and discussing their scope. Finally, Section V concludes our paper by highlighting the strategies used and the most important findings.

II. Problem Statement

The objective of this research is to develop an autonomous classification model based on images to determine the conditions of blackberry fruit throughout the harvesting and marketing process. It is intended to use this model for the construction of a low-cost embedded system that is easy to use with farmers. With this system, the farmers will be able to identify in time the problems of the fruit in their harvest, reducing negative effects on production. The handling of this fruit must comply with certain processes that guarantee its quality, i.e., avoid the proliferation of pests and diseases that attack the crop, as well as maintain its growing conditions. Changes in these processes often affect the plant from the root to the fruit, potentially lowering the volume of the harvest. When one plant gets infected, the damage quickly spreads to other plants, generating large losses for growers. These crop problems are not only due to the misuse of insecticides or soil, but the weather plays an important role. Low temperatures produce frosts that influence the weakening of the plant and therefore facilitate the incorporation of pests and diseases.

Pests and diseases are not the only problems that cause damage and losses in this crop, an extreme ripening of the blackberry causes fermentation, making it impossible to consume. Blackberry is consumed fresh, inadequate handling and storage processes affect the quality of the fruit, an effect that also spreads rapidly throughout the product.

As a solution strategy, we propose an image categorization model based on a convolutional network. We propose the use of a ResNet (Residual Neural Network) trained and tuned with a proprietary dataset to identify three fruit states: ripe fruit (category 0), unripe fruit (category 1), and rotten fruit (category 2). This architecture is chosen due to its high performance in similar problems, and its small size which facilitates its use in a low-cost embedded system. The aim is that such a system can identify possible problems in the fruit early, before spreading and infecting the whole crop (harvest). The general model of the proposed system is shown in Fig. 1.

III. Methods

In the preliminary performance tests, the ResNet model obtained the highest average and category performance. The ResNet version of 50 layers deep (ResNet-50) was implemented, seeking the smallest possible size for the model. The great advantage of this model is that it reduces the depth by sending information forward, skipping layers, and improving at the same time the learning capacity [30]. The coding of the model was performed in Python 3.8.5 with support for numpy 1.19.2, scikit-learn 0.23.2, scipy 1.5.2, OpenCV 4.4.2, and matplotlib 3.3.2.

One of the essential features of our categorization model is that it must be able to produce results with images captured in real environments, such as those that a farmer could capture with his cell phone. In this way, the system would be easy to manipulate in real environments, and the categorization model would produce reliable results. To test this argument, we built our dataset from images supplied mainly by local farmers and experts in fruit handling. In addition, this database was supplemented with public images of fruit conditions. The images were not manipulated to extract or remove information from them, but the leading actor was always the fruit.

The training of the convolutional model was performed according to the following characteristics:

- **Dataset**. We built our balanced dataset with 100 images in each category (300 images in total, Fig. 2). The images in each category correspond to states identified by fruit condition experts. According to the performance of the system, this dataset can be increased if this increases the categorization performance. The possibility of continuous updating of the database and online training is proposed.
- **Manipulation of the Dataset**. The image processing was done with OpenCV. The images were randomly

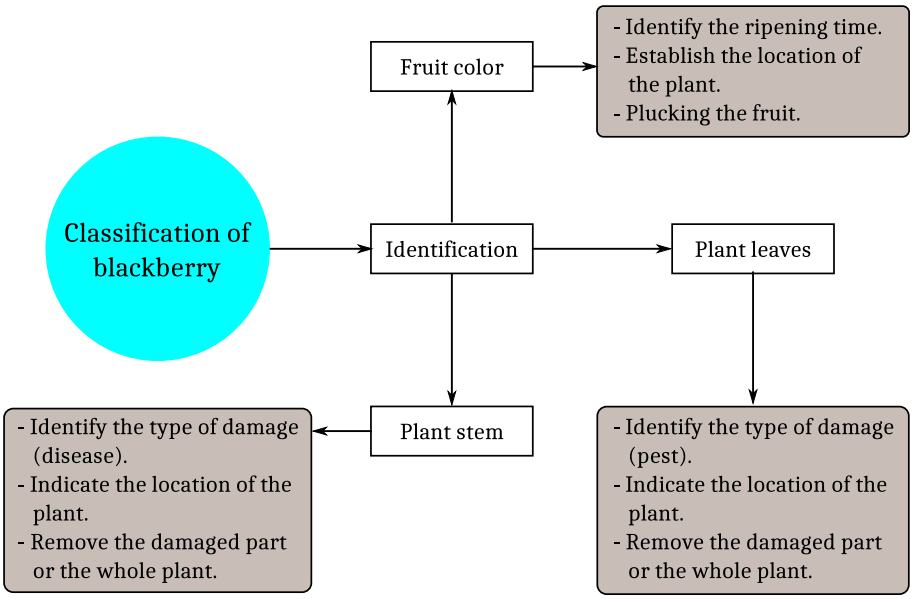

Fig. 1. General Diagram of the Classification and Control Scheme of the Blackberry Plant.

shuffled and scaled to a size of $32'times32$ pixels to reduce the complexity of the code. This size is conditional on the performance of the model, but in initial tests, it showed a high capacity to retain features while considerably reducing the processing power required on the embedded hardware. The images were processed in RGB matrices and normalized to the working values of the convolutional network.

- **Training and Validation**. To build the model, training is performed with 70% of the dataset (random selection of images), while the remaining 30% is used for validation. The optimization is performed with the Stochastic Gradient Descent (SGD) function, and the loss calculation is performed with the Categorical Crossentropy function. The training was performed over 30 epochs, and at each step, the accuracy and Mean Squared Deviation (MSD) error values produced for both training and validation data were controlled. The number of epochs was defined according to the learning capacity of the model, avoiding over-fitting.

- **Model Assessment**. The performance of the model was evaluated using three metrics: Precision, Recall, and F1-score. These metrics were calculated for the validation images in each category of the model, as well as its average behavior. The convolution matrix was also used to identify problems related to false positives and false negatives.

We use a ResNet-50 model looking for architecture with high performance, but at the same time suitable for propagation on embedded hardware (Fig. 3). This deep network is inspired by cells of the pyramid of the cerebral cortex to form equivalent functional blocks. This functionality is achieved using jumping connections to send information forward layers of the structure. It is thanks to these jumps that this deep model manages to avoid gradients that fade away during training, which is what gives it its high performance. This structure makes sense when all the intermediate layers are linear or are superimposed on the nonlinear layer, otherwise, the re-use of weights in the forward layers would not make sense. The ResNet-50 model has five stages, each with a convolution and identity block. Each convolution block contains three convolution layers, as does each identity block. With this structure, the model has a little more than 23 million parameters to be adjusted.

IV. Results and Discussion

The capacity and performance of the model were evaluated throughout the training with both training and validation data. Accuracy (Fig. 4) and the behavior of the loss function (Fig. 5) were calculated throughout each epoch. The Accuracy of a classification model indicates the number of correct predictions for the total number of input images. In Fig. 4 the red curve shows the Accuracy behavior for the training data, while the green curve shows the same metric for the validation data. The Accuracy of the training data remains always high, while the behavior of the validation data remains very poor, at least until epoch 13, from which the performance of the validation data increases according to the model fit.

Fig. 5 shows similar behavior. The red curve again shows the behavior for the training data, while the green curve shows the error produced by the validation images. Although in both cases there is error reduction, the initial model had a good performance for the training data, and the most marked reduction in error is observed in the validation data. Without wishing to cause training bias, the model was tuned to produce better behavior for unknown images. Again, the reduction in error becomes more marked from epoch 13 onwards.

The confusion matrix of the model allows to observe graphically the overall performance, as well as in each category, and allows for calculating the Precision, Recall, and F1-score metrics (Fig. 5). The matrix uses a heat grading that assigns

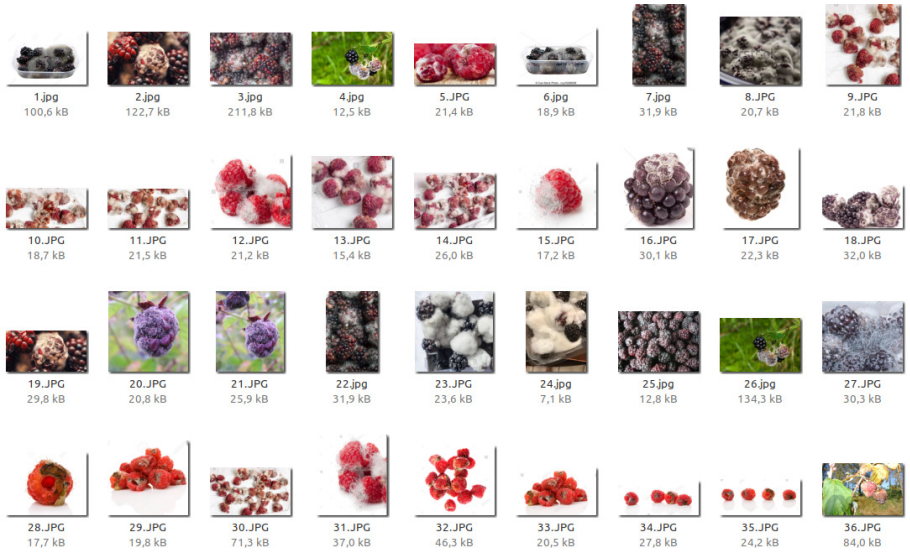

Fig. 2. Sample Dataset used in Category 2 (Rotten Fruit).

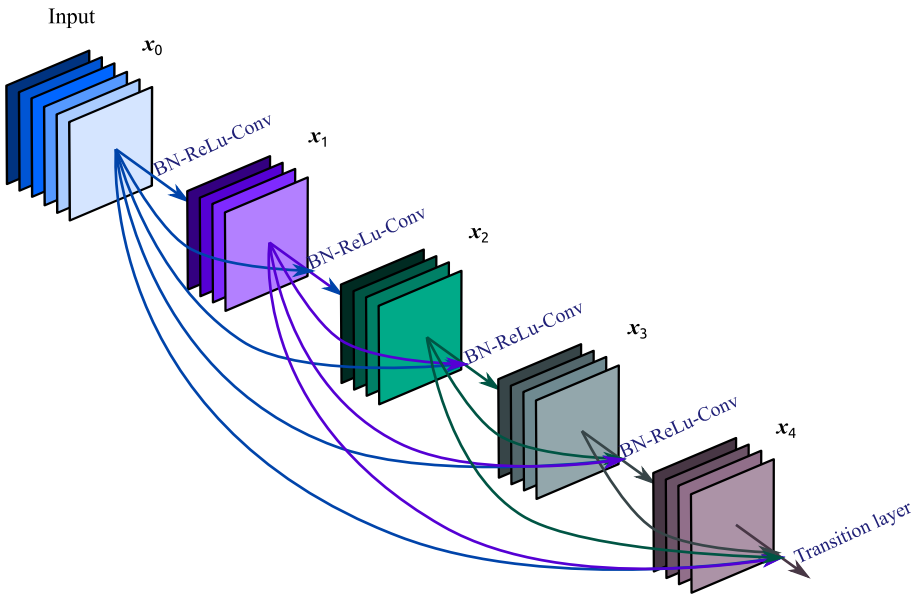

Fig. 3. ResNet-50 CNN Architecture.

light colors to high values, and dark colors to low values. The main diagonal in Fig. 6 with light colors, and the dark colors above and below it, show high categorization performance. Specifically, it is seen that in the ripe fruit category, 21 of the images are correctly classified, with very low percentages of false positives and false negatives. In the category of immature fruit, it is seen that it had more difficulties in the classification, since it only classified 18 of these, and in the category of rotten fruit it had the best performance since it was able to correctly classify 27 of the images.

We also calculated the Precision, Recall, and F1-score metrics for the model using the validation data (Table I). The accuracy of the model indicates how good the model is at placing the correct images in a given category, i.e., how many of those placed in a category belong to it. Our model obtained an accuracy of over 68% in all categories and an average value of 76%. Although not perfect, the values are more than good for the proposed development. On the other hand, the Recall shows how many of the positive ratings in each category belong to that category. In category 1, as indicated in the confusion matrix, we have a relatively low value (51%), but the values for the other categories exceed 84%, which speaks very well of the model. The average value for Recall is 75%. Finally, F1-score corresponds to a weighted average of the first two metrics, so it combines their qualities. The model obtained a value per category of over 75% and an overall average value of 73%.

This categorization model is being evaluated on the

DragonBoard™ 410C development board from Arrow Development Tools. This system is powered by a 64-bit ARM®Cortex™ A53 Quad-core processor and 1 GB of RAM. The system has been configured with Debian Linux, and in initial testing has demonstrated high real-time performance. Further evaluation will be conducted in the future development of this research.

Compared to traditional strategies for the identification and categorization of fruits, our proposal presents excellent advantages for implementation in real systems, not only because of the high performance reported by the model but also because of the possibility of working with images with minimal or no previous processing, which allows farmers to manipulate the tool and produce reliable results immediately directly. This advantage is further enhanced by the lack of the need for complex, high-cost hardware, which allows the development of prototypes on small embedded systems.

V. CONCLUSION

This paper presents an image categorization model of blackberry fruit as a strategy for the construction of an autonomous identification system to support the process of cultivation and marketing of the fruit. The ResNet-50 convolutional neural network was selected for the development of the model due to its high performance and small size. This network was trained, tuned, and validated with a proprietary dataset separated into three categories coinciding with the state of the fruit. The code was developed in Python with Keras and TensorFlow support, and a model with good performance suitable for embedded applications was generated. During training, the Categorical Crossentropy function was used as a loss function, and the Stochastic Gradient Descent function was used as an optimizer. The evaluation of the model was performed with the Precision, Recall, and F1-score metrics, as well as the confusion matrix of the model. According to the results with the validation data (Precision of 76%, Recall of 75%, and F1-score of 73%) the model has adequate

performance for the development of the prototype, also, the behavior throughout the training allows intuiting that it is still possible to increase the learning and performance of the model. It is expected that the system can be used to perform on-site fruit sorting, allowing the early identification of rotten fruit, reducing damage at harvest, and handling the product. Future directions of the project are oriented to allow real-time updating of the database and evaluation of the system on hardware prototype.

***Abstract*—Companies constantly rely on customer support to deliver pre-and post-sale services to their clients through websites, mobile devices or social media platforms such as Twitter. In assisting customers, companies employ virtual service agents (chatbots) to provide support via communication devices. The primary focus is to automate the generation of conversational chat between a computer and a human by constructing virtual service agents that can predict appropriate and automatic responses to customers' queries. This paper aims to present and implement a seq2seq-based learning task model based on encoder-decoder architectural solutions by training generative chatbots on customer support Twitter datasets. The model is based on deep Recurrent Neural Networks (RNNs) structures which are uni-directional and bi-directional encoder types of Long Short-Term Memory (LSTM) and Gated Recurrent Units (GRU). The RNNs are augmented with an attention layer to focus on important information between input and output sequences. Word level embedding such as Word2Vec, GloVe, and FastText are employed as input to the model. Incorporating the base architecture, a comparative analysis is applied where baseline models are compared with and without the use of attention as well as different types of input embedding for each experiment. Bilingual Evaluation Understudy (BLEU) was employed to evaluate the model's performance. Results revealed that while biLSTM performs better with Glove, biGRU operates better with FastText. Thus, the finding significantly indicated that the attention-based, bi-directional RNNs (LSTM or GRU) model significantly outperformed baseline approaches in their BLEU score as a promising use in future works.**

I. Introduction

Providing excellent customer service while engaging with their clients has become more pivotal than ever in today's digitally connected era. Companies engage with customers to assist them with pre-post sale items regularly upgraded due to technological advancements or the communication revolution. Over the years, face-to-face physical meetings and phone calls have been the two most dominant communication methods. Since the rise of the internet, various ways have evolved, from email to social media, installing the mobile application to fill out a form on a website, and eventually waiting for a follow-up. Recently, the increasing use of real-time messaging such as Twitter, Facebook Messenger, WhatsApp, Telegram, Slack, etc., has led to a fundamental transition in how people would prefer to connect with businesses. While most of these communication channels have common characteristics, including online chat, which initially relies only on humans to conduct mutual communication, the baton now is passed to virtual agents or assistants called chatbots. Chatbots, the trendy platform led by virtual assistants, function as customer service representatives who negotiate conversations with clients to improve the user experience and services.

Chatbots are the subsequent major advancement in conversational services, which allow some business companies to communicate through messaging systems, like Twitter and Facebook Messenger, based on artificial intelligence and machine learning. Chatbots can be defined as computer programs living in messenger applications and providing specific services via emulating an interaction with a human through text messaging or a virtual voice [1] [2]. Owing to the overwhelming prevalence of chatbots as messaging is the most commonly used customer assistance medium; therefore, there is a need for the company to invest in a chatbot to support serving their customers' needs as applying in the context of service chatbots. Consequently, companies can strengthen employees' productivity to serve more customers with other services.

Chatbots' primary purpose is to facilitate the conversation between machines and humans in natural language conversation; as in the human viewpoint, these interactions should resemble humans as closely as feasible. Consequently, achieving this has become a fundamental task, with numerous researchers seeking the optimal way for having a chatbot to behave like a human. An effective chatbot should be able to comprehend the user's message, retrieve appropriate information according to the given statement and respond accordingly so that the user perceives the conversation as human-like.

The existing chatbots work just on pattern matching inputs and then finding a scripted answer corresponding to the information presented. The downside to this technique is that it cannot lead to a completely satisfying conversation due to the limitation of discourse within a specific domain with a clear goal. To handle the user's input utterances, Eliza, PARRY, and ALICE, to name a few were among the first chatbots to employ rudimentary parsing, pattern matching, or keyword retrieval approaches. These techniques require handwritten rules to generate responses. Due to the domain-specific

nature of these practices, they were effective at preserving context. However, as the knowledge space expands and users' expectations upsurge, for instance, when engaging in chitchat as in [3], it then becomes difficult to predict users' intentions and considered as not cost-effective, as all the possible patterns must be built manually with a great deal of effort to have a large number of patterns for generating responses.

As artificial intelligence (AI), machine learning, and natural language processing (NLP) techniques advance, researchers and practitioners seek to use data-driven methods incorporating capabilities of deep learning techniques such as RNN, LSTM, and Sequence-to-Sequence (Seq2Seq) model in constructing chatbots automatically and minimizing hand-written rules chatbots techniques. Minimizing the hand-written rules requires the chatbots to be designed based on modular form. This modular form consists of several components: a natural language understanding (NLU) component that turns user text or speech input into semantic representation, an internal state update component that updates the conversation memory (dialogue state tracker), and dialogue policy are used to decide what the following system action will be (dialogue policy), and a natural language generation (NLG) component for producing a response to the user. Training each modular system component typically necessitates a considerable quantity of tagged dialogue data. In contrast to its end-to-end counterparts, the system is more interpretable and stable due to its modular design.

On the other hand, researchers and practitioners recently tried to implement the end-to-end approach utilizing the seq2seq learning task model based on the neural machine translation problem. This attempt is due to the fact that the end-to-end process needs less annotation, giving it an additional viable choice for commercial use cases [4]. In addition, the performance of each component in a modular system is not representative of the entire system because each element is optimized separately [5]. Nevertheless, its end-to-end design makes it uncontrollable [5].

Furthermore, the evolution of machine learning, AI and NLP techniques has encouraged the academics and developers to create chatbots that employ various design strategies. However, despite these advancements in design, chatbots still face several hurdles in comprehending incoming requests, interpreting them, providing acceptable replies, and sustaining a user dialogue. Therefore, academics and developers continue to improve chatbot development techniques to meet the demands of both consumers and service providers. Consequently, it is essential to find a new method to enhance the accuracy of the user utterance's understanding and chatbot's response in service chatbot application. Thus, the fundamental objective and contribution of the current paper aim to present and implement a seq2seq-based learning task model based on encoder-decoder architectural solutions by training generative chatbots on customer support Twitter datasets. These generative chatbots are important to predict automatically an appropriate and automatic response to customers' queries and extensively evaluate their effectiveness in a variety of circumstances under various baseline models, training hyperparameters, and architectures.

The remaining sections of the paper are organized as follows. In Sections II and III, reviews of related works and descriptions of the models are provided, respectively. The methodological approach is presented in Section IV. Section V contains the experimental study of the research, while Section VI includes the conclusion and recommendation for future work.

II. Related Work

Seq2seq learning task models have been implemented in numerous natural language processing tasks, such as chatbot, machine translation, question answering, text summarization, image captioning, sentiment analysis, etc. Initially, seq2seq learning comprising encoder and decoder(E2D) structure was introduced in [6] for Neural Machine Translation (NMT). With the support of gate mechanisms such as LSTM [7] and GRU [8], the problem of vanishing or explosion can be controlled, enabling the model to obtain far longer sentences.

To better capture the dependencies in utterance, bidirectional and reverse order practices are commonly used to design the seq2seq models [9] [10]. Yet, at the same time, this approach also has a fixed-length vector (context vector) issue. This issue arises in the decoding process because the source sentences will compress the input regardless of the length vector this neural network needs as a context vector, especially when the source sentence is long [8]. Indirectly, this process leads to incorrect responses, as each word in the answer may have a close relationship with various sections of the words in the request.

A study was done in [11] and [12] combated the problem by adding an attention mechanism layer and integrating it into the decoder by repeatedly reading the representation of a source sentence, which remains fixed after being generated by the encoder. Hence, the model is able to search for relevant parts to predict a targeted word and attain cutting-edge machine translation performance. Inspired by the great commission in machine translation, the researchers and developers attempt to apply this technique to other tasks, including chatbots. For instance, in [13], the author also used seq2seq learning by comparing the performance of chatbot-generated responses between LSTM, GRU, and Convolution Neural Network (CNN). Unlike the above approaches, our work integrates an additive attention model to align the relevancy of input and output for improving question-answer. In addition, a study in [14] also employed attention mechanisms to the encoder-decoder architecture in enhancing question-answer relevance.

In [15], the authors implemented an attention-based with encoder-decoder neural architecture with the knowledge graph, and the corpus joins embedding as input in a task-oriented based chatbot. In contrast to [16], the authors added information regarding the conversation history and external knowledge collected from the search engine to enhance the seq2seq chatbot. In [17], the authors allocated labeled data to hierarchical categories using the attention-based Seq2Seq model. In the research, when answer predictions were inconsistent, a slot-filling method was used to determine which questions needed to be asked in order to make correct predictions.

All the above-related works focus less on examining the effects of complementary mechanisms in deep learning, such as batch size, lstm size or types of embedding in different seq2seq chatbot architecture. Therefore, this work attempts to

focus more on investigating such effects through experimental study as presented in Section V.

III. Model Description

This section describes and explores our model architecture based on the word representation model, seq2seq RNNs (LSTM, GRU, biLSTM, biGRU), and an attention mechanism.

A. Word Representation Model

For a computer to comprehend the meaning of the words and sentences, the text data must be converted to a numerical format. Embedding (encoding or vectorizing) is the term used for this concept. Character embedding, word embedding, and phrase embedding are only a few examples of many other types of embedding. Among various types of embedding, the word embedding is most commonly employed [18]. Word embedding is a way to model language that maps words to vectors of real numbers. It encodes words or sentences with several dimensions in vector space. The embedding layer can be initialized using pre-trained word vectors such as Word2vec, Glove, or FastText as implemented in this research word. A detailed description of the word embedding models is presented in the following subsection:

1) Word2Vec: Word2vec is a predictive embedding technique that uses the low dimensionality of word vectors to learn fine word vectors from massive data sets containing billions of words. There are two main architectures of Word2Vec for producing a distributed word representation, namely:

- Continuous bag-of-words (CBOW) model
  - This architecture is based on the language model of a feed-forward neural network [19]. It seeks to anticipate the current word based on the surrounding context by minimizing the loss function
- Skip-Gram model
  - Unlike the CBOW model, this model is aimed to predict surrounding words given the current word.

2) Glove: The Global Vectors for Word Representation (GloVe) enhances the Word2vec approach proposed in [20] at Stanford in 2014 for effectively learning word vectors. Conceptually, the Word2vec approach only considered local contexts but did not utilize a global context. Previously, the conventional vector space model representation of words was built using matrix factorization techniques such as Latent Semantic Analysis (LSA), which gave a better result than global text statistics. This model is also called a count-based model. Count-based models learn their vectors by reducing the co-occurrence counts matrix's dimensionality. However, this technique does not give a promising result as a learned method or predictive model such as Word2Vec captures the meaning and performs an arithmetic operation that can pose semantic or syntactic relationship of words, for example, $king - man + woman \rightarrow queen$. Thus, by merging the global matrix factorization and local context window approaches with the help of a bilinear regression model, GloVe indirectly benefits from both techniques.

3) FastText: FastText, made available by Facebook, Inc, is one of the contributions to prediction-based word embedding models. The usually cited work for this model is from [21] and [22]. The motivation behind the FastText model is because of the shortcoming of word embedding models that disregard the word's morphology and learn a distinct vector for each word.

The improvement is made based on the Skip-Gram model introduced in [23], wherein each word is represented as a bag of character n-grams. Each word is mapped to a set of n-grams, and the skip-gram model is modified to regard each word vector as the sum of its n-grams, which is based on the assumption that similar groups of letters express identical meanings.

Since word vectors are composed of known n-grams, hence can also be computed on unknown words. Consequently, even a word not in the vocabulary is assigned a vector based on its subword units. This unknown term is even more essential for inflected languages, as some inflected forms of words are uncommon and may not even be present in the training set. Training the FastText embedding is faster than the majority of other options due to their simplicity and efficient implementation.

B. Sequence-to-Sequence (seq2seq) Learning Task Model

Seq2seq learning task was initially proposed in machine translation for training models to map the sequence of input between one domain (e.g., German sentences) to output sequences in a different domain (e.g., the same sentence translated to English). Due to its promising result, many researchers investigated and worked by adopting this technique in various tasks such as image captioning, text summarization, and chatbot (question and answering task). The bot generates a natural language response as an output sequence given a natural language question as an input sequence.

The most typical architecture for constructing a seq2seq learning problem is using the encoder-decoder architecture. This architecture in the seq2seq learning task manifested in three parts: encoder, context vector (final hidden/internal state vector), and decoder, as the name implies. The encoder attempts to convey the meaning of the input sentence by encoding it into a fixed-size hidden representation. This hidden representation is converted to output by a decoder. The fundamental structure of this model is based on two RNNs (or can be used as another type of RNNs such as LSTM/GRU for better performance) [6]. Encoding the input into a vector representation employs one RNN as the encoder that captures the context and essential information of the input sequence. On the other hand, the other RNN (as a decoder) will then take this vector as input and use it to generate the output sequence. The basic architecture of the seq2seq model in training mode is illustrated in Fig. 1.

Based on this figure, let $x = \{x_1, x_2, x_3, ..., .x_n\}$ represent the words contained in each input statement or utterance (where n being the statement's length) is mapped in the form of embedded representation (φ^{x^n}) and passed to a variant type of RNN models such as LSTM or GRU. The embedded representation can be either pre-trained embedding such as Word2Vec, Glove, and FastText or jointly trained during model training to convert words into dense vectors, as mentioned

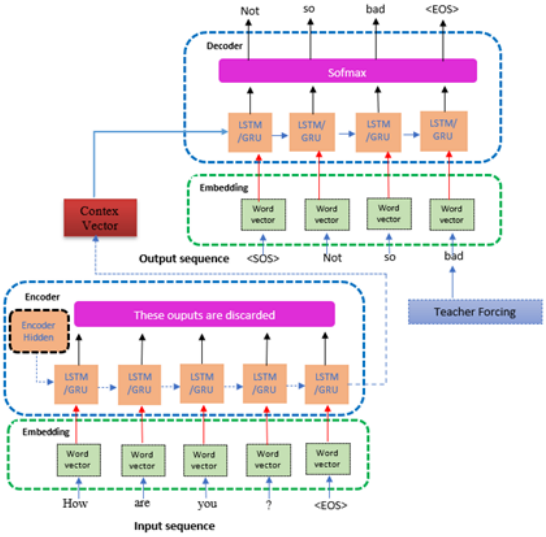

Fig. 1. Basic Encoder-Decoder Architecture While Training.

in the previous section. RNNs also take the first encoder hidden state as the input. RNNs take all these embeddings and sequentially give hidden representation and output vectors at each time step. Hence, it takes a word and a hidden state of the previous state as an input and provides one output and updated hidden state until it reaches the end of the input mark with a unique token known as <EOS>, the outputs at each time step of the encoder part are all discarded since outputs will be summarized by the context vector (C). This context vector contains information about all of the input items that enable the decoder to predict accurately. Equations (1) and (2) illustrate the computation of hidden states and context vectors, respectively;

$$h_m = f_1(\varphi^{x^n}, h_{m-1}) \tag{1}$$

$$c = f_2(\{h_0, h_1, ...h_M\}) \tag{2}$$

where h denotes as the hidden state, c denotes the context vector constructed from the encoder hidden states and f_1, f_2 are nonlinear functions such as LSTM / GRU in this case.

The context vector also acts as the decoder's initial hidden state to pass information from the encoder to the decoder. Before passing to the decoder, this work considers uni-directional or bi-directional encoders, wherein bidirectional encoder; there will be one forward RNN and one reverse RNN. The processing of an input sequence occurs in both directions (forward and backward). The forward and backward hidden states are then combined before being transmitted to the decoder.

In the decoding phase, at the first timestep, the <SOS> token is given as input to RNNs along with the context vector. <SOS> marks the beginning of decoding, and it generates the first word of the chatbot response by looking at the context vector. This decoding first generated output of RNNs probably *"Not"*. For the next timestep, the *"Not"* will be given as the input along with the previous timestep hidden state. This step will provide an output as *"so"*. This output generation will continue until it reaches a unique token known as <EOS> is encountered. Considering the context vector as c, and all previously predicted output as $\{y_1, y_2, y_3, ...y_{t-1}\}$, the decoder has been trained to anticipate the following token y_t. This prediction is the maximum likelihood estimation of y_t. The prediction is given y, the output vector, and c, the context vector. Thus, the $p(y)$ is computed as in Equation (3):

$$p(y) = \prod_{t=1}^{T} p(y_t|y_1, y_2, y_3, ...y_{t-1}, x_t) \tag{3}$$

and produces a token with a conditional probability for each timestep t through the following Equation (4):

$$p(y_t|y_1, y_2, y_3, ...y_{t-1}, x_t) = g(y_{t-1}, s_t, c_t) \tag{4}$$

where $g(.)$ is a softmax function and s_t is the decoder's hidden state at the timestep t which can be computed as in the Equation (5) as follows:

$$s_t = f(s_{t-1}, y_{t-1}, c_t) \tag{5}$$

1) Long Short Term Memory (LSTM): LSTM was developed as a short-term memory solution and initially proposed in [7]. LSTMs are a type of RNN that uses specific hidden states to manage long-term dependencies better while memorizing inputs over time [7]. The difference from standard RNN is how the hidden state is calculated within LSTM cells. LSTMs architecture has an internal cell state that acts as a transport highway that can carry and filter the information in a sequence by adding or removing it. The adding and removing information state is controlled by a structure known as gates.

Gates have sigmoid activations identical to the tanh activation, whereas rather than squishing values from -1 to 1, it squishes values from 0 to 1. This value is significant when updating or removing the data as every value multiplied by 0 is 0, allowing the values to be vanished or be 'forgotten'. On the other hand, every value multiplied by one will result in the same value, remaining unchanged or 'preserved'. Subsequently, the network learns which information is irrelevant and may be removed and which information should be retained with this activation function. Three more gates are generally added in contrast to standard RNNs cells, namely, forget, input, and output gates, as shown in Fig. 2.

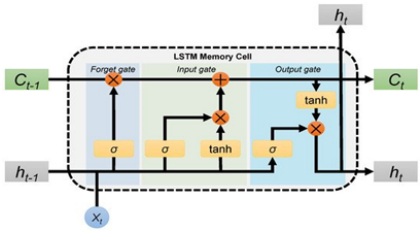

Fig. 2. The Long Short-Term Memory Introduced in [7].

2) Gated Recurrent Units (GRU): GRUs is a more recent generation of RNN cells compared to an LSTM introduced in [8]. The author has introduced two gates: the update gate and the reset gate, as depicted in Fig. 3. The update gate combines the forget and input gates in GRUs and operates similarly to LSTMs, controlling what information to discard and add. On the other hand, the reset gate is a different gate used to

specify the amount of prior information that can be discarded. In GRUs, it also merges the hidden state and cell state, and thus, the output gate is no longer needed. Therefore, this model is simpler while gaining more popularity than regular LSTM, with fewer parameters and faster training than LSTM [8].

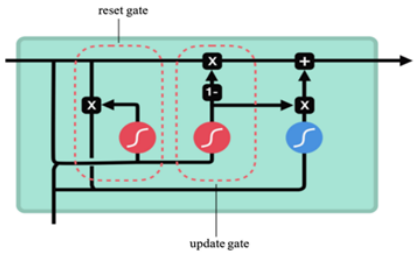

Fig. 3. Types of Gates in GRU Cell Introduced in [8].

3) Bi-Directional RNNs Cell: The previous section discusses the implementation of uni-directional RNNs, which means it runs in a single direction. This research attempts to employ bidirectional RNNs (both for LSTM and GRU) to improve model performance by incorporating past and future context information. This bidirectional means each layer has two RNNs: one running in the forward direction of the sequence (from left to right) and another running in the backward direction (from right to left) to capture dependencies in two contexts [24]. The resulting forward and backward outputs are concatenated before being passed on to the next layer, as shown in Fig. 4. The encoded representation of each word now has the information of the reverse and the future words of the particular word to predict output better.

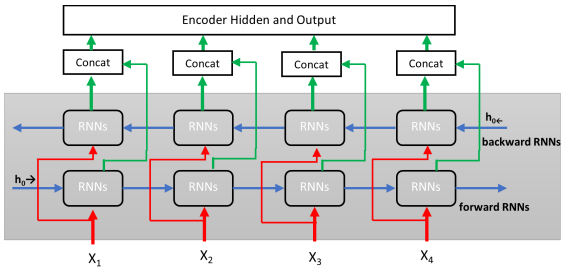

Fig. 4. The Bi-Long Short-Term Memory (biLSTM) Process Captures Sequential Features. The Last Hidden Layer of the LSTM is Extracted as Features Representing the Text.

4) Neural Attention Mechanism: The previous section describes the seq2seq model based on RNNs. These RNN structures utilize the temporal dynamics of the input data to generate sequential output data. However, the output created at a particular timestep and the input sequence used to obtain that result may or may not be relevant remains uncertain. Moreover, in the seq2seq model using RNNs, all the intermediate states of the encoder output will be discarded, and only its final states (context vector) will be used to initialize the decoder. This technique incorporates well with short or medium sequences; however, as the lengths of the sequence grow, a single vector becomes congested and more challenging to analyze long sequences into a single vector.

Meanwhile, RNNs sequentially process tokens while preserving a state vector representing the data observed after each token. The information from the inputs can be arbitrarily propagated in the sequence through the continuous encoding of the data. Due to the vanishing gradient problem, the model's state towards the end of a long sentence typically does not have information about earlier tokens. As a result, the process does not perform as expected. Long sequences benefit from LSTM, reducing disappearing and exploding gradient effects, albeit not entirely eliminated. Furthermore, RNN architectures may be unable to handle increasingly complex feature representations in order to produce reliable outputs.

The aforementioned issue was resolved with the introduction of attention mechanisms introduced in [11] and [12]. Attention processes enable a model to directly examine the condition of an earlier point in the sentence and derive conclusions from it. The attention layer has access to all previous states. It can weigh them according to some learned measure of relevance to the present token, allowing it to provide more precise information on distant relevant tokens, as illustrated in Fig. 5. It decides which source elements are the most important at each decoder step. The encoder does not need to condense the whole source into a single vector in this case; instead, it provides token representations for all of the source data (for example, all RNN states instead of the last one). In addition, the key concept behind attention is not to throw away these intermediate encoder states but to make use of all the states to create the context vectors that the decoder uses to produce the output sequence through attention weight. The attention weight is computed to decide which part of the input was relevant and subsequently determine the output.

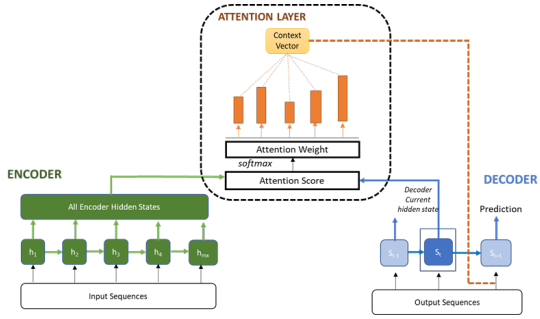

Fig. 5. Attention-Based E2D.

In the attention process, the relevance of each word in the input sequence will be determined for each output cell. For each y_t in the output y, it is influenced by the context vector c_t (source context for decoder step t) are used in an information filter for all hidden states $h = \{h_1, h_2, h_3, ..., h_{m_x}\}$ of the encoder, which can be computed as in the following Equations (6), (7) and (8):

$$c_t = \sum_{i=1}^{m_x} \alpha_{t_i} h_i \tag{6}$$

Where α_{t_i} is calculated by

$$\alpha_{t_i} = \frac{exp(e_{ti})}{\sum_{j=i}^{m_x} exp(e_{tj})} \tag{7}$$

Where $e_{ti} = align(s_{t-1}, h_i)$ refers to the additive score function that considers

$$e_{ti} = V_a^T tanh(W_a s_{t-1} + U_a h_i) \quad (8)$$

Where α_{t_i} indicates the attention weights that the model has learned, W_a ,U_a and V_a, implies another weight parameter for the model to learn. The align is an alignment model for evaluating the relationship between the input of position i and the output of the position t.

IV. Methodological Approach

This section gives an overview of the current research methodological approach to previously discussed implemented models. Fig. 6 depicts the methodology steps involved in this work as follows:

- *Dataset Preparation* – The dataset is collected using publicly available datasets from free online websites which we examine the data and explore the dataset using some fundamental Exploratory Data Analysis (EDA).
- *Data Prepossessing* – Load the text, perform pre-processing or data cleaning, and do a train-test split. In this phase, we build questions-answer pair. Append <START> and <END> to all the answers. Create a Tokenizer and load the whole vocabulary into it with the help of embedding techniques for feature extraction.
- *Modeling* – Define the model. We implement an encoder-decoder architecture-based seq2seq learning task model with and without attention to a different variant of RNN cells
- *Training and tuning* – The model will be trained and tuned with the help of various hyperparameter optimization and regularization techniques to overcome overfitting during training. We aim to minimize the objective function during training by reducing the loss.
- *Results* – The trained model will be evaluated using a valid/test set through BLUE score and validation loss during training based on predicting answers.

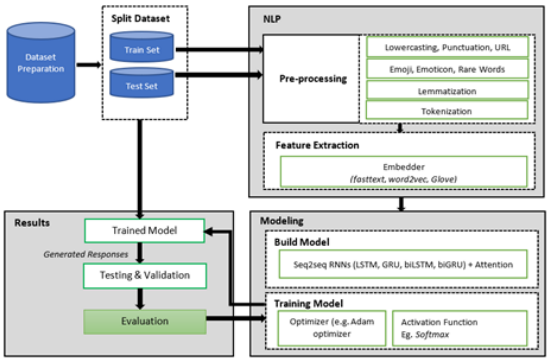

Fig. 6. Illustrates the Methodology Steps.

V. Experimental Study

This section presents different experiments conducted to study the functionality of various models employed (as mentioned in the previous section) and thoroughly examine their performance. The experimental results are compared based on the effect of several variables such as the encoder types, adding an attention layer, variant of embedding, the number of hidden sizes, and batch sizes. The dataset used in the experiment, experiment settings, evaluation methods, and qualitative analysis of experimental results are described in the following subsections. before

A. Datasets

The experiment trains and evaluates the models using the *"Customer Support on a Twitter (CST)"* dataset from Kaggle[1]. The CST dataset was collected in 2017 with a huge, innovative corpus of tweets and replies for the advancement of NLU and conversational models, along with research into modern customer service techniques and impact. It consists of 2,811,774 tweets and replies, with 1,537,843 (54.69%) tweets generated from consumers and 1,273,931 (45.31%) generated from customer supports agent. Among these 1.5 million customer tweets, about 1.27 million received replies from customer support agents, and 0.23 million otherwise. One of the main reasons to use this dataset is that it contains real-life conversations between customers and customer support agents with natural responses from support agents for accurately explaining problems and solutions. Moreover, it is practical since it permits a relatively small message size restriction for recurrent networks.

While conducting an exploratory analysis of the dataset, it can be observed that there are 108 customer support brands represented in the dataset, and 597075 consumers' requests are answered. The top 20 customer support replies related to the company brand are depicted in Fig. 7.

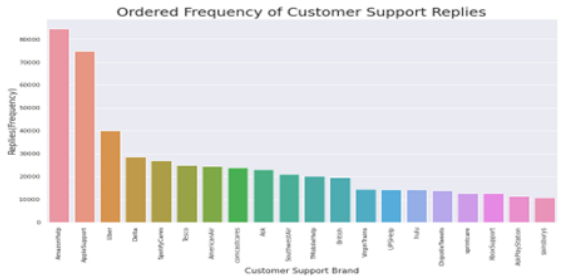

Fig. 7. The Top 20 Customer Service Replies by Brand.

In addition to this observation, it was identified that Amazon's customer service responded to a large number of inquiries, followed by Apple and Uber. There are a lot of companies in the dataset that have minimal responses or had no responses at all.

As shown in Table I, the information in the dataset must be restructured to create a conversational dataset between consumer and customer support agents suited for the current

[1]https://www.kaggle.com/datasets/thoughtvector/customer-support-on-twitter

TABLE I. DATASET FEATURES DESCRIPTION

Features	Description	Datatypes
tweet_id	The unique ID for this tweet	Int64
author_id	The unique ID for this tweet author (anonymized for non-company users).	Object
Inbound	Whether or not the tweet was sent (inbound) to a company on Twitter. This feature is useful when re-organizing data for training conversational models.	Bool
created_at	Date and time when the tweet was sent.	Object
Text	The text content of the tweet.	Object
response_tweet_id	IDs of tweets that are responses to this tweet.	Object
in_response_to_tweet_id	IDs of the tweet is in response to, if any.	Float64

study. In the restructuring process, the dataset features must be filtered by selecting only inbound tweets that are not retweeted. Then, apply the *"in_response_to_tweet_id"* and *"tweet_id"* features to associate each tweet with the relevant reply based on the inbound feature, excluding instances where response tweets are not from a company. As the data is still in unstructured text data, additional preprocessing is required to eliminate unnecessary features such as emoji and emoticons, lower casting, non-English tweets, etc. The new dataset has 794,299 rows and six columns consisting of *'author_id_x'*, *'created_at_x'*, *'text_x*, *author_id_y'*, *'created_at_y'*, and *'text_y'*, where *x* and *y* are represented as a question from consumers and answered by customer service agent respectively.

Training and validation are conducted independently on 75% and 35% of the entire dataset. The model is termed accurate if the predicted response matches the ground-truth answer. This current research incorporates the Bilingual Evaluation Understudy (BLEU) score function to evaluate the performance models.

B. Experimental Settings

The study compares the attention-based approach to related baseline models that do not employ attention mechanisms to evaluate how well the models work. These models are implemented in a python-dependent package on a deep neural network framework called TensorFlow [25] and Keras[2]. We trained models on a GPU with 3082 CUDA cores and a VRAM of 12GB. The model is trained for 500 epochs (a high value is set since the study employs the early stopping technique) and tested on a batch size of 64, 128, 256, and 304 (the number can be divisible by 8). While the hidden size of LSTM and GRU is tested on 100, 200, and 300 units. For the optimization, the study uses the Adam optimizer with a learning rate of 0.003 [26]. A gradient clipping of 50.0 is implemented to combat the 'exploding gradient' problem, preventing the gradients from expanding exponentially and causing the cost function to either overflow (with undefined values) or overshoot cliffs. All the weights and biases are initialized using Xavier and glorot uniform distribution [27].

This study uses 300-dimensional pre-trained word embeddings for Fasttext[3], GloVe[4], and Word2Vec[5]. An early stopping technique with patience four is adopted to combat overfitting. Table II shows the hyperparameters and their corresponding ranges for training the models. It also presented the best-performing hyperparameter for each of the models.

TABLE II. HYPERPARAMETER SETTING

Parameter	Range	Final Setting
Max input Length	39	39
Word embedding	FastText/Glove/Word2vec	FastText/Glove
Embedding size	300	300
Encoder types	Unidirectional/Bidirectional	Bidirectional
Learning Rate	0.003	0.003

C. Performance Evaluation Metrics

Following [13] and [15], this current study adopts BLEU as suggested in [28] best to evaluate the performance of our model. According to the definition provided in [28], BLEU evaluates the co-occurrences of n-grams in the reference human translation and recommended answers. It computes the n-gram precision for the entire dataset, compounded by a brevity penalty to penalize brief translations. The more closely a machine translation resembles a professional human translation, the better.

The BLEU score compares the chatbot-generated output text (hypothesis) to a human-generated response text (reference). It specifies how many n-grams from the output text are included in the reference. The BLUE score can take on any value within the interval [0, 1] and is technically defined as Equation (9).

$$BLEU = BP \times \left[\prod_{n=1}^{N} precision_n\right]^{1/N} \tag{9}$$

Where N is the maximum n-gram number $n = [1, N]$ (N=4 in our evaluations). BP (brevity penalty) and $precision_n$ are defined with Equation (10) and (11), respectively.

$$BP = min(1, exp(1 - \frac{ref_{lenght}}{out_{lenght}})) \tag{10}$$

Where ref_{lenght} is reference length, and out_{lenght} is the chatbot output length

$$precision_n = \frac{\sum_n min(m^n_{out}, m^n_{ref})}{\sum_{n'} m^{n'}_{out}} \tag{11}$$

Where m^n_{out} is the number of n-grams matching the reference in the chatbot output, m^n_{ref} denote as the number of n-grams in the reference, and $\sum_{n'} m^{n'}_{out}$ implies the total number of n-grams in the output of the chatbot.

The BLEU scores were computed using the blue score module from the translated package on the nltk[5] platform, which was built in Python.

D. Results and Comparison

This section elaborates on the experimental results from our model on the mentioned dataset. The experiment assessed the performance of the different models based on encoder types and various types of embedding with varying parameters by comparing models to baseline RNNs such as LSTM and GRU. After multiple experiments, the study concluded the result of the promising hyperparameter and settings as presented in Table II. One of the models uses a pre-trained 300-dimensional word embedding as a hidden size tested on varying numbers of 100, 200 300, where the hidden size of 300 gives a promising result of a pre-trained 300-dimensional word embedding.

The experimental results on all the models indicated that the bidirectional encoder type attention-based models achieved promising performance and outperformed the neural networks that do not use an attention mechanism as a baseline. The different hyperparameters are used to test each model, and the promising performing hyperparameters for each model are shown in Table II. The impact of some of these hyperparameters will be highlighted, and an example of generated response based on several models is presented in the following subsections.

1) Effect of Encoder Type in E2D Architecture: This section evaluates the performance of the two distinct encoder types used in these models. In comparison to a uni-directional encoder, the model performance with bi-directional encoder types yields promising results, as shown in Fig. 8. This situation might happen because the bi-directional encoder works by preserving the information from both sentence directions, allowing the network to predict the next word better as it can understand the sentence context more. Thus, the bi-directional encoder is promising to be used for further analysis in this study.

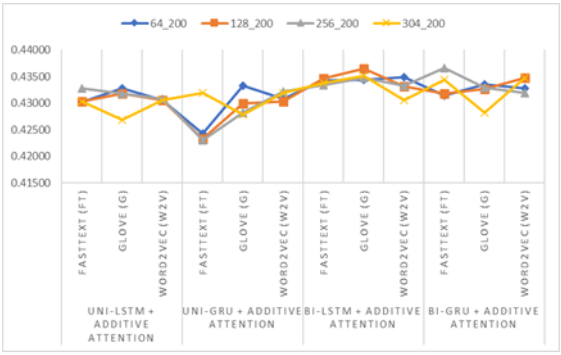

Fig. 8. E2D Network of RNNs with Different Encoder Types and Embeddings.

2) Effect of Attention Layer in E2D Architectures: This section uses hyperparameters from Table II to evaluate the RNNs E2D model with and without attention. As depicted in Fig. 9, the model's performance with attention vastly outperforms the RNNs E2D model without attention on this dataset. Therefore, the attention-based models improve the predictive performance of the Seq2Seq chatbot models. Furthermore, in comparing the performance of the RNNs types, the LSTM gives promising results in almost all models, as shown in Fig. 8. However, the GRU model can be an option if computational time is considered since GRU trains faster than LSTM, and the result for this dataset is not much different than LSTM.

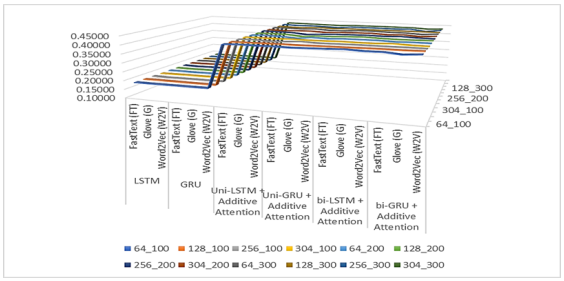

Fig. 9. Encoder-Decoder Network Model with and without Attention.

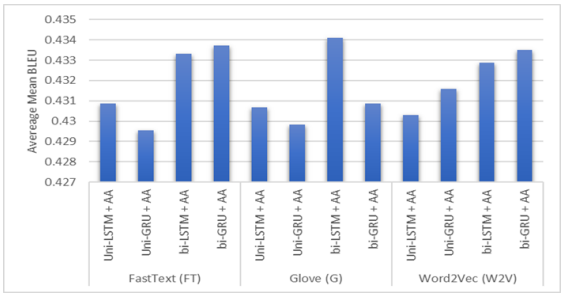

Fig. 10. Different Embedding Types in Encoder-Decoder Architecture.

3) Effect of Different Embedding Types in Encoder-Decoder Architectures: The performance of the RNNs models with varying types of embedding (FastText, Glove, and Word2Vec) is analyzed by finding the BLEU score among different variants of the models. As shown in Fig. 10, FastText and Glove embedding types give better performance for this type of chatbot dataset. Moreover, these embedding types perform better when integrating with a bi-directional encoder with LSTM (for Glove embedding) or GRU (for FastText).

4) Effect of Hidden Sizes in E2D Architectures: The performance of RNNs encoder-decoder models with different hidden sizes/units is evaluated in this section. The hidden size parameter is tested on 100, 200, and 300 units with a fixed embedding size of 300, as in Table II. Most models produce better results for 200 or 300 units, where 42% of each out of total models occur, as presented in Table III. Since a fixed embedding size of 300 is used, the good hidden size is preferable to be an equal size with the embedding size as indicated in this experiment result for this dataset.

5) Effect of Batch Sizes in E2D Architectures: The different batch sizes evidenced in this experiment were $B = [64, 128, 256, 304]$ with hyperparameter setting as in Table II. As illustrated in Fig. 10, the smaller batch size of 64 produces better results amongst models. Furthermore, the batch size of 64 with 300 hidden sizes produced more promising results in this experiment dataset, indicating best used for further analysis in this research. The smaller batch sizes correlate to stability during the training and are better for accuracy. On the other hand, the larger batch size is better for computational speed. Nevertheless, batch size should be adequate so that the data would fit into memory. Due to the limitation of memory

space, the experiment can be done with a maximum batch size of 304.

VI. Qualitative Analysis

To qualitatively comprehend the model's performance gained with a different experiment configuration, as shown in Table II, the study prepares the outputs responses for a specific customer inquiry. The customer's query may be based on an emotive or informative question. For the informative type customer query instances, *"When is delta is last scheduled flight?"*, predicted responses are given in Table III. On the other hand, Table IV shows an example of an emotional types question.

As observed, most RNNs models' response prediction can provide general and reasonable answers for customer queries. However, both types of questions can predict better responses by implementing bi-directional RNNs based on the actual or target response. Based on the emotional type query, the bidirectional with attention models can predict the specific word, the *"account"*, rather than *"details"* (a general response but acceptable) as referred to in the actual reaction. Moreover, the models are more emotional in responding to customer queries than humans for both types of questions. Conversely, the informative queries and asking for particular information requests are difficult to formulate, and the resulting responses are less pertinent to the question. However, by looking at the answers of various models, it was discovered that bidirectional LSTM with attention generates better logical statements, and the response appears to be indistinguishable from the actual one.

TABLE III. Example of Generated Response for Informative Type Question (64_300 FastText)

Customer Questions	When is delta is last scheduled flight?
Seq2seq E2D LSTM	hi there i am sorry to hear that you are having a problem with the app please do your confirmation number i will be happy to help tab
Seq2seq E2D GRU	i am sorry to hear that you are having trouble with your flight please do your confirmation number so i can take a look at your flight tow
Seq2seq E2D LSTM Unidirectional + Attention	hi there we are not showing any announcements on this flight if you have any other questions please let us know by
Seq2seq E2D GRU Unidirectional + Attention	i am sorry for the delay in your flight i am showing that you are not able to get a gate to clear your flight tow
Seq2seq E2D LSTM bidirectional + Attention	i am sorry to hear that you are not able to get through to us please do me your confirmation number and i will gladly look into it for you ¡end¿
Seq2seq E2D GRU bidirectional + Attention	hi there we are not sure what you mean we are here to help please do us your confirmation number so we can follow up ¡end¿
Actual	**certainly as soon as we get a response from the appropriate team that has the info we will be sure to tweet you**

VII. Conclusion and Future Work

As a conclusion, we attempt to construct a generative service chatbot to automatically respond to customers' queries for assisting companies in having a 24-hour support system. To construct this system, seq2seq learning task models based on encoder-decoder architectures (with and without attention as the baseline) are deployed. This study further investigates these models through different RNNs structures (LSTM and GRU), encoder types (uni-directional and bidirectional), and different embedding types (FastText, Glove, and Word2Vec) and tested with varying parameters of training.

TABLE IV. Example of Generated Response for Emotional Type Question (64_300 FastText)

Customer Questions	you have lied gave me the run around have the worst customer service ever so disappointed i cant work without internet
Seq2seq E2D LSTM	i am sorry to hear that you are having trouble with your internet service i would be happy to help please do me the details of your issue
Seq2seq E2D GRU	i am sorry to hear that you are having trouble with your internet service i would be happy to help please do me the details of your issue
Seq2seq E2D LSTM Unidirectional + Attention	i apologize for the issues you are having with the services have your concerns been addressed if not i will be
Seq2seq E2D GRU Unidirectional + Attention	i am sorry for the poor experience can you please do pm the full service address and name on the account as we
Seq2seq E2D LSTM bidirectional + Attention	i am sorry to hear about the poor experience can you please do the full service address and name on the account as we assist
Seq2seq E2D GRU bidirectional + Attention	i am sorry to hear that you are having issues with your internet services please do your account details to help
Actual	**it is unfortunate you are having trouble to better assist please do me the account number thank you ami**

Based on the experimental results, the bi-directional RNNs (LSTM and GRU) attention mechanisms produced promising results for further work in a chatbot. Moreover, there are not many effects typed of embedding as well as batch size and hidden sizes for this dataset since the result is not significantly different. However, the stability of the result is obtained from batch size 64, with 300 hidden sizes (as the same value with embedding size) combining with FastText or Glove can be opted for further work. Additionally, based on the findings for this dataset, it is proven that while biLSTM performs better with Glove, biGRU operates better with FastText. Overall, adding an attention layer improved the BLEU score compared to the baseline models.

The significant of findings from this research work is that the proposed attention mechanism has demonstrated its ability to meet the aforementioned requirements. Therefore, this proposed work provides an extension of the existing technique in developing chatbots. The attempt is made through end-to-end approaches by using seq2seq learning task model adoption from neural machine translation. A potential direction for future research can be explored and examine the variant of attention mechanism based on different scoring functions in comparing to the current experimental results and findings. In addition, the experiment also can be investigated in other deep learning architectures such as generative adversarial neural network and training parameters, including varying learning rates, dropout rates, optimizer, and activation functions.

Acknowledgments

This research is partly funded by Ministry of Higher Education Malaysia under grant R.J130000.7851.4L942. The authors would also like to thank the Universiti Malaysia Sarawak (UNIMAS) and Universiti Teknologi Malaysia (UTM) for providing the resources used in this research work.

***Abstract*—Automatic caption generation from images has become an active research topic in the field of Computer Vision (CV) and Natural Language Processing (NLP). Machine generated image caption plays a vital role for the visually impaired people by converting the caption to speech to have a better understanding of their surrounding. Though significant amount of research has been conducted for automatic caption generation in other languages, far too little effort has been devoted to Bangla image caption generation. In this paper, we propose an encoder-decoder based model which takes an image as input and generates the corresponding Bangla caption as output. The encoder network consists of a pretrained image feature extractor called ResNet-50, while the decoder network consists of Bidirectional LSTMs for caption generation. The model has been trained and evaluated using a Bangla image captioning dataset named BanglaLekhaImageCaptions. The proposed model achieved a training accuracy of 91% and BLEU-1, BLEU-2, BLEU-3, BLEU-4 scores of 0.81, 0.67, 0.57, and 0.51 respectively. Moreover, a comparative study for different pretrained feature extractors such as VGG-16 and Xception is presented. Finally, the proposed model has been deployed on an embedded device for analysing the inference time and power consumption.**

***Keywords*—Bangla image caption generation; encoder-decoder; bidirectional long short term memory (LSTM); bangla natural language processing (NLP)**

I. Introduction

A picture is equivalent to million of stories. It is simple for people to narrate these stories, but challenging for machines to illustrate them. In the domain of intuitive systems, machine generated image captioning is an amalgamation of computer vision and NLP. Semantically and syntactically correct image caption generation is challenging for the machine compared to human beings. However, automatic caption generation from image content has a significant number of real life applications from the field of human machine interaction (HCI) to robotics.

According to World Health Organization (WHO), almost 2.2 billion people in the world have a near or distance vision impairment[1]. Automatic image caption generation plays a significant role for visually impaired people by converting the caption to speech to have a better understanding of their surroundings.

Automatic speech generation for the humanoid robot is a challenging task which involves generating caption by understanding the robot vision. Therefore, automatic image caption generation has considerable impact in the field of robotics. Content creation for social media platforms has become a professional sector which has created a large job sector for the young generation. However, content needs proper captioning before publishing in social media platforms. Therefore, providing automatic suggestions for image captioning is handy for content creators on social media platforms.

In recent years, image caption generation has become a relatively active field of research and therefore a significant number of research has been found in literature where most of the researchers focus on image caption generation in the English language [1], [2].

Though Bangla is the seventh largest language in the world with 215 million speakers globally[2], far too little effort has been devoted to Bangla image caption generation. Researchers have not addressed automatic image captioning in Bangla for a long period of time due to a lack of an enriched dataset. After development of required dataset, several researches have been conducted on Bangla caption generation from visual image [3], [4], [5], [6], [7].

However, the performance metrics given in the previous related work show that the quality of the generated Bangla image caption is not quite satisfactory. Therefore, there is a clear scope for further improvements in automatic Bangla image captioning. Moreover, we did not find any attempt to deploy the model on an embedded device.

[1] shorturl.at/hRWZ6
[2] $https://www.vistawide.com/languages/top_30_languages.htm$

The objective of this research work is to develop a image captioning model that can automatically generate Bangla caption with better performance compared to the models found in the previous related works. In addition to proposing an end-to-end system, the trained captioning model is deployed within an embedded device in order to evaluate the efficiency of the model.

We designed a model architecture using a deep learning based encoder-decoder model which takes an image as input and generates the corresponding Bangla caption as output. The encoder network consists of a pretrained image feature extractor while Bidirectional LSTMs are used in the decoder network for caption generation. We explore different pretrained image feature extractors such as VGG-16, Xception, and ResNet-50 for the encoder network. The model is trained and evaluated using a Bangla image captioning dataset named BanglaLekhaImageCaptions. We have achieved the best training results for the encoder-decoder model with the ResNet-50 pretrained feature extractor. The final training accuracy during convergence is 91% and the BLEU-1, BLEU-2, BLEU-3, and BLEU-4 scores are 0.81, 0.67, 0.57, and 0.51, respectively, which is the state of the art result for automatic Bangla image captioning.

The major contributions of this paper are:

- Trained and validated the state of the art model for automatic Bangla image caption generation using an encoder-decoder based model architecture.
- Explored different pretrained image feature extractors such as VGG-16, Xception, and ResNet-50 for the encoder network and found the model with ResNet-50 provides the best BLEU score for Bangla image captioning.
- Finally, Deployed the proposed model on an embedded device for analysing the key performance metrics such as the inference time and power consumption.

The remaining sections of the paper are organized as follows: The literature review covered in the Section II. The Section III presents an overview of the dataset. Section IV provides a comprehensive breakdown of the proposed system. In Section V, all the experimental details during training and validation of our model are stated. In Section VI, findings and comparisons of this research is provided. The conclusion is located in the Section VII. The remainder consists of references.

II. Literature Review

In this section, we illustrate the evolution of research in the field of automatic caption generation for images. Moreover, the recent development of Bangla image captioning in literature is presented.

After conducting a rigorous literature review, we have found that there are two types of techniques based on traditional machine learning and deep learning to generate automatic image captioning [8], [9].

Early research on automatic image captioning utilises traditional machine learning techniques such as similar image retrieval based captioning [10] and template matching based image captioning [11]. However, the generated captions are limited by a predefined corpus with images or templates and their corresponding captions as labels. Therefore, traditional machine learning techniques fail to generate relevant image captions if the input image has significant differences from the predefined corpus.

The recent impressive progress in the fields of computer vision and NLP has paved the way to deploying deep learning techniques to generate image captions automatically. Image captioning involves vision encoding for a high-level understanding of image features and language decoding for caption generation using the features generated from vision encoding. The encoder-decoder based deep learning model is the most effective technique to address vision encoding and language decoding. In literature, vision encoder is designed using stacked Convolutional Neutral Network (CNN) [1], and graph-based network [2]. Moreover, various pre-trained feature extractors such as VGG-16, InceptionResnetV2, and Xception have been deployed for vision encoding [3], [12] The language decoder is implemented using variations of Recurrent Neural Networks (RNNs) such as LSTMs and GRUs [2]. In addition, self attention based transformer models are utilised to design the language decoder [13].

A considerable amount of effort has been devoted to developing automatic image captioning techniques in languages such as English [1], Chinese [14], Japanese [15], Arabic [16], Hindi [17] and German [18] where large datasets related to image captioning are already available.

Due to a lack of an enriched dataset, researchers have not addressed automatic image captioning in Bangla for a long period of time. However, after the development of the required dataset, Bangla image captioning has become an active research area among researchers. Table I presents an overview of related literature on Bangla image captioning with information on model architecture designed, dataset used during training and evaluation, and BLEU score as evaluation metrics to measure the quality of the generated caption by the model.

Rahman et al. [12] has developed the first Bangla image captioning dataset named BanglaLekhaImageCaptions. They have trained and evaluated an encoder-docoder model using their own dataset, where the encoder network utilises a pre-trained feature extractor called VGG-16, and the decoder network is designed using stacked LSTMs network. However, they have not calculated the BLEU score on their whole test dataset and have only reported the BLEU score for a few sample test images during evaluation, where the BLEU score is unsatisfactory.

Kamal et al. [6] have proposed a similar encoder-decoder model mentioned in [12] for Bangla image captioning where the encoder network consists of a VGG-16 pre-trained model and the decoder network consists of LSTMs network. Moreover, they have utilised the same BanglaLekhaImageCaptions dataset for training the model. However, they have evaluated the model by calculating the BLEU score for the test dataset, which was missing in [12]. The achieved BLEU-1 score for the model is 0.67 on the test dataset.

Jishan et al. [4] have proposed a hybrid encoder-decoder

TABLE I. AN OVERVIEW OF RECENT RESEARCH WORKS ON BANGLA IMAGE CAPTION GENERATION

Research	Year	Dataset	Modeling techniques	Performance
Humaira et al. [3]	2021	BanglaLekhaImageCaption	InceptionResnetV2 or Xception + BiLSTM or BiGRU	BLEU-1: 0.674, BLEU-2: 0.53, BLEU-3: 0.45, BLEU-4: 0.344
Khan et al. [5]	2021	BanglaLekhaImageCaption	1D CNN+ResNet-50	BLEU-1: 0.65, BLEU-2: 0.45, BLEU-3: 0.28, BLEU-4: 0.175
Palash et al. [7]	2021	BanglaLekhaImageCaption	ResNet-101+Attention mechanism+decoder	BLEU-1: 0.69, BLEU-2: 0.63, BLEU-3: 0.58
Kamal et al. [6]	2020	BanglaLekhaImageCaption	VGG-16+LSTM	BLEU-1: 0.67, BLEU-2: 0.44, BLEU-3: 0.32, BLEU-4: 0.24
Jishan et al. [4]	2020	BNLIT	CNN+BiLSTM	BLEU-1: 0.65, BLEU-2: 0.47, BLEU-3: 0.33, BLEU-4: 0.23

based model where they suggested a custom CNN architecture responsible for extracting image features and utilising Bidirectional Long Short Term Memory (BiLSTM) as a decoder for caption generation. They have trained and evaluated their model using their own dataset called Bangla natural language image to text (BNLIT). They have achieved a BLEU-1 score of 0.65 after evaluating their model on the test dataset.

Khan et al. [5] have suggested an end-to-end image captioning system where ResNet-50 is for image feature extraction and one dimensional CNN for generating captions, and they used BanglaLekhaImageCaption dataset to train and test their model. Their proposed system achieved a BLEU-1 score of 0.65.

Humaira et al.[3] have presented a performance evaluation of Bangla captioning systems using pre-trained models such as InceptionResnetV2, Xception as encoders and BiLSTM or BiGRU as decoders while using the BanglaLekhaImageCaptions dataset. They have achieved a maximum BLEU-1 score of 0.674 after evaluating their model.

Palash et al. [7] have provided a novel transformer-based architecture that automatically generates Bangla captions from an input image. They have proposed a new transformer architecture with an attention mechanism as a decoder and employed ResNet-101 as an encoder. They have trained and evaluated the model using the BanglaLekhaImageCaptions dataset and achieved a BLEU-1 score of 0.69.

From the previous related works, it is evident that there is a clear scope for further improvement in BLEU score of the Bangla image captioning model. In addition, we did not find any attempt to deploy the model on an embedded device.

In this research work, an encoder-decoder network for Bangla image caption generation and explore different pre-trained image feature extractors for the encoder network is proposed. Finally, we deploy the Bangla image captioning model with the best BLEU score onto an embedded device.

III. DATASET

In the research work, the BanglaLekhaImageCaptions dataset proposed by Rahman et al. [12] is utilized. The downloadable dataset is available online in Mendeley Data[3]. This dataset includes photos with Bengali annotations.

All of its captions are annotated by native Bengali people. There are only two captions tagged with each image in this dataset, yielding a total of 18308 descriptions for the 9154 images. BanglaLekha has 5270 distinct Bengali words. All popular picture captioning datasets are primarily influenced by western culture, with the majority of annotations performed in English. Using such datasets to train an image captioning system for Bangla is not effective. Thus, requiring the necessity for a culturally significant dataset in Bengali to generate acceptable image captions from images related to Bangladeshi and greater sub-continental culture. From the dataset, 80% data is used to train the model, and after training, the remaining 20% is used to evaluate and validate the model.

[3]https://data.mendeley.com/datasets/rxxch9vw59/2

IV. PROPOSED SYSTEM

In this section, you present the proposed model architecture for Bangla image captioning.

We have designed an encoder-decoder based model architecture. Fig. 1 shows a high level overview of the model architecture. As we are working with both image data as input and text data as output, extraction features from image and application of word embedding to the text data is required.

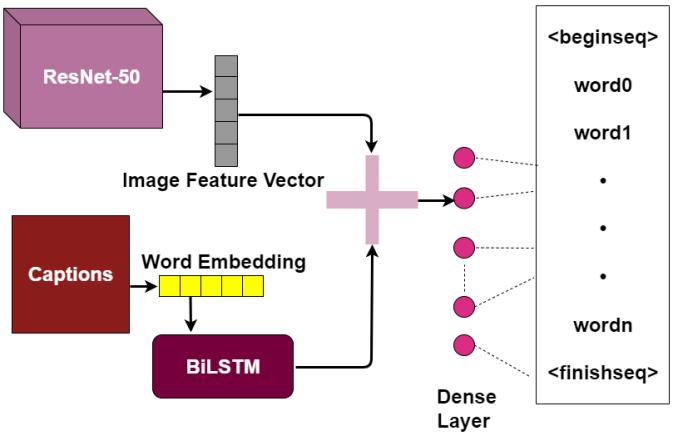

Fig. 1. Overview of Caption Generation Process.

Feature Extraction

A key component of image captioning is the extraction of visual features. We are deploying a pre-trained model called ResNet-50, which has already been trained on millions of images from the ImageNet dataset [19]. As the model is solely utilised for feature extraction, the final two layers have been eliminated, leaving the GlobalAveragePooling layer instead of

a dense layer as the final layer. In contrast to the MaxPooling layer, which generates a 2D matrix, the GlobalAveragePooling layer generates a vector with a dimestion of (None, 2048). The input shape for ResNet-50 is (224,224,3). Therefore, all the photos are reshaped to match this dimension. In the input shape, 3 specifies the number of channels, since the images are in RGB format, the channel number is set to 3.

Word Embedding

Before passing words to RNNs like LSTMs or BiLSTMs, they must be embedded, which turns words into vectors. The embedding layer makes it possible to turn each word into a vector of fixed length and size. The generated vector is dense and contains real values as opposed to merely 0s and 1s. The fixed size of word vectors is the key reason for expressing words with fewer dimensions and in a more efficient manner. In this manner, the embedding layer functions as a lookup table, where the words are the keys and the word vectors are the values. This embedding task is accomplished using the embedding layer of the Tensorflow framework. Using an embedding layer, rather than manually setting values for each word, the embedding values are learned during training. The input and output shapes of this layer are (None, 39) and (None, 39, 128), respectively.

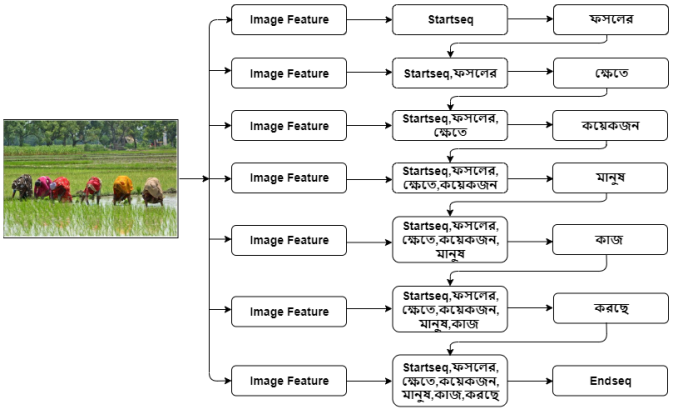

Fig. 2. Example of Word Sequence Generation.

Generation of Word Sequence

Each image in the BanglaLekhaImageCaptions dataset contains only two captions. The maximum and minimum word lengths are 39 and 26, respectively. Although a decrease in word count tends to result in a higher evaluation score [3], the goal of this research work is to develop meaningful, descriptive captions for real-life scenarios, so we use 39 as the fixed word length. During training, zero-padding is employed to increase the length of sentences that are shorter than the fixed maximum length. In addition, a beginseq token and a finishseq token are appended to each pair sequence for identification purposes throughout the training phase. In the training phase, the picture features are extracted from images and the next word in the series is generated using word vectors. Fig. 2 depicts the input-output pair.

In consideration of the limitations of RNNs, LSTMs are a superior option for word generation [20]. However, LSTMs only learn from prior words; for creating syntactically and grammatically accurate sentences, it is also necessary to preserve the knowledge of succeeding words. Therefore, the suggested model uses BiLSTMs, which retains the knowledge learned in both directions, i.e., from both preceding and succeeding words. Fig. 3 depicts the data-flow in BiLSTMs, where P_0,...,P_n are the input words and Q_0,...,Q_n are the outputs of the BiLSTMs which are determined by Eq. 1, where Q_i is output at i^{th} time when activation function h is utilized to weight W_Q and bias B_Q taking into account for forward activation m_i and backward activation n_i at i^{th} time.

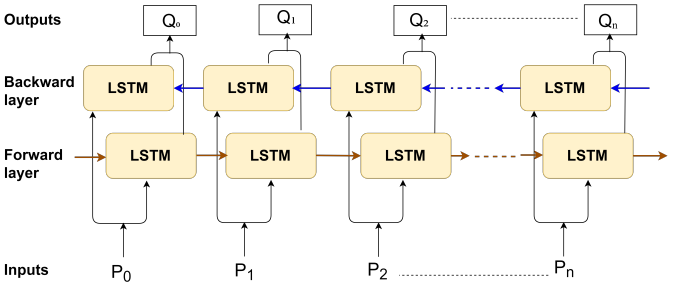

Fig. 3. Illustration of BiLSTMs having P_0,...,P_n as Inputs and Q_0,...,Q_n as Outputs.

$$Q_i = h(W_Q[m_i, n_i] + B_Q) \tag{1}$$

Each LSTM in the BiLSTMs comprises of three gates: input, forget, and output gate. The input gate indicates what incoming information will be stored in the cell state. The forget gate determines what information to discard from the cell state, whereas the output gate provides output at i^{th} time. The corresponding equations for these gates are Eq. 2, Eq. 3, Eq. 4, respectively.

$$j_i = \sigma(W_j[H_{i-1}, P_i] + B_j) \tag{2}$$

$$k_i = \sigma(W_k[H_{i-1}, P_i] + B_k) \tag{3}$$

$$l_i = \sigma(W_l[H_{i-1}, P_i] + B_l) \tag{4}$$

Here, j_i, k_i, l_i is the input, forget and output gate, sigmoid function is represented by σ, W_j, W_k, W_l are the corresponding gate's weights, H_{i-1} is considered to be previous LSTMs block's output at time $i-1$, P_i is the input at i^{th} time and B_j, B_k, B_l are the corresponding gate's bias.

Encoder

The encoder consists of two components, one for managing image feature vectors and the other for managing word sequences. ResNet-50 [21] is used to extract image features originally. These image features are transferred first to a dense layer with 128 units and then to a RepeatVector layer. The RepeatVector layer repeats the inputs for a predetermined number of times. The input to this layer is (None, 128). The RepeatVector's output shape, however, is (39, 128), as

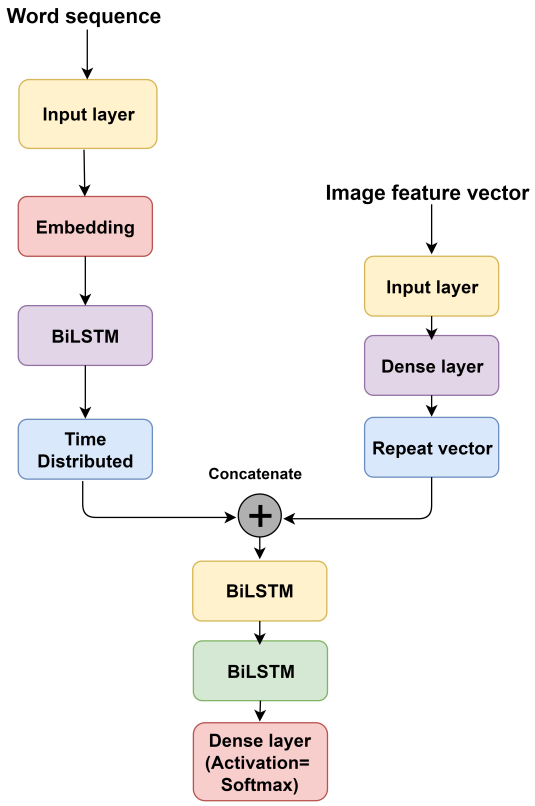

Fig. 4. Encoder-Decoder Model Architecture.

the inputs need to be repeated 39 times to match the output dimension of the other half of the encoder, which handles word vectors. The encoder's word vector processing side includes an embedding layer, a BiLSTM layer with 512 units, and finally a TimeDistributed layer. In contrast with the regular LSTMs, input travels in both directions, and knowledge from each side can be utilised in BiLSTMs. Additionally, it is a potent instrument for modelling the sequential relationships between words and phrases in each direction. In short, BiLSTMs add an additional LSTMs layer that reverses the flow of information, which indicates that the input sequence streams in reverse in the second LSTMs layer. The TimeDistributed layer uses a specified layer (a dense layer with 128 units in the suggested model) for each input vector. Both sides of the encoder have the same output shape, which is (39,128). Their outputs are concatenated and sent to the decoder.

Decoder

The decoder comprises of two BiLSTMs layers and a dense layer. The decoder sends the combined output of the encoder to the first BiLSTMs with 256 units, and the output of the first BiLSTMs is fed to the second BiLSTMs with 512 units. The output of the second BiLSTMs is finally sent to a dense layer with a softmax activation function for word prediction. The model architecture of the encoder-decoder is shown in Fig. 4.

V. Experiments

In this section, a detailed discussion of the experimental details during training and validation of the proposed model architecture for Bangla image captioning is provided.

Experimental Setup

During training of the model, the hardware configuration comprised of a Ryzen 7 3700x CPU, 16GB DDR4 RAM, and Nvidia GTX 1070 8GB graphics card. We implemented our encoder-decoder model using the Tensorflow 2.6 deep learning framework within the Python 3.8 programming language. We deployed the trained Bangla image captioning model onto a Raspberry Pi 4 model B with 8GB RAM.

Parameter Setting

During training, $categorical\_crossentropy$ is used as loss function. Batch size is set to 485. Moreover, $RMSprop$ is selected as the optimizer. $RMSprop$ optimizer selects a distinct learning rate for each parameter during training, which significantly increases model performance. The weights of the model are updated following the Eq. 5 and Eq. 6 during training while using $RMSprop$ optimizer.

$$v_t = \beta_{t-1} + (1-\beta) * {g_t}^2 \tag{5}$$

$$W_{new} = W_{old} - \frac{n}{\sqrt{v_t + \epsilon}} * g_t \tag{6}$$

Here v_t is the average movement speed of gradient, g_t is the cost, β is the moving parameter and in the proposed model its value was 0.99. To calculate the new weights W_{new}, we subtract learning rate (η) times cost g_t which is divided by root over sum of v_t and a constant ϵ of very small value, from the old weights W_{old}.

Performance Metrics

To evaluate the performance of the proposed Bangla image captioning model, we calculate the BLEU score for the generated caption by the trained model. An individualised N-gram BLEU score is the assessment of matching grammes of a particular order, whereas cumulative BLEU scores relate to the computation of single n-gram scores for all orders from 1 to n. Consequently, the cumulative BLEU score is the most reliable metric for evaluating the real-world performance of a sentence generation algorithm. A cumulative BLEU score greater than 70 indicates that the sentence generated by the machine resembles a caption provided by a human. Calculation of cumulative BLEU score is given in Eq. 7, where c refers to length of predicted sentence and r refers to length of the original sentence and p stands for precision.

$$BLEU = min(1 - \frac{r}{c}, 0) + \sum_{n=1}^{4} \frac{logP_n}{4} \tag{7}$$

VI. Result Analysis

In this section, the results found during the training and validation of tge proposed encoder-decoder model for Bangla image is presented. Moreover, we summarise the findings of our research work.

We trained our encoder-decoder model for 90 epochs. Fig. 5 and Fig. 6 exhibits the accuracy curve and the loss curve,

respectively, and it is apparent from both curves that the model converges after 70 epochs. After 70 epochs of training, the proposed model attained an accuracy of 90% and a loss of less than 0.2.

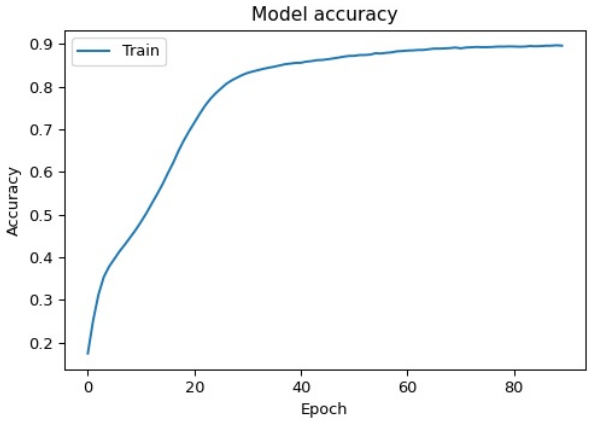

Fig. 5. Accuracy vs Epoch Curve.

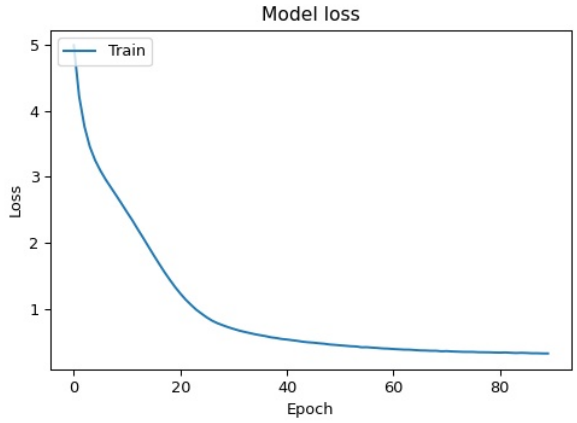

Fig. 6. Loss vs Epoch Curve.

We have implemented three popular pre-trained feature extractors namely VGG-16, Xception, and ResNet-50. Table II shows the BLEU score on the test dataset for the trained models using different pretrained feature extractors. It is found that ResNet-50 performs best as a feature extractor as compared to the VGG-16 or Xception model. The BLEU scores shown in Table II are cumulative BLEU scores.

From Fig. 7, it is evident that our encoder-decoder model with ResNet-50 pretrained model provides a significant improvement in BLEU score compared to the BLEU score stated in the previous research work on the same BanglaLekhaImageCaptions dataset. All of the machine-generated captions displayed in Table III are generated using test samples from the BanglaLekhaImageCaption dataset, which are unseen to the model during the training phase.

Table IV demonstrates that ResNet-50 outperforms the other two feature extractors when evaluated on new data from real-world scenarios. When VGG-16 and Xception are used

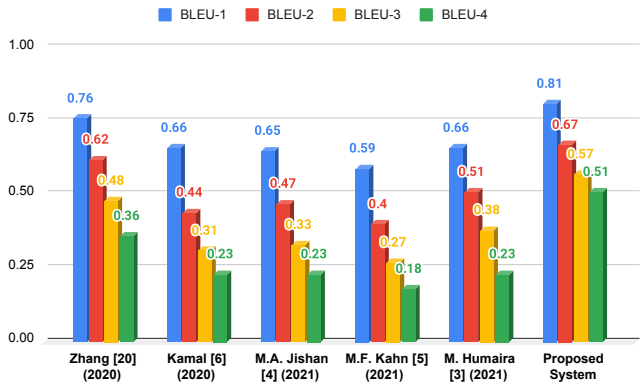

Fig. 7. Accuracy Comparison of Proposed System with Other Research.

as feature extractors, it is observed that the generated captions lack meaning and do not correspond to the meaning of the input image.

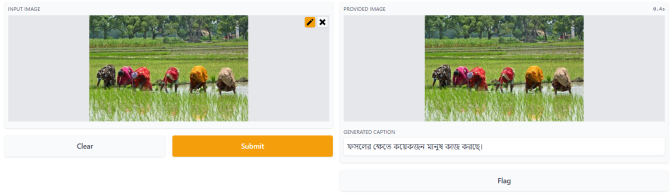

Fig. 8. Web Integration.

For demonstration purposes, we have implemented the model in a web application. This model can also be used for information translation, to assist blind individuals in comprehending their surroundings by converting generated text to speech, and for many other purposes. Fig. 8 depicts an interface for Bangla image captioning within a primary web portal. When a web application receives an image as input, the image is sent to the back-end for image processing and text production. The resulting caption is then shown in the output textbox.

Finally, we have deployed our model on a Raspberry Pi 4 model B with 8GB of RAM. From Table V it is observed that the model only requires 122Mb of storage and the average inference time after testing 100 images was 400ms for ResNet-50 as feature extractor. In addition, the system consumes only 1000mA of current at full load. On the contrary, although flash occupation and energy consumption are similar for all three models, when ResNet-50 is used as a feature extractor, the model takes the least amount of average inference time to generate a caption.

VII. Conclusion

In this research, we have successfully developed and deployed an encoder-decoder based deep learning model named "CapNet" that can generate syntactically and semantically correct and relevant Bangla captions from an input image and deployed the model into an embedded device. The model is trained on a public dataset named BanglaLekhaImageCaption

TABLE II. CUMULATIVE BLEU SCORES COMPARISON ON BANGLALEKHAIMAGECAPTIONS DATASET OF VARIOUS PRE-TRAINED MODEL USED IN ENCODERS OF THE PROPOSED MODEL

Experimental Models	BLEU-1 score	BLEU-2 score	BLEU-3 score	BLEU-4 score
VGG-16 with encoder-decoder	0.45	0.38	0.34	0.31
Xception with encoder-decoder	0.38	0.32	0.29	0.27
ResNet-50 with encoder-decoder	**0.81**	**0.67**	**0.58**	**0.51**

TABLE IV. CAPTIONS GENERATION COMPARISON USING THREE PRE-TRAINED MODELS AS FEATURE EXTRACTOR IN THE ENCODER

Input Image	ResNet50 incorporated model	Xception incorporated model	VGG-16 incorporated model
	তিনজন বন্ধু মিলে একসাথে দাঁড়িয়ে আছে। (Three friends are standing together.)	একজন পুরুষ সারা শরীরে দিয়েছে। (A man gave the whole body.)	২ জন ছেলে একটি লাইব্রেরীতে দাড়িয়ে ছবি তুলছে (2 boys are standing in a library taking pictures)
	অনেকগুলো নারী ও পুরুষ একসাথে আছে। (Many men and women are together.)	একটি মূর্তি আছে। (There is a statue.)	কিছু ছেলেমেয়ে একসাথে দাড়িয়ে এবং বসে আছেন একটি স্কুলের জায়গায়। (Some children are standing and sitting together in a school place.)
	কিছু মানুষ একটি ক্লাস এর ছাদে দাড়িয়ে এবং বসে আছেন ছবি তোলার জন্য। (Some people are standing and sitting on the roof of a classroom to take pictures.)	ঘরের সামনে কয়েকজন নারী ও কয়েকজন পুরুষ দাড়িয়ে আছে। (A few women and a few men are standing in front of the house.)	অনেকগুলো পুরুষ গোল হয়ে বসে আছে। (Many men are sitting in a circle.)
	পাশাপাশি তিনজন পুরুষ দাঁড়িয়ে আছে। (Three men stand side by side.)	একজন পুরুষ বসে ছবি তুলছে। কয়েকজন বালিকা দাঁড়িয়ে আছে (A man is sitting and taking pictures. Some girls are standing)	একজন বয়স্ক পুরুষ ও একজন নারী আছে। (There is an old man and a woman.)
	একজন নারী বসে আছে। (A woman is sitting.)	দুইজন পুরুষ একজন পুরুষকে এ পানিতে নেমে আছে (Two men are pushing a man into the water)	২ জন ছেলে এবং ১ জন হাতে একটি ব্যাগ নিয়ে বসে আছে একটি ফুলের বেঞ্চে একটি কপালে বই ধরে চেয়ে আছে। (2 boys and 1 with a bag in hand are sitting on a flower bench holding a book on their forehead.)

which has 9154 images with two captions per image. The model has attained the highest cumulative BLEU scores compared to all the previous works on Bangla image captioning that utilised this dataset. In addition, a comparison among three pre-trained image feature extraction models namely ResNet-50, VGG-16, and Xception is provided for the encoder network and it is found that ResNet-50 yields the best BLEU score for Bangla image captioning. Finally, we have deployed our model on a Raspberry Pi 4 model B with 8GB RAM and analysed the inference time and power consumption. In the future, we will enlarge the Bangla image captioning dataset by collecting and labelling more image data and training our model for achieving a higher BLEU score. We will deploy the trained Bangla image captioning model into an Android application so that visually impaired people can have a better understanding of their surroundings.

TABLE V. INFERENCE TIME, ENERGY CONSUMPTION AND FLASH OCCUPATION OF THE PROPOSED MODEL

Model	Flash occupancy (in Mb)	Inference time of proposed system (in ms)	Energy consumption (in mJ)
ResNet-50 with encoder-decoder	122	400	1000
VGG-16 with encoder-decoder	121	1100	1000
Xception with encoder-decoder	119	800	1000

ACKNOWLEDGMENT

We appreciate the financial support provided by the Institute of Energy, Environment, Research, and Development (IEERD, UAP) and the University of Asia Pacific.

***Abstract*—This paper proposed a "Locally Adaptive K-Nearest Neighbor (LAKNN) algorithm" for pattern exploration problem to enhance the obscenity of dimensionality. To compute neighborhood local linear discriminant analysis is an effective metric which determines the local decision boundaries from centroid information. KNN is a novel approach which uses in many classifications problem of data mining and machine learning. KNN uses class conditional probabilities for unfamiliar pattern. For limited training data in high dimensional feature space this hypothesis is unacceptable due to disfigurement of high dimensionality. To normalize the feature value of dissimilar metrics, Standard Euclidean Distance is used in KNN which s misguide to find a proper subset of nearest points of the pattern to be predicted. To overcome the effect of high dimensionality LANN uses a new variant of Standard Euclidian Distance Metric. A flexible metric is estimated for computing neighborhoods based on Chi-squared distance analysis. Chi-squared metric is used to ascertains most significant features in finding k-closet points of the training patterns. This paper also shows that LANN outperformed other four different models of KNN and other machine-learning algorithm in both training and accuracy.**

***Keywords*—LANN algorithm; Standard Euclidian Distance; variance based Euclidian Distance; feature extraction; pattern classification**

I. Introduction

Nearest neighbor classifier is a simplest, oldest and wide-ranging method for classification. It classifies an unidentified pattern by choosing the adjacent example in the training set and measured by a distance metric. It is one of the most common instance-based learning method. Simplicity, transparency and fast training time are the advantage of this algorithm. Instances of nearest neighbor denoted as a point of Euclidian space. It is a conceptual method that can be used to approximate real-valued or discrete-valued target function. K nearest neighbor algorithm is best suited for small data sets and which datasets have less features. This algorithm considers close relationship for similar things. In other words, the similar things of neighbors are considered one of them. For example, if mangoes' appearances is more similar to apple, orange, and guava (fruits) than horse, dog and cat (animals), then most likely mango is a fruit.

In pattern recognition problem, a feature vector $x = (x_1, ——X_q) \epsilon \Re_q$, is considered as an object like J classes, and the goal is to form a classifier that allots x to the exact class from a given set of N training samples. The simplest and alluring approach to solve this problem is the K Nearest Neighbor (KNN) [1][2] classification. Rather than fixed data points this method works on continuous and overlapping neighborhoods [3]. This method uses different neighborhood for each single query so that all points in the neighborhood are adjacent to the query to the extent possible [4][5][6]. KNN uses Straight Euclidean distance to discover the k-closest points from query point [7][8][9][10]. This can influence a real less important feature more than that of others to classify a pattern and misclassify the pattern due to dissimilar metric in measuring the feature values [11][12]. It can seriously affect in the training set with high dimensional feature space [13]. Several biases are introduced in KNN for high dimensional input feature space with limited samples [14].

A modified metric of Standard Euclidean Distance is proposed here, which uses the variance of each feature to give identical influence on the decision to all dissimilar metrics in the feature values [15]. Distance is weighted as chi-squared metric that discovers most relevant features in finding k-closet points to the pattern under consideration from the training space [16].

A locally adaptive form of nearest neighbor classification (LANN) is proposed here to upgrade the obscenity of dimensionality [17]. An effective metric is used here to compute neighborhoods which determines the local decision boundaries from centroid information, and then shrink neighborhoods in directions orthogonal to these local decision boundaries, and extend them parallel to the boundaries [18][19] [20].

To give all features equal influences on the pattern classification a variance based Euclidean distance metric is used in the proposed algorithm instead of straight Euclidean distance metric. The variance of each feature is calculated during training.

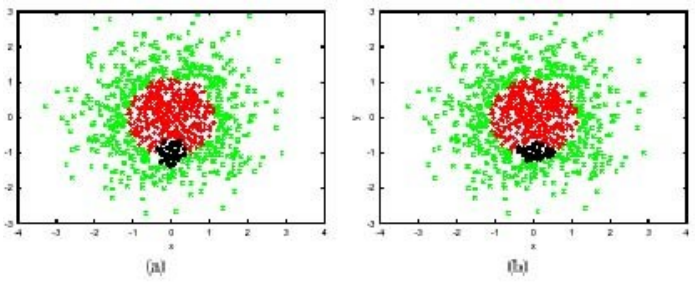

Fig. 1. Neighborhood of the Query Point.

Fig. 1 shows an example. There are two classes and both classes data are produced from a bivariate standard normal

distribution. The radius of class one data is less than or equal to 1.15, while radius of class two is greater than 1.15. As a result, class one is surrounded by class two. Fig. 1(a) shows the nearest neighborhood of size 50 of a query located at (0, -1) near the class boundary. This neighborhood is computed using the Euclidian distance metric Fig. 1(b) displays the neighborhood of same size computed by using the adaptive nearest neighbor classification algorithm. The amended neighborhood is elongated along the direction of the true decision boundary and constricted along the direction orthogonal to it, which is the most relevant direction for the given query.

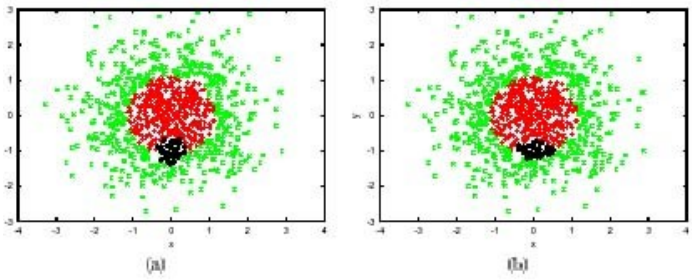

Fig. 2. Spherical Neighborhood of the Query Point.

Fig. 2 Plot (a) shows the spherical neighborhood of the query point (0, -1) containing 50 points (shown as darker circles). Plot (b) shows the corresponding neighborhood found by the proposed algorithm also containing 50 points. After applying the adaptive procedure, the neighborhood is constricted along the most relevant dimension and elongated along the less important one.

This paper proposed an algorithm that can be used in many practical applications of pattern recognition problem in machine learning technology for pattern classification tasks. It has been compared experimentally with KNN, DANN and C4.5 in a large number of artificial and natural learning domains. Experimental result shows that use of Variance based Euclidean distance metric and FRW perfectly removes the problem of constant class conditional probabilities in KNN and improves the performance of KNN.

II. Literature Review

Locally adaptive KNN algorithms indicate the value of k that should be used to categorize an interrogation by accessing the outcomes of cross-validation calculations in the resident locality of the query [21] [22]. Local KNN procedures are exposed to complete analogous to KNN in experimentations with twelve frequently secondhand data sets.

Deepti et al. [23] proposed a Quad Division prototype for stirring uneven class distribution by using Selection based K-nearest Neighbor classifier. Here the performance of QDPS based on KNN technique is assessed in fraud detection in mobile advertising. The utility of the QDPSKNN is likened with base model KNN and other selection methods, namely NearMiss-1, NearMiss-2, NearMiss-3, and Condensed Nearest Neighbor (CNN).

Suyanto et al. [24]introduced a new variant of KNN called Multi-Voter Multi-Commission Nearest Neighbor to observe the profit by enhancing the Local Mean based Pseudo Nearest Neighbor. MVMCNN is gained extra nearby than LMPNN. And then compared it with two single voter models: KNN and BMFKNN, however it shows the multi voter model better decision than the other model.

Armand et al. [25] proposed a metaheuristic search algorithm named Simulated Annealing, to choose an optimal k, thus rejecting the prospect of an exhaustive search for optimal k. Hence, the result is compared with in four different classification method to determine a substantial development in the computational competence compared to the KNN methods.

D. Maruthi et al. [26] introduced an effective classification system for MRI brain tumor and for giving grade of brain tumor images. The images are classified by using the adaptive k nearest neighbor classifier. However, the classification and segmentation arrival method are valued by accuracy, sensitivity and specificity.

Jieying et al. [27] proposed a precise image interpolation with adaptive KNN for searching image on the input image patch and conduct them for nonlinear mapping among low resolution and high-resolution image patches.

Jianping et al. [28] offered a local mean representation based k nearest neighbor classifier to increase the performance of classification and exceed the primary issues of KNN classification. They used two databases UCI and KEEL and also three common databases that carried out by liken LMRKNN and KNN based. However, it shows the LMRKNN significantly outperforms the KNN based methods.

Some previous works on K-Nearest Neighbor Algorithm for Pattern Classification that we have discussed above (Table I). Apart from this, no such similar topic related work exists as far as our knowledge. Our primary focus is to propose an algorithm that can be used in many practical applications of pattern recognition problem in machine learning technology for pattern classification tasks. It has been compared experimentally with KNN, DANN and C4.5 in a large number of artificial and natural learning domains but there is no work found that use the comparison among AI and NLP domain. Besides, no relation is shown in any research as per our study with use of Variance based Euclidean distance metric and FRW which perfectly removes the problem of constant class conditional probabilities in KNN and improves the performance of KNN.

III. Methodology

LANN has three main components: Variance-based Euclidean distance Metric, Feature Relevance Weight (FRW), the best K value using the majority voting scheme [12] [13]. LANN uses a variance based Euclidean Distance metric to find the adjacent neighbors of a query point from the training space and then the class is assigned with the majority class of the neighbors. The component of each feature in the distance is normalized using the variance. While finding the nearest points, distance component of each feature is weighted with chi-squared distance metric to work out the most relevant features.

The main steps of the algorithm and the working procedure are as follows (Fig. 3):

TABLE I. RELATED WORKS ON LAKNN

Ref. No	Description	Model	Limitation
[23]	Proposed a Quad Division Prototype Selection based K-nearest Neighbor classifier for establishing stirring uneven class distribution.	QDPSKNN, PS method	This method is not works well over real time large sized datasets.
[24]	Introduced a new variant of KNN called MVMCNN which is planned to observe the profits by enhancing LMPNN.	KNN, MVMCNN, LMPNN, BMFKNN	It does not give complete inquiries for the definite datasets.
[25]	To choose an optimal K value proposed a metaheuristic search algorithm and also eliminate the prospect of an exhaustive search	KNN, Adaptive algorithms, Parameter Optimization	The adaptive KNN method can't achieve good performance.
[26]	Introduced an effective classification system to classify MRI brain tumor	AKNN, Median filter	Can't provide an explanation in optimization computation complexity problem.
[27]	Proposed an accurate image interpolation with adaptive KNN searching and nonlinear regression.	AKNN	Do not explore deep learning models.
[28]	Proposed a k nearest neighbor classifier based on local mean representation.	KNN, LMRKNN	Can't explore deep learning models.
[29]	Introduced a method named density based adaptive k nearest neighbor.	Nearest Neighbor Classification, Density based method DBANN	can't create extra artificial examples to recompense for smaller class
[30]	An adaptive procedure monitoring system was planned base2d on the KNN rule.	KNN	This method does not suitable for simple processes.

Step-1: Start several Leave-One-Out Tests (Test index "T") for a single neighbor (T=1) to a threshold value (T=10). For each Leave-One-Out test, each example in the training space is classified according to the step 2 to 7.

Step-2: For each test point x0 in training space in each leave-one-out test (Query point index "j" of each "T" value, Given input parameters: K0, K1, K2, L), Initialize a feature relevance weight "wi" to 1 for each feature component in Euclidian distance measure in equation 1.

$$D(x,y) = \sqrt{\sum_{i=i}^{q} w_i \frac{x_i - y_i^2}{variance(i^{th} feature}} \tag{1}$$

$$Variance(ithfeature) = \frac{\sum_{i=1}^{N}(x_i - \overline{x})^2}{N} \tag{2}$$

$\overline{x}$is the mean value of ith feature, where q is the number of features of each point. x, y are the two data points and distance between x and y data point is D (x, y). xi and yi are the ith and ith feature value of x and y data point respectively. Equation 1 measures Euclidean distance with the normalized weight of each feature according to the variance of that feature that are in training data set. wi is the feature relevance weight for each feature.

Step-3: Compute K0 nearest neighbors of x0 by means of the variance based weighted Euclidian distance metric using equation 1 for $w_i = 1$.

Step 4: For each feature i, i =1…..q, compute feature relevance measure through equation 3 to equation 7.

$$\overline{r_i}(x_0) = \frac{1}{k} \sum_{z \varepsilon N(x_0)} r_i(z) \tag{3}$$

where $N(x_0)$ represents the neighborhood of x_0 holding the K_0-nearest training point.$r_i(x_0)$ denotes the capability of feature i to predict $Pr(j|z)s$ at $x_i = z_i$ and defined as follows:

$$r_i(z) = \sum_{j=1}^{J} \frac{[Pr(j|z) - \overline{Pr}(j|x_i = z_i)]^2}{\overline{Pr}(j|x_i = z_i)} \tag{4}$$

The nearer $\overline{Pr}(j|x_i = z_i)$ is to $Pr(j|z)$, the additional information features i carries for predicting the class posterior probabilities locally at z.$\overline{Pr}(j|x_i = z)$ is the conditional expectation of $p(j|x)$, given that xi assumes value z, where xi represents the ith feature of x.$Pr(j|z)$ and $\overline{Pr}(j|x_i = z_i)$ is estimated as follows:

$$Pr(j|z) = \frac{\sum_N^{n=1} 1(x_n \varepsilon N_i(z)) 1(y_n = j)}{\sum_N^{n=1} 1(x_n \varepsilon N_1(z))} \tag{5}$$

1(.) is function which acts as indicator, such that if the argument is true it returns 1 and if false then returns 0. $N_1(z)$ is the neighborhood centered at z containing K_1 nearest training points.

$$\overline{Pr}(j|x_i = z_i) = \frac{\sum_{x_n \varepsilon N_2(z)} 1(\mid x_{ni} - z_i \mid \leq \triangle_i) 1(y_n = j}{\sum_{x_n \varepsilon N_2(z)} 1(\mid x_{ni} - z_i \mid \leq \triangle_i)} \tag{6}$$

$N_2(z)$ is the neighborhood centered at z containing K_2 nearest training points, the value of $\triangle_i$ is selected from the interval containing a fixed number of L points:

$$\sum_{n=1}^{N} 1(\mid x_{ni} - z_i \mid \leq \triangle_i) 1(x_n \epsilon N_2(z)) = L \tag{7}$$

Step 5: Update Feature Relevance Weight (FRW) "w_i" according to equation 8 to equation 9. Feature Relevance Weight (FRW) is calculated by:

$$w_i(x_0) = (R_i(x_0))^t / \sum_{q}^{l=1} (R_i(x_0))^t \tag{8}$$

where $R_i(x_0)$ is defined by

$$R_i(x_0) = (max) Tj(r_i)(x_0) - (r_i)(x_0) \tag{9}$$

t = 1, 2 giving quadratic weighting scheme. In all our experiments we obtained optimal value for input parameters $K_1 = 5$, $K_2 = 10\%$ of N, K_0= 15% of N. L is set to half of the K_2.

Step 6: Iterate steps 2 to 5 again, in this situation each feature has some FRW value.

Step 7: Using Step 2 to 6 a FRW for each feature is obtained. Using FRW in variance based Euclidian distance metric; distance of all examples in training data set with query point x0 is calculated. The examples are ordered in ascending according to their distance value. Among them, a total of "T" examples are chosen from lowest distance to T th point. The class value with maximum number of examples is taken as the class value (majority voting scheme) of the query point x_0.

Step 8: All examples in the training space are classified following the steps from 2 to 7.

Step 9: Error rate is calculated for Tth Leave-One-Out test.

Step 10: All (T=10) Leave-One-Out Tests are completed and error rate is recorded for each test. Test with minimum error rate is chosen as best k-value for the training data set.

Step 11: Using the best k-value; classify any query point following the steps from 2 to 7.

The algorithm of LANN appears to be complex, but the core of LANN is the application of three main components: Variance based Euclidean distance metric, Feature relevance weight, Choice of the best k-value.

Algorithm (Dtraining, x0)

INPUT: $D_{training}$: a set of training examples.

x_0: a query point to be predicted.

OUTPUT: A predicted class value for x_0.

q=No. of Features in the training data set.

N=Total no. of Example in Training dataset.

for T=1 to threshold value (T=10) **do**
  for j=1 to N **do**
    x_j=An example from $D_{training}$
    D= $D_{training}$ - x_j
    Initialize FRW w_i=1 //Label-1//
    for m=1 to 2 **do**
      P=compute weighted distance of x_j by the equation 1 from D.
      $N(x_j)$ =Sort the examples(D) in ascending on P and choose K_0 neighbors from lowest distance.
      Q=compute weighted distance of $z \varepsilon N(x_j)$ by the equation 1 from D.
      $N_1(z)$ = Sort the examples(D) in ascending on Q and choose K_1 neighbors from lowest distance.
      $N_2(z)$ = Sort the examples(D) in ascending on Q and choose K_2 neighbors from lowest distance.
      for each dimension i , i=1...q, compute Relevance Measure $\overline{r_i}(x_i)$ through equation 3 to 7. **do**
        Update FRW w_i according to the equation 7 to 9.
      end for
    end for
    Compute weighted distance of x_j using the new FRW w_i by equation 1 from D. //Label-2 //
    E=Choose "T" neighbors from D Apply majority voting on E and classify x_j.

  Calculate error rate for "T" test.
end for
K = Choose best T with lowest error rate.
Compute a FRW for x_0 following steps from "Label-1 to Lablel-2".
F = Choose "K" neighbors from $D_{training}-x_0$ Class C =Apply majority voting on "F"
Return "C"

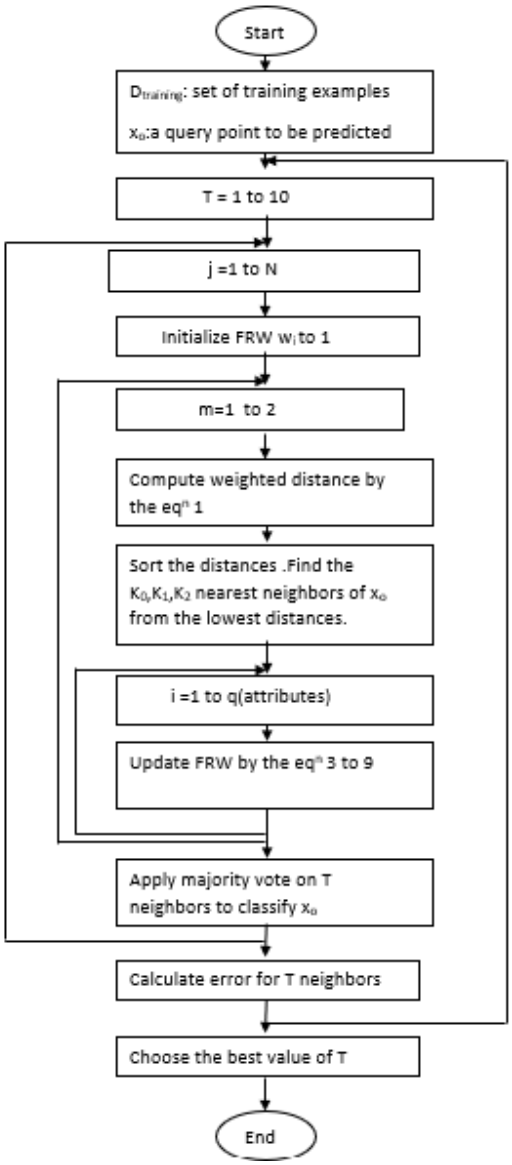

Fig. 3. Flowchart of LANN.

IV. Experimental Result

Twelve different real data sets are studied for experimental analysis of LANN. The Breast Cancer, Iris, Diabetes, Glass,

Vowel, Sonar, Hepatitis, Wine, Segmentation, Lymphography, Liver-Disorder and Lung-Cancer data are taken from UCI Machine Learning Repository [4]. All for the datasets we perform Leave-One-Out test to measure performance (Table II).

TABLE II. DOMAINS USED IN THE PROPOSED ALGORITHM (LANN)

Description of the domains used in experimental study.			
Domain name	Size	No. of classes	No. of Attributes
Breast Cancer	699	2	9
Iris	150	3	4
Diabetes	768	2	8
Glass	214	6	9
Vowel	528	11	10
Sonar	208	2	60
Hepatitis	150	2	19
Wine	178	3	13
Segment	2310	7	19
Lymphography	148	4	18
Liver-Disorder	345	3	6
Lung-Cancer	32	3	56

Table III shows the leave one out test result for 12 datasets. Table III depicts the Leave-One-Out error rates for the four methods under consideration on the twelve real world data.

The above table shows error rates (%) for different K-values. Column 1 of Table III shows that the minimum error rate is 2.43 for K=4 in breast cancer dataset. Column 2 of Table III shows minimum error rate 3.33 for K=2 for Diabetes dataset, minimum error rate for Iris dataset is 3.33 that shown in column 3 of Table III, So, the best K-value is 6. Minimum error rate for Glass dataset is 24.76 for k value 4 is shown in column 4 of Table III, 9.13 is the minimum error rate for k value 4 for sonar dataset shown in column5 of Table III, for k value 2 minimum error rate 0.56 is found for Vowel dataset that shown in column 6 of Table III, column 7 of Table III shows the minimum error rate of Hepatitis dataset which is 21.33 for k value 2. Minimum error rate of Wine dataset, Segment dataset, Lymphographic dataset, Liver disorder dataset and Lung Cancer dataset is 1.68 for k value 2, 1.63 for k value 4, 8.10 for k value 2, 22.31 for k value 4, 37.5 for k value 4 are shown in column 8, 9,10,11 and 12 respectively of Table III.

After completion of all Leave-One-Out tests we calculate the error rate of LANN by the following:

$$Errorrate(\%) = \frac{No.of\backslash failures" * 100}{TotalNo.ofInstances}$$

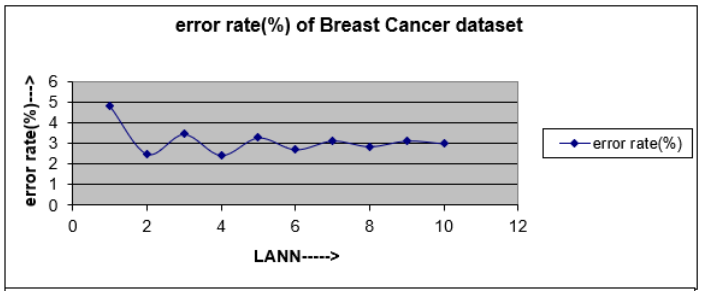

Fig. 4. Error Rate (%) Graph for Breast-Cancer Dataset.

"Fig. 4"' shows the error rate (%) graph for Breast-Cancer dataset for C4.5, DANN, KNN, LANN where the error rates

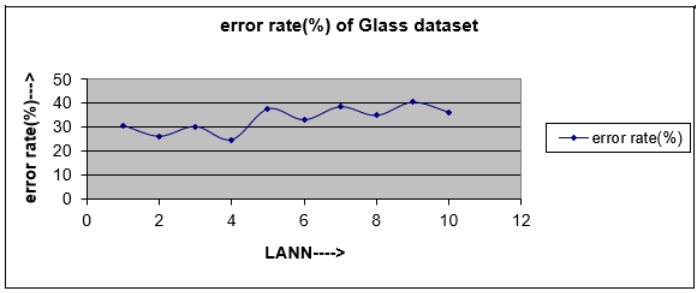

Fig. 5. Error Rate (%) Graph for Glass Dataset.

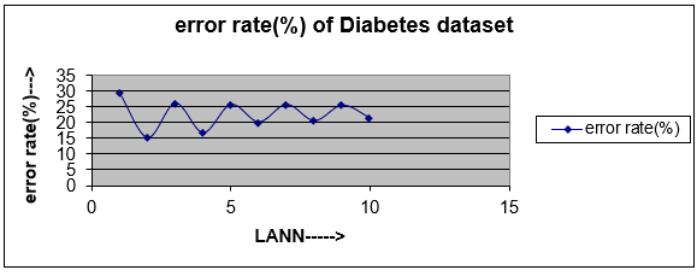

Fig. 6. Error Rate (%) Graph for Diabetes Dataset.

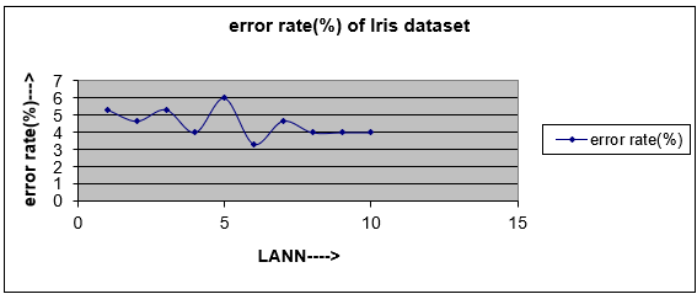

Fig. 7. Error Rate (%) Graph for Iris Dataset.

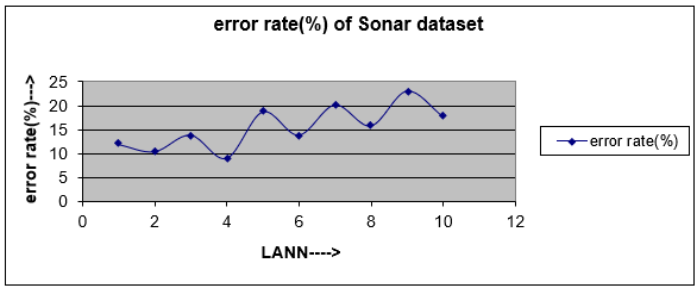

Fig. 8. Error Rate (%) Graph for Sonar Dataset.

4.70, 3.10, 4.10, 2.43 respectively. "Fig. 5" is for Diabetes dataset where the error rate is 25.00 for C4.5, 18.10 is for DANN, 24.40 is for KNN and 15.10 is for.Error rates for Iris dataset is shown in "Fig. 6". For this dataset the error rate is 8.00 for C4.5, 6.00 for DANN, 8.00 for KNN and for LANN it is 3.33; Glass dataset's error rate is shown in "Fig. 7" where the error rates for C4.5, DANN, KNN, LANN are 31.80, 27.10, 28.00, 24.76 respectively.Error rates for Sonar dataset is shown in "Fig. 8" which shows 23.10, 7.70, 12.50, 9.13 for

TABLE III. THE LEAVE-ONE-OUT TEST RESULTS FOR 12 DATASETS ARE GIVEN BELOW

	Breast cancer	Diabetis	Iris dataset	Glass dataset	Sonar dataset	Vowel dataset	Hepatitis dataset	Wine dataset	Segment dataset	Lympho graphy dataset	Liver Disor-der dataset	Lung Cancer Dataset
1	4.86	29.16	5.33	30.84	12.01	0.75	40.00	3.37	3.10	21.62	37.68	50.00
2	2.80	15.10	4.66	25.54	10.50	0.56	21.33	2.80	1.90	8.10	23.23	38.10
3	3.86	26.04	5.33	30.37	13.94	2.08	33.33	3.93	2.82	14.18	35.65	65.62
4	2.43	16.66	4.00	24.76	9.13	1.51	26.66	1.68	1.63	9.45	22.31	37.50
5	3.29	25.65	6.00	37.85	18.75	5.68	32.00	2.80	3.19	17.56	35.94	65.62
6	2.71	20.05	3.33	33.17	13.94	3.97	26.00	1.68	2.90	13.51	24.63	46.87
7	3.14	25.65	4.67	38.78	20.19	8.71	30.00	3.37	4.42	18.91	39.71	70.00
8	2.86	20.44	4.00	35.04	15.86	7.00	26.00	2.81	3.10	15.54	26.95	68.75

four algorithms. “Fig. 9” shows the error rate for Vowel dataset for C4.5, DANN, KNN, LANN where error rates are 36.70, 12.50, 11.80, 0.56 respectively. Error rate (%) for Hepatitis dataset is shown in “Fig. 10” where the error rate is 18.40 for C4.5, 20.40 is for DANN, 22.30 is for KNN and 21.33 is for LANN. Wine datasets error rate is shown in “Fig. 11” the error rate (%) for C4.5 is 12.10, for DANN error rate is 13.50,14.60 is for KNN and 1.68 is for LANN. “Fig. 12” the error rate (%) where the error rates are 3.70, 2.50, 3.60, 1.63 for C4.5, DANN, KNN, LANN respectively. From “Fig. 13” error rates has been observed for Lymphography dataset where the error rate is 21.90 is is for C4.5, 17.70 for DANN, 19.30 is for KNN and 8.10 is for proposed LANN. Error rates for Liver-Disorder dataset is shown in “Fig. 14” where the error

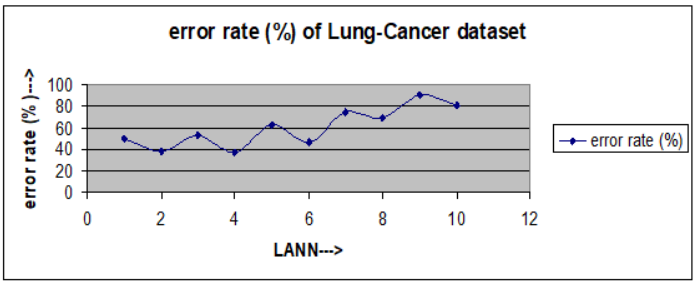

Fig. 15. Error Rate (%) Graph for Lung-Cancer Dataset.

rates are 35.10, 32.30, 34.50, 22.31 for C4.5, DANN, KNN, LANN respectively. "Fig. 15" depicts thr error rate for Lung-cancer dataset, where the error rate for for C4.5 is 57.50, for DANN it is 45.90, for KNN it is 47.90 and for LANN it is 37.50.

From the comparison Table IV it is observed that the average error rate (%) of proposed algorithm (LANN) is 12.32 whereas the average error rate (%) for C4.5, DANN, KNN are 23.17, 17.23, 19.10. Thus it can be said that, the efficiency of LANN is better than the above algorithms (Fig. 16).

TABLE IV. COMPARISON OF LANN W. R. TO OTHER ALGORITHMS

Domain no.	Domain name	C4.5	DANN	KNN	LANN
1	Breast cancer	4.70	3.10	4.10	2.43
2	Diabetes	25.00	18.10	24.40	15.10
3	Iris	8.00	6.00	6.00	3.33
4	Glass	31.80	27.10	28.00	24.76
5	Sonar	23.10	7.70	12.50	9.13
6	Vowel	36.70	12.50	11.80	0.56
7	Hepatitis	18.40	20.40	22.30	21.33
8	Wine	12.10	13.50	14.60	1.68
9	Segment	3.70	2.50	3.60	1.63
10	Lymphography	21.90	17.70	19.30	8.10
11	Liver Disorder	35.10	32.30	34.50	22.31
12	Lung-Cancer	57.50	45.90	47.90	37.50
	Average	23.17	17.23	19.10	12.32

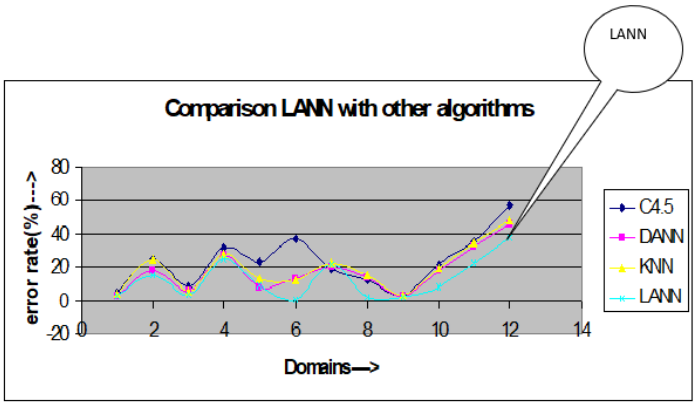

Fig. 16. Error Rate (%) of Different Domains. Horizontal Axis gives the Domain's no. and the Vertical Axis gives the Corresponding Error Rate.

V. DISCUSSIONS

There are basically two parts for pattern classification. By using an algorithm the first part creates feature vector from a given image and these features are used in the second part to learn a machine to classify an unknown pattern.

These two parts are not completely independent, this means machine learning algorithms may be benefited by knowing how the features are extracted from an image and feature extraction may be more fruitful if the type of machine leaning algorithm is known. However, the limitation of this paper is it only explored second part. That is, this work emphasis on to build a system which can classify an unknown image or pattern by using machine learning from a given set of database, all of which feature vectors have already been broken down into by an image processing algorithm. For example, the Segment dataset that is used in this work is an image classification problem. After applying the proposed algorithm (LANN) on the Segment dataset, the classification error rate is observed as 1.6%, whereas the error rates for C4.5, DANN, KNN are 3.7%, 2.5%, 3.6%, respectively. It proves that the LANN performs better than other existing algorithms in image-classification problems (Fig. 17.)

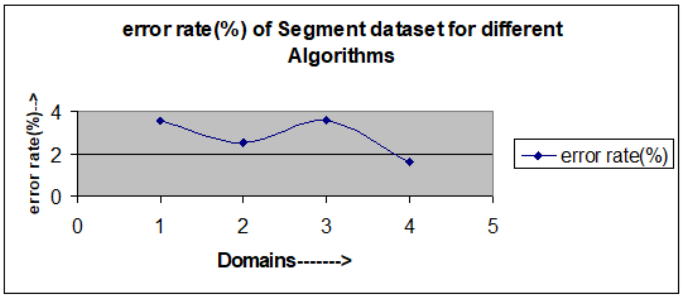

Fig. 17. Comparison of Error Rates (%) of Proposed Algorithm (LANN) with Other Algorithms for Segment Dataset.

VI. CONCLUSION

LANN presents a new variant of nearest neighbor method to classify pattern effectively. To produce neighborhood, it uses a flexible metric that are elongated along less relevant feature dimensions and constricted along most influential ones. By using this technique, the class conditional probabilities tend to be more homogeneous in the modified neighborhoods. From the experimental result it is clearly shown that LANN can potentially improve the performance of K-NN and recursive partitioning methods in some classification problems. The results are also in favor of LANN over other adaptive methods such as C4.5 and DANN.

***Abstract*—Nowadays, phishing is a major problem on a global scale. Everyone must use the internet in today's society in order to cope up in the real world. As a result, internet crime like phishing has become a serious issue throughout the world. This type of crime can be committed by anyone; all they need is a computer. Additionally, hacking may now be learned quickly by anyone with programming and mathematical skills. The adoption of various techniques by anti-phishing toolbars, such as machine learning, may enable users to quickly identify a fake website. As a result, researchers are now particularly interested in the problem of detecting fraudulent websites. Machine learning techniques have been offered throughout the entire process to more precisely identify fraudulent websites. To find the best accurate outcome, classification with random parameter tuning and ensemble based approaches are utilized. A user-friendly interface has also been suggested to make the system more accessible to the public.**

I. Introduction

Technology has made individuals more dependent than they have ever been before. As the price of electronic devices such as smartphones, tablets, personal computers, laptops, and so on continues to drop, an ever-increasing number of people are able to purchase them and are using them. However, the rise of cyber dangers has been the most significant in recent decades. Phishing, which is responsible individually for 90 percent [1] of the data breaches, is one of the most common methods that people are tricked into giving over their personal information. People who conduct most of their financial transactions and shopping online are the most likely to fall victim to phishing scams. Criminals used to extort money from unsuspecting victims by threatening them with guns, stealing their cars, or by using force. When compared to less developed countries, industrialized nations have a lower incidence of this particular form of criminal activity. But in recent years, phishing has become a significant issue all around the world. This is due to the fact that one does not require any kind of weapon in order to commit this form of crime; all that is required is a computer. In addition, the availability of books and guides to follow on the internet makes it possible for anyone who is mathematically savvy and has some experience with programming to learn how to hack. The Federal Bureau of Investigation estimates that more than 26 billion dollars have been stolen from businesses and individuals around the world. In addition, the number of new websites that are used for phishing is continually expanding. Fig. 1 indicates new phishing websites are increasing year by year which is an immense threat for users. Therefore, cutting-edge research needs to be carried out in order to neutralize this danger. Also many cyber security training are providing by both government or by private companies which rises the awareness of people basically in the form of games [2] to [3].

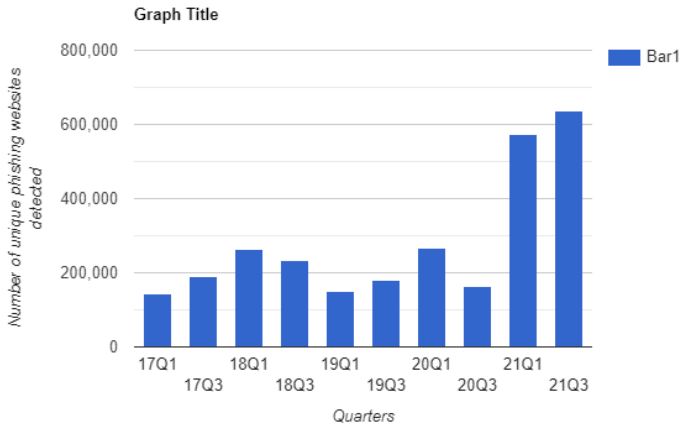

Fig. 1. The Number of New Phishing Websites from First Quarter of 2017 upto Third Quarter of 2021 by Statista.

Internet scams that use email, social media, and websites to steal private information are called phishing. Attackers take advantage of both system flaws and user ignorance. As a result, researchers must design solutions at both the technical and user-level levels. It is possible to protect yourself from Phishing by using a variety of different methods. Anti-phishing toolbars primarily protect users on their computers' local machines from phishing attacks. Games and other awareness campaigns are used to educate people about the issue [4] to[5].

Machine learning, rule-based, visual similarity, and other non-content-based methods are used by anti-phishing toolbars to identify phishing sites. Malicious URL detection technology aids users in spotting malicious links and wards off attacks from harmful websites. So, the first motivation is to give safety to the users. Another motivation is to increase the reliability of such technology. For that, increasing the accuracy of the system is a crucial factor which has been done in this research work. As a result, we conducted a comprehensive study of the current literature on phishing types, anti-phishing techniques, and anti-phishing toolbars in order to better understand the faults of existing toolbars and provide researchers with improved solutions. In order to compile the papers, we used Google Scholar as a database. Supervised Machine Learning with different Features Selections has been used in the past to detect phishing websites [6]. Classifiers that use wrapper-based techniques typically have the most useful features and the best overall performance [7] to [8]. Multi-model simulations are used in this phase for higher performance accuracy [9]. In order to achieve the highest level of accuracy, a hybrid model incorporates the greatest elements of multiple models while minimizing the negatives of each. The most accurate results are obtained using ensemble methods [10] to [11]. Using wrapper feature selection and ensemble learning, a phishing detection software will be created. Wrapping features selection approach delivers the most desired features in order to acquire the most accurate outcome. In addition, an ensemble technique is utilized to find the accuracy of all classifiers and select the best classifier to fit with it in order to forecast phishing websites.

Section II shows the literature review and Section III briefly describes the methodology and design of our study. Section IV elaborates the experimental results and Section V concludes with limitation and some recommendations of future work of the study.

II. Literature Review

Many researchers worked previously on analysing phishing websites. Our technique is to combine their works and get a better result. Also there exists many phishing apps and some are in the form of games which literally use live servers to detect urls [12]. We went through the past works and try to improve the accuracy of models and propose a user friendly interface to detect them.If we want to run a detection app successfully then we have to dig into the process first. M.A Tahir [11] proposed a hybrid model to detect phishing sites using supervised learning algorithm. He used machine learning methods and combine them to find the best accuracy but skip the feature selection methods. Zamir [13] proposed a diverse machine learning method to detect phishing websites wheres they skip the part of using feature extraction methods. Sharivari [14] also proposed a system where they used almost every classification techniques. R.kohavi [7] shows wrapper based features selection classifier work with all the possible features subsets and utilizes a ml classifier as an evaluation function of the features subsets. The highest evaluation is considered as the best feature subset. W.Ali [6] tried to propose a system with machine learning classifier and the feature selection method. He found that random forest with wrapper based feature selection method gives the highest accuracy of 97.3%. The most accurated result found is 97.4%. Our proposed system is to improve their accuracy by using same dataset. Also there are so many apps or games and they mainly use live servers or open source to detect urls [12].Our project is to make a user friendly app with our proposed ml method.

There exists many methods to detect fake urls. Some based on machine learning techniques and skip features selection methods. In our project we use classifiers as well as feature selection methods and also implement this as an application. The researchers applied simple feature identification and extraction techniques. It can also be possible to get more accurate results by using more powerful classifiers in ML such as category boosting and Deep Learning algorithms also can handle this type of problem. The existing models did not extract as much as features like us. So, the reduced number of feature extraction in the existing models is a gap. There is scope to improve the accuracy of the existing models. In the next section we will describe how we overcome this lacking found a better way to overcome some problems.

III. Methodology and Design

Methodology is considered as the best part of any research. It implements the answer of the questions start with “How?”. It’s a tremendous way to ensure the acceptability of the work through valid and reliable results. For this proposed method, we have gone through several steps. At first valid data have been collected. Then this data have gone through several steps till a user interface use this model to predict the urls. Machine learning classifiers combining with feature selection methods have been used and react native is used for given it a real life application.

There are two major steps to illustrate this project. First of all selecting the best features among all features and then select an ensemble machine learning method to get the result.

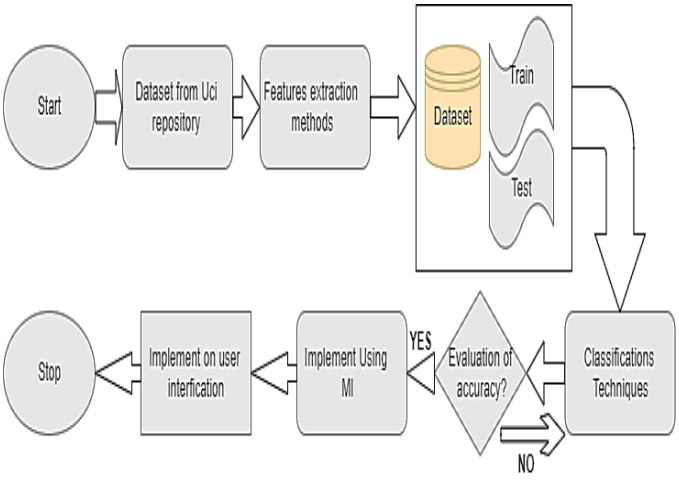

Fig. 2. Flow Chart for whole Process.

Fig. 2 illustrates the methodology of phishing website detection based on supervised machine learning classifiers with features selection method.

Fig. 3 illustrates the classes we have used for Ml model classification and feature extraction methods.They have been rotating to find the best accuracy among them.

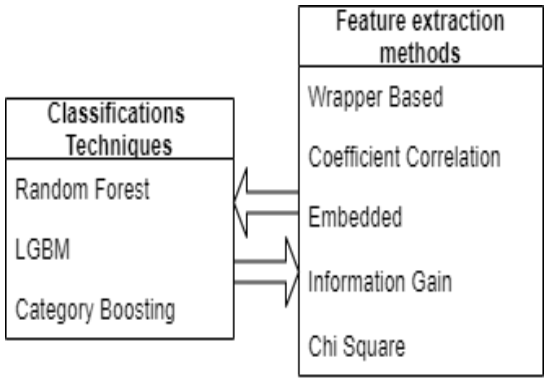

Fig. 3. Loop between Ml Model Classifiers and Features Extraction Technique.

Five steps are required to be accomplished in order to detect the phishing website: dataset collection, features extraction, features selection, training of machine learning classifiers, and evaluation of machine learning classifiers

The dataset of our project were collected from the UCI Machine Learning Repository, which is freely available for use. This dataset consists of 11055 rows and 30 columns which were used to extract several website features [15]

A. Explanation of Proposed Method

The complete explanation of the proposed method is given in this section. The basics of all procedures in the methodologies are discussed.

1) Data Preprocessing and Analysing: For building a good accurate model preprocessing of data is must. Otherwise the model may fail to give correct results. Data processing is a term which is basically processing of raw unusable data to suitable machine data.Using J48 algorithm [16] is very helpful in examine the data categorically and continuously. Fig. 4 shows the preprocessing procedure of the data. Here we have used basic types of data preprocessing methods in our project.

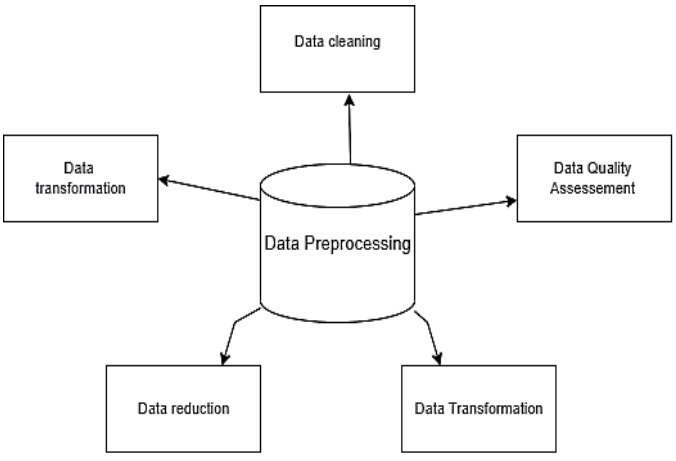

Fig. 4. Data Pre-Processing.

The following are some fundamental data preprocessing methodologies that have been implemented in the proposed method.

1) We have dropped one column which only indicates the index value sequentially for all the records.
2) Then We have analysis the unique classes for each of the data.
3) Next we have replaced all the values of records to 0 or 1
4) Those records who have missing values are also eliminated.

2) Feature Extraction: ML can't work best on choosing all the features. So feature selection method is used for dealing with crude content straightforwardly. It reduces the dimension of feature space.During feature extraction, uncorrelated and useless features will be removed which can help to fit the best useful algorithm and can improve the accuracy of the model

Wrapper Based: Subset of features are used and with each subset, train a model. We add or remove features based on the accuracy given by the subsets.It is also possible to utilize wrapper classification algorithms that combine dimensionality reduction and classification, although their computational costs are considerable and their discriminative power is limited. Furthermore, in order to achieve high accuracy, these strategies rely on the effective selection of classifiers. There are three types of wrapper based selection:

1) Forward Selection
2) Backward Elimination
3) Stepwise Selection

In our proposed method Stepwise selection secured best accuracy among all of the features selection methods.

Correlation Based: High correlated features depends each other and linearly inter dependent, hence have almost the same effect.When a feature expansion doesn't result in an improvement, the algorithm moves on to the next best unexpanded subset. The entire feature subset space is searched by this approach without any restrictions. As a result, there should be a limit on backtracking. The program then returns the feature subset that produced the highest merit up to that point.

Information Gain: The information gained is a system where amount of information improved before splitting them are counted. This is actually the mutual information between two random variables.Determining an attribute's relevancy and, consequently, its position inside the decision-tree, is the main goal of the Information Gain. An attribute (variable) with numerous distinct values prevents the information gain from effectively differentiating among the attributes.

Chi Square: Categories in a dataset are tested using the chi-square method. We determine the Chi-square among each element and the intended outcome and then choose the features with the highest Chi-square scores. It assesses whether the relationship between two categorical data in the sample corresponds to their true relationship in the population.

3) Machine Learning Algorithm: Machine learning is a learning technique and getting new information without explicit instruction with the aid of training data. Basically, there are two different categories of machine learning methods.

1) Supervised

2) Unsupervised

The method of learning from leveled data known as "supervised learning" provides an output for each input. In accordance with this, the algorithms operate. Unsupervised learning refers to the type of learning when the training or operation is carried out on an unlabeled dataset. To discover related features, the algorithm aggregates data of a similar type. Whatever the case, the labeled data is used to develop our model. A supervised learning problem can thus be used to frame the issue. There are two different kinds of supervised learning algorithms.

1) Classification
2) Regression

As we have used Supervised learning technique and dataset is classifed, in the next part we will only discuss about supervised classification methods.

Random Forest: A random forest is a ml method for tackling classification and regression issues. It makes use of ensemble learning, a method for solving complicated issues by combining a number of classifiers.

Numerous decision trees make up a random forest algorithm. The random forest algorithm creates a "forest" that is trained via bagging or bootstrap aggregation. The accuracy of ml algorithms is increased by bagging, an ensemble meta-algorithm.

Based on the predictions made by the decision trees, the (random forest) algorithm determines the outcome. It makes predictions by averaging or averaging out the results from different trees. The accuracy of the result grows as the number of trees increases.

Light Gradient Boosted Machine: A framework and a type of gradient boosting is called a light gradient boosting machine, or LGBM. Light GBM is based on Decision tree methods, just as another gradient boosting method. We can decrease memory utilization and boost efficiency with the aid of Light GBM.

The primary distinction between Light GBM and other gradient boosting frameworks is that Light GBM grows leaf-wise and in a vertical orientation. The other algorithms, however, grow horizontally in a level-wise fashion. The leaf that produces the least inaccuracy and the most efficiency is chosen by Light GBM. This approach is significantly more beneficial in lowering the mistake percentage. In other words, it expands leaf-wise whilst others grow level-wise.

Category Boosting: The CatBoost algorithm plays an essential part for supervised machine learning applications and is based on Gradient Descent. It will work effectively for issues involving categorical data. A series of decision trees are generated sequentially when training this model because the CatBoost technique is based on gradient decision trees. Each new tree that is created as training goes on has a lower loss than the one before it. It is employed for a variety of functions, including weather forecasting, self-driving cars, recommendation systems, personal assistants, and search.

4) React Native APP: Basics of react native: JavaScript provides the framework for React Native, which allows developers to write genuine mobile applications that run natively on iOS and Android devices [17]. It is based on React, which is a JavaScript toolkit that Facebook uses for designing user interfaces; however, rather than targeting browsers, it targets mobile platforms. To put it another way, web developers now have the ability to create mobile applications that have a look and feel that is genuinely "native", and they can do it from the convenience of a JavaScript library that we are already familiar with and adore. In addition, the majority of the code that you create may be shared between platforms, which makes it simple to develop applications for both Android and iOS at the same time using React Native. Fig. 5 indicates that how server and app are interacting with each other.

Architecture of our react native app:

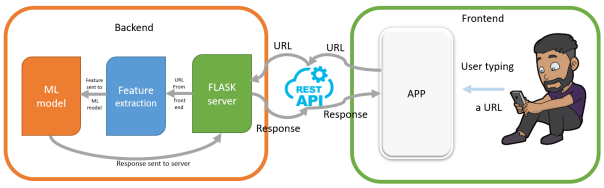

Fig. 5. Architecture of React Native.

The architecture has mainly two parts. Backend and frontend. Each part is divided into some essential parts.

5) Implementation of Machine Learning Model:: The steps required to implement are as follows:

- **Step-1:** At first we collected the data from online [15]
- **Step-2:** Then we did some analysis of the data which we have already discussed.
- **Step-3:** We did some preprocessing of the data that is necessary for building the models. We first balance the dataset as the data were very class imbalanced. Then we classified data and discard the record which have null values
- **Step-4:** Then we did the most important part which is feature extraction. We have used the wrapper based,embedded method, correlation coefficient, information gain and chi square. Then we implemented this techniques one by one with ensemble machine learning techniques.
- **Step-5:** After feature extraction, we have split the dataset into train and test set. We have used 70split from the same dataset.
- **Step-6:** We have built the machine learning model. We have used ensemble models [10] like Random forest, LGBM, Catboosting method. And then We have implemented this methods with features extraction methods which We have discussed already in the previous part.
- **Step-7:** After building the model we evaluated the performance of the model. And then implemented this methods to the user interface.

6) Implementation of User Interface using our Machine Learning Model:: Here we will discuss about the user interface which will be a real life url detector using our machine learning approach [18]. Backened: Here a server is created to communicate with the frontend and ML model. It sends the response of ML model to the frontend.

Flask Server
Flask is a python framework. With the help of Flask, a server was created. It receives URL via REST API from frontend. It is also responsible to send the response of ML model to REST API.

Extracting Features
Features from URL are extracted at this end. The extracted features are then fed into the ML model.

Response form ML Model
With the help of the features, the ML model creates a response whether the URL is phishing or safe.

Frontend: The frontend supplies the URL to the Backend through REST API.

App
The react native app receives input from user. The URL is saved to its state and then it is sent to the REST API. The API sends it to the server.

User
The user gives an URL as input to the App. The user also can see the response of the ML model in the app interface.

IV. Results

Performance are the outcomes and the most important parts of a project. The better a model performs the more useful that model is. In the previous chapters all the steps for the proposed methodology has been explained. Now it's time to evaluate the model. In this section we will describe the overall outcomes and we will show our proposed model with the traditional approaches. The performance and the real life user interface will be discussed here.

A. Dataset Description

The dataset of our project have already discussed in the previous chapter. Dataset were collected from the UCI Machine Learning Repository, which is freely available for use. This dataset consists of 11055 Urls and 30 columns which were used to extract several website features [15].

Fig. 6, 7, 8 and 9 present the symbol count, ip count, url length and shortening url feature, respectively. Their characteristics is put on x axis and on axis respective numbers is kept. Here -1 means the feature has no impact to make it malicious, 0 means neutral and 1 it is used to identify the url as malicious. Here count for some features are given. we have tried this for all of the features which indicate how many individual classes for each of the features.

B. Impact Analysis

Fake url has a great impact on society.It has also a tremendous impact on almost every sectors of life like economy and politics. It has become a curse nowadays. So detecting the fake url is much needed thing to overcome this global issue. Some impacts are shown below:

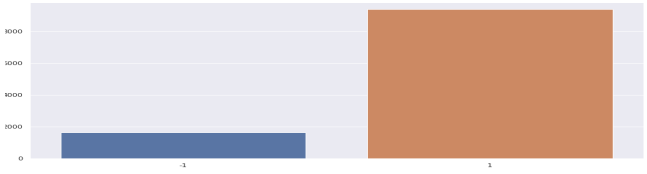

Fig. 6. Symbol Count.

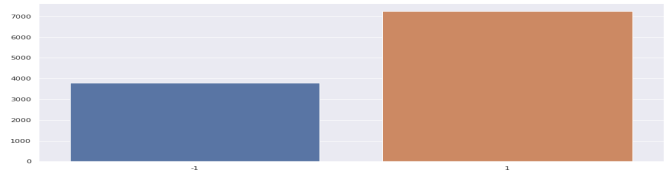

Fig. 7. Ip Count.

1) Social and Environmental Impact: Phishing on social media sites like Instagram, LinkedIn, Facebook, or Twitter is referred to as social media phishing. Such an assault aims to take control of your social media account or to steal personal information. The negative impacts of phishing on a business are numerous and include financial loss, loss of intellectual property, reputational harm, and interruption of daily operations. These outcomes combine to reduce a company's value, sometimes with disastrous results.

2) Ethical Impact: The act of designing and carrying out simulations that are certain to cause stress and anxiety in all levels and roles of your employee base is ethical impact of phishing. The high rate of undesirable actions—such as clicking on a link, opening an attachment, or entering login information based on private or delicate topics—is not being generated on purpose or with predetermined objectives. Without the right context, these strategies are certain to endanger your program. An atmosphere of trust will be difficult to restore, regain, or establish.

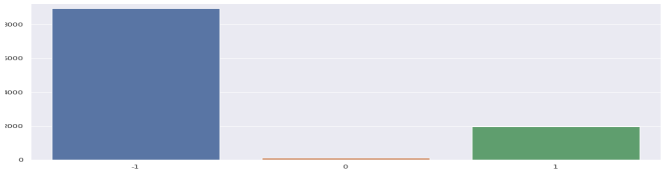

Fig. 8. Url Length.

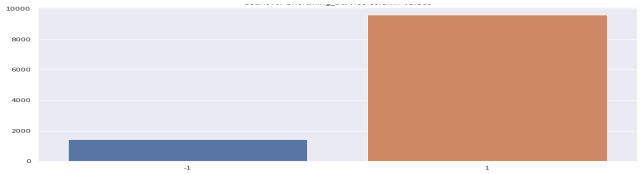

Fig. 9. Shortening Url.

C. Evaluation of Proposed Method

In this section, the method of our propose system will be shown step by step. Here we will discuss about our feature extraction technique, ensemble machine learning and finally the connection with the server.

1) Feature Extraction: For feature extraction procedure we have used wrapper based, embedded method, Correlation and Coefficient, Information Gain, Chi square method. But checking the performance with ml techniques, we have come to a decision to use wrapper based feature extraction. It gives the highest result among all of them [7]. In this dataset, there were thirty columns before using feature extraction method. Fig. 10 shows the columns before extracting features.

```
Index(['having_IPhaving_IP_Address', 'URLURL_Length', 'Shortining_Service',
       'having_At_Symbol', 'double_slash_redirecting', 'Prefix_Suffix',
       'having_Sub_Domain', 'SSLfinal_State', 'Domain_registeration_length',
       'Favicon', 'port', 'HTTPS_token', 'Request_URL', 'URL_of_Anchor',
       'Links_in_tags', 'SFH', 'Submitting_to_email', 'Abnormal_URL',
       'Redirect', 'on_mouseover', 'RightClick', 'popUpWidnow', 'Iframe',
       'age_of_domain', 'DNSRecord', 'web_traffic', 'Page_Rank',
       'Google_Index', 'Links_pointing_to_page', 'Statistical_report'],
      dtype='object')
```

Fig. 10. Before Wrapper Used.

Then using wrapper, we got the performance of each of the subsets and came to know which subsets give the most accurate result which is shown in Fig. 11.

	feature_idx	cv_scores	avg_score	feature_names
1	(7,)	[0.88891904115784 71]	0.888919	(SSLfinal_State,)

```

Fig. 14. Accuracy.

Here in Fig. 13 shows the heatmap of random forest classification. Heatmap actually provides realtime analytics to understand the performance.

Here it shows that RF gives the highest result of 97.47% among all others and best suitable for proposed system.

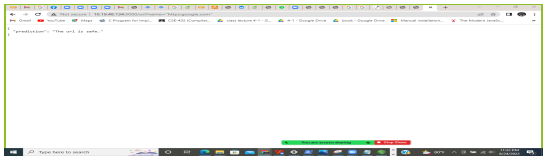

Fig. 15. Connecting with Server.

Finally in Fig. 15 shows our user interface connected with the server system.

D. Evaluation of Performance

In this section we will show a comparative analysis of the performance between our proposed methodologies and

traditional approaches. At first we will show the analysis with different feature selection methods with different machine learning methods done by the base papers. Then we will show the performance of our proposed methods we have tried. Here, at first the performance of the traditional approaches are shown. In Fig. 16 shows the performance done by the previous paper [13]. The highest performance is done by using NN classifier + Random forest + bagging which is about 97.4.

Techniques	Highest achieved accuracy (%)
PWP using RF classifiers (Ibrahim and Hadi (2017)	95.2
Intelligent detection using RF (Subasi *et al.* (2017)	97.3
Proposed method using stacking	97.4
Proposed method using RF	97.3

Note: PWP = phishing web sites prediction

Fig. 16. Performance by Paper [13].

In Fig. 17 shows the performance done by the previous paper [14]. The highest performance is done by using Random forest which is about 97.3.

Fig. 18. Performance of Paper [6].

The performance of our proposed system is given in Table I.

TABLE I. PERFORMANCE OF OUR PROPOSED SYSTEM

Model	Features	Accuracy
Random Forest	Wrapper	97.377
Random Forest	No Feature Selection	97.40
Random Forest	Embedded	97.1058
Random Forest	Correlation Coefficient	97.47
Random Forest	Information Gain	96.65
Random Forest	Chi Square	97.467
Light Gradient Boosted	Wrapper	97.36
Light Gradient Boosted	No Feature Selection	97.40
Light Gradient Boosted	Embedded	97.07
Light Gradient Boosted	Correlation Coefficient	97.40
Light Gradient Boosted	Information Gain	96.77
Light Gradient Boosted	Chi Square	95.99
Category Boosting	Embedded	96.29
Category Boosting	Correlation Coefficient	97.13
Category Boosting	Information Gain	96.77
Category Boosting	Chi Square	95.9

In our proposed system, the performance are given in Fig. 19. Here the overall performance is better than the previous references. We can see that Random forest model with wrapper feature selection shows the accuracy of 97.377%, with no feature selection and also with correlation shows slightly better result as 97.40%, 97.47%. Light Gradient boosted and Catboost also have better performance with the features selection methods. But most accuracy are shown by using Random Forest with Coefficient based feature selection which is approximately 97.47% RF with Coefficient feature selection for our proposed system.

Then we have used react native to get the real life application using our proposed method. we have used flask server as backened. Then in the traditional approach we have extract a url which will be collected from user then extract it into our desired features. Next pickle file of ml is connected with that. Lastly, frontened is designed which can get data from user and give them a result using our machine learning approach.

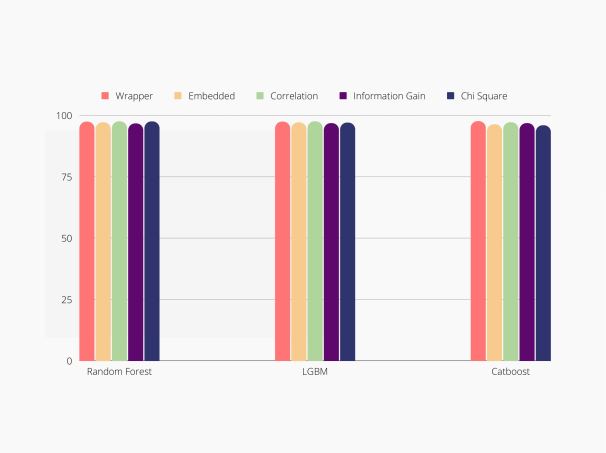

Fig. 19. Performance Measurement.

Fig. 20 shows the home page of the application. The input is given by the user and then it will be extracted and test whether its real url or fake one. The results of the input url can be fake or real which is given side by side. Fig. 21 showing that input url is malicious as well as fake one. Fig. 22 shows the input url is real one.

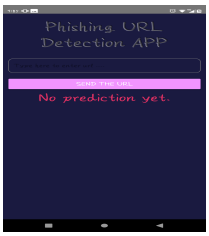

Fig. 20. Home Page.

Fig. 21. Fake Url.

V. Conclusion and Future Work

We have precisely improved the performance using machine learning techniques with feature extraction methods comparing with the traditional approaches. we have found above 97.47% of performance using these methods. We have used both Machine Learning and feature extraction techniques to create the models. We have trained and validate from same distributed data to create the model and evaluated it from different distributed of test data. After the evaluation the best models are Random Forest combining with Coefficient feature extraction. Next we have used our machine learning model to create an application by using react native.The app can classify whether the url is fake or real by using our machine learning model.

Due to some hardware limitations and the limited amount of time, we couldn't use more existing methodologies like deep learning, neural network etc.We had to experiment continuously and carefully to build the models and use every possible methods. We couldn't apply all the features for our existing application. And the app is hosted on local server. So in future it's structure can be better by using all features We have already got from our machine learning model and also can improve the user interface. Different types of embedding techniques also can be used and the existing methods like deep learning, tuning, data cleaning can better its accuracy.

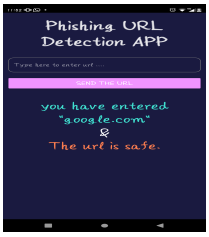

Fig. 22. Safe Url.

A Prototype Implementation of a CUDA-based Customized Rasterizer

Nakhoon Baek
School of Computer Science and Engineering
Kyungpook National University
Daehak-ro 80, Daegu 41566, Korea

***Abstract*—In these days, we have high-performance massively parallel computing devices, as well as high-performance 3D graphics rendering devices. In this paper, we show a prototype implementation of a full-software 3D rasterizer system, based on the CUDA parallel architecture. While most of previous CUDA-based software rasterizer implementations focused on the triangle primitives, our system includes more 3D primitives, and extra 2D primitives, to fully support 3D graphics library features. Currently, our system is at its prototype implementation stage, and it shows successful results with 3D primitive handling and also character output features. Our design and implementation details are presented. More optimizations and fine tunes will be followed in near future.**

Keywords*—3D rasterization; CUDA implementation; OpenGL emulation

I. Introduction

Web3D applications are designed to fully display and navigate web sites using 3D graphics features. Fundamentally, the Web3D applications need 3D rasterization process, either on the web-browser side, and/or on the web-server side. In this paper, we present a prototype implementation of 3D rasterizer, based on massively parallel processing features, as a framework for 3D web and associated application domains.

Massively parallel computing features are now widely available in many areas of computer science and engineering. From the 3D graphics rendering point of view, the 3D rendering pipelines are naturally developed to use massively parallel processing features. Additionally, we can also use the massively parallel computing features, especially with CUDA (compute unified device architecture) [1] and OpenCL (open computing language) [2].

Since these massively parallel pipelines, the 3D graphics pipeline and the high-performance computing pipeline, have many common characteristics, there have been several works to integrate these two different pipelines into a single one. More precisely, they tried to implement the 3D graphics rendering pipeline, on the existing parallel computing pipeline [3].

In previous works, they focused on the feasibility test, and most of them provides mainly the triangle rasterization process, with massively parallel computing libraries. In contrast, we aim at the full-scale 3D graphics rendering library implementation. For example, to provide the full features of the OpenGL (open graphics library) system, we need much more rather than the triangle rasterizer. At this time, we have a prototype implementation, which shows the possibility of the CUDA-based rasterizer, with several 3D graphics primitives and also extra 2D graphics primitives. It is the distinguished point of our work, in comparison to the previous works.

We start from presenting the previous works in Section II. Our motivation and overall design of the 3D rendering system based on CUDA will be presented in Section III. Implementation details and results from the prototype implementation will be followed in Section IV.

II. Previous Works

In 1990's, the programmable graphics pipeline has been introduced [4]. Rapidly, the GPU (graphics processing unit) became a computing device, with the concepts of GPGPU (general purpose GPU). In 2000's, the massively parallel computing devices including CUDA [1] and OpenCL [2] are available.

Since the programmable graphics pipeline and the massively parallel computing pipeline have common features, there have been several trials to implement the graphics processing features on the massively parallel processing devices. Some of them are summarized in the followings.

Mesa 3D graphics library [5] was originally implemented with CPU computing powers. Mesa is actually started as a re-implementation of widely-used 3D graphics libraries, including OpenGL [6] and Vulkan [7]. In its components, Mesa provides a full-software implementation of rasterizers, called "swrast". This implementation enables the 3D graphics rendering and 3D graphics shader features on CPUs. However, this CPU-based implementation is very slow, as we can expect, and thus, used only for limited purposes. Since this implementation was already available in 1990's, it actually affected its following implementations of software 3D graphics rasterizers.

Intel Larrabee project [8] was actually a hardware architecture, while it also aimed to provide an efficient software implementation of the 3D graphics rendering features. From the parallel processing point of view, the Larrabee project implements a binned renderer to increase the parallel processing features, and to reduce the memory bandwidth. Unfortunately, the Larrabee project was cancelled, and later rearranged to make high-performance computing processors.

FreePipe [9] is a fully-programmable 3D graphics pipeline, implemented in CUDA programming library. It developed some special features for the efficient rendering, even in a single pass rendering, with CUDA atomic operations. It shows good performance for small-size objects, while the

performance drops rapidly for large-scale and/or large-size objects, mainly due to the CUDA atomic operation behaviors.

CUDARaster [10] and its followers [11], [12], [13] are also software 3D graphics rendering pipeline implementations, with CUDA. CUDARaster was implemented for a specific CUDA model of Fermi, and it also uses some assembly-level codes, for optimization purpose. Unfortunately, it cannot be executed on the new CUDA architectures, since it was highly tuned and dependent on the old CUDA architecture.

The cuRE [14] is another rasterizer implementation to resolve the drawbacks of the previous implementations. This new rasterizer architecture can be executed on various modern CUDA architectures. It also shows several modifications, including direct wireframe rendering, programmable blending, and others.

Although we have some rasterizer implementations, especially based on the CUDA parallel processing architecture, our work aims to finally implement the full-scale 3D graphics system. Thus, we will include more 3D graphics primitives, and also 2D graphics primitives. The design and implementation of our system will be presented in the following sections.

III. Overall Design

In the case of OpenGL, they need at least the following 3D primitives:

- Points: A set of 3D points can be displayed. Additionally, they can set the radius of the point, or equivalently, the point size. The initial point size of 1 means a single pixel point, while we can also specify more big size points, which will be displayed as circles or rectangles on the screen.
- Line segments: A pair of 3D points can specify a 3D line segment. A sequence of line segments can also be displayed. In most cases, they use the line width of 1, to show one pixel wide line segments. With larger line widths, we can display thick line segments.
- Triangles: A set of three 3D points can define a triangle. A sequence of triangles are also possible, with triangle strips and triangle fans. Those triangles are usually filled with specified colors, or texture images.

In the previous works, they concentrated on the triangle primitives. In fact, the CUDA-based implementation of the triangle primitive is sufficiently difficult work, to be optimized and finely tuned. Also, we need to consider that most of 3D graphics scenes are constructed with triangles, since modern computer graphics object models are mostly based on the 3D triangle mesh models.

For a full-scale 3D graphics library implementation, we naturally need all of these 3D output primitives: points, line segments, and triangles. Additionally, for practical reasons, some 2D primitives are also needed to full-scale implementations. As an example, the resetting or updating of 2D rectangular areas in the framebuffer areas and/or in the texture image areas are needed frequently, even for the 3D graphics libraries.

Mostly required 2D operations are actually *bit-blt* (bit block transfer) operations, and can be summarized as follows:

- rectangular fill: The given rectangular 2D framebuffer (or image) area will be updated with the given colors (or numerical values). This operation can be used for the clearing of the whole or any partial framebuffer area.
- pixmap bit-blt: A pixmap means a 2D array layout of pixel values. A colorful image can be the typical cases. The image will be transferred (or more precisely, copied) to the specified rectangular area in the framebuffer or in the texture image area.
- grayscale bit-blt: A grayscale image can also be transferred to the framebuffer area.
- bitmap bit-blt: A bitmap represents a black/white image, through representing a black/white pixel with a single bit. This format is frequently used for bitmap fonts. Through transferring the bitmaps on the screen, we can display characters on the screen for extra information display.

For the overall design of the system, the 3D output pipeline will be maintained as the main stream pipeline. Fig. 1 shows the full 3D graphics pipeline of OpenGL 2.0 and OpenGL ES 2.0, which supports the vertex shaders and fragment shaders. It is used as the start point of our implementation. Our current prototype implementation focuses on the primitive assembly and rasterizer module.

The essential role of the "primitive assembly and rasterizer" module is converting the given 3D coordinate specifications to a set of 2D pixels, which are targets to be updated. The vertex shader and the fragment shader can be regarded as the preprocessing and post-processing to this module.

At this time, our CUDA-based implementation is based on the commercial CUDA-capable graphics cards. Thus, our prototype implementation is realized as a set of CUDA kernel programs, as shown in Fig. 2.

User inputs and rendering operations are provided through the C/C++ API function calls, to prepare the 3D graphics data in the CPU memory area. The 3D graphics data will be copied to the CUDA memory area, similar to the typical CUDA programs.

A big-size CUDA memory area is dedicated to the "logical framebuffer", which act as the real framebuffer, but cannot be displayed directly on the screen. Instead, the "logical framebuffer" is shared as an OpenGL texture image, and an independent OpenGL program is executed to simply display the logical framebuffer texture image on the screen.

For embedded systems, we can customize the current implementation, with new hardware display circuit supports, as shown in Fig. 3. With customized display logic implementations, the "logical framebuffer" can act as the real physical framebuffer. In this case, the display speed will be much more enhanced. This customized display circuit support will be the future works. In the next section, we will explain our current CUDA kernel implementations.

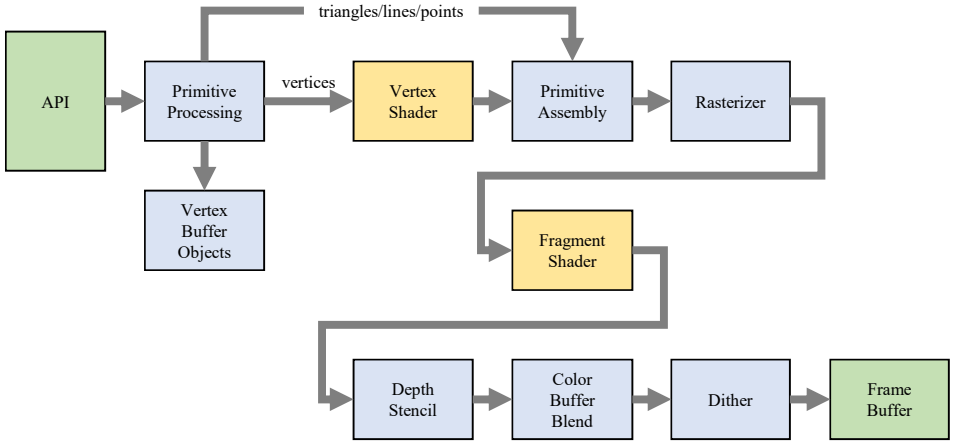

Fig. 1. A Typical 3D Graphics Rendering Pipeline.

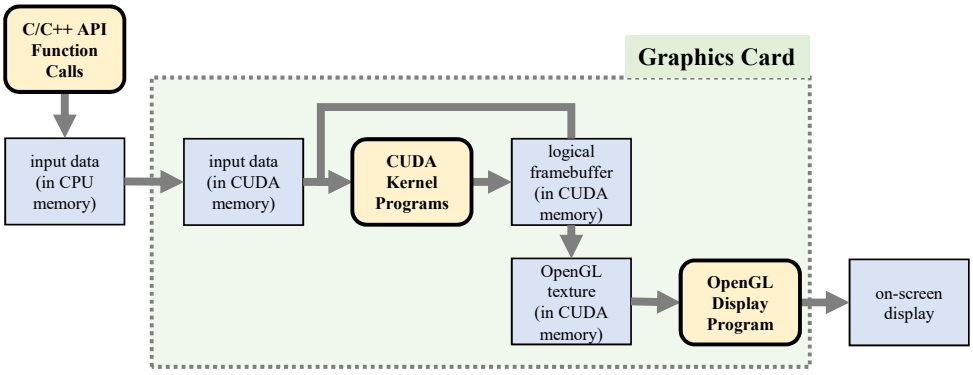

Fig. 2. Our Current CUDA-based Implementation Layout.

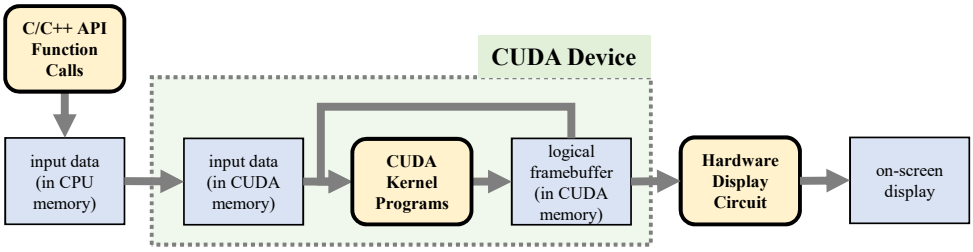

Fig. 3. Another Possible CUDA-based Implementation Layout.

IV. Implementation

The core of our implementation is a set of CUDA kernel programs, whose layouts are based on the rectangular division of the screen. It is actually typical approaches used in most previous works. As shown in Fig. 4, the whole screen (as an example, 1,280 by 1,024 pixels) is divided into a set of rectangular tiles. Each tile consists of 32 by 32 pixels, or equivalent, 1,024 pixels.

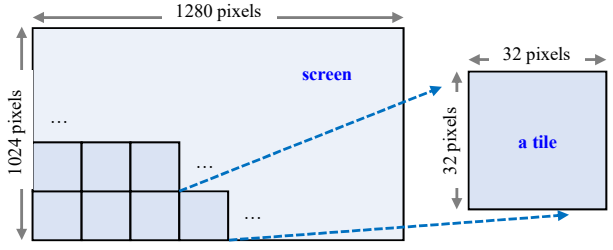

Fig. 4. The Screen Layout with Tiles.

From the CUDA programmer's point of view, it is convenient to allocate a single thread for a pixel on the screen. Thus, as shown in Fig. 5, we use a 2D thread block of 32-by-32 thread layout. This 1,024 threads are actually the current CUDA limits to the maximum number of threads in a single thread block. Then, to make the whole 1,280-by-1,024 threads,

we use 40-by-32 blocks for the CUDA grid. Thus, the whole grid corresponds to the whole screen. The grid is divided into 40-by-32 thread blocks, while the screen divided into that numbers of tiles. And, the 32-by-32 thread block corresponds to the thread block.

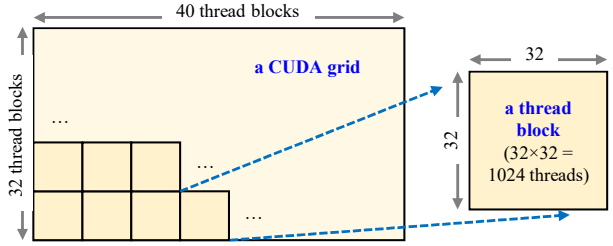

Fig. 5. The CUDA Grid Layout with Thread Blocks.

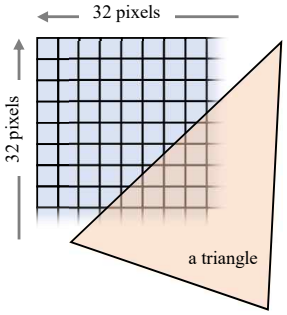
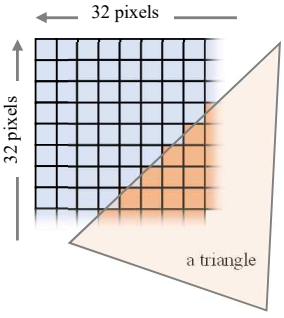
This thread block layout has some benefits. In the case of triangles, the pixels, or equivalently, the CUDA threads can decide whether they are located in the interior of a given triangle or not, in a massively parallel way. Each thread will calculate the signed areas of some configurations, from the given window coordinates of the vertices. Only the interior threads will turn on their corresponding pixels, to display the given triangle on the screen, as shown in Fig. 6.



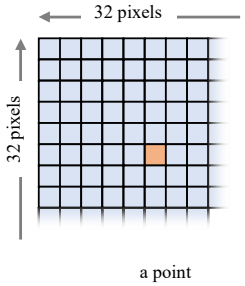
(a) A Triangle Overlaid on the Tile



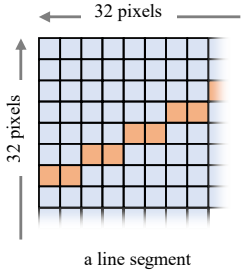
(b) The Triangle Rasterization Result

Fig. 6. A Tile-Based Rasterization Example for a Triangle.

In the case of points and line segments, the tile based approach can be inefficient, especially for the single pixel points and the single pixel wide line segments. For a single pixel point, the thread block should launch totally 1,024 threads, due to the CUDA kernel launch mechanism and our thread block configurations. Then, only one thread will turn on the pixel, while others all should discard their processing, as shown in Fig. 7(a). Similarly, a single pixel wide line segments, at most 32 pixels will be turned on, even though initiating totally 1,024 threads, as shown in Fig. 7(b).



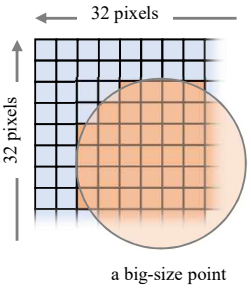
(a) A Single-Pixel Point Case



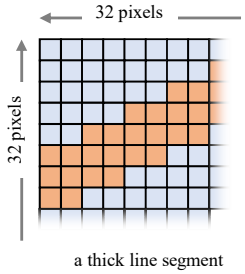
(b) A Line Segment with One Pixel Width

Fig. 7. A Tile-Based Rasterization Example for a Point and a Line Segment.

In contrast, the tile based approach can efficiently works with big-size points, and think line segments. As shown in Fig. 8(a), the big-size points are typically implemented as circles, and the threads in the tile can check whether they belongs to the interior of the circle or not, similar to the triangle cases. Thick line segments can also be handled efficiently, as shown in Fig. 8(b). The effective threads can check their corresponding conditions in a massively parallel manner.



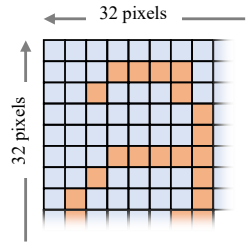
(a) A Big-Size Point Case



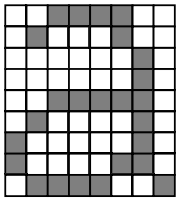
(b) A Thick Line Segment Case

Fig. 8. Another Tile-Based Rasterization Example.

The tile-based approach can work for most of bit-blt operations. For a given rectangular region, the threads will get the corresponding pixel information, and then update their own pixels, to get the final result. As a direct application of these bit-blt operations, we added character display features to our implementation. In this case, the true type fonts are pre-processed to get the character font information and the grayscale image of each character [15], as shown in Fig. 9(b). Our thread blocks will process the character font information, and finally show the character on the screen, as shown in Fig. 9(a).



(a) A Character Display Example



(b) A Grayscale Image from True Type Fonts

Fig. 9. A Tile-Based Rasterization for Character Display.

At this time, our prototype implementation shows the basic rasterization CUDA kernels are working well. As an example, Fig. 10 shows the screen shot of the triangle rasterization result, from our CUDA-based rasterizer implementation. It shows the correct display of the triangle coordinates, as specified in the input vertex specifications.

Additionally, the barycentric interpolation of interior points are also demonstrated. We specified different vertex colors at each vertex of the triangles. The interior pixels have the interpolated colors, according to the barycentric interpolation, specified in the OpenGL specification [6].

Unlike the previous works, our CUDA-based rasterizer implementation supports more output primitives, in addition to the triangle primitives. Fig. 11 shows a demonstration of 3D points, from our prototype implementation. It shows the circular points, as expected.

As another distinct example, we implemented the text output routines, with underlying bit-blt primitive support. Our CUDA kernels support bit-blt operations, and we use some grayscale or bitmap images of the true type fonts, with the free true type font library [15]. The images are blended into the screen, to make smooth font display results. Fig. 12 shows an example screen shot of our font rendering result, with more than 100 text output results, each of which specify random text colors and a complete sentence to be displayed. It shows that our CUDA-based implementation has some

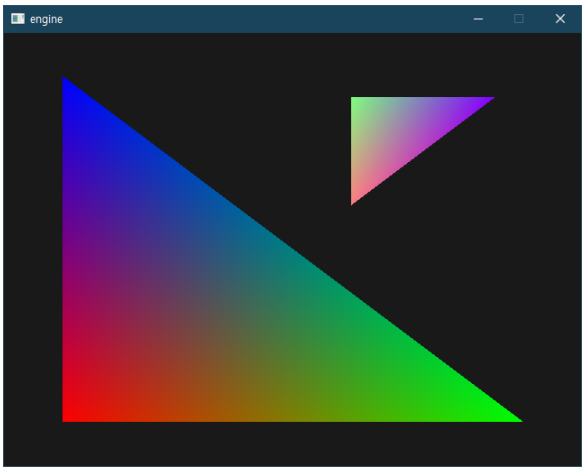


Fig. 10. A Screen Shot of Triangle Rasterization, from our CUDA-Based Rasterizer Implementation.

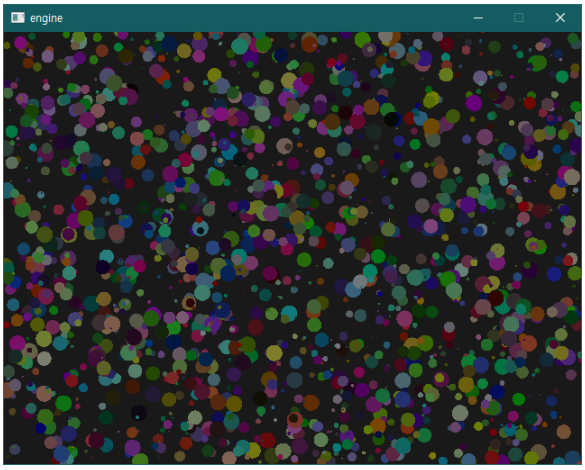

Fig. 11. A Screen Shot of Point Rasterization, from our CUDA-Based Rasterizer Implementation.

distinguished points, in comparison to the previous rasterizer implementations.

V. Conclusion

Our motivation was implementing the 3D graphics rendering pipeline on the massively parallel computing pipeline. In this case, we can make a full-software implementation of the graphics rendering features. To realize this goal, we started to implement common 3D rendering features on the CUDA architecture.

Since we aimed to get a full-scale implementation of typical 3D graphics library, we selected several 3D graphics primitives including points, line segments and triangles. Additional image handling operations are also needed, and we added some 2D pixel level primitives. Currently, our prototype implementation shows those primitives are working well. More fine tunings and optimizations should be followed, and they will be our near future works.

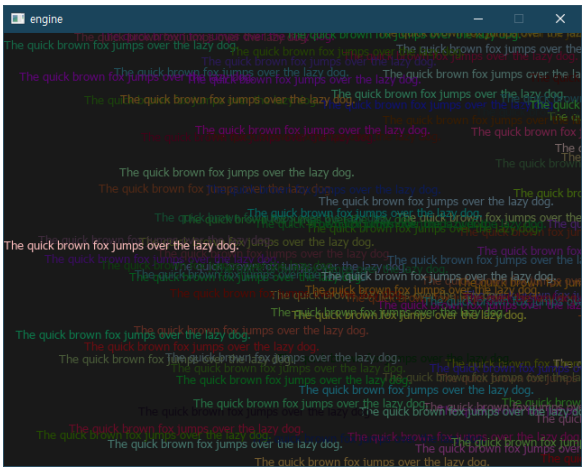

Fig. 12. A Screen Shot of True-Type Font Rasterization, from our CUDA-Based Rasterizer Implementation.

ACKNOWLEDGMENT

Mobile App Design: Logging and Diagnostics of Respiratory Diseases

Diana Cecilia Chávez Cañari[1], Ángel Vicente Garcia Obispo[2], Jose Luis Herrera Salazar[3], Laberiano Andrade-Arenas[4], Michael Cabanillas-Carbonell[5]
Facultad de Ingeniería y Negocios, Universidad Privada Norbert Wiener, Lima, Perú[1,2,3,4]
Facultad de Ingeniería, Universidad Privada del Norte, Lima, Perú[5]

***Abstract*—Over the years, a wide variety of respiratory diseases have caused a high mortality rate throughout the world. This was again observed with the appearance of the pandemic, COVID-19. In addition, the most affected are people living in extreme poverty. The objective is design a mobile health application for the registration and diagnosis of respiratory diseases. For this, the RUP methodology was applied, because it easily adapts to various types of projects. Its use, together with the UML process development software, allows the analysis, implementation and documentation of object oriented systems. For validation, a user survey was carried out and the questionnaire was based on the dimensions of functionality, efficiency, effectiveness and satisfaction. Obtaining as a result a positive qualification to the design of the application and its acceptance due to the reduction in the time to obtain the diagnosis. In conclusion, a mobile health application design was successfully carried out so that patients can register and have the diagnosis of respiratory diseases from the comfort of their home.**

***Keywords*—Mobile app; Covid-19; diagnosis; respiratory diseases; RUP methodology**

I. Introduction

In the world there are a large number of diseases of varying degrees of danger that affect the respiratory system. From 2020 to the present, COVID-19 caused by the SARS-CoV-2 [1], virus is characterized by symptoms similar to those of a common cold. As it progresses, it causes multi-organ damage, including respiratory distress [2]. Therefore, this pandemic has generated a high rate of morbidity and mortality worldwide. The people most likely to have a fatal prognosis are those who present pre-existing diseases to contagion, so they are classified as a high-risk group. The most vulnerable people are the poorest people [3].

Another disease that strongly affected Latin America is influenza. This was observed in the research [4], where the author compared information from 10 countries (Guatemala, Honduras, El Salvador, Nicaragua, Costa Rica, Panama, Ecuador, Brazil, Argentina and Chile). The data analyzed were influenza A subtypes H1N1, H1N1pdm09, and H3N2, influenza B subtypes Victoria and Yamagata, and non-subtypes of both types. The results showed that of the 37,087 cases reported between the years 2004-2012, the most predominant was type A influenza.

On the other hand, the investigation [5], was carried out in Peru, between the years 2011 and 2016 due to the large number of deaths caused by acute respiratory infections (ARI). The purpose of this study was to make known which were the most affected departments. For this, geographic information systems were used. From there, information was obtained on the existing conditions in those areas. The findings showed the various factors that caused the disease in Peruvian children under 5 years of age.

Thus, currently going through the global pandemic, COVID-19, people have become more aware of health care [6]. This situation allowed mobile healthcare applications to expand and evolve faster and stronger. The development of smart mobile health applications allow improving the effectiveness and efficiency of various processes. The use of monitoring features, appointment booking scheduling, self-diagnosis, emergency care and home visit received a positive response from users. Given these results, the RUP methodology was used in the software development process because it provides techniques that team members must follow in order to increase their productivity and generate a high-quality product.

In this context, the present work objective to design the prototype of a mobile health application that presents characteristics of remote registration and diagnosis through a questionnaire of symptoms. Being these relevant factors to avoid the prolonged time of exposure to various pathogens that further complicate their clinical picture. Therefore, its importance lies in improving the effectiveness and efficiency of the registration control processes and patient care [7].

Finally, the structure of the work is broken down into six sections. Section II explains the review of the literature, section III the methodology, section IV the results, section V discussions, and finally section VI the conclusions and future work.

II. Literature Review

This section focuses on analyzing the different investigations related to this research work, finding its results and conclusions.

A. Background

COVID-19 appeared in Wuhan, China and is caused by the SARS-CoV-2 virus. This strain that infects humans became a pandemic due to its easy transmission. Reason that caused a high rate of sick and dead around the world. The studies carried out showed that the greatest number of deceased were

elderly people and those who had pre-existing diseases. Little by little, the specialists were documenting information about this lethal disease and sharing it with the rest of the countries in order to find a solution. In addition, the most reputable web platforms around the world were very important in order to obtain real-time statistics on reported cases [8]

The rapid increase in cases of the global COVID-19 pandemic was due to the fact that doctors in this country initially had great difficulty in identifying infected people. This highly contagious disease is characterized by causing acute respiratory distress syndrome. Therefore, in case of presenting some other disease, the mortality rate increases [9].

In Peru, the MINSA website reports data about the population and Covid-19, such as the number of positive cases, numbers of hospitalized, deceased and vaccinated, number of people who underwent antigen and rapid tests. This information is found segmented by departments of the country and months, but general statistics are also found [10].

B. Related Work

The Rational Unified Process (RUP) [11] methodology can simplify the process of analysis and design of information systems, but of course, each method will have its advantages and disadvantages in certain situations and conditions. Using the RUP method you can accept changes to improve existing prototypes so that they can produce an acceptable system, and the changes that occur are considered as part of the development process itself.

This research [12] explains that mobile applications, by integrating medical records electronically into the health record system of hospitals, facilitate the management of medical treatments and interventions. The application made for the local hospital Sidi Said located in Meknès - Morocco resulted in a high rate of approval by patients by obtaining positive results in improving their health by monitoring their illnesses at home and by the patients. doctors, who with timely information could make better health decisions.

Today there are various techniques applied in desktop, web and mobile environments; which facilitate the human being to carry out a series of processes according to the author [13]. In this sense, the use of technologies for the diagnosis of respiratory diseases becomes a very favorable process when a chatbot is used together with a mobile application because it allows more accurate results.

Artificial intelligence (AI) occurs in different contexts such as industry, biology, computer science in order to give solutions. It has been widely demonstrated that in order to make this tool highly effective, the knowledge of expert professionals is required. According to [14] this entered information is contrasted with the data entered by those people who present symptoms of respiratory diseases. Using the information provided by experts increases the accuracy of the result that indicates the diagnosis of respiratory diseases presented by the individual.

The author's research [15] focuses on pneumonia; respiratory infection resulting in inflammation of the lungs. The causes of this respiratory disease can be attributed to viruses, bacteria or fungi. Rural people in developing countries have limited access to doctors, medical diagnostic centers, and hospitals. Therefore, for this article, a smartphone-based app for preliminary detection of pneumonia using X-ray images was designed and developed. The app was developed in Android Studio and incorporated the Tensor Flow library.

The mobile technology model proposed by the author [16], for online ambulatory health care information, uses a cloud platform. The model consisted of four phases: 1) The selection of structured data; 2) The integration and storage of data in a cloud database; 3) Real-time data testing using a data analytics service; 4) The results of the pharmacological consultation are displayed through a mobile application and the geolocation service can determine the closest pharmacies to the current location of the patient.

In summary, different research works were compared and it was observed that the authors focus on the development of mobile applications for the health sector with attributes such as functionality, quality and design. However, no reference is made to existing integration problems in the health system, which makes it difficult to obtain information from all health centers in the country.

III. Methodology

For the development of the application, the analysis of various methodologies was contemplated; According to [17] the development of good software depends on the use of adequate methodologies that allow compliance with existing standards for this type of project. This section explained the methodology, as well as the tools used in the development of a mobile application to improve the registration and diagnosis of patients with respiratory diseases in Lima-Peru. Its uses are due to the fact that they help in reaching objects in an agile way.

The methodology that served as a guide for the development of the project was the Rational Unified Process (RUP) methodology, according to [18] it allows adjusting various components and repeating phases of the cycle as many times as necessary until the software meets the requirements and objectives. Among the functions it offers are the assignment of tasks and responsibilities within the company to guarantee the production of high-quality software.

The development of the mobile application was carried out in Android Studio, according to [19], the integrated development environment (IDE) was introduced in the years of 2013 and is based on IntelliJ. What makes it a powerful code editor is that it provides built-in services and allows for a wide variety of customization options for Android app development.

SQL Server was used as a database manager as a knowledge base in which the user interacts in order to manage possible diagnoses based on the questions asked in the mobile application, according to [20] the importance of Database security is something that has to be considered in projects, giving as an example basic database security guidelines.

A. RUP

The methodology called Rational Unified Process (RUP), was applied with the purpose of creating high quality software. This agile methodology allows developing projects on a small

and large scale, since it adapts to the needs of different types of projects, especially in the use of each role. Additionally, it can also be used in projects that require reengineering [21].

1) RUP Life Cycle: Fig. 1 shows the life cycle of the RUP methodology where spiral development is implemented according to [22]. In the life cycle, tasks are performed in four stages or phases where a variable number of iterations occur. The first few iterations (during the Inception and Discovery phases) focus on understanding the problem and the technology, defining the scope of the project, eliminating critical risks, and establishing a baseline.

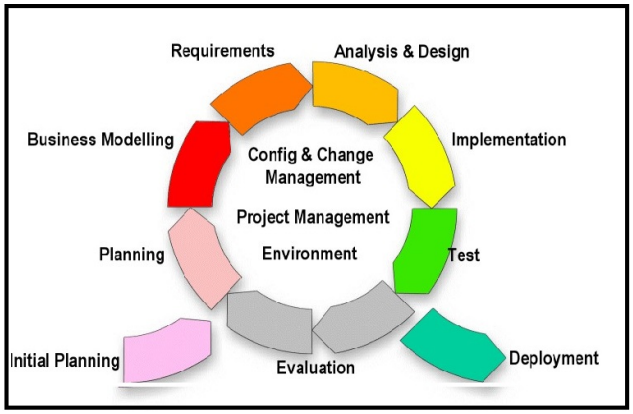

Fig. 1. RUP Life Cycle.

2) Phases of the RUP Methodology: The RUP methodology it is divided into four phases: Introduction, which defines the business case and scope of the project, identifies the most important use cases for the system and the stakeholders that interact with the system; in the development phase, an architectural prototype is built, which ensures minimizing risks and loss of information; construction phase to add functionality to the system; and the purpose of the transition phase is to deliver the system to the end users and make the appropriate adjustments or improvements, since failures often occur during testing [23].

3) Key Principles of the RUP: The RUP is based on 6 key principles; adapt to the process, maintain the balance of priorities, demonstrate value iteratively, allow collaboration between teams, focus on quality and raise the level of abstraction [24].

B. Tools and Programming Language to Develop the Prototype

This segment detailed the tools to be used to develop the prototype of the mobile application focused on improving the registration and diagnosis of respiratory diseases caused by Covid-19, as well as the programming languages to be used and the database.

1) Mockplus: The fabrication of the prototype was carried out in Mockplus [25], a tool that facilitates the creation of prototypes. It makes design faster, smarter and easier. It is integrated with more than 100 components with which any software prototype for mobile, web and desktop applications can be designed. Also, you can work online and offline on Windows PC.

2) Android Studio: Android Studio is an environment integrated development (IDE) that has a large number of methods and access to components that allows you to develop applications on Android. According to [26], this powerful code editor based on IntelliJ IDEA has a wide variety of development tools and offers various productivity functions.

3) Java: For the development of this application, the Java programming language because it is compatible with Android Studio. According to [27], this high-level programming language allows developers to write more robust, secure and stable code. It is widely used by programmers because it is a high performance, dynamic, simple and easy to understand language. In addition, it provides great advantages such as improving the efficiency of programming and the practicality of the software.

4) SQL Server: The Microsoft SQL Server tool (MSSQL) that allows you to store and manage the confidential data of both people and companies is regularly updated. This relational database manager is used by many users because it adapts correctly to various development platforms, such as .NET [28]. Additionally, according to [29] Android Studio with the Java language together with the SQL Server database. The integration of these technological tools allows the company's objectives to be achieved because it contributes to the improvement of processes where it is necessary to manage large volumes of data.

IV. Case Study

A. Development of the methodology

Based on what was mentioned above and the procedures that were detailed, an Android application based on registering and diagnosing people who present symptoms of respiratory diseases will be implemented.

1) Start Phase: This section defines the scope of the project with the clients, the risks associated with the project are identified, the plan of the phases and the subsequent iteration are drawn up, the software architecture is also detailed in a general way.

Definition of the Scope of the Project with the Clients:

To know the existing needs, the interview was used as a data collection instrument. The information obtained can be seen below:

- Patient: Let it be a mobile application to have quick access to registration and notifications in case of rescheduling of a medical appointment.
- Receptionist: Display the dates, hours and specialties of the doctors, taking into account the limit number of visits per shift and the shift changes made.
- Doctor: That the application be interactive with patients so that they can improve the diagnostic process.

Table I shows the methodologies and the platform used for the development of the project.

TABLE I. METHODOLOGY AND PLATFORM FOR DEVELOPMENT

N°	Description
1	Methodology learned in the university journey
2	Methodology used to date in various companies
3	Applied in small and large scale projects

2) Elaboration Phase: At this stage, define the requirements and is where a preliminary solution is designed, use cases are selected to define the underlying system architecture, and the first domain analysis is performed.

Definition and Determination of Requirements: After collecting the information from the business actors, the most relevant requirements for the development of the project are determined.

Table II mentions the functions that the system will present.

TABLE II. FUNTIONAL REQUIREMENTS

Code	Description
RF01	Enter the app
RF02	user management
RF03	Log management and diagnosis

Process Use Cases Table III lists the people who participate in the process related to the system access use case and the actions they should perform.

Table IV mentions the people who participate in the process related to the registry and diagnosis management use case and the actions that they must carry out.

Fig. 2 shows how the different parts of the system interact with each other in order to carry out a task, and the order in which the interactions are performed when executing a specific use case.

Table V shows the table based on the sequence model where the tasks to be performed by the system are mentioned.

3) Database Construction Phase: the basis of The aforementioned data was designed based on a rigorous analysis of the requirements that were obtained from the interviews with the different users, including doctors, patients and the receptionist. Observing the database from all perspectives will help avoid errors.

TABLE III. LOGIN USE CASE DIAGRAM

Use cases	Use cases
Actor	Doctor, Patient and Admission
Description	Each actor must enter the system, entering their username and corresponding password.
Preconditions	The staff requests user registration from the administrator.

TABLE IV. LOG MANAGEMENT AND DIAGNOSIS

Use cases	Log management and diagnosis
Actor	Doctor
Description	The medical actor will fill out the diagnostic questionnaire for respiratory diseases
Preconditions	The staff must have the role of doctor

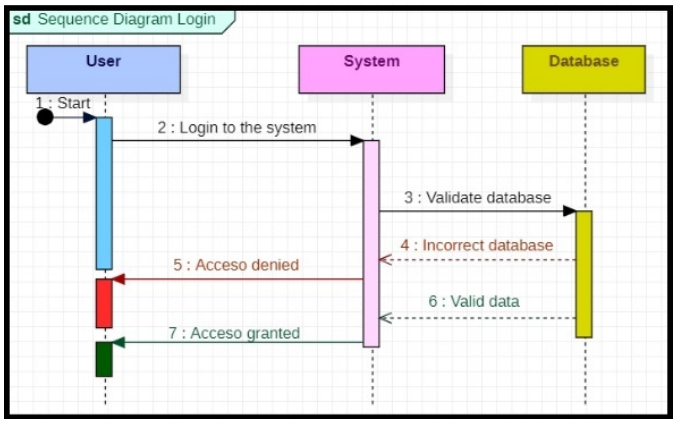

Fig. 2. Sequence Diagram Model.

TABLE V. SEQUENCE DIAGRAM MODEL

Code	Description
MDS01	Enter the app
MDS02	user management
MDS03	Log management and diagnosis
MDS04	care management

Fig. 3 shows the schema of the database in which the various tables and the relationships between different entities of the system are shown.

4) Construction Phase: The function of this phase is complete system functionality, clarify outstanding requirements, manage changes accordinglyo the evaluations made by the users, and improvements are made for the project.

In Fig. 4(a) you can see the login, which is where the user and password are validated to start the session and in Fig. 4(b) the home screen is shown in which there is a layer that is used to receive notifications, a section with information related to the respiratory system, a section for locating the closest hospitals to your location and an icon to display the menu.

In Fig. 5(a) the options menu is displayed to access the COVID-19 survey, survey history and profile interfaces and in Fig. 5(b) the Covid-19 prediction interface is observed where The symptoms presented by the patient are selected and saved.

In Fig. 6(a) is the interface where it is shown the graph of the probability of presenting a respiratory disease, below the recommendations and then options to communicate with a health personnel and in Fig. 6(b) the survey history details all the times the survey has been carried out, the disease detected, the date, state and probability percentage.

In Fig. 7(a) the user profile is presented, consisting of the photo, full name and role of the user, followed by icons of social networks with which it can be linked, under general vision options, settings and change of password and in Fig. 7(b) you can see the option to change the password displayed where you must enter the current password, the new one, repeat the new one and press the button to change the password for this to be done.

In Fig. 8 you can see the option to disconnect that allows

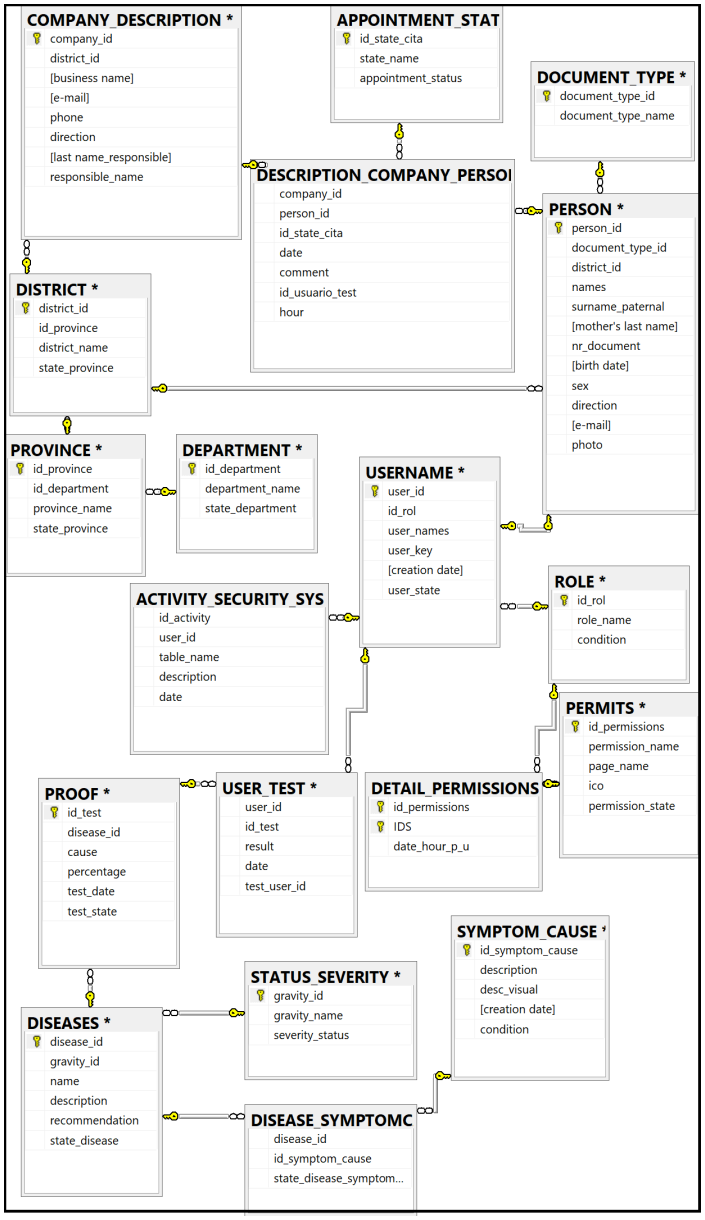

Fig. 3. Database.

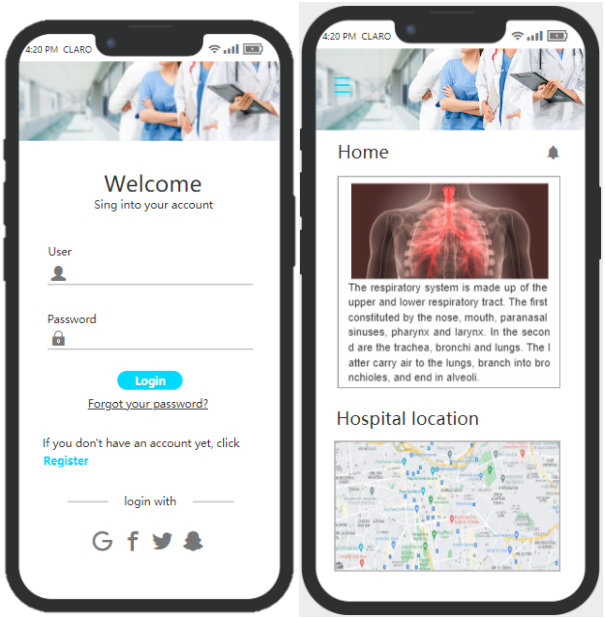
you to exit the session, which will redirect the user to the login view.

5) Transition Phase: In this phase, the purpose is ensure that the software is available to end users, correct errors and defects found in acceptance tests, train users and provide the necessary support.

V. Results

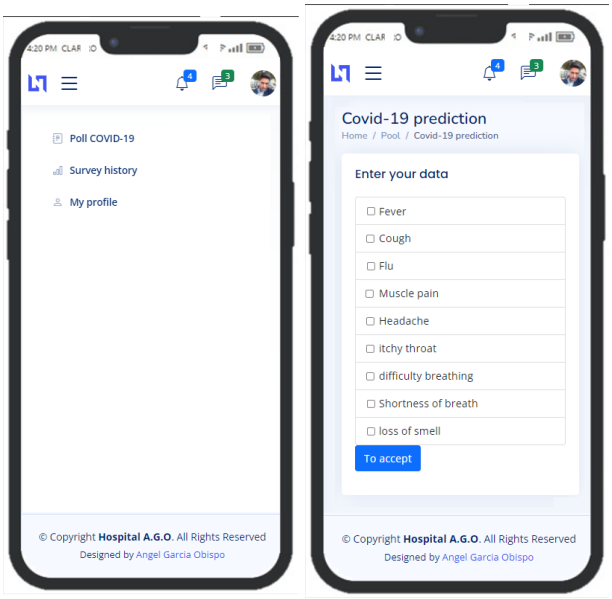
A. According to the Prototype

Fig. 4 presented the login and home modules. The first module allows entry to the session after verifying that the entered user has been previously registered; in addition, the password must correspond to said user; this is done for security reasons. Fig. 5 presented the menu of options offered by the application and the prediction of Covid-19. In the latter, the



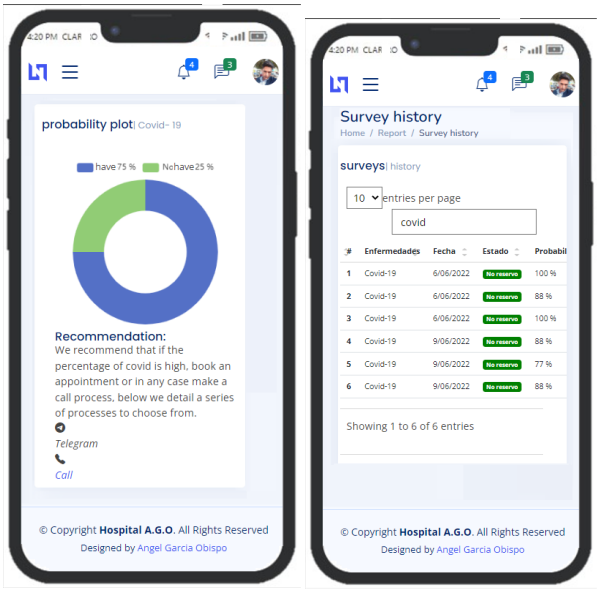
(a) HU-07 (b) HU-08

Fig. 4. Login and Home Prototype.



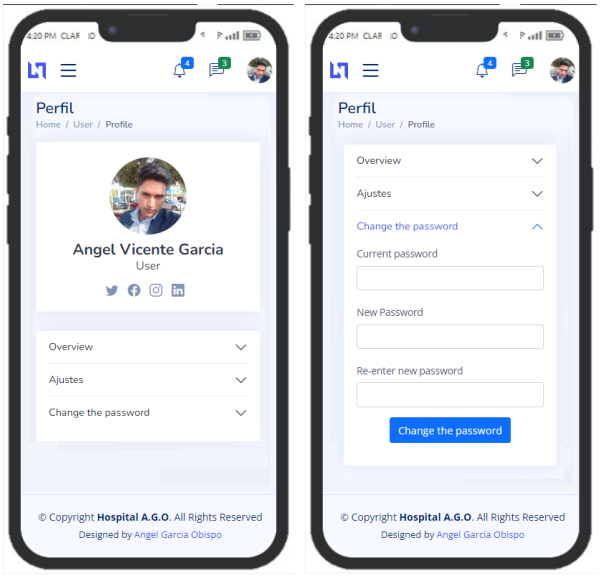
(a) HU-09 (b) HU-10

Fig. 5. Menu and Prediction of Covid-19.



(a) HU-11 (b) HU-12

Fig. 6. Probability of Covid-19 and Survey History.



(a) HU-13 (b) HU-14

Fig. 7. Profile and Password Change.

user selects the symptoms that they present and when pressing the To accept button, Fig. 6 will show the probability that a person has of have Covid-19 according to the information entered and the survey history where it is recorded each time the symptom survey has been carried out. On the other hand, Fig. 7 presented the profile and password change modules and finally in Fig. 8 the option to disconnect was presented, which allows to exit the session correctly.

1) The Results According to the Dimensions: What research method the survey technique was used to know the

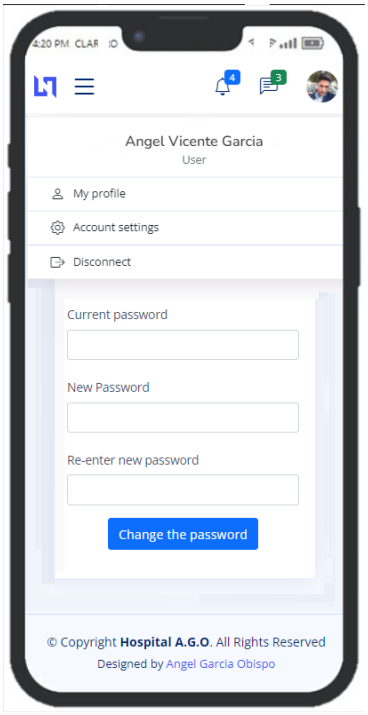


Fig. 8. Disconnect.

TABLE VI. ACCORDING TO THE SURVEY

Dimension	N°	Question
Functionality	P01	Do all the filling fields allow to enter the data correctly?
Functionality	P02	Do all the buttons work correctly?
Functionality	P03	Is the data saved correctly?
Functionality	P04	Does the application correctly show you the closest hospitals to the area where you are?
Functionality	P05	Does the signs and symptoms questionnaire allow multiple selections?
Effectiveness	P06	Do you perceive any slowness in the use of the application?
Effectiveness	P07	Does the result shown by the application correspond to the diagnosis given by your doctor?
Effectiveness	P08	Should the questionnaire be updated depending on whether new symptoms are found?
Efficiency	P09	¿La navegación es fácil e intuitiva?
Efficiency	P10	Does it take time to display the results or give an answer?
Efficiency	P11	Are all the functions of the application easily accessible?
Efficiency	P12	Did the application allow you to obtain a diagnosis quickly?
Satisfaction	P13	The results obtained that were evaluated with the doctor. Did I demonstrate the effectiveness of the application?
Satisfaction	P14	Do you feel that the application is user friendly?
Satisfaction	P15	Are you satisfied with the questionnaire?

opinion of users (patients, doctors and other users) about the application. To do this, 15 questions were asked that are grouped into four dimensions as shown in Table VI.

2) About the Survey: Upon completion of the user survey, it was possible to obtain 51 answers that allowed generating Table VII. It shows in detail the results obtained in the

response options yes, regularly and no presented by each of the questions asked. In Fig. 9, the results obtained in each of the dimensions are presented graphically according to the response options.

TABLE VII. RESULT OF EACH QUESTION IN PERCENTAGE

Dimension	Numero pregunta	Si	Regularmente	No
Satisfaction	P13	41%	39%	20%
	P14	100%	0%	0%
	P15	20%	78%	2%
Funcionalidad	P01	100%	0%	0%
	P02	100%	0%	0%
	P03	100%	0%	0%
	P04	41%	59%	0%
	P05	80%	0%	20%
Eficacia	P06	2%	59%	39%
	P07	59%	41%	0%
	P08	100%	0%	0%
Eficiencia	P10	2%	59%	39%
	P11	61%	39%	0%
	P12	22%	78%	0%
	P09	100%	0%	0%

The measurement of the scale was made based on 1 which denotes a high approval of the application, 2 denotes a medium approval of the application and 3 denotes a low approval of the application.

3) Phase of Assigning Scores to Securities: In this phase its purpose is to assign a range of values to the answers of the questions in order to know if the application meets the needs of the users. These will be in accordance with the assigned dimensions in order not to neglect the answers obtained. The score to be taken into consideration is found in Table VIII.

4) Assignment of Scale Indicators: In this phase its purpose is to define the percentage of the validity of each question with the sole purpose of obtaining a better validity of the program. Table IX serves to determine the scale in which the application is found.

5) About Data Analysis with SPSS: Next the graphs obtained from SPSS are detailed.

In Table X it is observed the Frequency percentage of each question and answer.

About the Chart Fig. 9 details the graph obtained based on the results obtained, favoring the implementation of the program, hoping that the survey obtained is the most appropriate to obtain the result.

TABLE VIII. ASSIGNMENT OF SCORES TO SECURITIES

B. About the Methodology

The selection of the methodology used in this research work was made after making a detailed comparison with each of them. Due to the qualities found and based on the nature of the project, the RUP methodology was chosen. The reasons why it stood out from the others is that despite being structured, it is also flexible and because it allows tests to be applied in the various phases of software development, which guarantees the delivery of a quality product.In the option of choosing between the Rup and Scum methodology, Rup was chosen since it was adapted to the research carried out; since Scrum works with sprint and finished product adapting to change, instead Rup allowed to work with the identification of functional requirements that are modeled through prototype design. It also allowed to make the documentation for each stage.

VI. DISCUSSIONS

The analysis of the literature review [11] allowed us to compare the RUP methodology against other software development methodologies, in order to use the best option

for the present work. From here, the RUP methodology could be identified as the best alternative due to its adaptability. On the other hand, in the investigation carried out, a series of findings were found due to the survey carried out where 79 percent were satisfied, coinciding with the author [30], regarding the use of a tool for detecting respiratory diseases in mobile phones, notwithstanding the research carried out by the author [14], it is very different since they used an interview looking at the opinion of the users involved. Regarding the prototype, the author [31], coupled the topic of a prototype on a web page and compare it with the research carried out, not having a coincidence since it limits us to only web prototypes without the use of an expert system. According to the efficiency results obtained, it agrees with the author [16], in that there isa fast response when displaying the results. Likewise, there is concindence with the function of diagnosing respiratory diseases with mobile application of the authors [15], however, they differ in the way of obtaining data on the symptoms presented by users.

VII. Conclusions and Future Works

In conclusion, in the present research work it was possible to successfully design a mobile health application for the registration and diagnosis of patients with respiratory diseases, by using the RUP methodology for its development, the quality of the product is guaranteed. In addition, it is supported by the survey of 51 users; which validated that the application meets the criteria of functionality, efficiency. efficacy and satisfaction. Likewise, the application allows people who suffer from respiratory diseases to register their information and have diagnosis from the comfort of your home. Regarding the limitations of the research, there is the lack of validation of the prototype by experts, since the collection of information about respiratory diseases was collected only from the bibliographic review. In addition, the data used for the survey has been limited to symptoms that occur in a small group of respiratory diseases; this is due to the time in which the data collection was carried out.

Based on the designed prototype, it is recommended to expand the functionalities of the application in future research in order to more accurately detect respiratory diseases. Future research is needed to expand the collective understanding of the application of other emerging technologies in health applications and to optimize diagnostic results in patients with respiratory diseases.

Summarizing Event Sequence Database into Compact Big Sequence

Mosab Hassaan
Faculty of Science, Benha University, Egypt

***Abstract*—Detecting the core structure of a database is one of the most objective of data mining. Many methods do so, in pattern set mining, by mining a small set of patterns that together summarize the dataset in efficient way. The better of these patterns, the more effective summarization of the database. Most of these methods are based on the Minimum Description Length principle. Here, we focus on the event sequence database. In this paper, rather than mining a small set of significant patterns, we propose a novel method to summarize the event sequence dataset by constructing compact big sequence namely, BigSeq. BigSeq conserves all characteristics of the original event sequences. It is constructed in efficient way via the longest common subsequence and the novel definition of the compatible event set. The experimental results show that BigSeq method outperforms the state-of-the-art methods such as Gokrimp with respect to compression ratio, total response time, and number of detected patterns.**

***Keywords*—Sequence data; compressing patterns mining; minimum description length**

I. Introduction

Detecting the key patterns from a database is one of the main objectives of data mining. There are many studies for mining all patterns that satisfy some constraints (such patterns may be frequent patterns as in PrefixSpan [11], CM-SPADE [19], PRISM [15], and [20] , or closed patterns as in [24][7][14][2], or maximal patterns as in [3], [23]). Rather than mining all patterns, existing methods mining a set of patterns that is significat for summarizing the dataset. There are many methods to define this significant patterns. One of these methods is the Minimum Description Length (MDL) principle [21][12][6][22] which has proven to be particularly the winner one.It is based on the insight that any regularity in the dataset can be used to compress the dataset. Note that, the more we can compress, the more regularity we have found. More details about MDL are described in next section.

For itemsets data, Krimp [13] is based on MDL principle. For sequence data, the authors of SeqKrimp [8][9], Gokrimp [8][9], and SQS [18] used MDL principle to compress the sequence data. More details about these algorithms are illustrated in the related work section (Section III).

In this paper, we focus on the event sequence data. Our objective is to search for a summary of the given event data sequences. The size of this summary must be very small compared to the size of the event sequence dataset. Also this summary must converse the all characteristics of the original event sequences. The existing methods mine a significant patterns that compress the dataset well. Some of these methods generate the sequential patterns as a first phase. Then the significant patterns are selected with respect to MDL as a second phase. Note that the significant patterns is only a small subset of the set of all the sequential patterns and the process of mining all sequential patterns is very expensive process. Therefore, the other existing methods devise some effective pruning methods to prune the ineffective parts of the search space that do not contain any significant pattern. Unfortunately, the process of the pruning the ineffective parts of the search space consumes more time if it not used efficient techniques.

Contribution. From above, all existing methods apply the mining process to search for the significant patterns. In contrast, our proposed method donot apply the mining process. Instead of, all event sequences in the dataset are merged into only one compact big sequence. In other words, our proposed method detects only one significant pattern which is the compact big sequence. Note that, the detected big sequence must be compact as much as possible. Therefore, we introduce an efficient method for constructing the big sequence to reduce the size of big sequence as much as possible. The construction method is based on the longest common subsequence and the novel definition of the compatible event set. Our compact big sequence converses the all characteristics of the original event sequences via preserving the order of events as in the dataset and also associating with each event in the big sequence a list of sequence ids that contains this event. To confine the larger size of the lists of sequence ids, we can represent them as sets of bit-vectors. Here, the consecutive zeros in the sets of bits-vector are compressed in efficient way.

Organization. This paper is organized as follows. Section II defines the preliminary concepts. Section III presents the related work. Section IV presents our proposed algorithm. Section VI reports the experimental results. Finally, Section VII concludes the paper.

II. Preliminary Concepts

Let $E = \{e_1, e_2, ..., e_m\}$ be a set of m distinct events. Event sequence $S =< u_1, u_2, ..., u_l >$ over E is ordered list such that $u_i \in E$. Event sequence $W = \{w_1, w_2, ..., w_h\}$ is subsequence of the event sequence S if there are h integers $(j_1, j_2, ..., j_h)$ such that $1 \leq j_1 < j_2 < ... < j_h \leq l$ and $w_1 = s_{j_1}$, $w_2 = s_{j_2}$,... ,$w_h = s_{j_h}$. Event sequence with length l is called an l-sequence. Event sequence database $\mathcal{D}$ = $\{S_1, S_2, ..., S_n\}$ is a set of event sequences where $|\mathcal{D}|$ = n. For example, consider Table I which contains an example of event sequence database $\mathcal{D}$ with $|\mathcal{D}|$ = 8. The sequence S_5 = $ABCB$ is subsequence of the sequence S_1 = $ABCBC$ ($S_5 \sqsubseteq S_1$). Also we can said S_1 is supersequence of S_5.

Definition 2.1: **Longest Common Subsequence.** Given two event sequences X and Y, the longest common

TABLE I. EVENT SEQUENCE DATABASE, $\mathcal{D}$

Sid	Sequence
S_1	$ABCBC$
S_2	$ABAA$
S_3	$CABAC$
S_4	CAC
S_5	$ABCB$
S_6	$CBAC$
S_7	$BCAB$
S_8	$ACBBA$

subsequence between X and Y denoted as $lcs(X, Y)$ is a longest sequence Z that is a subsequence of both X and Y.

Problem Definition: Given event sequence database $\mathcal{D}$, the objective is to find a summary, $\mathcal{S}$ of $\mathcal{D}$ such that $\mathcal{S}$ conserves all characteristics of $\mathcal{D}$ and the size of $\mathcal{S}$ is sharply less than the size of $\mathcal{D}$. ($|\mathcal{S}| << |\mathcal{D}|$).

III. RELATED WORK

In the beginning, we discuss the minimum description length in details as follows.

The Minimum Description Length

The minimum description length (MDL) principle [21][12][6][22] widely used in text compression. It used as a method for selecting a set of compressive patterns. If these patterns are used as a dictionary then we have {the potential} to maximally compress the dataset into a compact pattern encoding. In other words, these patterns represent the dataset in efficient way. Unfortunately, the process of selecting such patterns that based on MDL is NP-hard problem. Given a set of models $\mathcal{M}$, the MDL principle states that the winner model $M \in \mathcal{M}$ for the dataset $\mathcal{D}$ is the best model that provides the lossless compression. Formally, we optimize $Len(\mathcal{D}, M) = Len(M) + Len(\mathcal{D} \setminus M)$ where $Len(M)$ is the length in bits of the description of $\mathcal{M}$ and $Len(\mathcal{D} \setminus M)$ is the length in bits of the dataset when compressed with model M. MDL was applied to detect compressed frequent patterns from itemsets and sequences data. In next sections, we discuss the algorithms that based on MDL.

For itemsets data, there is algorithm called Krimp [13] that based on MDL principle. This algorithm is effective in solving the redundancy issue in the descriptive pattern mining. For sequence data, the authors of SeqKrimp [8][9] used MDL principle to compress the sequence data. This algorithm contains two steps. The first step generates the sequential patterns as candidates by using existing sequence mining method. The second step greedily checks the candidate set to find the useful patterns which together minimizes the description length. The SeqKrimp algorithm has two main disadvantages which are the process of generating the candidates is expensive and the patterns that do not belong to candidate set have no chance to be selected even if they have ability to minimizes the description length.

The authors of Gokrimp [8][9] mine a set of non-redundant sequential patterns that compress the sequence data using the MDL principle. GoKrimp do not generate candidates as in SeqKrimp. Instead of, it directly mines compressed useful patterns by greedily extending a pattern until no additional compression benefit added. To taming the hardness of the checks for additional compression benefit of an extension, Gokrimp proposed a dependency test which only selects related events for extending a given pattern.

As in GoKrimp, SQS [18] also directly mines the compressed patterns from the sequence dataset. The patterns are constructed iteratively. In each iteration, the pattern is selected if it achieves the largest MDL gain among the possible patterns. Note that, each iteration requires at least one scan of the sequence dataset.

IV. PROPOSED ALGORITHM

The method is based on the observation that the most event sequences in real dataset share the same subsequences. To avoid the overhead of duplicated computations, we propose big sequence method that merges all event sequences in the dataset into one big sequence abbreviated as BigSeq. The construction method of BigSeq is one of main operations in our algorithm. BigSeq must be compact and efficient. At the same time, it must conserve all characteristics of the original dataset.

To construct compact BigSeq, we should propose an efficient method to reduce the size of BigSeq as much as possible. Thus, we will propose a new efficient method to construct BigSeq. Next we discuss the steps of the construction method on the sequence dataset of Table I.

First, we select any sequence S in the sequence database, $\mathcal{D}$ (see Table I) as initial value of BigSeq. Suppose we selected the first sequence $S_1 \in \mathcal{D}$. Then the BigSeq is $ABCBC$. As we will see, some events will be inserted into the current BigSeq to generate the final BigSeq. Therefore, we set a temporary index for each event in the current BigSeq as follows. The temporary indices of events in the current BigSeq will be $i_1 i_2 i_3 i_4 i_5$ with $i_1 << i_2 << i_3 << i_4 << i_5$. We can assume the following $i_j = i_{j-1} + (j-1).\epsilon$ with $2 \leq j \leq 5$ and $\epsilon \geq 1$. For example, $i_3 = i_2 + 2\epsilon$ After generating the final BigSeq, we will set the actual value for each temporary index, i_j.

Second, for each remaining sequence S' in $\mathcal{D}$, compute the longest common subsequence between S' and BigSeq, namely $LCS(S', BigSeq)$. After that we store the positions in BigSeq for each event that belong to LCS and store also the remaining events in S', that do not belong to $LCS(S', BigSeq)$ (Note that these remaining events will be further inserted in BigSeq). For example, let S' be the sixth sequence, $S' = S_6 = CBAC$. We have $LCS(S', BigSeq) = LCS(CBAC, ABCBC) = CBC$. The positions of the three events (C, B, and C) of $LCS(S', BigSeq)$ in BigSeq are i_3, i_4, and i_5, respectively. We store these positions. Also, we store the remaining event, A, in S' that does not belong to $LCS(S', BigSeq)$. This remaining event, A, will be further inserted in BigSeq. The remaining events of each remaining sequence must be inserted in the correct position in the BigSeq. Therefore, we will associate with each remaining event e_r a range of positions in BigSeq. We expect that e_r will fall within this range in BigSeq. We call this range an **E**xpected **R**ange of **P**ositions for event e_r, namely $ERP(e_r)$. Recall let $S' = S_6 = CBAC$ then we have only one remaining event A. The position of the event A in S' falls between the positions of two events

B and C. Note that these two events (B and C) belong to $LCS(S', BigSeq)$ and their positions in BigSeq are i_4 and i_5. Therefore, we have $ERP(A) =]i_4, i_5[$. As a consequence, we should insert the remaining event A in BigSeq at a new position between i_4 and i_5. Table II shows the expected range of positions for each remaining event e_r, $ERP(e_r)$.

Finally, indeed, we do not insert each remaining event in BigSeq instead of we cluster the remaining events into compatible event sets. After that we insert only one **rep**resntative **e**vent, e_{rep}, for each compatible event set into BigSeq at a specific position p. This position p must belong to the expected range of positions of every event in the compatible event set of e_{rep}. See next definition of compatible event set and see next example.

Definition 4.1: **Compatiable Event Set.**
The event set is called compatible event set if the events in this set satisfy the next three conditions:

1) They have the same label;
2) They donot belong to the same event sequence;
3) The insertion of their expected range of positions in BigSeq is not empty.

Example 4.1: Given the event sequence database in Table I. Table II reports the initial value of BigSeq (S_1 [The first row]), the remaining sequences (S_2, S_3, S_4, S_5, S_6, S_7, S_8 [The first column]), the events of each remaining sequence S' that belong to $LCS(S', BigSeq)$ [The second column], and $ERP(e_r)$ for any remaining event, e_r ($e_r \notin LCS(S', BigSeq)$) [The third column].

Note that the underlined events in the first and second columns belong to $LCS(S', BigSeq)$ and the parameter $\delta \geq 1$. To distinguish among the remaining events (e_r in the third column of Table II) that have the same label, we assign superscripts for these events as follows. A^{km} means the m-th remaining event in the sequence k.

Now we will determine the compatible sets of remaining events. The remaining event can be belonged to more than one compatible event set. In this case, we add this remaining event to only one compatible event set. From the definition of compatible event set, If two or more different remaining events belong to the same event sequence then we must add them to different sets of compatible events. For example, since the two different remaining events, A^{21} and A^{22} belong to the same event sequence (the second event sequence, S_2), they must be added to two different sets of comaptiable events. Based on the definition of compatible event set and $ERP(e_r)$ in Table II, we have three **co**mpatible sets of **r**emaining **e**vents, $core = \{core_1, core_2, core_3\}$, where $core_1 = \{A^{21}, A^{31}, A^{41}, A^{71}\}$, $core_2 = \{A^{22}, A^{32}, A^{61}, A^{82}\}$, and $core_3 = \{C^{81}\}$.

Next we will discuss the computations of these three compatible sets of remaining events in details and how we conserve all characteristics of the original event sequence in the final BigSeq with respect to the event sequence database and $ERP(e_r)$ in Tables I and II, respectively.

The first compatible set of remaining events is $core_1 = \{A^{21}, A^{31}, A^{41}, A^{71}\}$. Note that all events in $core_1$ have the same label, A (Condition 1 in Definition 4.1) and they do not belong to the same sequence but they belong to sequences S_2, S_3, S_4, and S_7 respectively (Condition 2 in Definition 4.1). We have $ERP(A^{21}) = [p, p + \delta[$, where $p > i_2$. Recall, because $i_3 > i_2$, we can set $p = i_3$. Now $ERP(A^{21}) = [i_3, i_3 + \delta[$. Recall, $\delta \geq 1$ then we can set δ = 2. In other words, $ERP(A^{21}) = [i_3, i_3 + 2[$. The other expected range of positions are $ERP(A^{31}) =]i_3, i_4[$, $ERP(A^{41}) =]i_3, i_5[$, and $ERP(A^{71}) =]i_3, i_4[$. As the result, we have $ERP(A^{21}) \cap ERP(A^{31}) \cap ERP(A^{41}) \cap ERP(A^{71}) \neq \phi$ (Condition 3 in Definition 4.1). Thus, we insert in BigSeq at position $i_3 + 1$ only one event with label A (e_{rep1}) as representative for $core_1$. Note that we select the position $i_3 + 1 \neq i_4$, since $i_3 + 1 \in ERP(A^{21}), ERP(A^{31}), ERP(A^{41}), and\ ERP(A^{71})$.

The second compatible set of remaining events is $core_2 = \{A^{22}, A^{32}, A^{61}, A^{82}\}$. Note that $core_2$ satisfy coditions 1 and 2 in Definition 4.1 since all events in $core_2$ have the same label, A. the events in $core_2$ do not belong to the same sequence but they belong to sequences S_2, S_3, S_6, and S_8 respectively (Condition 2 in Definition 4.1). We have $ERP(A^{22}) = [p + \delta, \infty[= [i_3 + 2, \infty[$. The other expected range of positions are $ERP(A^{32}) =]i_4, i_5[$, $ERP(A^{61}) =]i_4, i_5[$, and $ERP(A^{82}) = [i_4, \infty[$. As the result, we have $ERP(A^{22}) \cap ERP(A^{32}) \cap ERP(A^{61}) \cap ERP(A^{82}) \neq \phi$ (Condition 3 in Definition 4.1). We insert in BigSeq at position $i_4 + 1$ only one event with label A (e_{rep2}) as representative for $core_2$. Note that we select the position $i_4 + 1 \neq i_5$, since $i_4 + 1 \in ERP(A^{22}), ERP(A^{32}), ERP(A^{61}), and\ ERP(A^{82})$.

Finally, the third compatible set of remaining events is $core_3 = \{C^{81}\}$ with $ERP(C^{81}) =]i_1, i_2[$. Since $core_3$ has only one event then it is compatible set that satisfy the three conditions in Definition 4.1. Thus, we insert the event C in BigSeq as representative for $core_3$ [e_{rep3}] at position between i_1 and i_2. In other words, we can insert C in BigSeq at position $i_1 + 1 \neq i_2$ such that $i_1 + 1 \in]i_1, i_2[$.

The initial BigSeq with its indices and the final BigSeq with its indices are reported at Table III(a) and Table III(b), respectively. The final BigSeq is $ACBCABAC$.Note that we insert the three representative C, A, and A in BigSeq at position $i_1 + 1$ (between i_1 and i_2), $i_3 + 1$ (between i_3 and i_4), and $i_4 + 1$ (between i_4 and i_5). Here the size of the final BigSeq is 8 after inserting the three representatives. Therefore, the actual indices of the events in the final BigSeq will be from 1 to 8 (i.e. 1, 2, 3, 4, 5, 6, 7, and 8). See the next definition for the size of the final BigSeq.

Definition 4.2: **The Final BigSeq Size.**
The Final BigSeq Size is $|final\_BigSeq|$ = $|initial\_BigSeq|$ + $|core|$, where $|core|$ is the count of compatible sets of remaining events, where $initial\_BigSeq$ is the initial value of BigSeq.

For example, with respect to the event sequence database and the data in Tables I and II respectively, we have the following $|final\_BigSeq|$ = $|initial\_BigSeq|$ + $|core|$ = $|S_1|$ + $|core|$ = 5 + 3 = 8.

From definition 4.2, to reduce the final BigSeq Size, we should reduce the count of compatible sets of the remaining events as much as possible.

To conserve all characteristics of the original event sequence in the final BigSeq, we should associate with each event e in BigSeq a list of sequence ids that contains the

(c) Insertion of the Three Representatives for the Three Compatible Sets in BigSeq with their Id List

event e, namely $e.id\_list$ as follows. First, since we select the first sequence as the initial value for BigSeq, we will add 1 (the id of the first sequence) to $e.id\_list$ for each event $e \in initial\_BigSeq = S_1$ [see Table IV (a)]. Second, suppose the case that the event $e \in LCS(S', BigSeq)$, where S' is a remaining sequence (i.e. $e \in S'$ and $e \in BigSeq$). In this case, we add the id of S' to $e.id\_list$ for each event $e \in BigSeq$ [see Table IV (b)]. Finally, we have three representative events for the three compatible sets of remaining events. As we mentioned before, we inserted the three representatives, A, A, and C in BigSeq at positions i_3+1, i_4+1, and i_1+1 respectively to generate the final BigSeq. For each representative event, e_{rep}, for the compatible set of remaining events, $core_k$, we add to $e_{rep}.id\_list$ the id of the event sequence that contains the remaining event e_r, for every $e_r \in core_k$ with k = 1, 2, and, 3 [see Table IV (c)].

Next algorithm outlines the BigSeq construction with sequence Id List.

Algorithm: BigSeq Construction with Sequence Id List

Input: Event sequence database, $\mathcal{D}$
Output: $BigSeq$ with $e.id\_list$ for each event $e \in BigSeq$.

1. Select an event sequence $S \in \mathcal{D}$ as $BigSeq$
   // Initial value of BigSeq = S
2. Add the id of S to $e.id\_list$ for each $e \in BigSeq$
3. $\mathcal{D} = \mathcal{D} - S$
4. $ERP = \{\}$
   //the set of expected range of positions
5. **for** each event sequence $S' \in \mathcal{D}$ **do**
6. $lcs = LCS(S', BigSeq)$
7. **for** each event $e \in lcs$ **do** // $e \in S'$ and $e \in BigSeq$
8. Add the id of the sequence S' that contains the event e to $e.id\_list$ in $BigSeq$
9. **end for**
10. **for** each event $e_r \in S'$ and $e_r \notin lcs$ **do**
    //e_r is remaining event
11. Compute $ERP(e_r)$
12. $ERP = ERP \cup ERP(e_r)$
13. **end for**
14. **end for**
15. Find the compatible sets of remaining events, $core$, based on Definition 4.1 and ERP
16. **for** each compatible set $core_k \in core$
17. Insert the representative event, e_{rep}, for $core_k$ into $BigSeq$ at position $p \in ERP(e') \; \forall \; e' \in core_k$
18. Add to $e_{rep}.id\_list$ the id of the event sequence that contains the remaining event $e_r \; \forall \; e_r \in core_k$
19. **end for**
20. **return** $BigSeq$ // The final BigSeq with $e.id\_list$

V. COMPRESSING EVENTS SEQUENCES DATABASE USING $BigSeq$ METHOD

The objective of this paper is to compress the event sequence database in efficient way such that we conserve all characteristics of the original database. In other words, we will compress the event sequence database into compact BigSeq with sequence id_lists. But when the size of event sequence database is large, the id_list size of each event in the corresponding BigSeq will be large. To confine the larger size of these id_lists, we can represent $e.id\_list$ of each event $e \in BigSeq$ as a set of bit-vectors, $B(e) = \{B_1, B_2, ..., B_m\}$, where each B_i is 8 length bit-vector (i.e. each B_i occupy 1 byte in memory) and suppose that the maximum $id \in e.id\_list$ is n then $m = |B(e)| = n/8$. Each position in each B_i corresponds to event sequence $S_{id} \in \mathcal{D}$ where $id \in [8 \times (i-1) + 1, 8 \times i]$. The bit at position j in B_i represents the presence or absence of the event $e \in BigSeq$ in the event sequence $S_{8\times(i-1)+j}$. See next example.

Example 5.1: The first event in BigSeq (in Table V) is $e_1 = A$ with the set of bit-vectors $B(e_1) = \{B_1\} = \{10010011\}$. Note that $B(e_1)$ contains only one bit-vector, B_1, since the maximum id in $e_1.id\_list$ = 8 (i.e. $n = 8$), thus $m = n/8 = 1 = |B(e)|$. The bits in B_1 represent the presence or absence of the event e_1 in the event sequences that have $id \in [1, 8]$. The bit at position 1 in B_1 is one, this means that $e_1 \in S_1 = S_{8\times(1-1)+1}$, etc. Given the final BigSeq with id_lists in Table IV(c), its corresponding BigSeq with bit-vectors is reported in Table V.

A. Compression Benefit

Suppose each event e occupy 1 byte in memory, then the size (in terms of bytes) of the original event sequence database, $\mathcal{D}$ (in Table I) is 34 bytes ($\mathcal{D}$ contains 34 events). Recall each B_i occupy also 1 byte in memory, therefore the size (in terms of bytes) of the BigSeq with bit-vectors (in Table V) is $|BigSeq|$ + $|B(e)|$ = 8 + 8 = 16 bytes. We can use the compression ratio to measure how well the data is compressed. The compression ratio calculated by dividing the data size before compression with the size after compression. In the above example, the compression ratio is $34/16$ = 2.125. In other words, the space saving (%) is (1 - (compressed size / uncompressed size)) $\times$ 100 = $1 - (16/34) \times 100$ = 52.9%. Here, we have an optimization that based on the observation that there are many consecutive zeros in each row of the bit-vectors. This is clearly grossly inefficient. Therefore, we can compress these consecutive zeros in efficient way as follows. Given array of bits (0 and 1), Bit_Arr, and paramter n. The output is the same as the input except for consecutive zeros. Note that, may be there are many sets of consecutive zeros in Bit_Arr. For each set of consecutive zeros, CZ, we do the following. If $|CZ| \leq n + 2$, we do nothing. Otherwise, we compress CZ into compressed CZ with size $n+2$ bits. The first and the second bits in the compressed CZ are 0 (indicator for compressing CZ) and 1 (indicator for doing the compression) respectively. The other n bits in the compressed CZ indicate how many times of zeros were repeated consecutively.

In the experimental results section, we will show the better compression ratio of BigSeq method against the state-of-art algorithm, GoKrimp, on many real datasets.

VI. EXPERIMENTAL EVALUATION

This section reportes the results of experiments on many real dataset. We compare the performance of Our proposed method, namely BigSeq with GoKrimp algorithm [8] [9]. Here, we exclude the two algorithms SeqKrimp and SQS from this experiment since GoKrimp algorithm outperforms them by one to two orders of magnitude. BigSeq is implemented in standard C++ with STL library support and compiled with GNU GCC. Experiments were run on laptop with Intel i3 2.4 GHz and 8G memory running Linux.

A. Datasets

Experimental evaluation are performed on a group of real datasets as follows. We used five real datasets namely, msnbc [10], Gene [16], TCAS [17] [4], Activity [1], and JBoss [5]. The corresponding information of these real datasets is summarized in Table VI, where $|\mathcal{D}|$ represents the number of sequences, $|E|$ is the number of the events, min_L, max_L and avg_L denote the minimum length, maximum length and average length of the sequences respectively.

TABLE VI. SUMMARY STATISTICS OF THE REAL DATASETS USED IN THE EXPERIMENTS

Dataset	$\lvert\mathcal{D}\rvert$	$\lvert E\rvert$	min_L	max_L	avg_L
msnbc	31790	18	9	100	13.33
Gene	2942	5	41	216	86.53
TCAS	1578	75	8	70	36
Activity	35	10	12	43	21.14
JBoss	28	64	51	125	91

B. Effect of Optimization

In this experiment, we show the effect of optimization of compressing the consecutive zeros, namely Opt, with respect to the compression ratio. Table VII reports the compression ratio of BigSeq with and without Opt on the three datasets (Gene, TCAS, and JBoss). From this table, BigSeq with Opt has the better compression ratio in all datasets. Note that the larger compression ratio is the better compression we have.

TABLE VII. EFFECT OF OPTIMIZATION WITH RESPECT TO COMPRESSION RATIO

Dataset	BigSeq with Opt	BigSeq without Opt
Gene	2.428	1.348
TCAS	3.384	1.585
JBoss	3.303	2.700

C. Performance of BigSeq against GoKrimp

From the previous experiment, BigSeq with Opt has the best performance with respect to compression ratio. Therefore, in this experiment, we will use BigSeq with Opt and we will call it as BigSeq for abbreviation.

The proposed method, BigSeq is evaluated according to the following criteria:

- *Compression Ratio:* To measure how well the dataset is compressed using BigSeq.
- *Total Response Time:* To measure the efficiency of BigSeq.
- *The Number of Patterns:* The number of detected patterns that used for compression.

1) Compression Ratio: Table VIII reports the compression ratio of the two algorithms on the five datasets. Recall, the larger compression ratio is the better compression we have. The BigSeq algorithm shows a better compression ratio in all datasets. For example, in Gene dataset, the compression ratio of BigSeq is 2.428 while the compression ratio of GoKrimp is 1.251.

TABLE VIII. COMPRESSION RATIO OF THE TWO ALGORITHMS (BIGSEQ AND GOKRIMP)

Dataset	BigSeq	GoKrimp
msnbc	1.648	1.123
Gene	2.428	1.251
TCAS	3.384	2.951
Activity	1.520	1.077
JBoss	3.303	1.541

2) Total Response Time (Sec): Table IX reports total response time (Sec) of the two algorithms on the five datasets. The BigSeq algorithm has the best execution time on all datasets. On msnbc dataset, Gene dataset, TCAS dataset, Activity dataset, and JBoss dataset, BigSeq outperforms GoKrimp by more than two orders of magnitude, more than one order of magnitude, more than three orders of magnitude, approximately three factors, and more than one order of magnitude respectively.

3) Number of Patterns: Table X reports the number of patterns that used for compression by the two algorithms on the five datasets. Note that BigSeq used only one pattern for all datasets. This pattern is the compact BigSeq itself.

TABLE IX. TOTAL RESPONSE TIME (SEC) OF THE TWO ALGORITHMS (BIGSEQ AND GOKRIMP)

Dataset	BigSeq	GoKrimp
msnbc	1.32	313
Gene	1.1	45.2
TCAS	0.135	199
Activity	0.066	0.239
JBoss	0.072	2

TABLE X. THE NUMBER OF PATTERNS OF THE TWO ALGORITHMS (BIGSEQ AND GOKRIMP)

Dataset	BigSeq	GoKrimp
msnbc	1	27
Gene	1	6
TCAS	1	33
Activity	1	2
JBoss	1	5

VII. CONCLUSION

In this paper, we focus on summarizing the event sequence dataset. Existing methods summarize the event sequence dataset by mining a significant patterns that compress the dataset well. In contrast, the novel proposed method, BigSeq summarizes the event sequence dataset by merging the event sequences into compact big sequence. The construction of the compact big sequence is done via the longest common subsequence and the novel definition of the compatible event set. Our compact big sequence converses the all characteristics of the original event sequences. Experimental results show that BigSeq method can achieve better performance than the state-of-the-art methods such as GoKrimp in terms of compression ratio, total response time, and number of detected patterns. As future work, we plan to adapt the BigSeq method for mining the frequent, closed, and maximal patterns in the event sequence dataset.

ACKNOWLEDGMENT

I wish to express my deep gratitude to my mentor Prof Dr. Karam Gouda. I am very grateful to my parents, my wife, my brother, and my sisters for their continuous moral support and encouragement.

***Abstract*—Intelligent networking is a concept that enables 5G, the Internet of Things (IoT) and artificial intelligence (AI) to combine as a way to accelerate technological innovation and develop new revolutionary digital services. In the intelligent connectivity vision, the digital information gathered by the machines, devices and sensors which make up the IoT is analysed and contextualized. It is anticipated that the high availability of 5G and its inclusion of a large number of connections would help promote the production of wearable devices used to monitor the different biometric parameters of the wearer. Since these are AI-based health systems, the data obtained from these devices will be analysed in order to assess a patient's current health status. This paper presents a detailed design for the development of intelligent data analytics and mobile computer-assisted healthcare systems.The proposed advanced PoS consensus algorithm provides better performance than other existing algorithms.**

***Keywords*—Big data analytics; 5G-enabled; IoT healthcare; fog computing; confidentiality**

I. Introduction

According to the HIS market, by 2035, the Fifth Generation (5G) of wireless transmission technology will enable more than $1 trillion worth of products and services for the healthcare sector. The main features focused on in 5G technology, for example, significant increase in speed, coverage, enhanced capacity, network energy and power, and increased bandwidth, impact across many divisions in big data analytics. For people who have diabetes a comprehensive sensing analysis is available. Many mechanisms and personalized building models using 5G smart diabetes testing of smart clothing and smart monitoring using smartphones and using big data clouds are suggested for patients as part of their personalized solution for diabetes monitoring in healthcare. Here, an overall comprehensive process regarding blockchain-based 5G-enabled IoT and also various challenges and integration with blockchain industrial automation with the 5G-enabled IoT are presented. In addition, existing gaps in scalability, interoperability and other challenges in 5G blockchain are discussed. The deficiencies in 5G from all the communication devices and drones and particularly in the field of healthcare are identified and these problems will be overcome with the help of ultra-high reliability.

A. Motivation and Scope

The scope of 5G definition relates to potential uses and how those likely affect healthcare. The Internet of Medical Things (IoMT) focuses on the impact of 5G on providers, hospital systems, medical device companies, pharmacy companies and telehealth. Several key companies plan to launch 5G systems as well as 5G wireless networks in healthcare products. In the long term, in the healthcare sector, 5G will help to profoundly transform remote diagnostics and consultations. 5G enables the IoT to have a more powerful bandwidth combined with lower latency; 5G will be the main focus of technologies such as Augmented Reality and Virtual Reality in the healthcare sector. Furthermore, 5G will allow widespread deployment of Artificial Intelligence (AI) which will transform the healthcare sector from manual to smart automation.

Blockchain and 5G are the most hyped technologies emerging in the common marketplace. As mentioned, several features are available in blockchain with 5G, including decentralized approach, immutability, allows localized availability, cost efficiency and security. Also, challenges regarding blockchain with 5G integration focus mostly on scalability of blockchain which needs improvement to deal with the high number of devices and each device must have a unique address. Furthermore, after the 5G technology is deployed worldwide, it is expected that the technology will allow medical professionals to be able to exchange data with patients instantaneously from anywhere. It is an easy way for hospital-like monitoring in patient's homes similar to how intensive care units are monitored nowadays. Blockchain technology is perhaps the silver bullet needed for industry. The blockchain functions as a distributed transaction ledger for various IoT transactions. The blockchain platform supports and uses simple key management systems. The Ethereum platform is capable of managing a more fine-grained way used in many IoT devices with successful smart Turing complete code.

B. Research Contribution

In this paper, we proposed a 5G-enabled blockchain e-healthcare framework. The focus of this framework is a patient e-health management system. E-Health introduced the fog/edge used for easy access of medical data, as well as patient safety and privacy concern. Blockchain is deployed in the e-health system. This consist of three interfaces (1) Near Processing Layer, (2) Far Processing Layer and (3) Data Sensing Layer, and an agent Migration Handler (MH) used to monitor and transfer tasks which will help to locate the client. The current healthcare system is not patient friendly because patients must continually spend time monitoring their illness instead of resting, which is inconvenient for the patients. Wasted patient time has been reduced in our proposed system.

C. Organization

In Section 2 the literature survey and comparison of existing ideas with 5G technology in healthcare and blockchain is presented, in Section 3 our idea is proposed in a detailed manner, in Section 4 the performance analysis of the proposed model with graphs is discussed, and conclusions and future work in the healthcare sector are presented in Section 5.

II. Related Work

Some studies discussed by Hossain et al. proposed an emotion detection methodology in the healthcare system. They used IoT devices to capture emotion images and speech recognition processes separately, and calculated the value of the detected emotion and validated it [1]. Latif et al. discussed the 5G wireless technology along with emerging technologies that will transform the healthcare system, specifically 5G with cloud computing and 5G with artificial intelligence, and in terms of economist and high potential pitfalls in development of the 5G health revolution [2]. Similarly, Nasri et al. proposed a smart mobile IoT healthcare system using 5G and smart phones to monitor patient's health risk factors. WBSN data was used to monitor and track patient pulse, temperature and oxygen in blood as well as other vital parameters of the patients [3].

Ahad et al. discussed diabetes diagnosis with the solution of comprehensive sensing analysis. They suggested patients could have personalized solutions for diabetes monitoring in healthcare, including many mechanisms and personalized building models using 5G smart diabetes testing on smart clothing and smart monitoring using smartphones and big data clouds [4].

Further, Mistry et al. [5] presented a comprehensive review on blockchain-based 5G-enabled IoT and various challenges stemming from integration with blockchain industrial automation and the 5G-enabled IoT. A comparison of existing gaps between the scalability, interoperability and other challenges in 5G blockchain was also presented. Ullah et al. discussed the driving with wireless industry and developing the next generation of technology so that mobile technology generation has improved facilities to be efficient in wireless fields. Vehicle-to-everything (V2X) will impact in 5G with all the communication and drones and particularly in the field of healthcare, and they identified deficiencies and overcame those problem with the help of ultra-high reliability [6].

Furthermore, Li discussed how the next generation of wireless remote technology will be useful for healthcare in existing models with respect to the expenses of healthcare services and the imbalance of medical resources and inefficient healthcare system administration. To overcome this, the IoT, big data analysis,artificial intelligence technology and 5G wireless are used to improve patient quality of healthcare service, and the cost inferable method is focused on [7].

Sigwele et al. proposed an information and communication technology utilizing IoT to limit medical errors and cost of healthcare. They discussed the IEE5GG with smartphone gateway connection to save energy, which is executed with the help of MEC while considering QoS and battery level CPU load, and resulting with an energy efficient framework [8].

Chen et al. proposed a 5G-C-sys for healthcare that aims at ultra-low latency in cognitive application and high reliability. They also developed a prototype platform for 5G-C-sys incorporated with speech recognition and emotion detection for the effectiveness in healthcare-based 5G C-sys technology [9].

Similarly, Boban et al. analysed the requirement in 5G technology and identified the gaps with the existing technologies. They overcame the challenges with drone and communication technologies [10].

Latif et al. discussed how 5G technologies, AI, IoT and Big data will revolutionize healthcare, and they provided an overview of how machine learning algorithms are integrated and able to detect the anomalies in the healthcare system. The authors also investigated remote consultation in e-health [11]. Lakshmanan et al. proposed a hybrid approach in combining PSO and ACO & BCO on routing protocol and applying the K-Means algorithm for clustering the nodes [12].

Furthermore, Manoj et al. [13] discussed a congestion adaptive navigation for emergency situations. They also used sensors for locating using GPS and then server takes an action using PIR in emergency areas. Logeswari discusses the analysis of packets having the fuzzy logic based on the greedy routing protocol. Two characteristics input metrics and fuzzy decision making system in VANETs were used [14].

Gomathi et al. [15] proposed an energy efficient routing protocol using wireless sensors with dynamic clustering UWSN routing technique. This will be helpful for researchers due to reduced power consumption, response time, avoids overload and improves throughput of the network. Vignesh et al. discussed fewer deployments in the cloud storage with low cost replication, higher availability and better performance in geo-replicated systems by data centres with these benefits [16].

Ishwarya proposed a project to reduce congestion in traffic and calculated current traffic with normal. If anything unusual is detected, then emergency vehicles pass through the signals; thus, solving the traffic problems [17]. Sivasangari et al. [18] compared security and privacy using fog computing. They also used the fog computing principle to use a smart gateway for an improved big data health monitoring system. Suganthi et al. discussed security improvement for web based banking and the authentication using fingerprints to avoid hacking or for fault detection [19]. Deepa et al. proposed an idea of detecting road damage by image processing in smart phones and sending the co-ordinate point to the cloud and from the cloud a user can see the road where the damages are because it will show on a map. From this, they can avoid accidents and so on [20]. Keerthi et al. [21] used convolutional neural networks (CNN) to identify dangerous lung disease tumours. The CNN technique has many features and can provide standard representation pneumonic radiological complexity, fluctuation and classification of lung nodule. Sivasangari et al. [22] proposed major concerns about WBAN regarding the security and privacy of the healthcare sector. The patient health data should reach the physician at the right time. Security has the greatest impact on the lives of humans, and an effective model SEKBAN that ensures security data based on ECG signal was implemented. Indira et al. [23] implemented an efficient hybrid detection using a wireless sensor network. Wireless devices are spatially distributed over

sensors and physical changes. The device network includes multiple detection over sensors with lightweight transport.

Tao et al. [24] discussed V2G technology for enabling renewable energy sources providing power in a smart grid. They proposed a fog and cloud hybrid model. Vilalta et al. compares the existing approach with the new proposed technologies and distributed field. This paper discussed TelcoFog's benefits and dynamic deployment with low latency, and managing orchestration architecture for TelcoFog service infrastructure [25]. Furthermore, Chaudhary et al. focused on challenges for future demands in integrated fog computing and cloud computing in the 5G environment, in collaboration with SDN, NFV and NSC. They also performed data analytics with device mobility, as well as discussed challenges and potential attacks on the data shared in 5G [26].

Ku et al. [27] discussed advances in the fog radio access network and fog–cloud based in hybrid system issues. GPP is used for communication and computational processing, and it is also used as a simulator for experimental tests. Furthermore, Yang et al. [28] proposed an SDN-enabled approach for cloud–fog interoperation in 5G, and aimed at quality of optimized network usage. Crosby et al. [29] shared, in terms of blockchain technology, all criteria that satisfy specific application in both sectors regarding finance. There are many opportunities for revolution in disruptive technology. The digital currency Bitcoin is highly controversial, but blockchain has proved to be useful and has found many applications.

Risius et al. discussed a framework in blockchain which they divided into three group activities and four level of analysis. This paper addresses research predominantly focused on new technologies in blockchain [30].

Dinh et al. proposed a survey about untangling blockchain data processing with its challenges, and they analysed four dimensions in production as well as research systems—distributed ledger, smart contract, cryptography and consensus protocol. They also conducted comprehensive evaluation for major systems such as BlockBench, Parity and Ethereum, and found blockchain performance closer to the database [31].

Huh et al. [32-45] discussed how to manage IoT devices using blockchain to easily control and configure IoT devices. They also used the RSA algorithm which is capable of managing devices with secret keys. They used Ethereum blockchain for coding in an efficient way [33-37].

III. Proposed Work

Fog/Edge computing is tackled by eHealth systems for an easy way of accessing and processing medical data, and ensuring the privacy and safety of patients. All Fog and Cloud have their administers interested in handling medical data that violates the privacy of patients. Blockchain deployed over Fog and Cloud will allow patient data processing and storage. The eHealth architecture consists of three interface levels: sensing, near processing, and far processing. Multiple instances of a Patient Manager include 3-level structures. The Agent Migration Handler (MH) uses Profile Monitoring to transfer a task or execute the task internally, which collects profile information from remote agents.

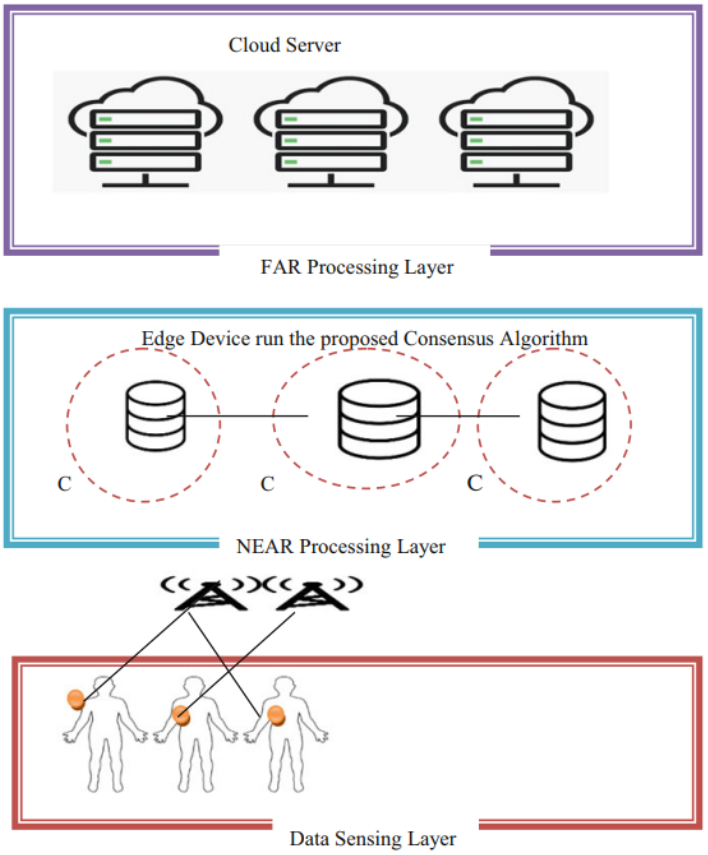

Fig. 1. Proposed Architecture.

Sensing layer: Smart devices, implantable sensors, smart watches, mobile devices and other devices monitor patients' body parameters. These applications use Bluetooth or ZigBee to convey to the mobile the physiological sign of a patient. Near processing layer: A hop away from the sensing devices of the data is where near processing level devices are generally located. Conventional switches, routers and low-profile devices are involved in the near networking layer. In a broad range of formats, healthcare facilities generate vast quantities of data, such as records, financial statements, laboratory findings, imaging tests, such as X-rays and CAD scans, and measurements of vital signs. Blockchain provides the ability to boost the data's authentication and integrity. This also helps to disseminate data inside the network or facilities. Such features have an effect on the cost, quality of data and reliability of providing health care across the system. Blockchain is an open, decentralized, intermediary-removing network. The blockchain healthcare solution does not require multiple authentication levels and provides everyone who is part of the blockchain architecture with access to the data. Data is made open and transparent for customers. Such apps will help to tackle the various issues facing the healthcare industry today. In the healthcare sector, blockchain's role is split into four stages. The proposed architecture is explained in Fig. 1.

The inspiration behind blockchain and 5G integration largely stems from the many benefits of blockchain in addressing security, protection, networking and service management issues in 5G networks. The proposed advanced Pos Consensus

algorithm is described below:

Algorithm 1 The Proposed Advanced Pos Consensus Algorithm

Input: Performance Transaction (PT), Reputation Transaction (RT), Stake Transaction, Agent Number (Ni) in a cluster

Output: Every fog agent generates $\mathrm{PTi}, \mathrm{STi}$ and produce RTi from the service provider

Form clusters with fog nodes within a threshold range (R)
for each cluster $k = 1 \in l$ **do**
  while Head election $=$ true **do**
    for member agent $i = 1 \in n_k$ of a cluster **do**
      Extract parameters from PT_i, RT_i to produce P_i, R_i and S_i
      $P_i = \frac{1}{1+e^{-\frac{\ddot{Y}}{r \times \alpha_i}}}$
      $R_i = \frac{1}{1+e^{-r}}$
      $S_i = \frac{1}{1+e^{-c}}$
      $f_i <-$ Decision Tree (P_i, S_i, R_i)
      $T_i = \Delta T \times \left(1 - \frac{f_i}{\sum_n^1 f_i}\right)$
      Every Member node in the cluster sets their timer (T_i)
    end for
    if (T_i) is expired **then**
      Then broadcast node id to the cluster for approval
    end if
    if approval count [node id] $>= 2/3 \times n_k$ **then**
      leader $_j <-$ nodeid
    end if
  end while
end for

A cluster within the Near Processing Layer of a certain geographic range (R). A cluster is formed by a fog/edge agent with a different patient member value, where a representative is selected to be the head of the cluster. The cluster head (also called the leader) is involved in running the blockchain consensus protocol by locking a certain amount of stake in the network. From each cluster, a cluster head (CH) is chosen, taking into account the member nodes' multi-criteria. The selection process includes the performance characteristics of a node, its reputation and the stake amount. Criteria are combined to measure a fitness value using a decision tree. The blockchain records the information of each node regarding the parameters listed, and can be retrieved from the blockchain. The performance parameters include device processing speed, storage capabilities, accessibility, variation distance coefficient and delay in transmission of an Agent. Here, MIPS processing capacities, memory space and availability are symbolized respectively as p1, p2 and p3.

T is the time interval for the selection of cluster head, and where T represents a limited random time period used to distinguish waiting time for the same fitness of the Agent. The Agent broadcasts its identifier across the cluster since its waiting time expires. The other cluster members verify the estimated fitness of the Agent and accept their approval for this Agent. In turn, every node in a cluster will participate in the PoS proposed. This consensus mechanism would be less vulnerable to an attack of 51% from each cluster than DPoS as a leader. The rich node, such as PoS, is less likely to become a cluster leader, as the cluster head is not only selected based on the locked coin.

Decision Tree is a supervised learning method which can be used for problems with classification and regression, but is preferred to solve problems with classification. It is a tree-structured classification where even the internal nodes represent the characteristics of a dataset, the branches represent the rules of decision and each leaf node represents the result.

IV. Performance Analysis

The assessment of the proposed programme with simulation settings and evaluation metrics is defined in this section. It also addresses the effects of various parameters such as energy usage and time for block generation. Various scenarios with different configurations are visualized through graph plot. For the following parameters, the performance of the updated mechanism and the existing mechanism will be investigated. Energy consumption: energy consumption refers to the energy needed for transmission, receipt of the transaction and simulated validation of the network of a number of blocks.

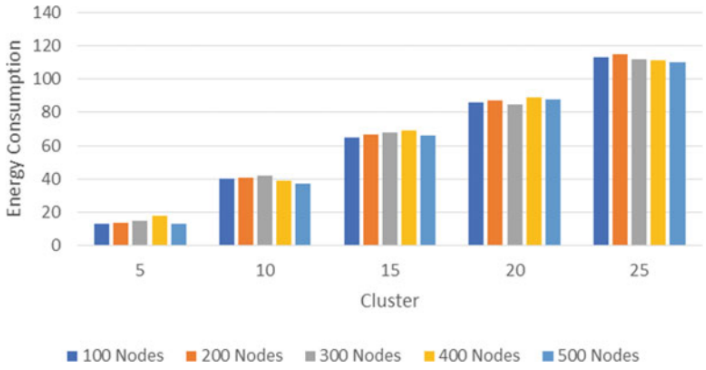

Fig. 2. Energy Consumption vs Cluster.

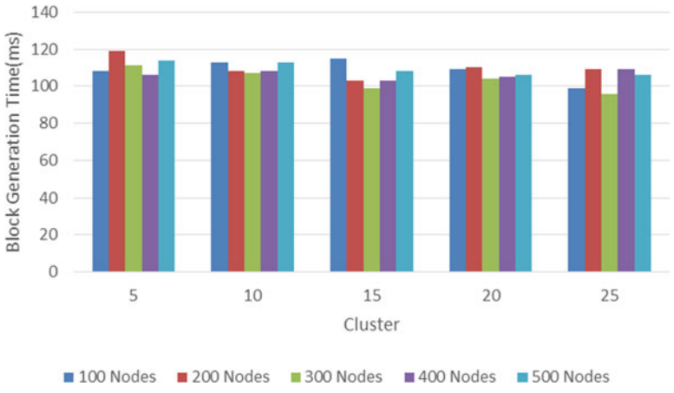

Fig. 3. Cluster vs Throughput.

Block generation time: This refers to the time required for a certain number of simulated network blocks to be uploaded, constructed and validated. In the simulated network, the updated process is executed five times and the output graphs are shown with average values generated from 10 execution runs. The regular one runs on a horizontal network and is supposed to function on a hierarchical network with the modified one. For both forms of consensus structures, nodes that lock digital coins into the network engage in mining. The energy consumption and execution time necessary for the development of 100 blocks are shown in Fig. 2, provided that the variable number of nodes and clusters is taken into account.

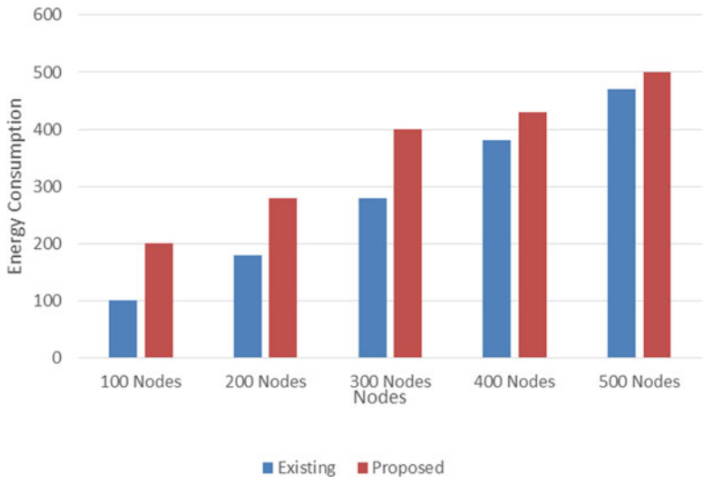

Fig. 4. Energy Consumption vs Nodes.

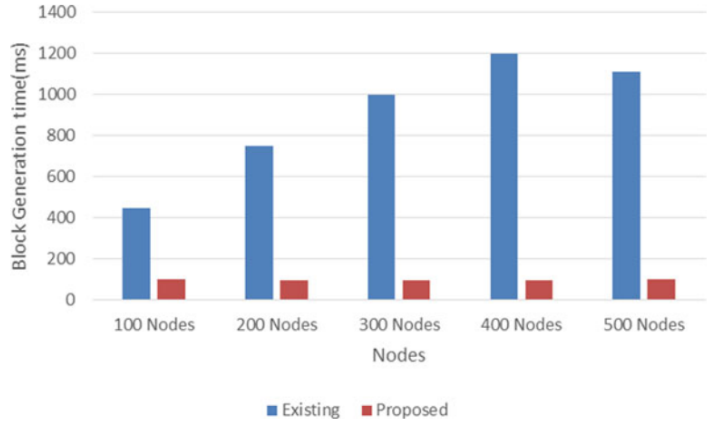

Fig. 5. Node vs Block Generation Time.

For unique clusters and nodes, the block generation time is shown in Fig. 3. The illustrated graph in Fig. 3 indicates that a pattern which is consistently lower or higher does not follow the period of block generation with a larger number of clusters. With a higher number of clusters, cluster heads collect transactions and construct blocks, with a higher number of blocks per second being generated. On the other hand, because of the delay in testing blocks, higher block generation time was also noticed for some higher cluster numbers.

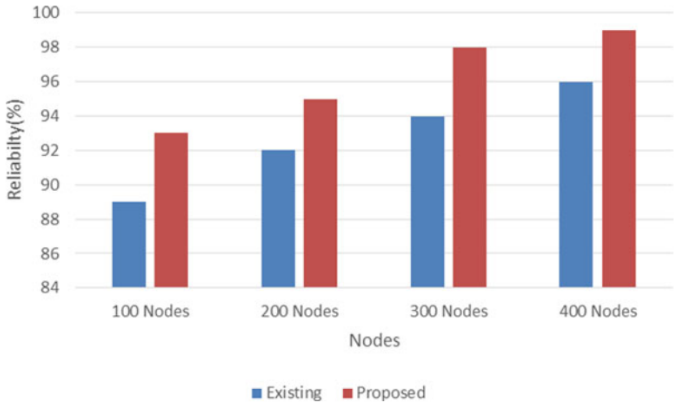

Fig. 6. Reliability vs Nodes.

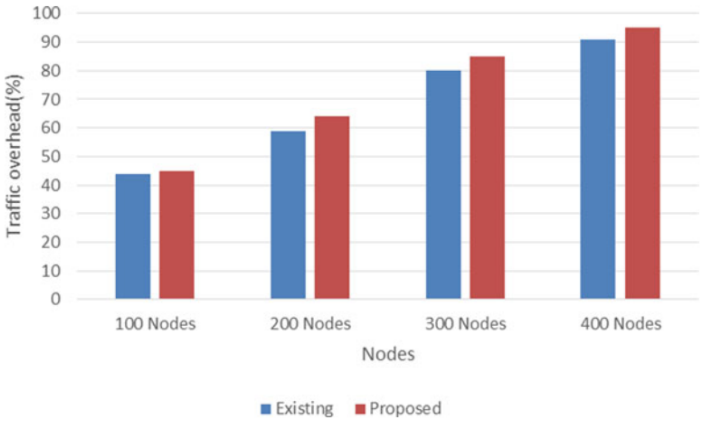

Fig. 7. Nodes vs Traffic Overhead.

In terms of power consumption and block generation time, the performance of the modified algorithm is compared to the standard one around. The revised algorithm shows a significant decrease in energy consumption compared to the regular one. A block is validated by a few selected safe miners in the updated one, but the standard one requires more than 50% node participation in the block validation process, resulting in higher energy consumption. Updated energy consumption remains almost constant for a comparable number of clusters with a greater number of nodes, while energy consumption tends to increase as the number of nodes within the network increases (Fig. 4).

Fig. 5 displays the updated and standard block generation period. The graph in Fig. 5 illustrates that the time for the standard generation of blocks is greater than for the updated one. As normal, different nodes send their transactions to one leader node for validation, and to broadcast across the network, a validated block is required. The approach thus consumes higher energy and makes it possible to take a longer time for the block's network-wide casting. In addition, some good miners are selected based on reputation, results and stake in the revised one, but a miner based on investment or stake alone is regularly nominated. We have painted

our architecture with an already proven architecture in terms of reliability and overhead touch. The protection protocol is correlated with these two performance metrics. The graph in Fig. 6 shows that our eHealth is more robust than the current system due to our decentralized Key Management and several three layer Patient Agent instances.

On the other hand, the diagram shown in Fig. 7 showed that our eHealth security mechanism provided greater overhead communication than the current one. An Agent needs a certain number of data encryption segments to be obtained from other neighbouring Agents to form the entire secret key. This technique activates overhead communication when exchanging hidden keys and authenticating. The relation between the different features and the current system [22] is shown in Table I. Similar to the cloud, with different protection strategies or without protection, different stakeholders deploy heterogeneous fog devices. Fog networks, through the identification and analysis of health information, are vulnerable to malicious attacks. In our architecture, the same patient agent replicated in the Mobile, Fog scheme and Cloud will protect wellbeing. To keep a Record of Malicious Attacks, sensitive medical information is analysed in the homogeneous replicated Patient Agent in order to protect the privacy or confidentiality of the patient.

A dropping assault occurs if a cluster head reduces the transactions. This is unlikely to happen because the cluster head will lose its reputation to share when it is detected as malicious. The consensus mechanism should select the malicious and cluster members who do not collect transactions for verification while the head of the cluster is down.

TABLE I. COMPARISON WITH EXISTING SYSTEM

Criteria	Proposed	Existing system
Confidentiality, availability and integrity	CAI high, PA homogeneous Responsive medical data task Edge nodes, using the ring signature, blockchain maintenance for metadata ensures several PAs Availability of service	Privacy is average, integrity is high, usability is high, Low because of centralized operations of blockchain Controller
Secure and energy efficient migration	High	Low
Communication overhead	High	Medium
Consensus mechanism	Light weight	Medium

V. CONCLUSION

In this paper, we built an eHealth program that deployed several instances of a three-layer Patient Agent software: sensing, near processing and far processing layer, which make the eHealth software more stable and fault-sensitive. We also defined how to implement the Patient Agent on a 5G unit. The dedicated Patient Agent application is able to handle the resources of 5G network slices. A performance analysis has shown that the emerging eHealth program will use blockchain technology to process health data in near-real time. The implementation of blockchain healthcare technology is difficult, with vast volumes of health data constantly being transmitted from wearable sensors.

***Abstract*—Software defect prediction is one of the most active research fields in software development. The outcome of defect prediction models provides a list of the most likely defect-prone modules that need a huge effort from quality assurance teams. It can also help project managers to effectively allocate limited resources to validating software products and invest more effort in defect-prone modules. As the size of software projects grows, error prediction models can play an important role in assisting developers and shortening the time it takes to create more reliable software products by ranking software modules based on their defects. Therefore, there is need a learning-to-rank approach that can prioritize and rank defective modules to reduce testing effort, cost, and time. In this paper, a new learning to rank approach was developed to help the QA team rank the most defect-prone modules using different regression models. The proposed approach was evaluated on a set of standardized datasets using well-known evaluation measures such as Fault-Percentile Average (FPA), Mean Absolute Error (MAE), Root Mean Square Error (RMSE), and the Cumulative Lift Chart (CLC). Also, our proposed approach was compared with some other regression models that are used for software defect prediction, such as Random Forest (RF), Logistic Regression (LR), Support Vector Regression (SVR), Zero Inflated Regression (ZIR), Zero Inflated Poisson (ZIP), and Negative Polynomial Regression (NPR). Based on the results, the measurement criteria were different than each other as there was a gap in the accuracy obtained for defects prediction due to the nature of the random data, and thus was higher for RF and SVR, as well as FPA achieved better results than MAE and RMSE in this research paper.**

***Keywords*—Software engineering; software testing; software defect prediction; learning to rank approach**

I. Introduction

Predicting the exact and precise defect number is the best and most accurate option for software engineers, but because of the difficulty of achieving this task in real scenarios, it is not enough to rely on classifying modules into defects or not, so there is a need for another solution that can improve the defect prediction performance and increase the quality assurance of confidence in defect prediction [1]. This solution can be achieved by using a learning to rank approach that supports defect prediction models to rank and prioritize modules based on certain factors [1].

The importance of SDP models for predicting software defects has been discussed by using the LTR approach to rank a program according to the number of defects. The new model is supposed to improve the performance of the existing defect prediction models. Predicting the number of defects in software modules using machine learning regression models. However, this paper proposes a new learning to rank approach that supports defect prediction models for ranking and prioritization.

Most of the research in the past decade has focused on proposing new indicators for constructing predictive models [1]. The most studied indicators are the source code and process metrics [2]. Source code metrics measure the complexity of the source code [2]. Process metrics are derived from software documents, such as version control systems and issue trackers, which regulate the entire development process. Process metrics quantify many aspects of the software development process, such as source code changes, ownership of source code files, and developer interaction. The process metrics used to predict errors have been validated in many studies [2].

Defect prediction research is generally based on machine learning [3]. Predictive models built using machine learning approaches can predict the probability of errors in the source code (classification) or the number of errors in the source code (regression). Some studies have proposed the latest machine learning techniques, such as: improving active learning and prediction. The researchers also focused on determining the accuracy of predictions. Failure prediction models attempt to identify failures at the system, component, package, or file/class level. According to recent research, errors in modules or methods can also be identified and changed to different levels. Better accuracy can help developers by limiting the scope of source code reviews ensure quality. Suggesting a pre-processing method for predictive model is also an important research put forward in error prediction research. Before building the model, the following methods can be used for prediction: function selection, normalization, and noise protection [3]. Through the proposed pre-processing method, the predictive characteristics of actions in related research can be improved [3]. The researchers also proposed methods to predict defects in software projects [3]. The majority of the above representative studies were performed and verified within an internal prognostic framework, and the predictive model was developed and tested within the same project [4]. However, this is difficult for new projects that lack development history information. Create a predictive model. Typical methods for predicting crossover errors are metric compensation [4], nearest neighbor (NN) filters, naive transfer Bayes (TNB), and TCA+ (state-of-the-art transfer learning approach). Adjust the predictive model by selecting similar instances, transforming data values,

or developing new models [4].

Another important topic for defect prediction between items is to study the possibility of cross-prediction. Several studies have confirmed that cross-prediction is difficult to achieve; only a few cross-prediction combinations are effective [5]. Determining cross-prediction capabilities will play a major role in predicting errors between projects. There are many studies on the possibility of cross-prediction based on decision trees [5]. However, their decision tree has only been tested on certain software datasets and has not been studied.

The purpose of the SDP for the classification task is to predict which modules are likely to contain the most defects in order to allocate efforts to improve software quality, which means relative prediction and extraction of the exact number of defects, but this requires many conditions and accurate data to give the exact number of defects, which becomes difficult when the data is too large. However, the Learning to Rank (LTR) method provides a linear model by directly improving classification performance. It has been verified that it is useful to make forward adjustments to the classification performance metrics of the SDP model for constructing classification problems [6].

In this paper, a new learning to rank approach was developed to help the QA team with the ranking of the most defect-prone modules. The proposed approach was evaluated on a set of benchmark datasets using known measures such as fault percentile average (FPA), cumulative lift chart (CLC), mean absolute error (MAE), and root mean square error (RMSE). Our proposed approach will be compared with the current learning to rank approaches used in defect prediction.

The paper is organized as follows: Section II presents work related to software defect prediction as well as learning to ranking methods. Section III presents the proposed model including the data sets as well as the evaluation metrics used. Section IV presents the implementations made in the paper and finally Section V presents the findings and discussions about them before ending with the paper's conclusion.

II. Related Work

A. Software Defect Prediction

There are many studies that address the issue of predicting software defects. Among them, for example, X. Huo and M. Li, in [4] who proposed a new perspective for software defect prediction. This clearly articulates the "pair-wise" relationship between the bad module and the clean module to better prioritize the modules that are prone to failure, thus using benchmark dataset to ensure software reliability. X. Jing et al. in [8] attempt to systematically summarize all the typical work on predicting software failures in recent years. Based on the results of this work, this paper will help software researchers and professionals to better understand previous failure prediction studies based on datasets, software indicators, scores, and technical modeling perspectives in a simple and effective way. A. Okutan and O. Yıldız in [9] used Bayesian networks to study the relationship between software performance and error propensity. They used 9 records in the Promise data repository and showed that RFC, LOC, and LOCQ are the most error prone. On the other hand, the effect of NOC and DIT on defects is limited and unreliable. Y. Ma et al. [10] looked at a cross-company defect prediction scenario in which the source and target data came from different companies. They presented a novel technique called Transfer Naive Bayes (TNB), which uses the information of all the proper features in training data to select training data that is similar to the test data. J. Zheng in [11] studied three cost-sensitive impulse approaches for driving neural networks to predict software failures using four datasets related to a single action from the NASA project. Experimental results show that threshold shift is the best choice for cost-effective prediction of software failures using neural network models from the three approaches studied, especially for project datasets developed in object-oriented languages. X. Jing et al. in [12] used vocabulary learning methods to predict software errors. They used the characteristics of open-source software measurement to study various vocabularies (including error-free modules and damaged modules and sub-words of general vocabulary) and sparse representation coefficients. The dataset from the NASA project is used as a benchmark for evaluating the performance of all comparison methods. Experimental results show that CDDL is superior to several typical current error prediction methods. G. Czibula et al. in [13] proposed a classification model based on the mining of relational association rules. It is a discovery of relational association rules that can be used to predict whether a software module is flawed or not. On the open-source NASA datasets, an experimental evaluation of the proposed model. The results reveal that the classifier outperforms existing machine learning-based defect prediction approaches for the majority of the assessment measures studied. I. Laradji et al. in [14] introduced a two-variant (with and without feature selection) ensemble learning technique that is robust to both data imbalance and feature redundancy. Poor characteristics do not affect ensemble learners like random forests and the proposed technique, average probability ensemble (APE), as much as they do weighted support vector machines (W-SVMs). Furthermore, for the NASA datasets PC2, PC4, and MC1, the APE model paired with greedy forward selection (improved APE) attained AUC values of roughly 1.0. S. Liu et al. [15] employed the FECAR feature selection framework with Feature Clustering and Feature Ranking to forecast software defects. Using the FF-Correlation metric, this framework divides original features into k clusters. Then, using the FC-Relevance measure, it selects relevant features from each cluster. The data is based on real-world projects such as Eclipse and NASA. P. Krause and N. Fenton in [16] Focuses on a model developed for the Philips Software Center (PSC) using the expertise of the Philips Research Laboratory, which is specifically designed to predict the number of errors in various testing and operational phases. Seven of the 28 projects can obtain comprehensive data (completed questionnaires, more project data, and more error data). The study was not as successful as expected, and the authors confirmed that more investigations will be conducted in the future. The research is still in progress.

Li, M. Shepperd, and Y. Guo in [17] investigated the use and performance of unsupervised learning techniques in predicting software defect by conducting a systematic literature review that identified 49 studies with 2456 individual experimental results that met our inclusion criteria and were published between January 2000 and March 2018. Everything is in order. In this study, unsupervised classifiers did not appear

to perform worse than supervised classifiers.

T. M. Khoshgoftaar and colleagues in [18] proposed a methodology that incorporates a feature selection approach for picking relevant qualities and a data sample approach for resolving class imbalance. They used nine software measurement datasets from the PROMISE software project repository. Experimental results show that feature selection based on sample data performs significantly better than feature selection based on raw data, and the fault prediction model can achieve the same effect whether the training data is sample data or raw data.

L. Son et al. in [19] proposed a methodological mapping where they dealt with nine studies questions similar to distinctive stages of improvement of a DeP model. They explored every issue related to the method from collecting records; Preprocess records, strategies used to build a DeP fashions for the metrics used to evaluate the overall performance of the model and statistical evaluation plans used to mathematically validate the results of the DeP model. Out of the full 156 research, they decided on ninety-eight research for addressing 9 studies questions fashioned for this systematic mapping.

M. Sohan et al. in [20] used a lot of project data to prepare a balance and unbalanced dataset to build a prediction of software defects. Experimental results show that no significant changes are observed between balanced and unbalanced learning models. For a balanced learning model with an unbalanced test dataset, only the AUC value (area under the curve) increases exponentially. X. Cai et al. in [21] proposed a hybrid multi-purpose dynamic local search Cuckoo Search (HMOCS) to simultaneously identify health solutions. The problem of class mismatch in the dataset and the selection of SVM (support vector machine) parameters is critical to the prediction software defect. Eight datasets were selected from the Promise database to verify the proposed model for predicting software failures. Compared with the results of 8 prediction models, this method effectively solves the problem of predicting software failure. W. Li et al. in [22] proposed a two-step classification method and a two-step classification method based on three-way decision-making to predict cost-sensitive software failures by using NASA data. On the same direction Abu-Alhija et al. [23] studied the impact of kernels and SVM on the performance of defect predictions. they found that RBF is more Superior than other kernels.

B. Learning to Rank Approaches in Software Defect Prediction

X. Yang et al. in [1] used the LTR methodology for a wide range of real-world datasets and provided a full evaluation and comparison SDP for the ranking job, which included 10 construction approaches compared to other approaches on eleven real-world datasets. The relationship between CLC and FPA was also explored, as well as the need for metric selection over two sets of data for SDP for the ranking assignment. For the ranking job, the LTR technique to building SDP models yielded good accuracy and clarity of understanding. Also Xiaoxing Yang et al. in [2] used the learning-to-rank approaches to anticipate software defects. They presented the experimental results, which include a comparison of their approach to three other approaches from the literature, as well as five publicly available datasets. They employed the evolutionary optimization method to directly optimize the model performance measure, fault-percentile-average, which is not the same as the loss functions. For most datasets, the proposed learning-to-rank approach outperformed linear regression and logistic regression in terms of fault percentile-average models. Z. Cao et al. in [3] employed a learning to rank based approach to address the lack of legacy specifications that quantify the possibility of a candidate rule becoming a specification using 38 interesting measures. The benchmark dataset contains 28 classes from the Java 6 SDK that have been manually identified as having specification rules. These guidelines were derived from the completion of 14 projects. Experimental results using classes from the Java 6 SDK show that our learning to rank-based technique can enhance the best ranking performance using a single measure by up to 66 percent. X. Yu et al. [5] investigated the effect of 23 learning to rank approaches for EADP using 41 releases of 11 open source software projects taken from the PROMISE data repository to examine the impact of 23 learning to rank techniques for EADP. When the 23 approaches are trained on the original feature subset, the experimental findings demonstrate that BRR performs best in terms of FPA, while BRR and LTR perform best in terms of Norm (Popt) subset.

M. Buchari Yu et al. in [6] used two public benchmark datasets to create and assess the implementation of Chaotic Gaussian Particle Swarm Optimization on the Learning-to-Rank software defect prediction methodology for train model parameter. They conclude that using Chaotic Gaussian Particle Swarm Optimization in a Learning-to-Rank strategy can increase defect module ranking accuracy in datasets with high-dimensional characteristics. Y. Ma et al. in [7] used a top-k learning to rank (LTR) approach in the scenario of CPDP. The PROMISE dataset shows that SMOTE-PENN outperforms the other six competitive resampling approaches and Rank Net performs the best for the proposed.

III. The Proposed Model

A. Dataset

In this paper, a benchmark dataset was used from several types of versions, and the dataset was collected from the GitHub libraries and from previous research. The dataset applied to the developed regression models was 28 in total with different features, as shown in Table I below. The methodology on which the dataset was applied is to read the required data, then it was ensured that the data did not contain null values, and then the data was divided into x (features) and y (total defect). Finally, feature scaling technique was applied to make the output the same standard as it mentioned in the implementation section.

B. Developing Regression Model

In this paper, a model was proposed to predict the defects of the software modules and then rank the most defect-prone modules using six regression models such as (Random Forest, Logistic Regression, Support Vector Regression, Negative Binomial Regression, Zero Inflated Regression, and Zero Inflated Poisson). However, after we prepared the dataset, we applied the data to our modules. They are divided into two categories: variations of the Poisson regression model and regression trees:

TABLE I. BENCHMARK DATASETS

1) Variations of Poisson Regression Model: NBR (Negative Binomial Regression) has been commonly used for SDP. ZIP, ZIR, and NPR are all variations of Poisson regression. When the response variable of the dataset contains a large number of zeros, the Poisson regression model will reduce the probability of zeros. Zero-inflated models can explicitly model the excessive occurrence of zero faults. Zero-inflated models assume that zero-defect modules come from two distinct sources.
2) Regression Trees: SVR, LR, and RF are different types of regression trees. RF is an ensemble classifier consisting of many trees, and outputs the average of individual trees .LR Random Forests is a set of decision trees that have been combined to form an ensemble. It is an approach for Supervised Learning. Several decision trees are used to process the input data. It is powered by constructing a variable number of decision trees at training time and displaying the class that is the mode of the classes or mean prediction (for regression) of the individual trees. SVR attempts to predict actual values. To separate the data, this technique employs hyperplanes. If this separation is not achievable, the kernel trick is used, in which the dimension is increased, and the data points become separable by a hyperplane. Logistic regression is a data analysis technique that is used to define and explain the connection between one dependent binary variable and one or more nominal, ordinal, interval, or ratio-level independent variables.

C. Evaluation Measures

In this paper, different measures were used to evaluate the accuracy of our modules, the goal of accuracy evaluation is to make it easier to determine which modules we evaluate is good. The evaluation method is to obtain the percentage. The percentage of defects in the preceding modules of the ranking is commonly applied. To evaluate SDP models for the ranking task. The following are the evaluation measures we used:

- Fault-Percentile-Average: FPA is one of the evaluation measures which could reflect the effectiveness of different prediction models across all cuts off values as shown in equation 1. FPA is the average of the proportions of actual defects in the top m (m=1,2,..,k) modules to the whole defects, which is a more comprehensive performance measure than the percentage of defects in the top 20% modules. A higher FPA means a better ranking, where the modules with most defects come first [1].

$$\frac{1}{k}\sum_{m=1}^{k}\frac{1}{n}\sum_{i=k-m+1}^{k}\frac{1}{n}n_i \tag{1}$$

  where:
  - k is the number of software modules.
  - n is the total number of defects in all modules.
  - m is the modules to the whole defects.

- Root Mean Square Error:
  RMSE stands for Root Mean Squared Error. The standard deviation of the errors that occur when making a prediction on a dataset is known as the RMSE. This is the same as MSE (Mean Squared Error), but the root of the number is considered when calculating the model's accuracy. The errors are squared before being averaged in RMSE as shown in equation 2. This means that RMSE gives larger mistakes a higher weight. This suggests that RMSE is far more beneficial when substantial errors exist and have a significant impact on the model's performance. This characteristic is important in many mathematical calculations since it avoids taking the absolute value of the error. In this metric as well, the lower the value, the better the model's performance.

$$RMSE = \sqrt{\left[\sum\left(P_i - O_i\right)/n\right]} \tag{2}$$

  where P_{i} is the predicted value for the i^{th} observation in the dataset. O_{i} is the observed value for the i^{th} observation in the dataset. n is the sample size.

- Mean Absolute Error:
  The Mean Absolute Error (MAE) is a statistic that assesses the average magnitude of errors in a set of predictions without taking their direction into account as shown in equation 3. The Mean Absolute Error is the average of the absolute differences between prediction and actual observation over the test sample, assuming that all individual deviations are equally weighted. It is less susceptible to outliers than MSE because it does not penalize large errors. When performance is measured using continuous variable data, it is commonly employed. It produces a linear value that equalizes the weighted individual disparities. The model's performance improves as the value decreases.

$$MAE = \frac{1}{n} \times \sum_{i=1}^{n} |o_i - P_i| \quad (3)$$

- Cumulative Lift Chart:
  A lift chart graphically Represents the improvement provided by the mining model to random estimation and measures the change in the form of elevation estimation as shown in equation 4. Through comparing the elevation estimates of different models, you can determine which model is better.

$$CLC = FBA - \left(\frac{1}{2k}\right) \quad (4)$$

  where k is the number of software modules.

D. Research Methodology

In this paper, a new learning to rank (LTR) approach was developed to help the QA team rank the most defect-prone modules in the software and thus reduce testing efforts using various regression models. The datasets used were taken from the standard dataset, and the datasets are divided into training and test data. In the Software Defect Prediction Program (SDP), training data and test data were selected in two separate ways. First, in the same dataset, the training and test data were randomly selected (or may be sequential). In the second stage, the training will be taken from the dataset as the previous version, and the test data from another dataset will be taken as the next version. The first approach was adopted and used. We then evaluated the data using known evaluation measures such as Fault-Percentile-Average (FPA), Mean Absolute Error (MAE), Root-Mean-Square Error (RMSE) and Cumulative Lift Chart (CLC). Our proposed LTR approach was compared with the current LTR approaches used in software defects prediction. Fig. 1 illustrates the research methodology used in this paper.

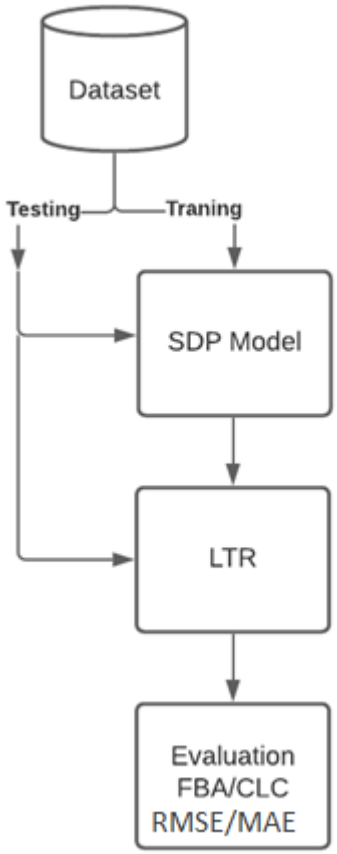

Fig. 1. Research Methodology.

E. Implementation

To prove the success of our proposed LTR approach, it is necessary to apply our work and show and compare the results. Various regression models were used in a separate way from previous studies, by applying the LTR approaches and the programming language that we will discuss. Python 3.6 and Spyder 3.2.6 were used to evaluate the accuracy of the ML regression models (SVM, RF, LR, ZIP, ZIR and NPR). In addition to the usage of Google Colab to run the existing LTR approaches to do comparison with the proposed LTR approach in this paper. Each model was developed separately from the others, but in this section, we collected the models to present the methodology in an obvious way. Each model was used from twenty-eight datasets. The databases were configured prior to use so that they were all applied in a uniform manner. We will go through the methodology in a clear manner by explaining the steps of the code.

IV. Result

In this paper, four evaluation measures were used to calculate the accuracy of our regression models, and we will present the findings in tables depending on the evaluation measures. Twenty-eight datasets were used over six regression models in this paper. The goal of this paper is to present the accuracy of our software modules by applying 5-fold cross-validation technique. The reason to use 5-fold cross-validation is to get the best result based on 28 datasets with different features.

A. Fault Percentile Average

By calculating the average accuracy of Fault-Percentile-Average using 5-fold cross validation, we show the values in Table II.

The goal of building these regression models was achieved by finding the model that contains the largest number of errors and comparing the machine-trained model with the outputs in the data. The accuracy was measured to discover the model that predicts the number of errors, and the accuracy expresses the result of the prediction of the machine in how close it is to the original result. Here, the closer the result is to zero, the better the result. From our experience, it is difficult to determine which model is better because of the amount of disparate data, but we can determine the best model by comparing the models on one dataset only.

Fault-Percentile-Average (FPA) evaluation measure was used based on previous studies, which were studied based on classification models, thus showed satisfactory results, but in

this paper, we applied it to six regression models on a larger scale, so that we used all available databases in the field of rank learning, and we have obtained satisfactory results. In this paper, we demonstrated the success of the error-percentage-mean scale. All results were not shown over-fitting on the result.

As seen in Table II, the columns represent all the datasets we used and the rows represent the regression models that we created, for example row ant-1.7 represents the first dataset to which Fault-Percentile-Average has been applied to show the accuracy results for the regression model that was built To determine the model that contains the largest number of program errors, and this accuracy represents the proximity of the learned data to the test data and here we find that the best reading for it is 0.81054, which represents the negative binomial regression model, and this result does not mean that it is the best model because it may depend on the nature of the data and the evaluation measure.

B. Mean Absolute Error

By calculating the average accuracy of Mean-Absolute-Error using 5-fold cross validation, the values shown in Table III.

Because we are using regression models in this paper, it is necessary to mention the measurement criteria for the regression, such as Mean Absolute Error. We have used the same methodology in building defect models that contain the largest number of errors and measuring the average accuracy of the models by using 5-fold cross-valuation on a twenty-eight dataset with all features. As shown in Table III, the accuracy results from using the evaluation of the Mean Absolute Error of the regression. It is clear that some results have exceeded the relevance because most of the datasets are intended for classification. However, satisfactory results were shown in some datasets. This does not mean that other models failed to show

accuracy in every way, but rather they showed satisfactory results according to the nature of the data.

C. Root Mean Square Error

Table IV shows the RMSE results based on different numbers of matrices. We applied 10 times 5-fold cross-validation over 28 datasets with all metrics. By calculating the average accuracy of Root-Mean-Square-Error using 5-fold cross validation, we show the values in Table IV.

This is another way to calculate mean precision with 5-fold validation using RMSE. As shown in Table IV, more than appropriate occurred in some of the data, and this is because the nature of the data is for classification and not for regression. However, we have achieved satisfactory results, and these results were mostly concentrated on two models (Linear Regression and support vector regression).

D. Cumulative Lift Chart

This is a way to evaluate the measure of our modules to show the relationship between two evaluation measures (FPA, MAE) in easy and effortless way by presenting the chart of all six modules we have used before as shown in Fig. 2. The charts show the performance of our regression models against other well known LTR methods algorithms [1-2] [3-10].

V. CONCLUSION

SDP models for ranking task manage testing resources more effectively by predicting which modules are likely to have more errors in the software program. SDP data is gathered by a variety of IT organizations and individuals, and it is noisy. As a result, estimating the number of errors per software

module is difficult, if not impossible, due to a lack of precise historical data. Some academics propose utilizing a ranking-based performance metric to assess SDP models such as CLC and FPA. However, contemporary SDP models have been enhanced to properly predict a specific number of errors. However, a decent model based on individual loss functions may fail to provide a satisfactory ranking. As a result, in this paper, we proposed a unique approach, distinct from earlier studies, for developing models by direct improvement of the ranking performance measurement. We applied the LTR approach to a wide range of real-world datasets in this paper and present a complete assessment and comparison of RF, SVR and LR with other approaches. We also estimated the error using FPA and MAE and then used CLC to explain the disparity between its results.

The following are the key findings from our research paper:

1) Employing the regression approach rather than the classification approach, as opposed to prior studies in the literature where the classification technique is employed. This is to highlight the contrast between the classification and regression models. Whether or not this model has mistaken, the data is divided into 0 and 1, with 0 containing no errors and 1 containing errors. This is known as classification. However, the regression models that we are working on estimate the number of mistakes in each website, which means that the first website based on the characteristics (x values) has a number of errors, and so the regression models train the model when the data enters it. The characteristics will predict mistakes that are either equal to or near to the amount of genuine errors. This is the point of using regression models.
2) Proposing a new LTR approach with scipy.stats and apply it to multiple models to compare and calculate accuracy. We discovered that the model produced using regression models accomplished what was expected of it in terms of identifying models with the highest number of errors, and the percentage of accuracy varied according to the type of data. And according to the comparison with the standard measures, we found that the model RF and SVR is better.

Based on the results and their comparison, we found that the measurement criteria differ from each other, so that we found a gap in calculating the accuracy in some measurements due to the nature of the random data, and FPA achieved better results than MAE, RMSE in this research paper.

***Abstract*—Nowadays, the Artificial Intelligence (AI) field has made a significant change in the real life. Numerous applications use the AI techniques for the purpose of assisting people in different life aspects. Furthermore, with the increased number of people with visual difficulties around the world, there is a need for such AI assistive applications which provide them an independent life. Limited affordable and appropriate solutions developed so far. In this paper, we present a personal AI-based assistive application called (Vivid) that supports visually impaired people being more independent. Vivid has many features such as identifying objects, objects' colors, recognizing text, and faces detection. It relies on using the mobile camera to sense the environment, and the machine learning techniques to understand the environment. By translating a meaningful information in audible sound for those users, Vivid does not require to have any visual ability. Moreover, the whole interaction with the user is only based on voice commands. The input from the user is captured as finger gestures on tablet or cell phone touch screen. In addition to Vivid, we also shade the lights on a supplementary application that notify/alarm visually impaired people of any nearby objects using sensors. These personal assistive applications were developed then tested on the real world and showed promising results.**

Keywords*—Artificial intelligence; machine learning; assistive technology; visually impaired

I. Introduction

Globally, there are around 285 million people who are considered visually impaired. Thirty-nine million of them are blind and the rest have considerably low visions abilities [1]. In the US, there were four million visual impairments cases in 2010, and are projected to be seven million cases and thirteen million cases in 2030 and 2050, respectively (NIH-NEI). Those people can benefit greatly and improve their life-independently by using AI-based assistive solutions. Even though many smartphone applications developed, limited applications focused on visually impaired people. It is very difficult for a blind or visually impaired user to use a smartphone effortlessly. However, there are several features that can allow those special users to utilize such technology seamlessly as regular users.

In this paper, we propose an AI-based assistive application (Vivid) for those targeted users which is affordable, accessible, and easy to use. Many of the required assistive features were combined such as: (1) colors identifier, (2) objects labels, (3) text reader, (4) facial expression, and (5) distance notifier. The first four features were implemented together in single camera-based application which allow the user to use (Vivid) without any assistance. The use of this application is based merely on finger gestures as an input, and voice feedback as an output. The user interface was made incredibly simple to provide seamless user experience for targeted users. Whereas the last feature "distance-notifier" was developed as a supplementary assistive application with Vivid. The reasons of separating these features in two different applications are: (1) reducing complexity; (2) the first application "Vivid" can be used totally by the blind person without the need for an assistant help, while the second application "distance-notifier", the user might need assistance from someone else to avoid wireless connection errors; (3) the user might only need to use the features provided by "Vivid" which are camera-based, thus, they only download "Vivid", which will provide more flexibility. Table I shows a brief description of the five features.

II. Related Work

The development of modern technologies helped to make all these technologies accessible by all categories of people. Modern technologies are not limited to be used by normal visually people only, however, they can be used by blind people as well. A few years ago, smartphones have been widely used by community – by normal people – and became most popular which touch our daily lives. Whereas, for visually impaired and blind people, technologies are still limited for them; however, the new technologies and smart solutions provided by smartphones encourage blind people to be more independent and self-reliance completely. Authors in [3], proposed a system that is based on Morse-Code, which is a code in which letters were represented by combinations of long and short light or sound signals.

Researchers in [4] raised a question in their study, how do blind users use smartphones? Usually, it depends on a screen reader that exists in its operating system, such as, Google operating system which known as Android, or Apple's system which known as IOS. But more than that, it depends on the presence of some other services, such as screen magnification and the development of night mode feature to suit some other visual disabilities. Moreover, there are other settings for disabled people within "General" menu under the name of "Accessibility". This feature allows disable people to choose what is suitable to them. In addition, smartphones have a feature which called "screen reader" to help in reading what is shown in the screen.

TABLE I. A BRIEF DESCRIPTION THE FIVE FEATURES OF THE VIVID APPLICATION

Feature	Description
Colors Identifier	To identify colors of any object by capturing an image of that object. Basically, the implemented algorithm detects the most dominant RGB colors, and identifies colors values; then, converts these values to colors names that are known by human. At the end, voice feedback is generated saying the identified color's name. This feature is not only assisted people with blindness, but also helps people who suffer from color-blindness.
Objects Labels	A machine learning tool, which is 'MLT kit' API [2] was used. The ML Kit mobile SDK brings all the Google's expertise on machine learning techniques to mobile developers in an easy-to-use package, our application can allow the user to identify any object name/label by taking an image of that object. For example, there is a "ball" object which the blind person cannot identify, by taking an image of that object, the application can identify it and tell the user it is a ball.
Text Reader	Again, by using the 'ML kit' API [2],this feature allows visually impaired people to be able to detect any written text and hear it; not only the text that is in braille. The user can take an image of the text by bringing the camera closer to where the text is written and taking an image of that text. The application then generates a voice version of that text.
Facial Expression	The 'ML kit' API [1] is used, this feature allows visually impaired people to be able to detect if there is a person in front of them with the use of face detector and then facial expression detector. User can take an image of the person in front of him/her by bringing the camera closer to where of his/her moving direction and take an image. The application then generates a voice version of that text.
Distance Notifier	To use this feature, the user will need a hardware sensor. The sensor is attached to the user as a belt and will notify/alarm him/her of any object that is getting closer or might hit him/her. The sensor used was Ultrasonic Sensor HC-S04, which is a hardware for identifying distances. The way how this hardware works, was by sending sound waves from the transmitter, which then, bounce off an object, and return to the receiver; the user can determine how far away something is, by the time it takes for the sound waves to get back to the sensor. To connect this sensor to the smartphone, we developed a separate application called "Distance-Notifier" that can handle wireless Bluetooth connection to this sensor and send alarms/notifications to the user.

Another study [5] discussed how smartphones can be used by blind people. In IOS, for example, it provides feature of screen reader known as "Voice Over", and it supports most of the languages in the world. When this option is activated, the use of this device is entirely different; the device turns into a speaker device. Any touch on the screen, will tell the user what is that touched point. For example, if the user touched an application icon i.e. (Facebook), the screen reader will say "Facebook twice to open" and will say this sentence in other languages as well. Next, the application is opened only after pressing it twice – this is similar to double-click the mouse when using a computer to move from one item to another. The screen is swiped from the left to right to go to the next item or application, or also to go to the previous item or application. With each swipe, a screen reader will utter the name of the item or application and the mechanism of its activation. The device is easy to use and depends completely upon gestures with fingers on the screen; it seems at the beginning a difficult job for blind people to use it, but it is actual requires some training to use it [5]. While IOS devices provide the service of Voice Over, Android devices which are widely used by people around the world provide the service of "Talkback" which is an accessibility service. It allows visually impaired people to interact with smartphones and use them regularly as everyone else does. It is based on spoken words, and other audible feedback that will give the user a full experience of what they are doing, and what the output produced by the device [6].

Authors in [7] said that we still convinced that modern technologies allow disable people to live in all life aspects with a realist and an effective manner. This enhanced the continuous development of modern technologies for those people. As discussed in [8], there were many text reader applications, such as, the scanner through the smartphone camera, and the conversion of written texts to audio. Moreover, authors in [9] implemented an Optical Character Recognition (OCR) program, which provides the opportunity to scan books and letters. The program works once any text has scanned, then, reads the text loudly. The OCR consists of a camera that captures the text, which then converted to speech through the program. The drawback of this program is that, this technique required a hardware in order to work sufficiently; which made it difficult to be available to everyone. However, by involving this technique into smartphones, it becomes more useful and usable [9].

Furthermore, an application developed by researchers in [10] which was based on two hardware devices. One for text input and the other for speech output. Basically, it works using a sensor component - as an eye - that captures any printed text. Then, it extracts the recognized text area, and produced a speech output - by the audio output device - for blind users. The main drawback of this application was the cost. Another study [11] showed the automation of text-to-audio. Basically, a pen-like device is used to convert any non-Braille text to audio. Any piece of text that a person would like to read, is converted to an audio signal; after that, by using the Bluetooth technology, these audio signals are transmitted to Bluetooth earphones. The authors in [11] believed that pen technology is lighter in the sense of it can be easily portable. This can change blind people life by allowing them to read whatever they desire.

In the International Conference on Computer and Information Technology [12], an Android system assistant for visually impaired people was developed which called Eye Mate which can help users to know where the obstacle is through vibrations. This android application provides navigation to a blind person and track his/her movement as well. This was based on a voice command; the application will generate a voice command according to the obstacle object position. The movement of a person are measured by using GPS which tracks the user position latitude and longitude. Furthermore, in [13] a sensor-based assistive device for visually impaired people was proposed. This device has a sensor to identify the distance between the person and a harmful object. Other studies [14][15] showed some devices that have been used by visually impaired people, however, these devices are big and not comfortable to use.

In [16], a proposed product called "Self-Energized Smart Vision Stick" developed for blind people, as shown in Fig. 1; the stick uses Arduino Ultrasonic Sensor. It is basically a sticklike a tool that provides safety and privacy to those people. This stick is attached to distance sensors to identify the distance between the stick and any nearby objects, then,

notify the user accordingly.

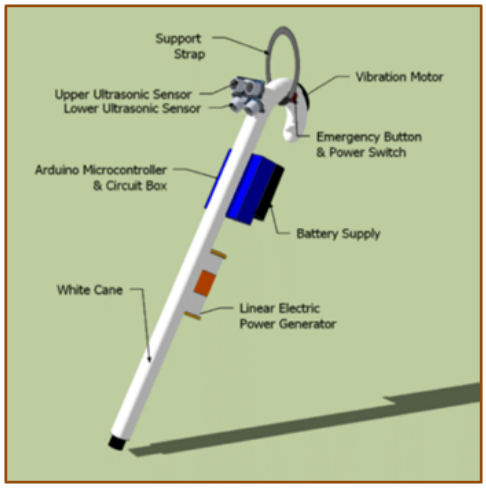

Fig. 1. General 3D Model of the Self-Energized Smart Vision Stick [16].

Authors in [17] declared that colors are a concern to blind people because it is a very important to them to know what the colors of their clothes are. There are many color-identifier applications proposed, such as "Color Reader" sensor. An American foundation for blind people invented a "color teller" an easy-to-use device, which helps visually impaired people to identify the color of any object. Moreover, the researchers in [18] highlighted the importance of colors, and implemented a device called "Coloresia". This device could convert any color into music or words. In addition, the American council for blind people [19] made a comparison between the color detectors applications in the market, and then, provided better solutions for these applications if needed. A list of other applications discussed that help visually impaired people in several ways, such as, a reader to identify colors and objects which work with QR technique [20].

Google Firebase is the newest technology of image labelling process. Image labelling provides information of what the images contain. With the use of ML kit API, it will enable the application to recognize objects within an image. Here, are some examples of objects that can be detected: people, activities, places, things, and so on. When it recognizes an object, it indicates a score of confidence level to show how confidently the machine learning could detect the object.

In [21], a video-based application was developed, where number of frames can be generated from the video, then, converting the images from RGB to Gray scale. This was done by applying ML algorithm, which set the key points of an object, then, match the object with the database object. If (object=database), then, convert the text to speech. Table II shows the advantages of "Vivid" as opposed to existing applications.

III. Materials and Methods

As stated in the previous section, our goal is to develop a comprehensive solution to help people with visual difficulties with low cost. Thus, we proposed a mobile application to assist visually impaired and/or color-blind people to be more independent by providing five features: Colors Identifier, Objects Labels, Text Reader, Facial expression, and Distance Notifier. We proposed two mobile applications which were linked together. The main application is "Vivid" and the second application is a "Distance-Notifier". The first application "Vivid" can be used totally by the blind person without the need for an assistant help, while the second application "distance-notifier", the user might need assistance from someone else to avoid wireless connection errors. The "Distance-Notifier" is connected to a hardware sensor that alarms/notifies the users of any nearby objects. We separated these features into two independent applications to reduce the complexity.

A. Vivid Application

Vivid is a camera-based application that captures objects/things and translates them into audible sound. Thus, considering our targeted users who will not be able to see the screen or to use the regular interface that consists of buttons and other controllers, Vivid was built with a simple interface. The features of colors identifier, objects labels, and anything reader are combined in single camera-based application that is called "Vivid". Thus, a blind/ visually impaired user can use "Vivid" application totally by himself/herself without any assistance because the use of this application is based merely on finger gestures for an input, and voice feedback for an output. The user interface was made incredibly simple to provide seamless user experience for blind/ visually impaired people.

The color identifier works over two steps: (1) find the dominant color D; (2), find what color is that. It estimate the dominant color by averaging the color of all pixels per channel $C_1, 2, 3(1 = red, 2 = green, 3 = blue)$:

$$C_i = \frac{\sum_{k=0}^{n} p_{\text{ik}}}{n} \tag{1}$$

where i is the channel number, k is the pixel index in the image and n is the total number of pixel in the image. The average RGB color is then refer to as the dominant color

$$D = (C_1,\ C_2, C_3) \tag{2}$$

After deciding the dominant color of the picture, RGB color is converted to HSV format. First, we get the maximum

$$C_{\max} = \max(C_1, C_2, C_3) \tag{3}$$

and minimum

$$C_{\min} = \min(C_1, C_2, C_3) \tag{4}$$

of the values from the three channels. Then,

$$a = C_{\max} - \ C_{\min} \tag{5}$$

Second, we calculate the value of Hue (H) and Saturation(S). H is calculated as follow:

$$H = \begin{cases} 0, & a = 0 \\ 60\ x\ (\ \frac{C_2 - C_3}{a} mod\ 6, & C_{\max} = C_1 \\ 60\ x\ (\ \frac{C_3 - C_1}{a} + 2, & C_{\max} = C_2 \\ 60\ x\ (\ \frac{C_1 - C_2}{a} + 4, & C_{\max} = C_3 \end{cases} \tag{6}$$

TABLE II. ADVANTAGES OF "VIVID" AS OPPOSED TO EXISTING APPLICATIONS

Existing Applications	Vivid
An Optical Character Recognition (OCR) program, which provides the opportunity to scan books and letters [9].	The mentioned technique requires a hardware in order to work sufficiently to convert text to audible sound, which made it difficult to be available to everyone. Vivid provides a solution to this drawback by involving this technique into smartphones. Since smartphones are accessible to almost everyone, getting access to this technology is only a few clicks away.
Portable camera based assistive text reading from handheld objects for blind person [10].	Vivid takes the advantage of already existing audio input/out means that are built in the smartphone. No additional hardware required. All the three tasks (scanning text, processing text, producing audio) are done instantaneously in one single device.
Automated electronic pen aiding visually impaired in reading, visualizing, and understanding textual contents [11].	The mentioned pen technology is light and portable. However, Vivid provides better advantages in a sense that despite of being available on a light, portable mobile phone, it is also accessible easily within a few clicks.
Android assistant EyeMate for blind and blind tracker [12].	The proposed technology uses GPS to track coordinates and notify of any obstacles. Vivid enhances this technology by using an Arduino sensor. The sensor measures the distance instead of using GPS system to provide better accuracy and more precise distance measurements.
Android assistant EyeMate [12].	In this application, the impaired person needs to deal with two different applications, (1) to capture contextual (distance of an obstacle, position of the sensors, environment around the user), and then, (2) to communicate with the other application to deliver this information to the user. Our Vivid's algorithm solved this issue by eliminating the need to communicate to any outsider. Thus, the algorithm itself handle the captured information and translate it to audible sound.
Optical devices for distance [14].	The technologies used by developing a device which made it too large and uncomfortable to use as compared to Vidid.
Self-energized smart vision stick for visually impaired people [15].	Using a sick that sense the nearby environment and obstacle is a smart idea. However, the stick is heavy, and the user needs to carry it around. Vivid provides a smart belt instead of a stick so that the user does not need to carry, they only need to wear it and the application will take care of notifying the user of any nearby obstacle.
Assistive technology products by the American Foundation for the blinds [16].	The foundation invented a "color teller" which is an easy-to-use device. It helps visually impaired people to identify the color of any object in front of them. However, Vivid is allowing the users to use the color detection services free of charge while the proposed device costs around 205 dollars.
Bilingual wearable assistive technology for visually impaired people [18].	The wearable hardware requires additional costs compared to Vivid which is merely a downloadable mobile application.
Color to sound converter for blind people [22]	The study suggests using a sensor called "Color Reader". Vivid on the other hand, does not require any additional sensors other than the camera of the mobile. The "color detection" algorithm integrated within Vivid uses the information captured by the camera and acts as a sensor that can identify colors.

Lastly, S is calculated using the following formula:

$$S = \begin{cases} 0\ , & C_{\max} \neq 0 \\ \frac{a}{C_{\max}}, & C_{\max} \neq 0 \end{cases} \tag{7}$$

Then, identifier takes the dominant color and classifies it to one of 12 predefined colors. Each of those colors has a range of numbers if the dominant color fill in the range, then it is classified with it. Table III shows the ranges of HSV values for color identification.Then,find what color is that by:

$$Color = f(H, S) \tag{8}$$

To make sure we are using state-of-the-art techniques, we used Android ML Kit called Firebase [2]. For object recognizer, it offers objects classification of 10000+ classes and 400 classes when working with the online version. The model's performance are measured in term of accuracy is the number of times the model correctly classifies an object. The accuracy for the model is 60% as reported by authors of ml kit library [2].

The model's architecture is MobileNet [23] to use minimal resources on the phone or tablet. For text reader, it recognizes the test in an image and split it into blocks which later read word-by-word out loud to the user. Lastly, facial expression recognizer, it has two features; first, it detects faces in the image then, second, it classifies the expression into smiling or not. The system output "There are no person" if there were no people detected in the captured image. If there is a person and its face is detected, it will classify the expression of the person. Then, it output the expression either smiling person or not smiling person.

Vivid application has a simple workflow which is described in Fig. 2. After launching the application, user manual will appear on the screen only if it is the first time the app has been launched. Otherwise, camera feed will be presented on the screen. Then, user press on the screen to capture specific picture of interest. Then, users have five core actions: swiping up to get object label recognition, swiping down for re-capturing picture of interest, swiping left for color detection, swiping right for text recognition and, finally, long-press for face expression.

Vivid application consists of two activities: the main activity and the image processing activity. The main activity as shown in Fig. 3(a) is the first interface the user will expect, which is responsible to capture the image. As shown in the figure below, the whole screen is merely the camera display, it would not be reasonable to display any sort of text output, graphic or buttons for user interaction with the app because the target users are visually impaired ones. Thus, user will interact by figure gestures. On this activity user can capture the desired object by bringing it close to the camera lens and then tabbing anywhere on the screen. Tabbing gesture will tell the camera to capture the scene at that moment and then send that captured content to the Image Processing activity for processing. However, the image processing activity as shown in Fig. 3(b) is responsible for processing the content captured in the previous activity. The interface again doesn't have any form of typical user interaction controls. Interaction is based on audible outputs and finger gestures. Once user hears the word "swipe" that indicate that the image is processed, and the application is ready to produce the output. User then can get the output using figure gestures of swiping in different directions to get different outputs as defined in the flowchart figure above.

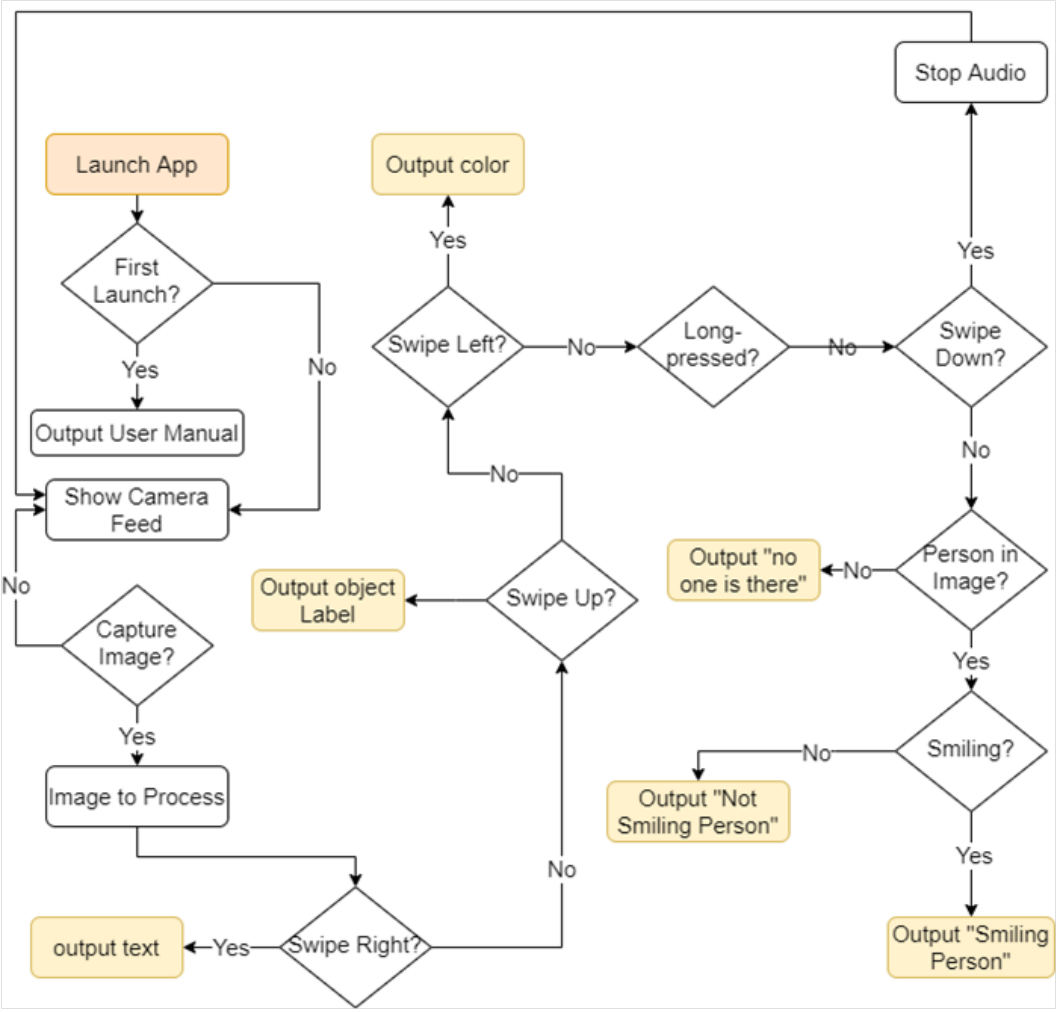

Fig. 2. Flowchart of Vivid Application. All Features and their Workflow of the Vivid Application is Explained in the Figure.

Fig. 3. Overview of the Interfaces of Vivid Application. (a) Main Activity. Camera Feed Showing before Any Interaction is Done by the User. (b) Image Processing Activity. After Taking a Picture.

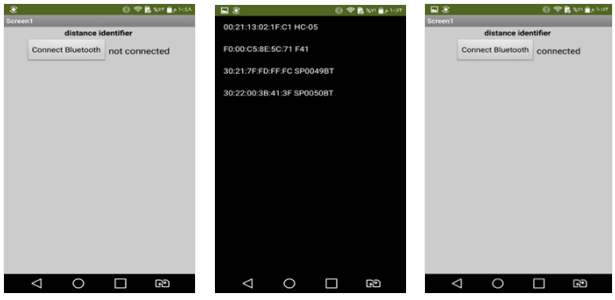
B. Distance-Notifier Application

Distance Notifier application uses a hardware sensor. The sensor is attached to the user as a belt and will notify/alarm him/her of any object that is getting closer or might hit him/her. The used sensor is Arduino Ultrasonic Sensor HC-S04, which is a hardware for identifying distances. The sensors would send sound waves from the transmitter, which then, bounce off of an object, and return to the receiver; you can determine how far away something is, by the time it takes for the sound waves to get back to the sensor. Therefore, to connect this sensor to the smart phone, we developed a separate application called “Distance-Notifier” that can handle wireless Bluetooth connection to this sensor and send alarms/notifications to the user. It is preferred that, to use an assistant person to setup and connect this application to the hardware, to avoid any connection errors. Afterwards, the blind user can receive notifications and alerts from this application.

Distance-Notifier application is a standalone which requires additional hardware. The additional hardware is Ultrasonic Sensor HC-SR04 and an Arduino [24]. The phone is connected to the Arduino using Bluetooth. The app receives the signals from the Arduino and output voice notification for the user. The voice notifications alert user about obstacles on her way. Fig. 4(a, b and c) shows in the interface of the distance notifier application. For the first interface we had a button that allows the user to select Bluetooth device, then, it will show to the user the list of Bluetooth devices, after the list, the user can select the desirable device. Finally, after selecting the device, the used connected and it will be ready to be used.

TABLE III. PREDEFINED COLORS FOR COLORS IDENTIFIER (COLORS ARE CAPTURED IN RGB FORMAT THEN CONVERTED TO HSV FORMAT)

Color	Condition Using Hue (H) and Saturation (S) values f(H,S)
White	$H + S > 59$
Black	$H + S < 35$
Red	$H >= 345 or H < 45$
Orange	$45 <= H < 75$
Spring green	$75 <= H < 105$
Green	$105 <= H < 135$
Turquoise	$135 <= H < 165$
Sky Blue	$165 <= H < 195$
Blue	$195 <= H < 225$
Purple	$225 <= H < 285$
Pink	$285 <= H < 315$
Crimson	$315 <= H < 345$



(a) Start Screen. (b) Selecting Device. (c) After Connecting with Device.

Fig. 4. The Interface of the Distance Notifier Application.

Distance notifier application workflow is shown in Fig. 5. After launching the app, users choose the distance identifier device from the list. Upon succession of connection, the app start notifies the user about obstacles in her/his way.

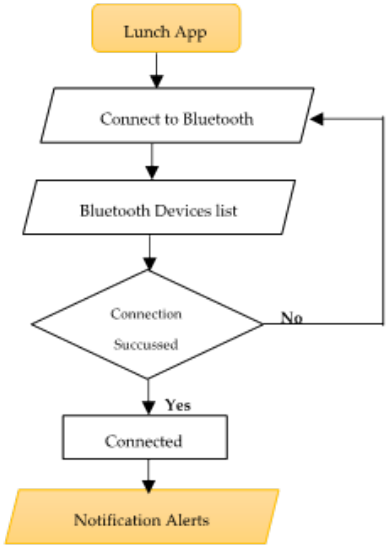


Fig. 5. Flowchart of Distance-Notifier Application.

IV. RESULTS

In this section, we present the evaluation of our experiment which conducted to evaluate the proposed applications' features in the real-world. The design of experiment and reporting of performance results are inspired by [25].

A. Test Cases

To test the proposed applications, we used it in multiple scienaros with various lighting conditions and poses. Our applications have five features: (1) color identifier, (2) object labels, (3) text reader, (4) facial expression, and (5) distance notifier. Fifteen test cases were desgined for each feature to be tested. Fig. 6 shows samples for the test cases with images. Test cases were designed to have veriaty in fabric, color, shape, camera pose and lighting conditions. For each feature 15 test cases was designed.

B. Experimental Results

An experiment is conducted in the real world using the developed two applications. Generally, the application worked with high accuracy as reported in Table IV ranging from as low as 33% and as high as 100%. Reasons vary for this some of which are due very long text, low light, blurred from moving camera or zooming too close or too far in an image. The color identifier is affected by lighting condition a lot as it shows in the accuracy. Future investigation on improving the accuracy of the color identifier is needed.

V. DISCUSSION

There are many ways to improve the accuracy of each feature. Research about each of them is extensive with rapid improvements. However, all this is out of scope of this work.

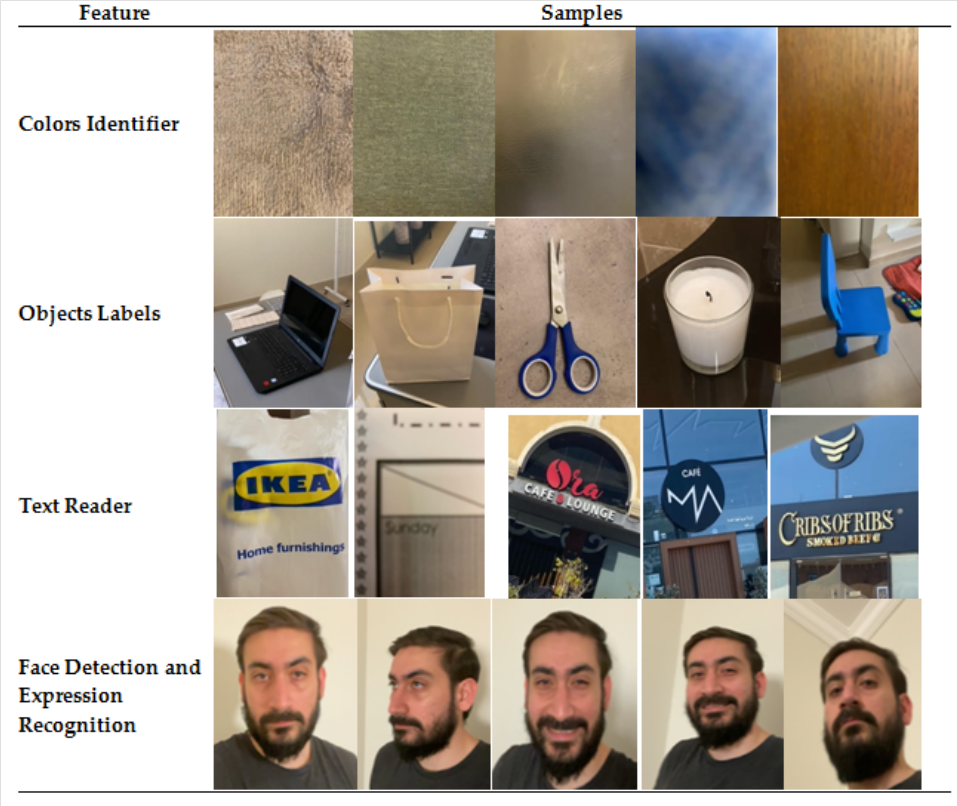

Fig. 6. Test Cases Samples for the Feature Tested.

TABLE IV. EXPERIMENTAL RESULTS FOR ALL TEST CASES FOR EACH FEATURE (INDICATES THAT THE RESULTS ARE REPRESENTED BASED ON THE PERCENTAGE OF LETTERS RECOGNIZE CORRECTLY AS PERCENTAGE OF ALL LETTERS IN THE IMAGE.).

Feature	# Test Cases	Obtained Results	Causes for Errors
Colors Identifier	15	33%	Low light - Blurred image - The image is too close or too far
Objects Labels	15	80%	Low light - Blurred image - The image is too close or too far
Text Reader	15	90%	Very long text - Low light - Blurred image - The image is too close or too far
Face detection	15	100%	
Facial Expression	15	93%	Head pose - Low light - Blurred image - The image is too close or too far
Distance Notifier	N/A	100%	

The focus of this work is to integrate state-of-the-art features that we believe are most beneficial for the application users at low cost. It is also important to note that this application has an interface for interaction without requiring the user to have visual abilities. This expand our application target audience from only partially blind people to complete blind people. One more group of people that could benefits who do not suffer from blindness or short of sight but not color blindness can benefits from this application as well. They can use color identifier when in doubt about the color they see. To this end, our experiment proof the validity of the application and the robustness to various condition in real-world environment.

VI. CONCLUSIONS AND FUTURE WORK

An affordable solution for people with visual impairments was proposed and implemented. Vivid application provides those users the ability to recognize objects, detect people in the scene and their facial expression, assist in identifying colors and help in reading texts. Additionally, an extra feature for obstacle avoidance was implemented using a secondary standalone application with attachable hardware which have relatively low cost. These applications were tested in the real world and provided very good results. The results of the experiments indicate that such an application is a viable option for assisting people in need at an affordable price.

Future work on this research includes improving the use of machine learning to identify colors instead of predefining the range and enhancing the text reader feature to include long texts and more languages for non-English speakers. More work will be done to improve the sensor by shrinking the device size to enhance its portability. Lastly, adding the navigation features to the distance-notifier application which will help the users not only to avoid obstacle, but also to navigate well based on the shorter route. Lastly, more experiments are needed to be conducted with subjects that are from the target user base which can highlight additional challenges and areas of improvements from user experience or robustness of the application.

***Abstract*—With the increase in vision-associated applications in e-commerce, image retrieval has become an emerging application in computer vision. Matching the exact user clothes from the database images is challenging due to noisy background, wide variation in orientation and lighting conditions, shape deformations, and the variation in the quality of the images between query and refined shop images. Most existing solutions tend to miss out on either incorporating low-level features or doing it effectively within their networks. Addressing the issue, we propose an attention-based multiscale deep Convolutional Neural Network (CNN) architecture called Parallel Attention ResNet (PAResNet50). It includes other supplementary branches with attention layers to extract low-level discriminative features and uses both high-level and low-level features for the notion of visual similarity. The attention layer focuses on the local discriminative regions and ignores the noisy background. Image retrieval output shows that our approach is robust to different lighting conditions. Experimental results on two public datasets show that our approach effectively locates the important region and significantly improves retrieval accuracy over simple network architectures without attention.**

***Keywords*—Convolutional neural network (CNN); image retrieval; attention mechanism; convolutional block attention module (CBAM)**

I. Introduction

In the last decade, due to our increased computational ability, there have been tremendous improvements in Deep learning [1], [2] and Computer Vision, leading to an exponential proliferation of applicational possibilities. Among the various engineering applications of computer vision ranging from Drug Design [3] to Monocular depth estimation [4], image retrieval has become an emerging one. This particular application has both academic and business ramifications. Academically, it can bring about new innovative approaches to solving image comparison problems, whereas commercially, it can create a disruptive shopping experience for the users. Among all the product categories, due to its dynamic product nature, variations, and immense use case, Clothing/Fashion has received the highest amount of attention.

When similar kinds of images (i.e., consumer to consumer or shop to shop) are compared, there is a certain homogeneity in the images. Thus, they can be treated as from the same domain, not neglecting multiple variations such as lighting, view, backgrounds, product orientation, etc. Nonetheless, comparing different kinds of images (professional with amateur) will contain images from other domains.

Despite the difference in image types, these comparisons can be achieved by analyzing the human-detectable details in the clothes, such as cloth category, color, pattern, prints on the clothes, and so on. Most current retrieval solutions [[5], [6], [7], [8], [9], [10]] incorporate deep learning models that convert actual images into vector representation so that the query image's embedding can be compared against all the images' embeddings from the list, and the closest one can be returned. For that, triplet loss is the most widely used comparative loss technique. As suggested by [[11], [10], [12], [13]], despite being superior to other approaches, the triplet loss approach has its demerits, such as the inability to achieve top performance, being computationally expensive, and being prone to noisy labels and outliers. To mitigate that improvement has been proposed by using the Centroid Triplet Loss function in [14].

Nevertheless, as described in [9], high intra-class variability in clothes and the possibility of different kinds of deformations for the same type of clothes were the significant hurdles for achieving the most acceptable retrieval results. The problem with most of these existing approaches is that it ignores low-level features and those which use low-level features take all the information without selecting discriminative features which introduce noise. Deep networks, which are being used as a solution, tend to go deep and lose vital information from low-level features. Shallow networks can provide those low-level features, but the output is prone to noise. Thus, some form of noise elimination is required. Attention mechanisms emphasize the essential features and suppress the non-essential features. CBAM [15] sequentially applies channel and spatial attention along the respective principle dimensional axes to achieve the same. A shallow network - combined with the attention layer - outputs noiseless low-level features. Thus we have proposed a new architecture that utilizes both deep and attention-shallow networks to extract high-level and discriminative low-level features.

Along with the new architecture proposal, other factors were also considered for improving the overall retrieval accuracy. Here are our contributions:

1) Experimentation with multiple architectures for Image retrieval.
2) Propose a new attention-based architecture for better retrieval performance.
3) Experimentation with the impact of image size on the model's performance.

4) Experimentation with different classification models as our backbone network.
5) Performance comparison across multiple fashion data datasets (DeepFashion [6] and DeepFashion2 [16]).

II. Problem Statement

From a consumer's point of view, there might be different scenarios where a user could benefit from various forms of fashion image comparison and automated searches. All such applications usually include these three kinds of image comparisons:

- Image comparison between a shop image with another shop image.
- Image comparison between a shop image with a consumer image.
- Image comparison between a consumer image with another consumer image.

Due to different image-type comparisons, we prioritize selecting distinctive features in fashion pattern matching, which - moreover - deals with these three main problems in pattern matching:

1) Common images contain different backgrounds, which are usually noisy features for the model. Even after cropping only the target section, the remaining background will still dominate the distinctive features and reduce the model's overall performance.
2) Clothes might contain only a small portion of areas that might cause differentiation from other clothes. Nevertheless, when we use all the features from the clothes to compare the similarity, there might be a low influence of the distinctive features, reducing the performance. Since the distinguishing area varies according to the type of clothes, we need a dynamic module that will focus more on those discriminating features.
3) The existing deep convolution networks - rightfully so - suppress the non-crucial features. While doing so, the low-level features are also being ignored in such a way that it is impacting the retrieval accuracy.

III. Methodology

In this section, we describe our proposed architecture (PAResNet50) with a two branched variation (DBAN) along with loss function, and augmentation policy used during training and testing the network.

A. Architecture

We use a deep Convolutional Neural Network (CNN) to generate feature embeddings. The feature vector is the abstract representation of patterns, color, and shape of the input images, which helps to distinguish between the two different clothes. We use a triplet-based network architecture with the ranking loss function to learn the feature vectors. As shown in the Fig. 1a, the three triplets q, p, and n are independently fed into three different deep CNN, which share similar architecture and parameters. The deep CNN computes respective feature embeddings ($\overrightarrow{q}$, $\overrightarrow{p}$, $and \overrightarrow{n}$) for triples p, q and n.

Inspired by [17], we use multiscale deep CNN. Our implementation is quite different than [17], we use ResNet-50 [18] instead of Alexnet [19] and a series of convolutional and CBAM [15] layers. As shown in Fig. 1b, it has two different parallel branches coupled at conv1 of ResNet-50 [18]. The two parallel branches are downsampled with 4:1 and 8:1 ratios respectively. The downsampled branches are followed by 3x3 convolutional and CBAM [15] layers, flattened to extract low-level features. The output from $conv5\_block3$ of ResNet-50 [18] is followed by a 1x1 convolutional layer and global average layer to extract high-level features. The high-level and low-level features are concatenated and followed by a dense layer to output the final embedding. Introducing an attention mechanism in the shallow branches helps the model to focus on the low-level details like color, texture, and materials regarding its shape. Since the low-level features have lots of noise, reducing the retrieval performance, we used CBAM [15] as the attention module to enhance the essential features while fading out the non-relevant information.

During image retrieval, the embeddings of each image are extracted, and cosine similarity between the embeddings is calculated to find the best matching clothes. Distance between the embeddings estimates the similarity or dissimilarity between the images. Similar images are closer in the embedding space while the dissimilar images are distant.

B. Attention Mechanism

Attention mechanism is a technique by which computers try to simulate how human vision focuses in terms of computer-based algorithms. It is a method that tries to enhance the significant parts while fading out the non-relevant information. It can dynamically adjust the weights based on features of the input image.

We use Convolutional Block Attention Module (CBAM [15])as our attention module. As in Fig. 2, CBAM [15] is composed of two sequential sub-modules, the Channel Attention Module (CAM) and the Spatial Attention Module (SAM).

a) Channel Attention Module: Channels are feature maps stacked in a tensor, where each cross-sectional slice is, basically, a feature map of dimension (h x w). The input feature map of the channel is regarded as a feature detector. Channel attention is calculated by compressing the feature map in the spatial dimension using max pooling and average pooling to obtain two different spatial context descriptors. The descriptors are fed into a shared network to produce a feature vector. The shared network comprises an MLP (Multi-Layer Perceptron) and one hidden layer. The output feature vectors from MLP are merged using element-wise summation, and the sigmoid function is applied to compute the channel attention map.

b) Spatial Attention Module: Spatial attention represents the attention mechanism masks on a single cross-sectional slice of the tensor or each feature map representing the Spatial Attention Map. As in Fig. 2, Spatial attention is calculated with the two different feature descriptions obtained from maximum pooling and average pooling in the channel dimension. The two feature descriptions are merged, and a convolutional operation is applied to generate a spatial attention map.

(b) Dual Branched Attention Network of PAResNet50

Fig. 1. Overall Architecture of PAResNet50 with Deep Ranking

C. Loss Function

We have used a triplet loss function with batch-all online-mining strategies. A batch of B embedding is extracted from a batch of B inputs. B is composed of C different styled clothes with N images each. A valid triplet $\overrightarrow{q}, \overrightarrow{p}, \overrightarrow{n}$ is generated from B embeddings. These three indices $(\overrightarrow{q}, \overrightarrow{p}, \overrightarrow{n}) \in [1, B]$ are query, positive and negative pairs, respectively. Batch all online mining produces a total of T (1) valid triplets

$$T = C * N * (N-1) * (C * N - N) \quad (1)$$

where $C * N$ is the number of query images, $N-1$ is the possible positive pair per query images and $C * N - N$ is the possible negative pair. Hinge loss is calculated from each valid triplets $(q, p, n) \in [1, B]$.

$$l(\overrightarrow{q}, \overrightarrow{p}\,\overrightarrow{n}) = max(d(\overrightarrow{q}, \overrightarrow{p}) - d(\overrightarrow{q}, \overrightarrow{n}) + \epsilon, 0) \quad (2)$$

where, ϵ is the margin and $d(\overrightarrow{x}, \overrightarrow{y})$ is the Euclidean Distance between $\overrightarrow{x} and \overrightarrow{y}$. The hinge loss function tries to push $d(\overrightarrow{q}, \overrightarrow{p})$ to 0 (i.e. pulling $\overrightarrow{q} and \overrightarrow{p}$ closer) and $d(q, n)$ to be greater than $d(\overrightarrow{q}, \overrightarrow{p}) + \epsilon$ (i.e. pushing $\overrightarrow{q} and \overrightarrow{n}$ farther). Our final training loss L is as follows:

$$L = \sum_{(\overrightarrow{q}, \overrightarrow{p}\,\overrightarrow{n}) \in B}^{T} l(\overrightarrow{q}, \overrightarrow{p}\,\overrightarrow{n}) \quad (3)$$

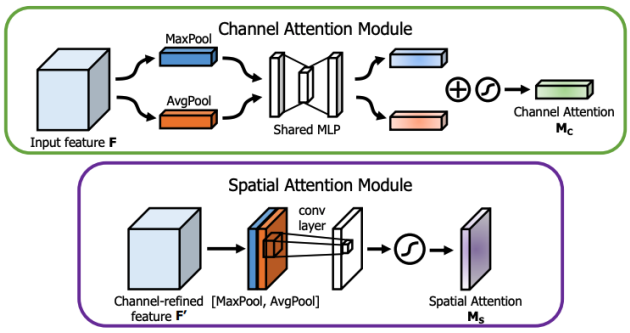

Fig. 2. Structure of Spatial and Channel Attention in CBAM. Source: [15].

D. Training Data Generation

For both DeepFashion [6] and DeepFashion2 [16] datasets we used the provided benchmark training sets and placed clothes with same style in a common style folder. These style folders were kept in their respective category folder. Each image was cropped with provided bounding boxes. For DeepFashion2 [16], back-faced and heavily occluded data were removed. We created a list of all the images available in the folder. Two images from each style/group were randomly selected during training to create a batch. The selected pairs were excluded from the list until the next epoch. Epoch is completed when there is no image pair left in the list.
We have only used geometric augmentation for both the query and shop images. The input images are horizontally flipped with 50% chance and rotated randomly in a range of $[-1, 1]$ degrees. This helps to increase the generalization performance and avoid over-fitting. Colour augmentation might change the original color of both query and shop images which might cause the corresponding pairs to be dissimilar, so we didn't use colour augmentation.

IV. Experiments

A. Datasets

a) DeepFashion [6]: The dataset contains over $800,000$ images with the information of categories, landmarks, bounding boxes, clothes attributes, and image pairs for Consumer-to-Shop/In-shop clothes retrieval. For this paper, we have only used the Consumer-to-Shop Clothes Retrieval subset which contains $33,881$ unique clothing products, $239,557$ consumer and shop images and $195,540$ consumer and shop matching pairs.

b) DeepFashion2 [16]: The dataset contains $491k$ diverse images from both consumers and shopping where each item is labeled with scale, occlusion, zoom-in, viewpoint, category, style bounding box, dense landmark, and per-pixel mask. For this paper, we only use Commercial-Consumer clothes pairs which continents $319k$ training sets, $34k$ validation sets, and $67k$ test sets. From the available dataset, we removed back-face and heavily occluded clothes during training.

B. Implementation Details

For the implementation, Keras [20] and TensorFlow [21] have been used as our deep learning framework. Likewise, Adam optimizer has been used to train the model with parameters $\beta_1 = 0.9$, $\beta_2 = 0.999$, $\epsilon = 10^{-6}$ and an exponential decaying learning rate of 0.96 for every 150000 steps with starting learning rate of 10^{-6}. For online triplet loss, margin of 1.5 has been set. We have used a batch size of 4 composed of 2 different styles of clothes with 2 images each. Each model has been trained for different iterations; the training is stopped according to the model's performance on validation loss. All the experiments have been performed in Kaggle with NVidia K80 GPU.

C. Evaluation Metrics

For the evaluation of retrieval performance, we use top-k accuracy, as in [[22], [6]]. The top-k accuracy is defined as follows:

$$P(K) = \frac{\sum_{q \in N} hit(q, K)}{|N|} \tag{4}$$

where, N is the total number of queries performed.

$hit(q, K) = 1$ is a hit, if at least one shop image appears within the top-K ranking for the query image q.

$hit(q, K) = 0$ is a miss, if no any shop image appears with in the top-K ranking for the query image q.

D. Experiments with Different Embedding Layers

In this experiment, we have used different embedding layers keeping other parameters unchanged. We used Flatten layer, Spatial Pyramid Pooling(SPP) layer, and Global Average layer after $conv5\_block3$ of ResNet-50 [18]. Table I shows that the flatten layer has the highest number of feature vectors with the lowest accuracy. But the global average layer has less number of feature vectors with the highest accuracy. In the flatten layer, redundant features and noise reduced the influence of discriminative features. But in the global average layer, there are mostly discriminative features. Therefore the retrieval performance depends upon the size of the feature vector. We didn't find SPP efficient compared to Global Average, so we used GlobalAverage as our embedding layer to extract high-level features.

TABLE I. Comparison of Top-k (k= 1, 5, 10, 20, 50) Retrieval Accuracy on DeepFashion2 [16] Dataset for Different Embedding Layers Performed on 256x256 Image Size.

Last layer	# size	mAP	top-1	top-5	top-10	top-20	top-50
Flatten	65536	0.687	0.445	0.629	0.712	0.784	0.865
SPP	21504	0.720	0.485	0.663	0.743	0.815	0.893
GlobalAvg	4096	**0.785**	**0.576**	**0.747**	**0.812**	**0.863**	**0.927**

E. Experiments with Different Backbone Networks

In this section, we have experimented with different classification models to find the best retrieval performance. From Table II, it can be clearly observed that ResNet-50 [18] architecture has significantly higher performance in comparision to VGG-16 [23], and MobileNetV1 [24], so we used ResNet-50 [18] as our backbone network in PAResNet50 [1].

TABLE II. COMPARISON OF TOP-K (K= 1, 5, 10, 20, 50) RETRIEVAL ACCURACY ON DEEPFASHION2 DATASET FOR DIFFERENT ARCHITECTURES PERFORMED ON 256X256 IMAGE SIZE.

Models	mAP	top-1	top-5	top-10	top-20	top-50
VGG-16 [23]	0.699	0.453	0.633	0.715	0.804	0.894
MobilenetV1 [24]	0.566	0.315	0.486	0.572	0.665	0.793
ResNet-50 [18]	**0.798**	**0.588**	**0.761**	**0.822**	**0.882**	**0.937**

TABLE III. COMPARISON OF TOP-K(K=1,5,10,20,50) RETRIEVAL ACCURACY ON DEEPFASHION2 DATASET FOR DIFFERENT IMAGE SIZES.

Image size	mAP	top-1	top-5	top-10	top-20	top-50
256x128	0.7896	0.567	0.746	0.817	0.879	0.939
256x256	0.798	0.588	0.761	0.822	0.882	0.937
320x320	**0.813**	**0.617**	**0.774**	**0.834**	**0.895**	**0.943**

F. Experiments with Different Image Size

To find the influence of image size in PAResNet50, we have experimented with different image sizes while keeping other parameters constant. From Table III, we found the input images of size 320x320 to be the best for our settings. Therefore, a larger image size helps to increase the retrieval performance so we used 320x320 image size in PAResNet50 for both training and testing.

G. Experiments with Different Architectures

We experimented with different kinds of architectures. They are as follows:

a) Simple Network(SN): It is a simple ResNet-50 [18] classification model pre-trained on Imagenet [25]. The output from $conv5\_block3$ of ResNet-50 [18] is followed by 1x1 convolutional layer, global average layer and a dense layer to extract a feature embeddings.

Fig. 3. a) and b) are the Top-1 and Top-5 Categories Retrieval Accuracy on DeepFashion [6] Validation Set. Each Model is Trained on Image Size of 320x320.

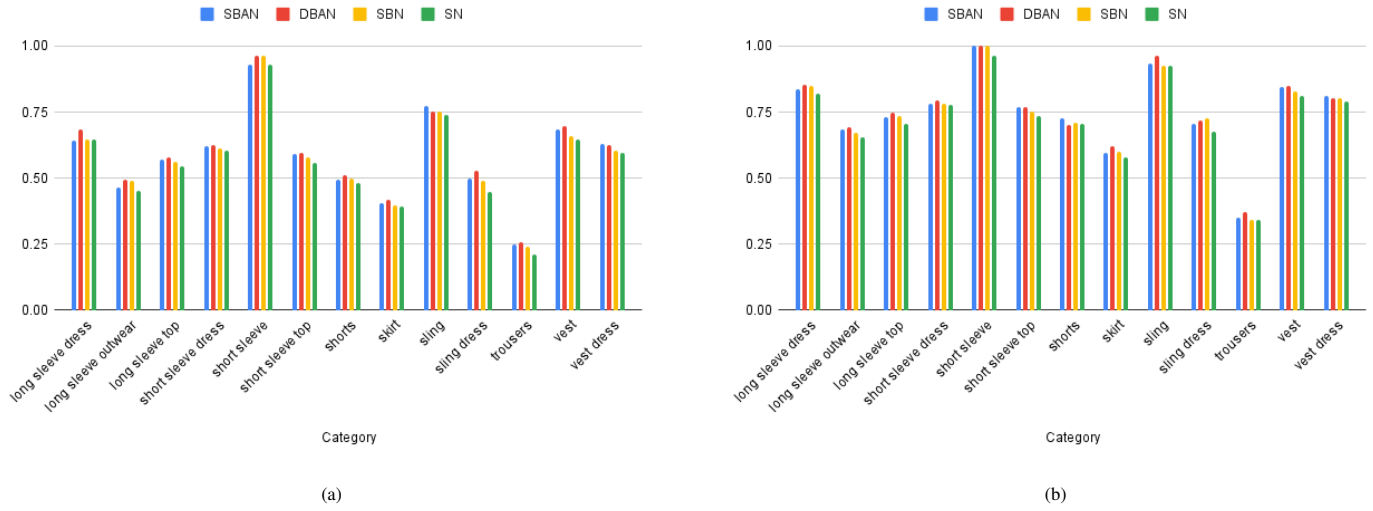

Fig. 4. a) and b) are the Top-1 and Top-5 Categories Retrieval Accuracy on DeepFashion2 [16] Validation Set. Each of the Model is Trained on Image Size of 256x256.

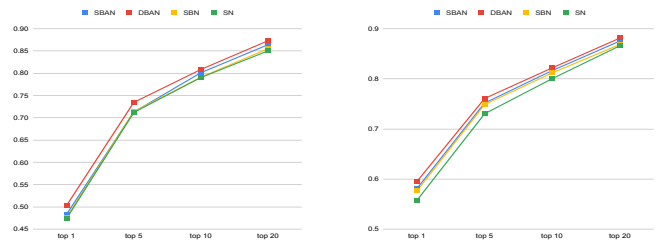
b) Single Branched Network(SBN): It is an extention to already existing Simple Network. A ResNet-50 [18] classification model coupled with a parallel branch. In the parallel branch, the output from $conv1\_relu$ is downsampled with a ratio of 4:1 and a series of convolutional layers is used. The output from the global average layer and the parallel branch is concatenated which is followed by a dense layer to extract the final feature embeddings.

c) Single Branched Attention Network (SBAN): This follows the architecture of Single branched network (SBN) here the convolutional layer in the parallel branch is followed by the CBAM [15] layer.

d) Dual Branched Attention Network (DBAN/PAResnet50): It is our final model, which has shown the best performance. It has two parallel branches with downsampling of 4:1 and 8:1, respectively. After downsampling on each branch, a series of convolutional and CBAM [15] layer is used which is followed by a flatten layer to extract low-level features. The outputs from the global average layer and the two parallel branches are concatenated and followed by a dense layer to extract the final feature embeddings. The architecture of PAResNet50 is shown in the Fig. 1.



(a) (b)

Fig. 5. a) and b) are the Comparison of Top-k(k=1,5,10,20) Retrieval Accuracy for Different Architecture on DeepFashion [6] and DeepFashion2 [16] Dataset Respectively. Each of the Model is Trained on Image Size of 256x256.

e) Architecture Comparison: From the Fig. 5, we observed that using low-level features directly from the branched network (SBN) slightly increases the model's performance compared to Simple Network (SN). The increase in performance is due to addition of low-level features. Adding a CBAM [15] layer in the branch ($SBAN$) further improves the performance since the attention mechanism suppresses the noises from low-level features. When two branches with an CBAM [15] layer ($PAResNet50$) are used to extract the low-level features, the model gets on additional fashion details (i.e., color, styles, and patterns) to learn, which significantly increases the retrieval performance. Therefore Dual Branched Attention Network(DBAN/PAResnet50) has higher retrieval accuracy in comparison to other architectures. We also applied attention mechanism on high level features by adding CBAM [15] layer on different blocks of ResNet-50 [18], but it didn't improve the performance. The attention mechanism didn't work well on high-level features.

To better analyze each architecture's performance, we evaluated the top-1 and top-5 retrieval accuracy for each category on both Deepfashion [6] and Deepfashion2 [16] datasets. Fig. 3 shows that PAResnet50 has improved the top-1 and top-5 retrieval accuracy on DeepFashion [6] for clothing, dresses, and tops while slightly improving in trousers. From the Fig. 4, we can see that on DeepFashion2 [16], PAResnet50 has the highest top-1 retrieval accuracy in all categories except sling and vest dress. In the top-5 retrieval accuracy, it has also performed well in the sling category.

H. Results on Deepfashion [6] and Deepfashion2 [16] Dataset

TABLE IV. COMPARISON OF PARESNET50'S [1] TOP-K (K=1,5,10,20,50) RETRIEVAL ACCURACY ON DEEPFASHION [6] AND DEEPFASHION2 [16] DATASETS WITH 320X320 IMAGE SIZE

Datasets	mAP	top-1	top-5	top-10	top-20	top-50
DeepFashion [6]	0.771	0.503	0.733	0.810	0.873	0.936
DeepFashion2 [16]	0.813	0.617	0.774	0.834	0.895	0.943

We trained PAResNet50 on both DeepFashion [6] and DeepFashion2 [16] datasets with image size of 320x320. Table IV shows that DeepFashion2 [16] dataset has higher performance in comparison to DeepFashion [6] since we have removed the back-faced and highly occluded images in DeepFashion2 [16], which reduced the conflict invalid image pairs. The back-faced and occluded clothes might have different colors, patterns, and texture, so when paired together, it forms invalid pair and decreases the training performance.

Results from Table IV confirm that our proposed model PAResNet50 is suitable for fashion image retrieval on different e-commerce websites.

I. Query Results

To better understand the output quality of PAResNet50, we analyzed the query results on different category images as shown in Fig. 6. The output is categorized into three groups best, good, and bad. The top three rows are the best output, retrieving the corresponding shop image in the top-1 list. The fourth and fifth rows are the good outputs, retrieving the corresponding shop image in the top-3 list. The bottom row is the bad output where the pair shop doesn't occur within the top-3 list. We can observe that our model can retrieve perfect matching images by learning fashion details such as colors, styles, patterns, and textures. In the second row first query, our model has retrieved the exact shop image even if the cloth is not worn (shape deformed). With results from the first-row second query and second-row second query, we can see that even under different lighting conditions, our model has delivered the exact shop image in the top-1 list. Therefore, our model is robust to different lighting conditions. In the second last row of Fig. 6, although the exact shop image is not retrieved in the top-1 list, visually similar colors and pattern-styled clothes are retrieved, which is a more challenging task for a human being. In the bottom row, even though the exact shop image doesn't appear in the top-3 list, the retrieved images are significantly similar to the query image.

J. Attention Visualization

To find the effect of the attention mechanism (CBAM [15]), we have visualized the attention map from PAResNet50. We

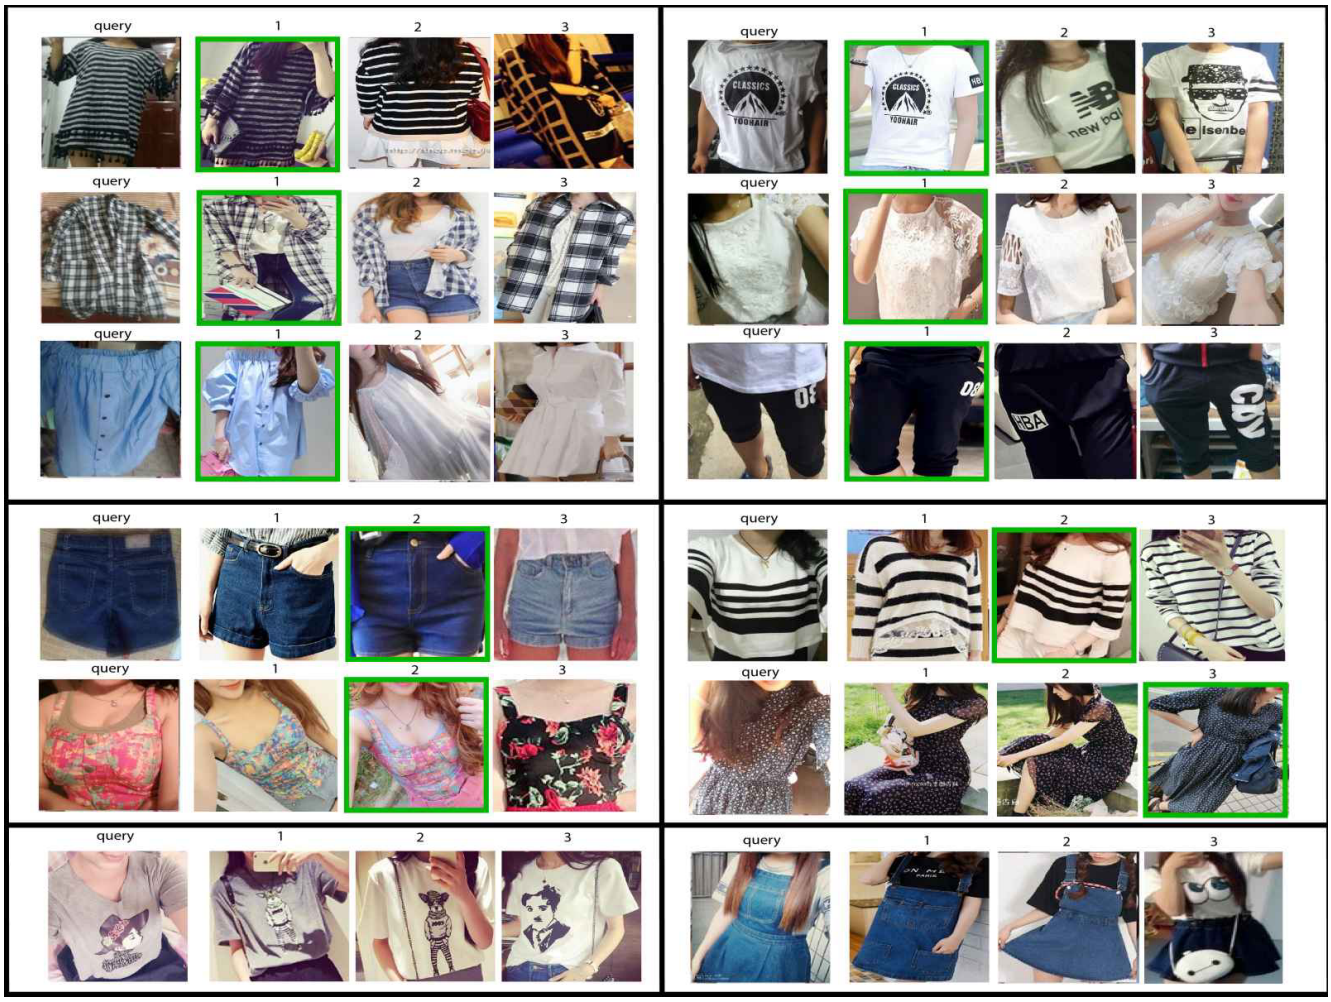


Fig. 6. Top-3 Retrieved Images for a Given Query on DeepFashion2 [16] Dataset. Green Box Indicates the Corresponding Shop Image.

Fig. 7. Visualization of Attention Map in the Query Images from PAResNet50 1. Red Indicates Higher Important Region while Blue Indicates Lower Important Regions.

used Grad-CAM [26] for visualization. From Fig. 7, we can clearly observe that our model has mainly focused on the local discriminative regions (e.g. logos, pictures, patterns, and text) in an input image while ignoring non-discriminative regions (e.g. background, plain region, and hand). Therefore only the discriminative features are used to find the matching images, which increases the retrieval performance of the model. Attention mechanism on the branch layer helps the network focus on only the important features while ignoring the less significant ones.

K. Experimental Summary

Overall, multiple experiments were conducted to find the best settings for image retrieval tasks. Table II, which is the comparison of different classification models (VGG-16, MobileNet, and ResNet-50), shows that ResNet-50 outperforms other models with a minimum margin of 10 percent in mAP metrics. Likewise, Table I clearly depicts that using ResNet-50 architecture with Global Average as embedding layer has performed the best with top-k (k=1, 5, 10, 20, 50) accuracy as 0.576, 0.747, 0.812, 0.863, 0.927 respectively. Further, to show the importance of low-level features and attention mechanisms in image retrieval tasks, we experimented with different architectures. Experimental results from Fig. 5, clearly indicate that Dual Branched Attention Network (DBAN) has achieved the highest retrieval accuracy. Analyzing the Fig. 3 and Fig. 4 demonstrates that DBAN works best in almost all categories. Also, the experiment concluded to observe the influence of different image sizes displays that higher resolution increases the model retrieval performance. As shown in Table III, an image size of 320x320 works best for DBAN. The query output from Fig. 6 helps to better understand the quality of DBAN which shows that this model retrieves visually similar colors and pattern-styled clothes and is robust to different lighting conditions. To further show the attention region of the DBAN, we have visualized the attention map in Fig. 7. We observed that the model has primarily focused on discriminative features. Therefore, it confirms that the attention mechanism ignores the noisy background.

V. Conclusion

In this paper, we have designed the PAResNet50 architecture to present the importance of the low-level features with an attention mechanism for image retrieval tasks. We found that two coupled attention branches in Dual Branched Attention Network(DBAN/PAResNet50) learn low-level fine details and effectively locate the local discriminative regions while ignoring non-significant areas. From various experiments, it can be inferred that incorporating low-level discriminative features along with high-level features improves retrieval performance. The query results exhibit the usability of PAResNet50 in a variety of categories for different e-commerce purposes. Experiments with different architectures(SN, SBN, SBAN, and DBAN) on two public datasets, DeepFashion, and DeeFashion2, demonstrate that DBAN(PAResNet50) outperforms other architectures with fewer or no attention branches. This result leaves room for the possibility of future enhancement in the retrieval accuracy by experimenting with a greater number of such multiscale attention branches.

***Abstract*—Control flow hijacking has been a major challenge in software security. Several means of protections have been developed but insecurities persist. This is because existing protections have sometimes been circumvented while some resilient protections do not cover all applications. Studies have revealed that a holistic way of tackling software insecurity could involve watchdog monitoring and detection via Control Flow Integrity (CFI). The CFI concept has shown a good measure of reliability to mitigate control flow hijacking. However, sophisticated attack techniques in the form of Return Oriented Programming (ROP) have persisted. A flexible protection is desirable, which not only covers as many architecture structures as possible but also mitigates known resilient attacks like ROP. The solution proffered here is a hybrid of CFI and watchdog timing via inter-process signaling (IP-CFI). It is a software-based protection that involves recompilation of the target program. The implementation here is on vulnerable RISC-V-based process but is flexible and could be adapted on other architectures. We present a proof of concept in IP-CFI which when applied to a vulnerable program, ROP is mitigated. The target program incurs a run-time overhead of 1.5%. The code is available.**

***Keywords*—Watchdog; return oriented programming; RISC-V; control flow integrity; software security**

I. Introduction

Securing software from hijacking and exploitation is a major step in software development lifecycle and has been faced with persistent challenge especially in the area of control flow hijacking. Attacks via Return Oriented Programming (ROP) [1] remain a source of concern in spite of existing basic and sophisticated protections. Basic protections like DEP/NX [2], which are generic do not mitigate ROP. This is because they are centered around blocking execution of injected code. Although these provide some measure of protections, attacks that stem from code reuse [3] like ROP which are not detectable by memory protection mechanisms, cannot be stopped by data execution prevention. On the other hand, the original CFI [4] relies on the precision of the Control Flow Graph (CFG). The CFG facilitates the detection of abnormal behaviour in the protected process but [4] inaccuracies in the CFG is one of the limitations cited by [4]. Besides, the classic CFI is a non-generic solution. Another non-generic CFI-based solution is Modular Control Flow Integrity (MCFI) [5] which offers a reasonably high level of precision. Recent studies also proffered solution in the form of PUFCanary FIXER [6], a hardware-based CFI which is also limited due to possible information leak where the PUFCanary FIXER inherits known canary limitations. There are other variations of CFI implementation which have contributed positively to the efforts to combat Control Flow Hijacks (CFH) but limitations exist. This could be due to specificity in the architecture that the solution was built on, as we have it in [4], or variation in source code language of target program as we have in MCFI [5], or general cost of implementation for hardware reliant fixes as exist in [7, 8], or the overhead incurred. Gaps and limitations in the realistic adoption of existing solutions inspire the continuous search for adaptable protection for vulnerable applications against attacks like ROP.

Aside from these limitations in existing protection techniques, studies on software protection are mainly implemented on specific system architectures focusing on elements that are involved in the execution of applications. Previous studies on protection measures have mostly focused on earlier architectures like x86 [4] and ARM [9]. This is justifiable because in past years, attention has been given to securing computers and servers which are mostly built on x86. However, in recent years, new technologies have emerged which require more options of protections. The RISC-V [10] technology is one of such which in recent years has gained popularity among producers of CPUs for automotive, smart devices, health tracking devices, etc., [11] because it is open source and more affordable. Also recently, the first laptop running on RISC-V processor has been introduced [12]. With these advancements in technology, a proactive measure of protection is desirable for vulnerable applications and the infrastructures on which they reside. RISC-V is an open-sourced instruction set architecture (ISA) and it was built on the already-established RISC technology [13]. Unlike most other ISAs, RISC-V was designed by academics and was made to be flexible and affordable, not only for use in academic research but also for deployability in hardware and software designs without incurring any royalties. For this reason, producers of embedded device, smart devices, etc., have opted for it. Not much attention has been given to securing RISC-V compared to other architectures like x86. Existing protections might not adequately provide the needed protection for RISC-V- based programs and systems.

Recent studies [14, 15] have highlighted gaps in existing protections especially for RISC-V programs and specifically against ROP as a result of hidden execution paths in the Control Flow Graph applied for implementing CFI. This study was embarked on with the goal to fill the gaps by increasing adaptability of protection mechanism for surmounting ROP. The concept implemented in this paper builds on a previous study [16] which proposed the possibility of securing vul-

nerable processes via inter-process communication. A novel approach was derived as Inter-process CFI (IP-CFI) which adopts the CFI concept alongside inter-process signaling and watchdog monitoring to detect abnormal behaviour in vulnerable applications. The vulnerable process is monitored by another process during execution. If a deviation is suspected in the control flow of the process, a watchdog function and inter-process signaling is triggered to further handle control flow monitoring.

According to [16], in-line CFI could be implemented by inserting labels to mark the start and end of each function with some additional instructions to perform checks on the flow of execution. In building on this technique, the watchdog adopts the time-out concept to extend monitoring whenever the process exceeds a stipulated time frame. The idea of watchdog monitoring is not new for securing systems. For example, study by [17] presents the *grenade* for monitoring mobile apps especially against denial of service (DoS) attacks. The research [17]'s *grenade* uses a countdown timer which is not reloadable once it begins to countdown. The author in [17] opted for this same technique to avoid a hijack of processors where a malicious program is able to extend its own life. In a similar line of thought, we avoid a possible extension of any malicious code execution by running a waiting time based on the intended purpose of the protected process. This is because unlike *grenade* which relies on the operating system timer, IP-CFI uses a monitoring program that is dedicated for monitoring a target process to increase flexibility. Some waiting time is also triggered in the target process and the monitor to achieve inter-process signaling. If a CFH is detected, further exploits can be prevented by an outright halting of the process.

The detection is made possible by initially analysing the vulnerable program to chart its intended execution path representing the CFG of the program, through static and dynamic analysis. In IP-CFI, values are passed from in-line CFI into shared memory where the monitor performs status check of the vulnerable process. Inter-process communication is achieved using atomic operation via semaphore and mutex on shared memory. Values that are used in the monitoring processes are stored in immutable registers and set in assembly code before completing compilation. Since IP-CFI is a software-based implementation which involves addition of enhancement code, the target program would require rebuilding after appending the enhancement code to implement the new protection.

This paper discusses the use of static analysis, dynamic analysis, RISC-V assembly coding, insertion of in-line checks for IP-CFI which provides a behaviour-based detection, and handling of CFH via Inter-process signaling on programs built and run on the RISC-V architecture. Most similar existing solutions are centered on the x86 system architecture and lack capacity to protect applications running on other CPUs like RISC-V. For this reason, the solution presented here is built around the RISC-V architecture but could be adapted for programs running on other CPUs. The rest of this paper is structured beginning with related works discussed in Section II. The methodology and implementation details are held in Section III while Section IV highlights the outcome of implementation, evaluation and application. Section V is a conclusion on this study and possible future works.

II. Related Works

Studies on software exploitation and protection have revealed control flow hijacks as a major source of concern in software security. Researchers have identified strengths and weaknesses of existing mitigation techniques by demonstrating various instances and concepts. The issue of CFH is particularly complex because there are different factors that need to be considered in proffering a lasting solution. This could be the consideration of the programming language of build, the low precision of CFG, CPU architecture on which the applications are running, and the cost of applying hardware solutions. The protection offered through CFI has potentials if applied alongside external enhancements. According to [18], CFI being a concept is flexible and could be enhanced by additional operations.

The classic CFI which was implemented on x86 architecture by [4] presented a promising solution to the challenge of CFH. A concept that relies on expected behavior, detection of deviations from expected behavior and trustworthiness of detector/enforcer. The classic CFI concept makes use of CFGs to apply inline reference monitoring (IRM) with which the protected application is rewritten. This was however found to be inefficient in its fine-grained form and not realistically implementable. Since the outcome of study by [4], other implementations have been studied in [5, 19, 6, 8], etc. These held some reliable outcomes with variations in structure, model, and platform but the mechanism still involves cross-checking flow of execution in comparison to intended flow. The integrity of the process is then enforced by introducing a halt or other forms of handlers to the situation.

Aside from existing limitations is realistic implementation of the classic CFI, recent studies [14, 15] have revealed the possibility of Hidden Execution Paths (HEP) which are not detectable and therefore omitted in the mapping when a CFG is built. While addressing ROP as a threat model on RISC-V, [14, 15] identified how ROP could persist on RISC-V platforms as a result of gadgets that could be obtained from overlapping code. It is therefore desirable to have a protection that is capable of an overview of the protected program. IP-CFI does not seek to know what gadgets are involved in the attack but to ensure the continuity of genuine execution and the termination of illegitimate flow in execution. Previous forms of CFI [4, 20] have their protection mechanism lying within the protected binaries which to an extent provides an impactful protection but the CFI itself might be unreliable due to low precision in CFG. In the case of [20], HEPs that were recently identified [14] could enable attack bypassing the checks. In this study, an additional monitoring process is adopted so that the in-line CFI could be monitored from outside of the target process while a watchdog is triggered if a deviation is suspected.

We present here a software-based protection. The classic CFI [4] was also software-based and was accomplished without recompilation of the program and no access to source code. This was made possible on the x86 implementation because CFG that was used in performing CFI checks were built using Vulcan [21]. Vulcan is not yet compatible with the RISC-V environment and as the program used here is a simple one, the CFG was done using Ghidra and Gdb for analysis. On the other hand, there exists compiler-based implementations like Gfree [20] which requires a part of the binary to be rewritten

and recompiled because the solution aims to eliminate gadgets that are based in libraries. Similarly, the protection here applies some additional lines of instruction to the protected target at the assembly level and also requires a full compilation into executable after the enhancement code has been inserted. The insertion of code has been automated but in-line checks are still inserted manually. A RISC-V target C-source code can be passed as argument into a startup script to be compiled with the enhancement code. The monitor however runs separately and need to be run concurrently as with the target program.

A state-of-the-art study presented in [18] observed that all eleven software-based CFI that were examined could be bypassed, although they each provided some protections in one way or another. They identified fine-grained CFI as a strong defense but incurs high overhead because of the use of shadow stack. Coarse-grained CFI on the other hand is a looser form that checks if control-flow transfers has originated from a return instruction and if its destination can be targeted. Three hardware-based CFI were examined and they were identified as difficult to be realistically implementable as such approach requires changes to the IT ecosystem that would incur additional cost on the system. [18] made conclusions that a hybrid form of CFI that combines existing protections might improve security in a CFI protected program. This study aims to adopt this suggestion by combining the use of In-line CFI, Inter-Process Monitoring (IPM), and watchdog time-out.

Another recent study [6] presents FIXER for protecting RISC-V applications using hardware. Subsequent improvement on FIXER involves the use of a PUFCanary [22]. This however had its own limitations in that a diversion may occur before the canary check, also FIXER does not protect against memory disclosure and it may cause the custom instruction to be bypassed.

[17] came up with a study back in 2000 with foresight on the advancement in technology in the future which we are now in. They foresaw a future where the use of computerised devices would become the norm and based on this, they presented the idea of *grenade* based on the concept of watchdog timer to protect against malicious mobile apps and ensure stability in services running on vulnerable systems. The use of a watchdog timer is a reasonable option for combatting a variety of attacks including Denial of Service (DoS) attacks. This is a relatable scenario as we find that ROP attacks on RISC-V, when chained in some particular order could lead to denial of service. The protection presented here adopts a similar approach by applying the watchdog concept alongside in-line CFI to ensure that such DoS attacks are detected and handled.

During this study, we identify RISC-V ROP gadgets that cause the denial of service. Among numerous possibilities of the outcome of ROP, DoS could occur when chained ROP gadgets don't include an instruction to redirect execution to a location where other chained gadgets could be executed. This would normally involve the use of a *ld* instruction to change the value of the previous return address to the next destination. For example, using *ld ra sp(40)* to load the malicious address from a stack under attackers control into the *ra* register to be fetched as next destination. If the gadget does not include this type of instruction, then the execution iterates over the last bunch of instructions via the previous value that is in the *ra* register causing a loop. In this case, execution results in a loop over the last bunch of instructions in the chained gadgets. The author in [17] also relate with a similar circumstance by giving another practical scenario where a bunch of code running on an electricity meter device should trigger a reload of credits to sustain service. However, an interference in transaction between user's bank and the meter, due to malicious code that leads to an endless looping of a bunch of code would not ensure that the meter is turned off if the user's account is not credited. This could be detrimental to the service provider as well as users.

There are various ways of evaluating new protections. The choice of percentage run-time performance evaluation is selected here because the executable binary changes after additional instructions have been added to it. A watchdog waiting time is included which inevitably increases run-time. In addition to these, the target now has to communicate with the monitor by passing out data via shared memory. All of these would impact the run-time as the program now does more than it was originally built to do. It is important to present the impact of the new technique with such useful detail so that the technique would adequately represent itself among other possible options. As producers of technological devices continue to build devices with variation in purposes, continuous study of possible protections for vulnerable software is needful. This continues to provide options in protections for users and vendors to choose from. This study has selected a distinct feature of watchdog waiting time combined with in-line CFI checks via inter-process monitoring as another means of enforcing CFI.

III. Threat Model

Previous studies have revealed ROP as a persisting threat to vulnerable programs. There could be other threats occurring in form of UAF [23] and double free [24], etc. This study focuses on ROP as a threat particularly when the chained ROP gadget ends up in a denial of service. The sample C program for this study was written with the bugs that are relevant for simulating the threat model. The program accepts input from user at some point in execution and also has a buffer overflow vulnerability which was leveraged upon to mount ROP attacks. Two new gadget finders were written to extract gadgets from the sample program and selected gadgets were chained to be passed into the target program as input to mount ROP attacks. The outcomes of the ROP attacks differed because of the difference in the ret gadgets and the order in which the gadgets were chained. A more detailed discussion on this would be featured in our future works. One of the outcomes from the various ROP attacks was selected for use here as threat model to demonstrate how the IP-CFI works. The gadgets were chained in a planned order such that when the byte stream is passed as input into the target process, a trap is hit where the program runs into a loop causing a denial of service.

IV. Summary of the IP-CFI Approach

In this section we discuss an overview of the IP-CFI approach. More details to elements in the protection system are given in Section V. The IPC-CFI is built as a protection system where the vulnerable process is monitored by another

process and values relevant for protection exist within the target process which is monitored by another process. The goal is to monitor the execution flow upon entry and exit from each function. The first step taken was to use GCC to compile the vulnerable C program with libraries inclusive so as to increase the possibility of having useful gadgets in the binary. Next, simple static and dynamic analysis on the vulnerable program to identify what elements are critical in the execution path of the process. Analysis tools were Ghidra for reverse engineering, Objdump for static analysis and Gdb for dynamic analysis. The analysis gave us a clear mapping of the intended control flow and the choice was made to insert lines of assembly instructions (enhancement code) to label all function prologues and epilogues.

The choice of *777*, *888* and *0* as values to be set as labels was made for experimental purpose and future works will introduce how the values could be hidden through encryption or applied at run-time. *777* is used to identify intended function prologues while 888 marks the unintended functions. The value *0* is passed at the epilogues to trigger a switch off in the in-line CFI value. The labels serve as values for in-line CFI checks as well as values for inter-process CFI checks. For inter-process, these values get written into shared memory through atomic operation of semaphore and mutex. The values are interpreted by the monitor as flags to indicate the status of the functions within the target during execution. This makes up the first part of the IP-CFI protection.

The second part of the protection involves the monitoring where the status value that was written to the shared memory is harnessed for further CFI checks. To achieve this, a C program was written which applies atomic operations to read into the shared memory. The program also implements a watchdog timer based on the status value read from the shared memory and halts the target process if a CFH is detected. In evaluating the effectiveness of the method, we analysed the run-time performance overhead. This was done by running two timed versions of the program with normal input 110 times. One version was the original program and the second version was one that had the enhancement code for protection applied before compilation. Data cleaning was done to eliminate 10 outliers form each data set and statistical analysis were done to validate the result of the two data sets of the run times in seconds. An average was calculated for each data set of 100 run-times. The average values were then applied to the formula:

Overhead = (Run-time with IP-CFI – execution time without IP-CFI)/execution time without IP-CFI

The overhead was calculated without the waiting time of 5 seconds which is required by the target process to enable inter-process communication. The overhead obtained is reasonable considering that some lines of code were inserted into the target for the new protection. The information obtained in the implementation were then used to make deductions and propose possible future works.

A. Exploitation and Protection Implementation Environment

The exploitation and protection implementation environment was set on a Linux Fedora computer system within which an embedded Linux Fedora RISC-V64 QEMU emulator (Fedora EM) was running as shown in Fig. 1. The use of the QEMU was necessary as the RISC-V architecture has not yet been adapted for direct run on PCs. The Fedora EM once started, was used to create, edit, compile and recompile the target program with all enhancements.

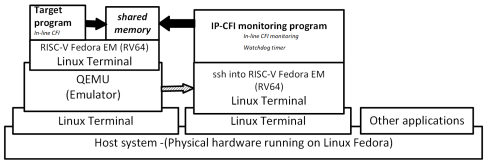

Fig. 1. Setting up a RISC-V System on QEMU Emulator

B. The Target Program

The target program used in this project is vulnerable to buffer/stack overflow and ROP. To simulate exploitation, we pass a of chain of ROP gadgets into the target. Details of this is given in Section V. Protection of the target in the first instance, adopts a CFI concept which makes use of checks inserted at the function prologue and epilogue of all direct functions. A comparison between the value that marks the intended function and the expected value from where it is called makes it possible for the CFI to detect a hijack. If the condition is not met, then the next instruction is executed, which halts the program, thereby avoiding further exploitation. As this In-line CFI on its own does not adequately protect the process from attacks stemming from ROP, we introduce other relevant protection concept in form of watchdog timing out where Inter-Process Communication (IPC) is used to establish IPM as a supervisory mechanism over the in-line CFI. In this case, the target process writes the in-line CFI value out into a shared memory and that value serves as the status value for an independent process to read and determine what action to take based on the status.

C. The IP-CFI Monitoring Program

The monitor is written in C program and values to be checked will be fetched from the relevant registers. It is an external independent process that is run concurrently with the IP-CFI-enabled target program to keep track of its execution. The external process consists of supervisory routine and a watchdog timing-out function which are implemented to ensure that the process maintains its intended flow. This Monitoring process communicates with the target program by reading its status from shared memory.

D. Shared Memory

In the Linux environment, there are two APIs that could be used to facilitate IPC- System V and POSIX. Both APIs provide IPC objects for reading and writing, but POSIX is safer to use as it does not permit execution for any category of user. According to [25], POSIX APIs are multithreaded-safe and we find it relevant for this project. POSIX APIs are also implemented with a backing file and we use that approach here to ensure compatibility, portability and persistence while the monitor accesses shared memory. In setting up shared memory, we mapped a shared file into the memory region *shm_open* using *mmap()*. The file could persist unless we delete it using

shm_unlink. We used *shm_open* to open the shared memory object and we used semaphore to avoid race conditions. The semaphore is also used as a mutex to lock/unlock access for the monitoring process and the target process.

E. Control Flow Integrity

CFI hinges on the ability of protection tool to observe the behavior pattern of the protected program during execution, detect anomalies and enforce the control flow integrity. The steps to it as implemented in IP-CFI is as follows:

1) Observing Program's Behaviour: The factors that are of importance in implementing this concept is a prior knowledge of expected flow of execution. This is a core step to the success of this method and it is achieved by carrying out thorough analysis on the vulnerable process. Each process varies in purpose, ability and vulnerability. The approach here is to establish the purpose of the process and identify vulnerabilities that are tied to the procedure by which that purpose is established. For example, a program that interacts often with users would have a higher attack surface. Also, processes that run for longer times will tend to be more vulnerable than short lived processes. The program is analysed by admin to identify the critical spots that lie within. The behavioural pattern is obtained from the CFG of the program prior to execution.

2) Detect Deviations: The success of a CFI-based protection depends on its ability to promptly detect a deviation from the expected pattern. Factors that are of importance here are the ability of the process to log in its status report into shared memory and to monitor delays in getting the status report value updated. The in-line value that is stored in the immutable registers are fetched and used to identify the status of the process. With this status, the watchdog is able to take the necessary action depending on the value read from shared memory. This also involves admin intervention prior to installation of the program. The time lapse that is permitted between the checks done by the watchdog is set prior to compilation.

3) Enforcing CFI: To enforce the integrity of the target process, CFI demonstrated here focuses on the external protection against CFH in a situation where attack bypasses in-line monitoring. This involves the insertion of instructions that enforce the CFI of the process. The enhancement code is inserted in assembly code into the protected binary. The needed elements for achieving these are relevant instructions and storage for the label values that are used in checking the legitimacy of each called function. The effectiveness of IP-CFI also lies in the trustworthiness of the detector/enforcer. To build an enforcer we combine two different sets of code in assembly language that are inserted into the target program - in-line CFI checks and Inter-process signaling code, and then a newly built external independent program that monitors the in-line CFI and inter-process status values.

F. The First Set of Enhancement Code

This fulfils the checks and enforcement of CFI and functions fully as in-line CFI. This relies primarily on the strategic positioning of checks in the target code. The positioning is determined by obtaining CFG of the program to see the possible pathway of execution. This involves a way of mapping out all subroutines in the program and identifying the direction of flow as intended by the programmer. A CFG could be built by making use of relevant reverse engineering tools. The authors in [4, 26] made use of Vulcan in developing a CFG but Vulcan is limited in use and is not implementable on RISC-V. Other useful reverse engineering tools are Ida and Ghidra which are effective in the x86 as well but none of these are yet to be effectively tailored to reverse engineer RISC-V-based applications. We have access to the sources code for our sample program here and that makes it a more straightforward process. However, in order to be able to use IP-CFI for programs that has been compiled without access to source code, a useful workaround that we applied was to use Ghidra on Fedora Linux running in x86 to reverse the x86 version of the same program. We found that this was useful foresight for easy analysing of the program in the RISC-V environment.

Further to this, static analysis informed us on the requirement for inserting the checks into the target. With these information, essential checks were inserted into the target in assembly code. The inserted in-line checks consist of fixed labels that mark intended functions along the execution pathway with matching values. Unintended functions along the execution pathways are marked with different values. At the beginning of execution, the value is set to *0* and would remain as 0 until a function call is made. If a function call is made, there would be two possibilities to the value which would either be a trigger to match the intended pathway or unintended pathway. The way labels are inserted would vary with the architecture of the underlying system. The RISC-V which is adopted here allows for straightforward storage of the values needed to achieve this process of the labels. The important objects for setting the values here are registers while the function prologue and function epilogues are used to position the in-line CFI checks and relevant action. Other pieces of code as shown in Fig. 2 that work in this phase are geared towards halting the target process based on the in-line CFI checks.

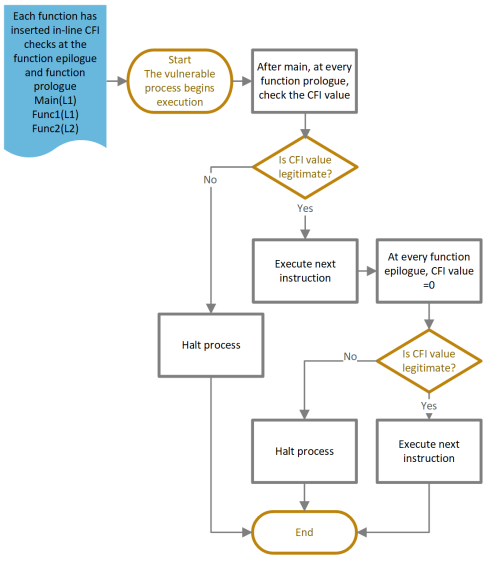

Fig. 2. Flow Chart of Target Process with In-Line CFI.

1) Wrongmove: This is a two-line instruction block that performs the halt to the vulnerable process by making a system call. For a sensitive program like the target, a proper handler needs to be triggered once a CFH is detected. Hence for this protection, the in-line CFI hands over control to the operating system by making an *ecall* on RISC-V. The *ecall* is an established RISC-V system call that ensures the transfer of control to the kernel so that the attacked process can be halted. This is achieved by setting the relevant value of *93* into a register *a7* in assembly code.

2) Storing the Label: The values used in the in-line CFI are set as numbers *777* and *888* to demonstrate the protection as these could be other values, provided that the value held by each of the intended nodes match the legitimate caller. An important decision that was made here is where to store the value to ensure that it is preserved throughout each function.

In RISC-V, values are stored in registers but the important register for storing our values were selected based on specific attributes. As the value in the label will be used for monitoring control flow status, it is important for the value to be unchangeable within its function. For this reason, the *s2-s11* registers are found suitable. These registers are referred to as saved registers. They have the ability to preserve the values stored in them within the function. Subroutines do not normally change the values and If they do, they will have to save the value and restore at the end of its execution.

For this purpose, only registers in this category can be used as other registers do not share the same attribute. They will either have specific roles or are temporary registers which means that the value that they hold will not be preserved. Apart from preservation, it is important and ideal to have labels that cannot be manipulated by attackers. This limitation is being studied for future improvement on the protection method. This would make those registers a strong tool for the implementation of this protection technique on RISC-V. For the demonstration here, the *s3* and *s4* registers were selected. Another option to using a known value as the label is to generate a scrambled value at run-time. This is however outside the scope of this study but is an area that could be considered for future studies. Outline of in-line checks as as follows:

G. The Second Set of Enhancement Code

This fulfils inter-process communication by logging status report from the target program to a shared memory. The status report is fetched from the outcome of the in-line CFI mechanism and values held in labels that have been set to mark the main execution path of the process, taking cognizance of its entry into and exit from critical nodes. This code is a new function that consistently writes the value contained in the *s3* and *s4* registers into a log to share the status of the target with a monitoring process.

1) Status Logging: The instructions that handle this step is inserted into the target assembly and it carries out *open*, *write* and *close* system calls to achieve this. It also applies an atomic operation involving a semaphore to these calls to avoid race conditions. Portions of this code were retrieved from [27] examples of shared memory.

H. IP-CFI

The CFI monitoring is enhanced by attaching an additional monitoring method involving another process attributed as not vulnerable as it runs with zero user interaction. The monitoring process performs the function of observing the target process by implementing an atomic inter-process signaling. The main tool that the monitor uses is information read from memory shared with the target process. In the case of ROP attack, it was observed that the status could appear legitimate whereas, a hijack has occurred undetected. For this reason, monitoring is extended to watchdog timing out.

1) The Watchdog Routine: The watchdog routine sets a counter to keep track of the target process. The demonstration in this report gives allowance of three cycles of checks by the watchdog. The first and second cycles could be enabled to restart the process without user intervention while the third cycle puts a halt to the target process. The number of allowable cycles can be adjusted to suit the performance or function of the protected program. For the demonstration here, the restart is not included for any of the cycles.

V. Implementation

As this protection is aimed at combating memory compromise through buffer/stack overflow that lead CFH via ROP input, promptness and accuracy in detecting deviations is very important it. The earlier a protection system is able to detect deviation and enforce integrity, the higher the chances of establishing a secure process.

A. Exploiting the Target

The first step to demonstrating the protection is to demonstrate an exploit. ROP is dependent on availability of gadgets and the ability of attacker to craft a byte stream to accomplish their malicious goal. Implementing ROP on RISC-V is more complex than x86 but is achievable. The aim is to control the execution from the stack by passing carefully crafted input through buffer overflow.

B. Gadget Finders

In order to make a variety of gadgets available to us, we wrote two gadget finders, *RETGadget* and *JALRGadgets* in Linux scripts and applied with the target as an argument to extract gadgets from it. The gadget finders are available and can work on RISC-V-based programs.

C. Passing Chained Gadgets

Once the gadgets were extracted, we mapped out ROP chains in various order based on a theoretical approach by [28]. According to [28], we can pass gadgets that will help us to store values and addresses in the registers that we intend to use to mount the ROP. The author in [28] classified the gadgets as functional gadgets and charger gadgets. The functional gadgets will hold the instructions for the actual attack while the chargers(linkers) gadgets will load the registers with addresses of the functional gadgets and other useful values. The linkers can be used to create a fake frame as shown in Fig. 3 and 4, which we can exploit further to pass malicious values into registers and other elements on the stack. Each of the ROP

chains was passed as input into the target to see how it could be exploited. In Fig. 3, the charger simply creates the fake frame with values loaded or copied from one location or register to the other. An exit is then called.

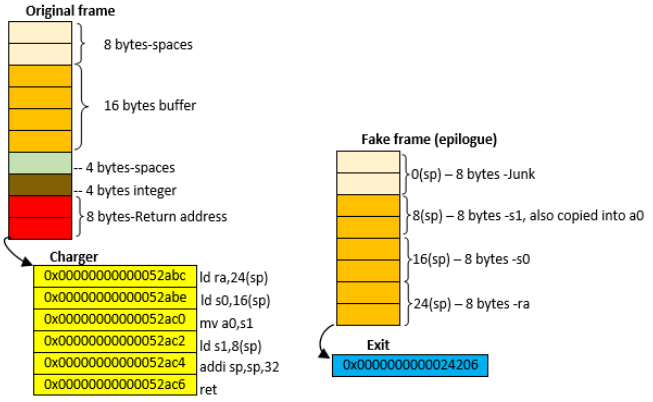

Fig. 3. Exploiting Target to Manipulate Some Registers and Exit Abruptly.

Further exploit is done as shown in Fig. 4 where two functional gadgets are chained to the linker. However, the outcome of this chained gadgets is different from that in Fig. 3 as this results in a loop. This is because we used a functional gadget that does not overwrite its previous value in *ra* register.

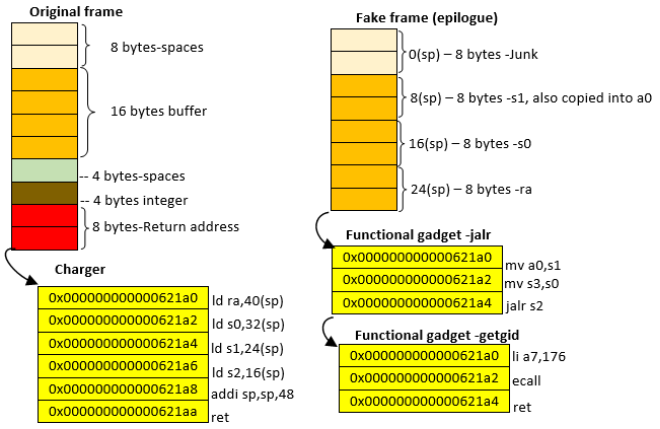

Fig. 4. Exploiting the Target to Cause a Loop.

The order in which gadgets are crafted in RISC-V would determine the outcome of the exploit. This has a lot to do with the value of the *ra* register that gets overwritten from time to time as execution steps into and out of library functions or other functions that get called within a function. This can only be detected during dynamic analysis and remains undetectable to user as no feedback is written to standard output but the process appears to be hanging as it doesn't crash. This a typical attack that could lead to denial of service and the IP-CFI protection is able to detect and handle it.

D. Protecting the Target

With the attack in place, we then applied the IP-CFI protection. The monitoring process is run concurrently with the target. Each time a new function is called in the target, the status is updated by the target process via the shared memory as shown in Fig. 5. The status value indicates what sort of function is being executed and at what stage of the function the execution is. Once the monitor reads into the shared memory, it

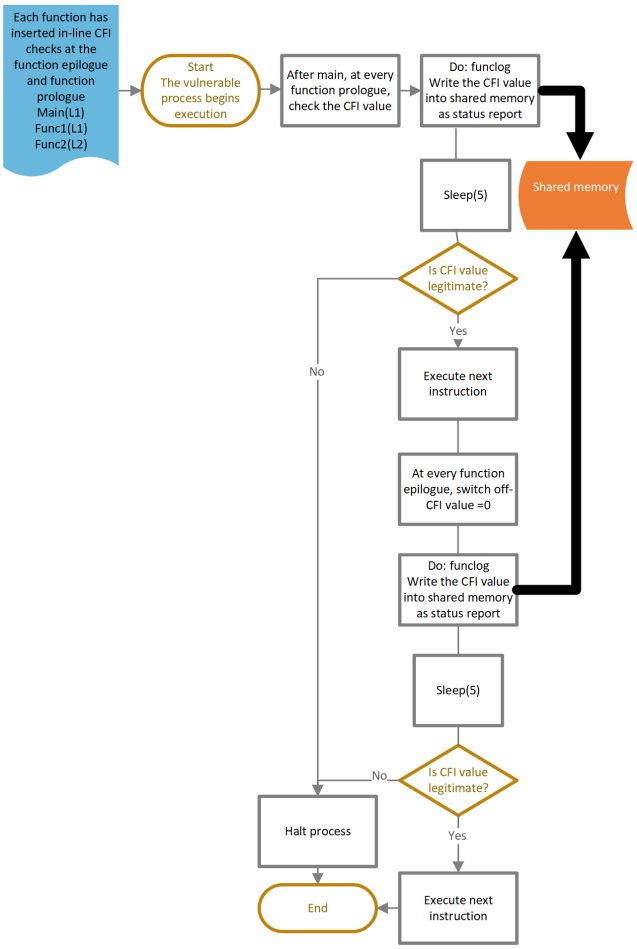

Fig. 5. Target Writes into Shared Memory.

takes the necessary action depending on the value. The denial of service is promptly identified and stopped. The possible flow of execution of the monitor based on the possible values that could be held in the status report is shown in Fig. 6.

E. Applying IP-CFI to a Source Code

There are three steps in setting up a program to use IP-CFI. We begin with the C source code and end up with an executable. The steps include two stages of compilation with the insertion of enhancement code between stages. The relevant scripts:*IP-CFI-make.sh* and *IP-CFI-full-compile.sh*, the monitor program *IP-CFI-monitor-watchdogv1*, and the enhancement code *IP-CFI-enhancement-code.s* are required.

Step 1:
Run *IP-CFI-make.sh* passing the C source code as argument

Step 2:
Find the resultant assembly (.s) and manually insert CFI-checks. Instructions are mapped out as follows:

Within main function:
Insert the following lines before the first call to a function

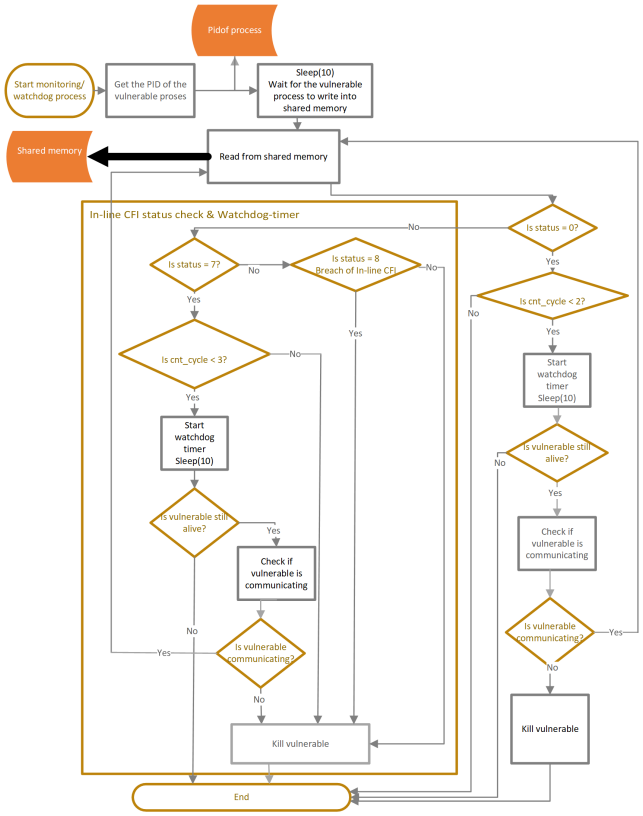

Fig. 6. Flow Chart Showing Inter-Process Monitoring as Status is Read from Shared Memory.

li s3,777 #set monitoring label for legit function

Within all intended functions that are not main:
Insert the following lines at the prologue:

Line 1:

li s4,777 #inserted for legit function

Line 4:

call IPCFIfunclog #log status

bne s4,s3,.Wrongmove. #enforce in-line CFI

Insert the following lines at the epilogue (just before *ra* register is loaded or before call to *exit*):

li s4,0 #Switch off CFI label

call IPCFIfunclog #update status

Within all unintended functions:
Insert the following lines at the prologue:

Line 1:

li s4,888 #inserted legit label

Line 4:

call IPCFIfunclog #log status

bne s4,s3,.Wrongmove. #enforce in-line CFI

Once all checks have been inserted save the file and exit.

Step 3:
Run *IP-CFI-full-compile.sh* passing the saved assembly (.s) file as argument. The resultant executable within current working directory can be run concurrently with the monitor. Work is in progress to fully automate these stages.

VI. Evaluation

In evaluating the protection, further observations were made with various forms of ROP chains passed into the target. An exploitable target was used. With the watchdog in place, the protection was applied to the target while different ROP chains were passed as input into it. The protection was found to be effective. The impact that the additional prologue and epilogue code might have on the execution time of the program was considered. In this section, we evaluate the new protection by obtaining the relative performance overhead with respect to our target program.

A. Results and Discussion

The outcome of analysing the run-time overhead of the new protection is discussed in this section. While IP-CFI effectively surmounts ROP with a run-time overhead of 1.5%, there could be variations in the outcome execution time based on the waiting time set in order to accomplish synchronisation between the monitor and the protected process. Details of how the run-time overhead is calculated are as follows:

Run-time type	***Average of run-time***
w/o IP-CFI	*3.26 ± 0.12 (milli seconds)*
w/ IP-CFI	*8.06 ± 0.16 (milli seconds)*

Run-time overhead w/ IP-CFI

((8.06 – 3.26)/3.26) = 1.47239264 (approx. 1.5%)

This presents a reasonable overhead when the additional pieces of code are included into the target. When the program is run concurrently with the monitor, some waiting time is required in order to establish communication between the target and monitor. This could vary from one program to another as it largely depends on the purpose of the program. For the sample program, a 5 seconds waiting time is applied to accommodate the time required for the monitor to read into the shared memory and take the necessary action.

While the full protection surmounts ROP, the waiting time applied appears to significantly increase the overall response time. However, the extra time incurred here is artificial. In reality, it is not additional run-time as the program would function fully without the waiting time. Waiting is needful to achieve interoperability between the two programs here and this outcome could differ if various scenarios are considered. In this instance, IP-CFI has been applied on a simple program and the outcome may vary more favourably with larger programs. On the path of the monitor, a 10 seconds wait is involved but this is independent of the target and does not impact the target run-time.

Furthermore, the run-time may vary slightly with the number of functions that accept the enhancement code. However, since the functions will only run one at a time, the overhead would not be greatly impacted. Also, optimization was set to *0*for the samples used here. The two options of level of protection could be applied to vulnerable process- one with full IP-CFI, and the other without the watchdog waiting time.

An alternative to the IPC via signalling, in order to monitor in-line CFI with less waiting time is the direct monitoring of the process from the kernel. A study by [31] presented this as a security measure but not with regards to CFI. According to [31], every process reports its logs somewhere in the file system and this could be harnessed as useful information for the kernel to monitor processes. If the kernel were to be used directly for monitoring the CFI, other related elements like the in-line CFI value and watchdog timing routine might need to be reconsidered.

A limitation of IP-CFI is that the values in the labels might leak and the registers that holds those values could be reused by an attacker. Although the impact of this with IP-CFI implementation against a CFH does not yet appear to be considerable. The possibility of locking the s3 and s4 registers is being considered for future works, as well as ways to encrypt the label values to generally improve on the IP-CFI protection.

Currently, RISC-V applications exist in highly sensitive eco-systems as they are commonly used and constantly running. IP-CFI is aimed as a broad spectrum of protection cutting across various eco systems. For efficiency, it is however aimed to protect applications that are built for long running services or those performing a single role. The RISC-V platform is well structured for such applications and is expected that the intended purpose of the application would inform the choice of protection. The RISC-V architecture is being implemented for several health monitoring devices. A recent study by [29, 30] presents a cutting-edge technology in form of an implantable medical device (IMD) for conditioning the human body electrical activity which runs on a RISC-V processor. [11] also produced a RISC-V-based microprocessor that could be used in devices for personalized health management aside from other devices like electronic voting machines, smart cards, etc. These devices match the category of devices that are dedicated for a single purpose and applications that are run on them might benefit from the IP-CFI protection.

VII. Conclusion and Future Works

Here, we have presented a proof of concept using IP-CFI, a new protection mechanism which is based on the concept of CFI combined with an external monitoring program. IP-CFI effectively resolves a denial of service from lingering when ROP is mounted. The main strength of the system is its ability to detect delays in change of the status value logged into shared memory where the monitoring process fetches information for taking actions towards maintaining the integrity of the protected program. With a prompt detection of delay, the target process can be halted to prevent furtherance of attack process.

The possibility of sustaining an execution while preventing furtherance of attack is an area that previous CFI solutions have not really addressed as CFI tends to halt processes once an attack is detected. One of the areas we explored in the process of this study is a way that the monitor could trigger a restart to the program rather than a halt. So far, we have no way of preserving existing data such that the restart of the process is done without side effects. This option would be explored in future works especially for environments that some of these vulnerable processes might require seamless continuity.

In this study, we have opted for a higher-level monitoring process to give us more control of the protection, as well as increase flexibility in the settings. The overall response time can be improved upon by optimising the IPC and setting the monitor to respond asynchronously. This is being considered for future works.

Towards Flexible Transparent Authentication System for Mobile Application Security

Abdullah Golam, Mohammed Abuhmoud, Umar Albalawi
College of Computing and Information Technology, University of Tabuk, Tabuk, 71491, Saudi Arabia

***Abstract*—Undoubtedly, Mobile Application Security (MAS) has made tremendous progress in implementing enhanced security protocols in the past decade. With the recent increase in the usage of mobile applications, concerns of privacy and security are increasing rapidly. Thus, the security measurement must be applied to satisfy security and privacy needs. On the one hand, the developer community works feverishly to develop mobile applications with innovative and usable layers and user-friendly for multigenerational customers. However, the security community, in particular, strives to make those layers secure. Therefore, the main objective of this research is to build a transparent authentication system in a mobile application. There are potentially many ways to implement an authentication mechanism such as the biometrics approach. It has features, which can be used to heightened security for the end-user. In these articles, we experimentally investigate the multigenerational customer base's factors such as age, convenience, easiness, memorizing new passwords, and understanding the precept of frequently changing passwords to enhance security. Additionally, we propose a system that will solve the common problems users face when starting the password resetting process. At the same time, in the MAS sector, we orchestrate the applications for better security encryption for the stored biometrics to ensure it, which makes it even more challenging for an adversary to bypass the system and reset the password. We conclude our research with a comprehensive security solution for MAS that considers user friendliness and data safeguarding.**

***Keywords*—Transparent security; authentication; UX/UI; forgetting password; reset password; biometric systems**

I. Introduction

Considering the tremendous development in the use of mobile applications and the search for hacker-proof programs that are gathering momentum, security problems have become a feature in the developer's mind to the point of obsession. This endeavour goes hand in hand with the need to enhance the user experience through user-friendly products in times of unprecedented demand for programs that combine security with simplicity and fun. To this effect, the duality 'Security' and 'Usability' operate as an interdependent set of elements, which the developer must incorporate with equal measure. The implications of failing this key operational balance between "Security" and "Usability" will most likely lead to a lack of security or to some difficulties in using the application.

For almost two decades, authentication has been a prominent issue in usable security research. The majority of these studies have concentrated on passwords and other similar authentication techniques that rely exclusively on a shared secret between the user and the computer system. Passwords must be strong enough to prevent guessing and must be memorable enough to not need to be written down. They must also be easy to type and lengthy enough to prevent guessing [1].

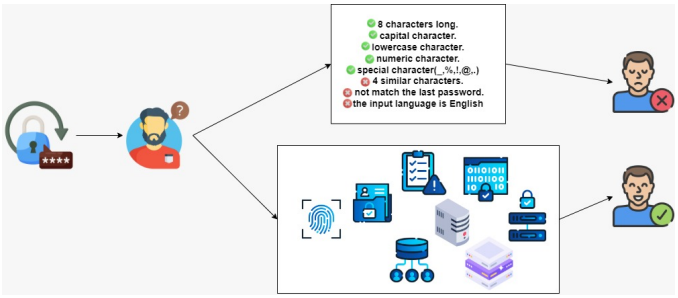

Fig. 1. Password vs. Fingerprint in an Authentication Process.

Transparent security related to mobile authentication can be implemented by physiological biometrics especially using fingerprint. In fact, the fingerprint is rare and difficult to obtain without the consent of the owner. It is also easy to adopt the fingerprint in giving access to the user with authority, as it is considered one of the most popular modern methods, which have been conducted multiple researches measuring the feasibility of this method in terms of ease of use and certainly security [2].

In Fig. 1, it is clear how the traditional method is complicated in resetting the password. For example, the user must not use the same password as the previous and that it is not identical to the name of the user and not to his personal data like date of birth. Also, it must contain symbols, uppercase and lowercase letters, and be at least eight digits long. On the other hand, you only need to pass your finger over the fingerprint sensor and in light of the unique data of the fingerprint. It is safe and has reliable features in its use to give access, Thus, using fingerprint in authentication satisfies the security measurements in a transparent manner. In most cases user do not feel what is happening in the background The system consists of very complex calculation in image processing and fingerprint Features extraction to verify the fingerprint provided by the user to give him access [3].

Although it is not in a user's interest to forget his password, many have done so. The age factor and how it affects the user's memory box, or the need to create as complicated a password as possible to keep the adversary at bay can inadvertently cause a person to forget their password. Either because we may have forgotten our password or due to a security breach, we find ourselves compelled to. As cybersecurity researchers, we must

use all possible means to make this process as secure and user-friendly as possible. Using biometrics that cannot be forgotten or stolen like a security token is one way, the other entails adding another layer of security encryption which must be applied on the stored biometric to ensure it will be even harder to bypass the system and reset the password. As a solution to this ongoing issue, we propose a system that will solve the common problems users face when starting the reset password process.

II. Background and Related Work

A. Transparent Security

Transparent authentication systems for mobile devices can be classified based on whether they use physiological biometrics such as fingerprint scanning or face recognition, or behavioral biometrics such as keystroke touch or walking rhythm. Physiological biometrics are widely regarded useful because they require a lot of computational power and high-quality photos, which are difficult to breach. Iris recognition, for example, requires the user to face the camera, takes longer to authenticate, and requires expensive additional hardware. Furthermore, iris recognition still faces obstacles such as detection, segmentation, coding, and matching [2]. Fingerprint recognition, on the other hand, with the progress of the smart phone industry and the adoption of technologies that provide users with a unique experience for their devices, does not face these obstacles. We find that most modern devices include a fingerprint sensor, and from this comes our focus in this paper on using this sensor to build a password reset system using the fingerprint, which is considered a transparent authentication system.

B. Usability vs. Security

Usually, the security part is sacrificed to complete the user experience part, and vice versa. The proposed idea is a balance between the two, leading us to the term "Transparent Security" intended to complete the security process so that the user does not feel the existence of complex security operations and where some waiting is required for the completion of these processes, usability techniques can be used to make waiting not boring by using usability emotional design. If the system is difficult to use, users will avoid using it. It must be taken into consideration that the effective use of applications and programs requires the programmer to implement usability while designing any program because that will affect efficiency and performance when using the program. The design of effective applications should consider the language, cognition and social interpretations of the user and the community. The word "Usability" also refers to methods for improving ease-of-use during the design process. Usability is defined by five quality components: learnability, efficiency, memorability, error, and satisfaction [4].

Security and usability are acknowledged as working in conjunction. There are examples of security and usability disputes, and these involve: password creation complexity instructions which will be hard to memorize, the enforcement of password masking to save passwords from being compromised, which sacrifices usability [5]. Information security is the defence of individuals, communities, or national interests, along with their information and noninformation-based properties, from the risks associated with their interactions with cyberspace. Users and their communities are among the properties that must be protected. Several security professionals and countries are now recognizing the need for users to be more informed and informed about information security [6].

C. Forgetting Problem

Forgetting is part of contextualization and guides immediate and potential information processing by encouraging environmental exposure and ensuring that knowledge is up to date, enabling timeliness and up-to-date [7]. The problem of forgetfulness cannot be overcome, as it is part of human nature. Therefore, different application developers must consider this human characteristic. As a result of Carnegie Mellon University password security research [8], strong passwords are not easy for users to implement and memorize, the problem is aggravated by users needing to implement and memorize special passwords for all online accounts they use. Joseph Bonneau and his colleagues evaluated 20 years trying to find a password-alternative proposition. They created a collection of 25 criteria that concerned usability, security, and deplorability and used them to assess different authentication methods. They concluded that there are no password alternatives that offer many advantages over conventional passwords. Furthermore, many did not meet a sufficient range of real-world constraints as password alternatives.

D. Password Resetting

Among the things used to reset the password is CAPTCHA [9]. This requirement is meant to ensure that the user is a real person, but the system is greatly affected by the user's experience in terms of clarity and ease of reading and may face challenges in determining the content displayed in front of him/her. These challenges sometimes impede the user from passing the selection point or force them to spend considerable time trying to pass beyond that identification test. Let us not forget, users may be of different ages, may have a low level of education and do not understand English, the preferred language by developers in use by CAPTCHA. The presence of vague characters is also another type of word blindness, which also leads to the character not being specified due to the overlap between the letters, and many of the examples are mentioned in discussing this method. However, the problem in terms of usability refers to the oversight of developers in failing to address the issue of age when designing their systems. The implications indicate neglect of certain age groups. For example, if the user is in an advanced age group, can CAPTCHA be made less challenging than the one designed for younger users? Moreover, there lies a challenge and what if the user is of Arab stock with no knowledge of the English script and is yet expected to answer questions written in English. Here lies a challenge that is too great to overcome. The main problems in this method can be summarized as follows:

1) Distortion issues.
2) Content issues.
3) Presentation issues.
4) Location and position.

The graphic design [10] of the password is used to make it more memorable, user-friendly, and secure. Put simply,

TABLE I. COMPARISON BETWEEN FINGERPRINT AND FACE RECOGNITION

Biometric System	Fingerprint	Face Recognition
Universality	Medium	High
Uniqueness	High	Low
Permanence	Medium	Medium
Collectability	High	High
Performance	Medium	Low
Acceptability	Medium	High
Circumvention	High	Low

the user presses the shape based on which he created the password and then logs into the system. The focus was on usability, and the goal was to test the user experience for the picture password. The questionnaires were used as a tool that covered many users of different categories, including age groups and cognitive achievement. The main argument for graphical passwords is that humans are better at memorizing graphical passwords than alphanumeric character passwords.

III. WHY FINGERPRINTS

There are seven features that determine biometric advantages: universality, uniqueness, permanence, collectability, performance, acceptability, and circumvention [11]. The concept of universality states that we can always be successful in finding our desired biometric features in the number of people who will be enrolled in the system. The term uniqueness refers to the number of distinct features a person has among people. Permanence is the evaluation of how far a unique set of characteristics endures or variates over time with maturity level. The concept of collectability refers to measuring how quick and easy it would be to obtain features that can be used to verify identity. Performance refers to a collection of measurements used to evaluate how well a given set performs. Speed, accuracy, and error rate are examples of these measurements. The acceptability of using biometrics evaluates how adequate and satisfiable it is. Circumvention refers to the ease with which a system can be fooled by a forged biometric feature. In mobile devices, the most widely used biometric sensors are fingerprint and facial recognition sensors [12].

The fingerprint is unique even in twins, it will be different and is distinct from one person to another. However, it can be forged like a dummy finger, new technologies have emerged which eliminate this problem by adding some pulse detector and temperature sensor. The fingerprint is a suitable biometric system, as shown in Table I, because it is hard to collect without user cooperation. In face recognition, it has a uniqueness problem due to the similarity between siblings, especially in a twins situation, and that will cause a problem if someone tries to access a system using face recognition like twins. Bad performance depends on many factors, such as the accuracy and speed to analyze. One of the problems of face recognition is that any person may get the face template of someone else from a far distance by using a super-zoom camera that captures long-distance shots, which causes alarming concerns. On the basis of these facts, it is suitable to choose a fingerprint as a biometric system in our proposed system because it will add a security layer and be easy to use and store.

IV. USER EVALUATION OF CLASSIC PASSWORD RESET

Interviews were conducted to evaluate the classic resetting password for various systems as presented in Fig. 2. Each system was developed with different types of password reset methods. The target participants we had interviewed use internet services for various purposes. Most of the usage orbits around browsing to benefit from the services provided on the Internet and to communicate with family and friends through social networking applications. Since social networking sites and other websites store cookies on user devices, the user does not log in by entering his/her username and password, often which means forgetting what they are. Participants in the interviews indicated that they may periodically reset the password, every six or twelve months, and look at the expiration date of the cookies. Therefore, most sites usually leave the configuration for this feature as default, which indicates the period for storing the cookies from six months to a year. Another factor that may cause a password to be forgotten is a different password for different platforms. To avoid the forgotten password, as most of the participants stated that they use the same password on more than one platform and app.

We want to explore the experiences of technical and non-technical Internet users with existing internet services for various uses. The goal is to determine what conditions may require the user to reset their password and what will make this process easier and more secure while saving the user time. The findings of the interviews conducted are as follows:

- The factors that motivate participants to change their password: some participants who may be either technically oriented users or plainly nontechnical change their passwords because they merely memorize their password to keep it safe.
- Degree of satisfaction with the reset password process (0-10): Most participants rated the process of resetting a password below 8 and this tells us that they did not reach their expected level of satisfaction due to the complex methods of resetting password, they feel the operators subject them to.
- The length of time it takes participants to reset a password: The method used in such a process consumes longer time, than the generally expected norm. This depends on the mechanism of resetting passwords, which affects the efficiency even though users understand the importance of the long-time process.

V. THE PROPOSED FLEXIBLE TRANSPARENT AUTHENTICATION SYSTEM

In the proposed system, our goal is to improve the quality of the user experience by using modern techniques such as biometric systems. In the sign-up phase, the system will ask a new user to enter their name, email address, mobile number, password and fingerprints, as shown in Fig. 3 and the Algorithm 1.

In the in-session log-in, it will ask for two things, the email address of the account and the password to gain access to it. If the user has forgotten his/her password, the user will select the forgot password batten. In this phase, there are few fields to complete. First, enter the account email address, then the

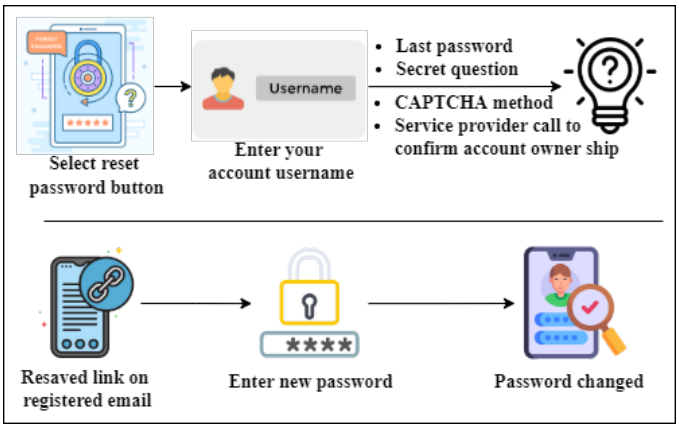

Fig. 2. Classic Password Reset Process.

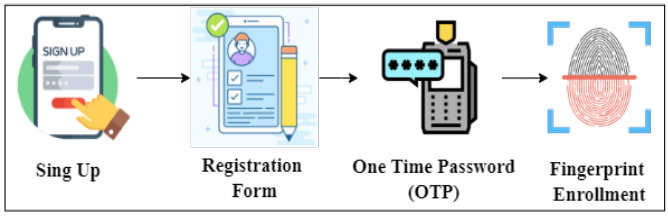

Fig. 3. Sign-Up Process.

user will get an OPT code (a temporary code sent to the user's phone) to confirm that the person trying to reset the password is the owner of that account. After that, the user will have the choice to choose from two methods to reset the password:

1) Fingerprint: if the user chooses to reset the password using the fingerprint method, the user will place it on the scanner, for the system will match the template. If the template matches, then the system will directly open the reset password page, explained in Fig. 4 and Algorithm 2.
2) Email address: if the user chooses the email address, the system will send a link to the user's email to reset the password. For a degree of flexibility that will support both usability and security, the proposed system has two methods for the user to choose from. It eliminates considerable problems by adding security layers and improving usability. Users may suffer from blurred vision, as in entering vague characters during the CAPTCHA test to reset password. Even users who have no blurred vision problem will feel discomfort when trying to enter vague characters during the CAPTCHA phase.

Biometrics, especially fingerprints, are widely used among other biometric systems in authentication tests. Most systems save the user's unique template of minutiae directly in the database as a special template for the user, which can be exposed to a possible attack. This unique and limited information is exposed to danger, as it is possible to reconstruct the fingerprint from the leaked information. To this end, there is a need to urgently enable protection of this information [13].

The hash algorithm is a complex mathematical function that transforms a collection of inputs into an apparently random output string of fixed length, so the same input string will always produce the same output string [14]. However, if the input string has changed even by just a single character, then the output string will be entirely different. Ordinarily, encryption implies incidentally scrambling information until a key is utilized to unscramble it. Hashing is frequently seen as a form of one-way encryption as you cannot go back from a hash to work out the first string; you can only go forward. In our proposed system, we read a fingerprint and then analyze the fingerprint and use base-64 hash to convert it into ciphertext. To avoid storing this ciphertext, we have treated this ciphertext as a password in terms of storing it in the database. Thus, we adopt an extra layer of security to hash the ciphertext using SHA-1 to satisfy the privacy of the user's fingerprint.

We utilize the salts technique to further thwart any rainbow table attack. Salts are short random sets of characters that are appended to the ends of a user password before they are hashed. Salts are automatically added after the user provides the fingerprint. Salts are generally stored in plaintext along with a hashed output, so the system knows which salt to use in regard to verifying a reset password.

Algorithm 1 Sign up using Fingerprint

```
Read User Email
Read Mobile number
Read Password
while not valid password do
    Read password
end while
password hashing(password)
send OTP to mobile
Read sent OTP from user
counter = 0
while is note valid OTP or counter < 3 do
    ** reenter the OTP message **
    Read sent OTP from user
    counter = counter + 1
end while
Read Fingerprint1 as Binary array
match rate = 0
while match rate < 75 do
    Read Fingerprint2 as binary array
    calculate match(Fingerprint1, Fingerprint2)
end while
match rate = 0
while match rate < 75 do
    Read Fingerprint3 as binary array
    calculate match(Fingerprint1, Fingerprint3)
end while
Encoding Fingerprint1 to Base64
Hashing Fingerprint1 SHA-1
Saver(email, mobile, password, Fingerprint)
```

VI. Experiment Results

We evaluate a simulated application of our proposed system so that we can have feedback about it while testing the usability of the system. The simulated application has been tested by eight participants. The average time to reset the password

Algorithm 2 Reset Password using Fingerprint

```
Read User Email
get mobile from storage
send OTP to registered mobile
Read OTP
counter = 0
while is not valid OTP or counter < 3 do
    ** reenter the OTP message **
    Read sent OTP from user
    counter = counter + 1
end while
get fingerprint from storage
is Match = False
while Match = False do
    Read Fingerprint as binary
    Encode Base64(user Fingerprint)
    Hashing Fingerprint1 SHA-1
    Match(user Fingerprint, Fingerprint from storage)
end while
Read New Password from user
hashing new password(new password)
update(password, new password)
```

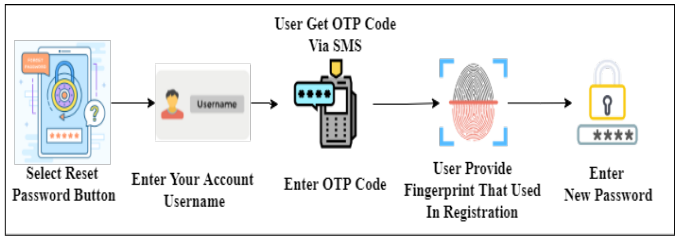

Fig. 4. Reset Password Process.

using the proposed system is 22 seconds that satisfies the user's experience without compromising the security, unlike the classical resetting system, which takes much time due to the challenge response system via email or other system. The evaluation gives us positive results on a lot of usability concerns, as presented in Fig. 5. These concerns included the time spent on the reset password process and the complicated process. 75% of the participants agreed on how easy and fast the password reset process is, while 100% agreed on the simplicity of the password reset process. Table II illustrates samples of participant's feedback.

TABLE II. SAMPLES OF PARTICIPANT FEEDBACK

Questions	Samples of Participant's Feedback
Differences between the classic resetting password and the proposed system.	'Many steps were shortened in the proposed system.'
	"Resetting the password in the proposed system is much easier than the available methods found in most of systems.'
	'In the proposed system, there is no need to leave the system, like email or SMS, and then through a link to do reset password.'
Is the proposed method tedious to reset password	'The proposed method is easy and not tedious'.
	Tow participants show concerns about saving the fingerprint template, whether or not it is safe.
Time	"It took short time".
complexity	"There is no complication".

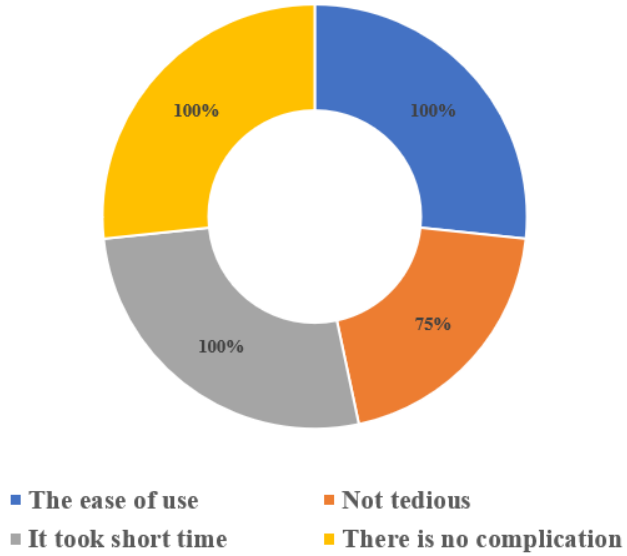

Fig. 5. Satisfaction Level of the Proposed System.

VII. CONCLUSION

Forgetting the password is a problem that exists and continues, it is part of human nature. The traditional method of resetting the password relies on increasing complexity, such as secret questions, which may affect the user experience. We propose a simulation of user authentication and the experiment includes a password-reset process. We use a fingerprint reader to emulate the mobile fingerprint sensor. Based on the simulation and evaluation results, the proposed system has several advantages over the challenge-responding system. The proposed system meets the security needs and at the same time provides usability. The user experience has a very large impact on usability. In the proposed system, to avoid direct saving of the template for the user's fingerprint, we encrypt the fingerprint and then use the Salt algorithm to be immune from decryption using available tools such as john the ripper and rainbow table. The new method of resetting the password gave us positive results in terms of usability and security. In the future, we are going to investigate the impact of biometric features in large scale systems and domains.

***Abstract*—Big Data-Driven Fabric Future Systems (BDD-FFS) is currently attracting widespread attention in the healthcare research community. Medical devices rely primarily on the intelligent Internet to gather important health-related information. According to this, we provide patients with deeply supportive data to help them through their recovery. However, due to the large number of medical devices, the address of the device can be modified by intruders, which can be life-threatening for serious patients (such as tumor patients). A large number of abnormal cells in the brain can lead to brain tumors, which harm brain tissue and can be life-threatening. Recognition of brain tumors at the beginning of the process is significant for their detection, prediction and therapy. The traditional approach for detecting is for a human to perform a biopsy and examine CT scans or magnetic resonance imaging (MRI), which is cumbersome,unrealistic for great amounts of resource, and requests the radiologist to make inferential computations. A variety of automation schemes have been designed to address these challenges. However, there is an urgent need to develop a technology that will detect brain tumors with remarkable accuracy in a much shorter time. In addition, the selection of feature sets for prediction is crucial to realize significant accuracy. This work utilizes an associative action learner with an advanced feature group, Partial Tree (PART-T), to detect brain tumor recognition grades. The model presented was compared with existing methods through 10-fold cross-validation. Experimental results show that partial trees with advanced feature sets are superior to existing techniques in terms of performance indicators used for evaluation, such as accuracy, recall rate and F-measure.**

Keywords*—Big data-driven fabric future systems (BDD-FFS); magnetic resonance imaging (MRI); partial tree

I. Introduction

Reliable and efficient collection and communication of observations from physical information systems that support the Internet of Things (IoT), for example sensors laid at faraway locations, to dominate centers are the current issues facing data detection in big data areas [1-3]. With the heavy use of devices in the healthcare trade, low-power communication equipment, and restricted reliability availability, there will be a variety of security threats. The most serious life threat facing the healthcare industry is brain tumors, which have a survival rate of less than 35 percent. With device management in the Internet of Things (IoT) [4-6], more specifically, in the Medical Internet of Things based on big data-driven future fabric (BDD-FFS) [7-8] systems, patient data can be hacked via botnets. As the result of, the security of BDD-FFS facilities is essential [9]. The disordered expansion of tissue in the brain was called a brain tumor, and it can lead to main (benign) or minor (malignant) tumors. A main tumor is a non cancer condition that does not propagate from one piece of the brain to another, yet a minor tumor is a cancer condition that maybe spread to other sections of the brain. In benign or malignant cases, the skull can compress and expand, causing damage to the brain and potentially life-threatening problems [10-11]. Therefore, accurate early prediction of brain tumors is crucial for their detection, prediction and therapy, which can only be ensured by exploiting safety schemes on the BDD-FFS device.

Brain tumors are often detected via biopsy, MRI or CT scan. In a biopsy test, a pathologist removes a few amount of material and checks it in line with a microscope to identify if there are signs of a tumor. While biopsy can accurately detect the presence of abnormalities, it can be unlucky for the patient. Second, the surgeon must be familiar with the accurate position and scale of the tumor when performing surgical tests.Therefore, MRI or CT scan is very important. One of the biggest merits of MRI compared with CT scan is that it is radiation-free, so it is healthy for human health. In addition, MRI can accurately detect tumors. However, extensive human MRI is a complex and unrealistic task, which relies on the technical awareness of doctors and technicians. In addition, a small number of radiologists will lead to higher cost and labor intensity of MRI analysis. Studies of approximations also suggest that radiologists filter out 15 to 25 percent of tumor treatments during screening [12]. Therefore, automatic recognition of brain tumors by MRI is a big change in medicine. Automatic recognition will allow doctors to predict the disordered growth of cells and tissues in the brain and

help repair early abnormalities. Many algorithms have been developed for calculating automatic recognition of brain tumors from MRI.

Although much of the work described above has validated various algorithms using computation to detect brain tumors, and some other experimental techniques have been executed to investigate brain tumors, the raised approach is known to be more accurate and precise. The method designed in this work has not been used to explore brain tumors in the above results. The complexity of partial trees is superior to all previous schemes. Partial trees showed better medical outcomes in terms of baseline and advanced features compared to other previous work.

The major contributions of the paper are the following:

(1) Aiming at the problem that traditional methods of brain tumor detection are cumbersome, unpractical and require radiologists reasoning time, a new technology is developed that can detect brain tumors with high accuracy in a shorter time.

(2) Since the selection of feature sets for prediction is crucial for real apparent accuracy. This work proposes an associative action trainer with a high-level feature union-PART tree (PARTT), to investigate the grade of brain tumor recognition.

(3) The results show that the partial trees with advanced feature sets are superior to the existing techniques in performance indicators such as accuracy, recall rate and F-measure.

The architecture of the rest of the papers is the following: Section II depicts the connect done in concerned areas, Section III portrays the materials and schemes involving the data union structure and raised mould, Section IV describes the outcomes and argument, and Section V supplies an survey of the paper and proposes some prospect discuss orientations.

II. Related Work

In literature [13], a computer assistance completely automated skill is exploited to detect glioma from multi-modle MRI images segment the tumor area from whole image. To diagnose tumors from brain MRI, a classifier called Naive Bayes is introduced. After detection, k-mean clustering and boundary prediction were served as collect brain tumor regions. The accuracy rate is more than 80%. In literature [14], large feature extraction proposals, in other sayings histogram of oriented gradients and gray rank concurrence matrix are applied to describe the graphicses. a segmentation scheme on account of color and edge detection was raised to investigate brain tumor regions. Budati aims at the problem that MRI is used as a result of low ionization and radiation in various medical imaging technologies, while manual detection takes a lot of trouble. Therefore, a machine learning technology is introduced to achieve the classification, recognition and detection effect of tumor or non-tumor areas in view of brain MRI dataset [15].

Automatic brain tumor detection, which graphics is segmented and classification is executed on brain MRI graphics applying genetic sequence that is meta-heuristic optimization scheme and support vector machine is proposed in [16]. The approach uses tumor attributes in genetic algorithms support vector machines feature extraction sociology. The tumor data classification is close to the user's views that are in view of dynamic style. The best Fuzzy in the light of Bayesian classification is a qualified method that has been raised to more the classification accurateness, only in case of the richness of details on these terraces allow them available for use as source data, in implantations depend on tumor cancer research fields [17]. Uma has a large number of violations in a specific website, and it is hard to analyze the data of the website. A new feature extraction method based on dependency parsing and sentiment dictionary is proposed. This feature is used in conjunction with dictionary-based features to classify specific data [18].

Pries et al. [19] concentrates on analysis of those research which comprise segmentation, detection and classification of brain tumors. The general process for a scheme which designed to classify brain tumors on FMRI or MRI scans is: Preprocessing the graphics such as though eliminating the noise, then segmenting the image, which generates the area which might be a brain tumor, and eventually classifying features like intensity, shape and texture of the area. The existing ML methods with regard to brain tumor detection have already been built. However, the above methods, even if emerging well outcomes, are not also employed. Therefore, all spatial pixels need to be converted into multi-directional ones.The application of Gabor transform for spatial to multidirectional image conversion is reflected in [20]. Gabor transform was applied to convert the noise filtered image into multi-dimension brain image. Mixed features such as GLCM, grayscale co-occurrence matrix and LDP, local derivative mode statistics and texture properties were calculated from the transformed brain images. Lu has developed a new computer-aided diagnostic system, called PBTNet, to validate the detection of primary brain tumors in MRI images because of the large differences between observers in the interpretation of MRI images [21].

Hazra was drawn in the detection and localization of tumor districts in the brain exploiting schemes raised by MRI images of patients [22]. The design scheme involves three steps: preprocessing, edge detection and segmentation. The pre-processing process relates converting the primitive graphics to grayscale image and eliminating the noise when it exists or sneaks in. This is accompanied with edge detection utilizing Sobel, Prewitt and Canny strategies with graphics enhancement technologies. Segmentation is then utilized so that the regions influenced via the tumor are obviously evident in the MRI image. Finally, K-means scheme is exploited to cluster images. Considerations on the correctness of tumor recognition and realistic placement of MRI images are given in literature [23]. A method for detecting brain tumors by easily utilizing magnetic resonance imaging (MRI) data was exploited in the research. Improve the quality of picture frame, convenient for patients to carry out tumor treatment and diagnosis. The proposed protocol improves MR image quality and the detection of brain tumors, making it easier for doctors to diagnose tumors. Due to the combination of automated image segmentation technology and automated and efficient brain tumor detection technology implemented on positron emission tomography (PET) images, Hagargi developed the operation and technology to detect brain tumors from PET images using artificial neural network (ANN). The network applies most artificial intelligence to the classification and

recognition of biomedical images [24].

Tahir [25] studied an image filtering and grayscale segmentation method for feature extraction. The extracted feature union are transmitted to a deep neural network to identify tumor areas. A strategy combining threshold segmentation, feature extraction and filtering procedure is designed in literature [26]. Solidity, area, and bounding box are the features used for classification. In [2], a hybrid kernel-based support vector machine (HKSVM) was designed to identify brain tumors from MRI. At first, anisotropic filters are applied to images to isolate them from noise, and morphological operators are used to complete image segmentation. Isolate tumor areas using area prop algorithms. Feature vectors were extracted from isolated tumor regions according to GLCM and strength-based histogram. In the end, the extracted feature union was transmitted to HKSVM for tumor classification. The above schemes mainly emphasis on MRI segmentation, which is used to detect brain tumors.

In addition, the above method focuses on the binary classification of brain tumors as normal and abnormal, and does not involve level 1 (i.e., meningioma, metastasis), level 2 (i.e., low-level glioma), level 3 (i.e., glioma), and level 4 (i.e., glioma) in the light of the World Health Organization. However, in the above discuss, this paper adopts a new computational strategy, an association rule learner, Partial Tree, which makes use of some advanced feature sets that have not been used before to classify brain tumors into multiple categories. The set of advanced features exploited in the research are cell count, angle, density, perimeter, and center of mass, which are described in subsection 3. As can be seen from Table I, this feature group has not been used for tumor detection and judgment in previous studies. However, experimental results show that, compared with currently approaches (namely, Bayesian networks, random trees, Rep trees, random forests and Naive Bayes), the use of advanced feature set partial trees performs better in terms of time complexity and accuracy.

III. SYSTEM MODEL

A. Data Collection

The MRI was downloaded from various online sites. A total of 70 MRI samples were collected, including 32 samples of grade I, 10 samples of grade II, 8 samples of grade III and 20 samples of grade IV. Above all, the picked MRI was preprocessed to extract the feature group, and then the extracted feature information was delivered to the partial tree system to gradually classify brain tumors. The flow chart of the proposed approach is shown in **Fig.1**.

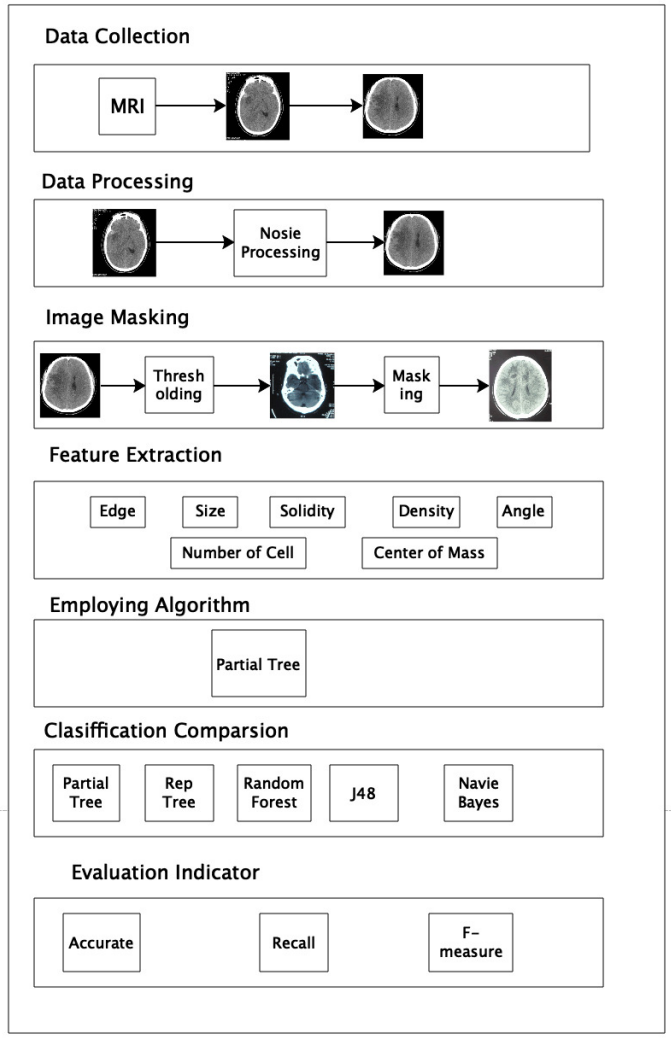

Fig. 1. Proposed Method Framework Diagram.

B. Feature Extraction

For the nature of feature extraction, some pre-processing processes are used for MRI, namely threshold segmentation and masking. According to the threshold segmentation, pixels are separated into different classification in view of their gray levels. The classification is regulated though the intensity value called the threshold. Pixels with larger intensity values fall into one classification, and pixels with smaller intensity values fall into another classification. It can be seen from the above literature that threshold is a common scheme that can successfully segment images. Therefore, the image can be segmented by threshold technology. In addition, the above data has not found the use of masking technology to identify brain tumors. The masking technology is introduced here as the preprocessing operation for detecting brain tumors, since in the case of the masking technology is appropriate for the image following the threshold, it will help to extract the features effectively.

Masking technology extracts features more effectively than other image processing schemes such as edge detection, mo-

tion detection and noise decrease, and is an effective performance of image processing. It can effectively measure the regional features and organizational structure in the image. Construct a duplication of the primary image and perform different AND, OR operations to meet its requirements. However, first use threshold segmentation on MRI, then construct a duplication of the image to employ the masking technique, and then use AND function to extract the required region. At the last, extract the features of the desired region. The feature set involves the number of cells, angular position, area, solidity, density, size, center of mass, perimeter, and so on. All of the above features are described the following.

1) Cell Number: Cell count refers to the entire amount of cells in the tumor area extracted. Use these factors to calculate the cell count using the following formula [27].

(1) The amount of small squares for counting according to the number of cells

(2) Count the number of large squares (tumor squares)

(3) Cell solution dilution

$$\text{The amount of cells} = \frac{\text{Number of large squares} \times \text{Cell solution dilution}}{\text{Number of small squares}}$$

2) Angle Position: The angle position shows details about the direction of tumor expansion in the skull. Tumors grow in a proportion of the brain that can travel vertically or horizontally through the brain at an angle.

3) Area: The size of the proportion shows particular details regarding the spatial spread of the tumor, namely, how much space the tumor can consume, in which S defines the region of the target (tumor) in the graphics, and x indicates the pixel value bigger than 1 and reaching N items in the region.

$$\sum_{x=1}^{N} Sx \tag{1}$$

4) Solidity: Solidity represents the density of the tumor and can be used to measure the number and size of depressions in the target boundary. The proportion of the brain tumor in the graphics target partitioned into the region of its convex hull is the solidity of the target graphics, which is expressed via formula (3)

$$Solidity = \frac{\text{Area Size}}{\text{Brain Convexhull}} \tag{2}$$

5) Density: Density is the key property applied to separate interest in an image region, which provides important information about image density.

6) Size: The size is considering the height and width of the objective image, which is built via multiplying though the number of horizontal and vertical pixels, as depicted in the Eq (4).

$$Size = \text{Horizontal pixels} \times \text{vertical pixels} \tag{3}$$

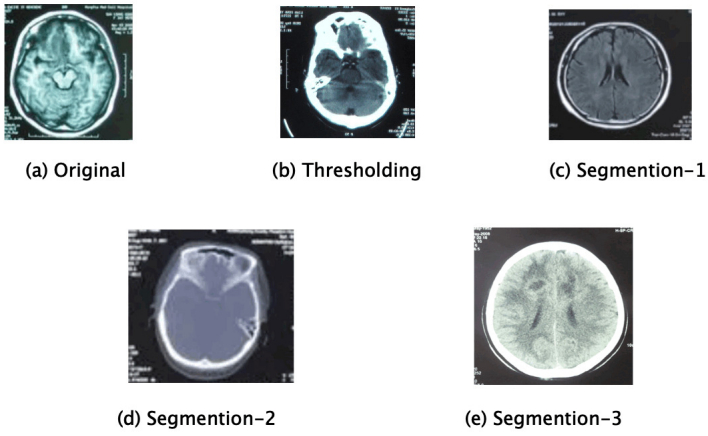

Fig. 2. Results from the Previous Process of Feature Extraction.

7) Center of Mass: The average value of each dimension in the target graphics is called the centroid, which is the median value of horizontal coordinate (x) and vertical coordinate (y) in the target graphics . The centroid is set by Eq. (5), which x, y and C respectively indicate the ordinate, abscissa and centroid of the object in the target image.

$$\text{Center of mass} = C \times \text{mean}(xory) \tag{4}$$

8) Perimeter: The perimeter refers to the sum of all external pixel boundaries in the target graphics. The most feasible approach to estimate the circumference of a brain tumor is to calculate the entire amount of edge pixels in the target graphics. Eq. (6) explains the representation of the perimeter.

$$\text{Perimeter} = \sum_{x,y} C(x, y) \tag{5}$$

which x and y define horizontal and vertical pixel values, while C represents the perimeter of the target in the target graphics.

The feature extraction procedure is shown in **Fig.2**. After feature extraction, the feature vector is transferred to the association rule learner, namely partial tree. The results demonstrate that the performance of partial tree is better than other algorithms, i.e., Random Trees, Rep Trees, Random Forests, and Naive Bayes are as above high-level feature collections on accuracy and time complexity.

IV. Partial Tree

Association rule learning tool has the ability to predict effectively. Therefore, this paper applies association rule mining model, that is, partial trees are used for grade detection of brain tumors. Partial tree is a mould designed by [28-29], which combines the merits of C4.5 and Ripper [30], and is used to yield a group of rules for efficient and accurate prediction. It takes advantage of Ripper's dial-and-conquer nature and

integrates it with C4.5 to prevent global optimization. C4.5 first builds an unpruned decision tree and transforms it into a rule union, and then simplifies rules by using a rule ordering strategy for each rule isolation. Finally, rules are set aside from the rule union to prevent global optimization until the rule set error is reduced. Ripper applies a divide-and-conquer approach to the set of rules. Only one rule can be introduced at a time, and the entities protected by this rule will be removed from the training sample. The rule generation process lasts up to the last entity of the training union. By combining the top features of C4.5 partial trees, a partial decision tree is initially constructed for the entities supplied in the dataset. Convert the leaves in the constructed tree with the largest coverage to rules, and then process the constructed partial tree to prevent global optimization. Entities protected by the yielded rule union are yet removed, and this process lasts until the final remaining entity in the dataset.

At first, some of the intelligibility of trees stimulated the use of them in hierarchical brain tumor detection in this paper. Second, it avoids global optimization, resulting in more noteworthy function in smaller time. In addition, it makes use of C4.5, which is a tree-based rule creation method, and from the existing research, tree-based method has the latent ability of identification. Therefore, a hybrid approach as a partial tree may perform better at extrapolating predictions. However, in this work, partial trees were found to have significant recognition of brain tumors and replace other existing methods such as Bayesian networks, random trees, Rep trees, random forests and naive Bayes in the light of time complexity and correctness.

V. Performance Evaluation

To verify the effectiveness of the algorithm, the following performance indicators are defined: accuracy (i.e., Acc), recall rate (i.e., Rec) and F-measure (i.e., F-mea). We use mathematical expressions (7), (8) and (9) respectively to describe the equations of these indicators.

$$Acc = \frac{TP}{TP + FP} \tag{6}$$

$$Rec = \frac{TP}{TP + FN} \tag{7}$$

$$F - mea = 2 \times \frac{Pre \times Rec}{Pre + Rec} \tag{8}$$

where TP represents true positive rate and is classified as brain tumor, FP is false positive rate, for instance, non-brain tumor is classified as brain tumor, FN is false negative rate, namely, brain tumor is classified as non-brain tumor. Consequently accuracy is the ratio between familiar instances of brain tumors that are correctly classified and all instances of brain tumors that are classified. Recall rate is the ratio between the amount of brain tumor instances that have been properly assorted and the whole amount of known brain tumor cases. The F-measure is the harmonic average of accuracy and recall rate.

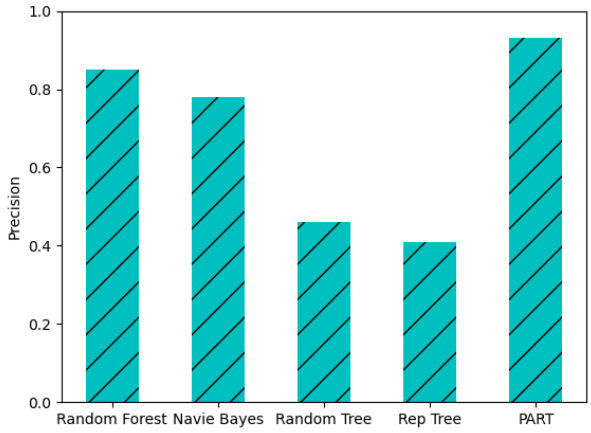

Fig. 3. Comparison of Accuracy between Partial Tree and Other Schemes.

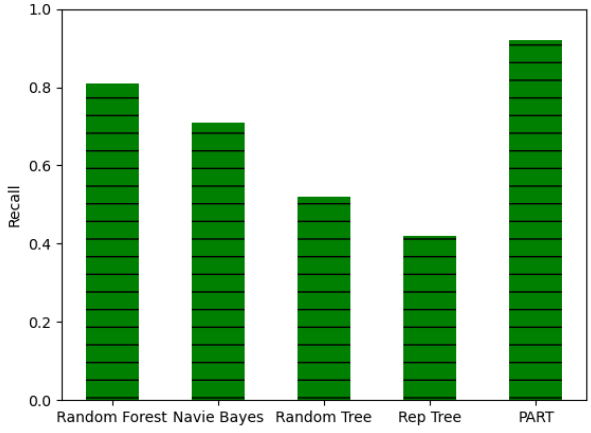

Fig. 4. Comparison of Recall with Partial Tree and Other Schemes.

A. Analysis of Experimental Results

To verify the efficiency of partial trees, it is compared with other competitive models such as random tree, Rep tree, random forest and naive Bayes. The performance comparison in accuracy, recall rate and F-measurement is shown in **Fig.3-5**. Compared with other technologies, partial tree will produce better results according to accuracy, recall rate and F-measure.

1) Performance Robustness: To verify the robustness of partial Tree performance, this paper compares it with the true positive (TP) rates of random Tree, Rep Tree, random forest and naive Bayes under different thresholds. The thresholds used are $t = 0.25$ to 0.95. **Fig.6** shows that the performance of some trees is more robust than that of other schemes because the TP rate is close to 1 while the TP rate of other methods is less than 0.85.

2) Computation Performance Cost: To verify the function of partial tree in computing cost, it is analyzed using mathematical and experimental algorithms respectively. The

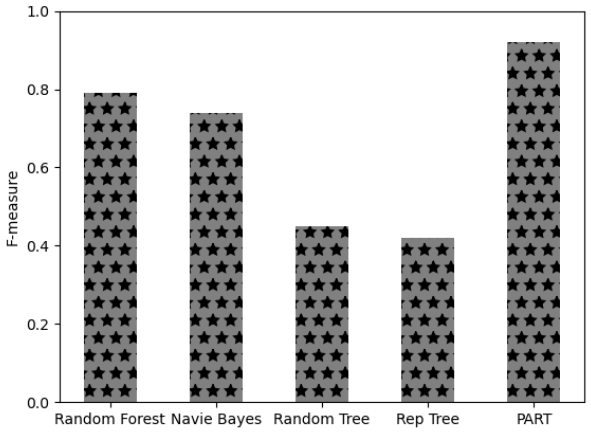

Fig. 5. Comparison of F-Measure with Partial Tree and Other Schemes.

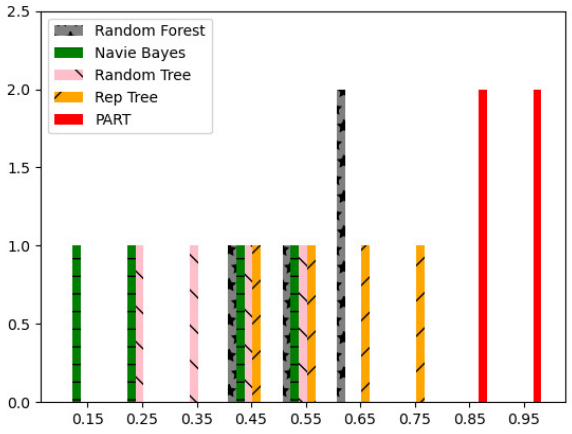

Fig. 6. Robustness Comparison of Algorithms under Different Thresholds.

TABLE II. ANALYSIS OF EXPERIMENTAL RESULTS

Algorithm	Correct Instances	Incorrectly Instances	Time (seconds)
Partial Tree	60	5	0.03
Rep Tree	30	35	1
Random Tree	32	27	1
Random Forest	50	15	0.3
Naive Bayes	48	18	0.2

TABLE III. THEORETICAL ANALYSIS OF DIFFERENT ALGORITHMS

Algorithm	Sample Size	Time Complexity (seconds)
Partial Tree	N+M	O($S \times NlogN$)
Rep Tree	N+M	O(N^2)
Random Tree	N+M	O(N^2)
Random Forest	N+M	O($M_{tree} \times N_{tree} \times NlogN$)
Naive Bayes	N+M	O($D \times N$)

mathematical performance analysis is shown in Table III, which N represents the amount of cases in the training and test set, where A denotes the amount of attributes, N_{tree} indicates the amount of trees built via the random forest, M_{tree} represents the amount of attributes sampled by every node of the tree, and D represents the dimension of features demanded by naive Bayes. According to Table III, for $\Omega(O)$, the time complexity of some trees is lower than that of Random Tree, Rep Tree and Random Forest algorithms. Compared with partial trees, naive Bayes is more effective in computation costs than partial trees, but less accurate than partial trees, as shown in Table III and Table II, which is very significant for correct diagnosis, prevention and therapy of diseases. Experimental analysis is denoted in Table II, which shows that it takes about 0.03 s to build a model for some trees. This is less time than other struggling approaches like random trees, Rep trees, and random forests.

Naive Bayes takes less time than partial trees. However, it can be concluded from Table III that the amount of cases of correct naive Bayes classification is smaller than the number of partial trees that may pose risks to the diagnosis, prevention and treatment of brain tumors.

Therefore, by studying an association rule learner with a different analysis called a partial tree, it can be concluded that some trees are superior to existing the most advanced technologies for instance Rep Tree, Random Tree, Random Forest and Naive Bayes in accordance with the correctness and computing expense. In addition, the set of high-ranking features described in the research, namely cell count, angular direction, density, centroid, and perimeter, still play a critical part in significantly making better the function of the brain tumor category-based model.

3) Impact of State-of-the-Art Features on Function: To verify the influence of state-of-the-art features presented in the research on brain tumor classification, the feature union was partitioned into two classes. The first class, called the benchmark feature, includes density, size, and area, whereas the second class, called the state-of-the-art class, includes cell count, Angle, density, perimeter, and center of mass. The all-around comparison of accuracy, recall rate and F-measure of

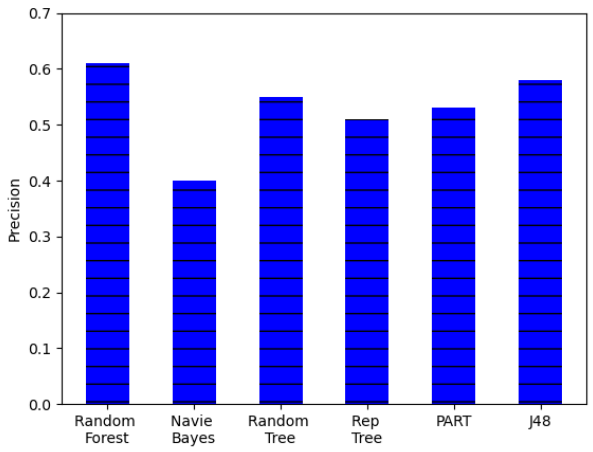

Fig. 7. Accuracy between Algorithms based on Baseline Features.

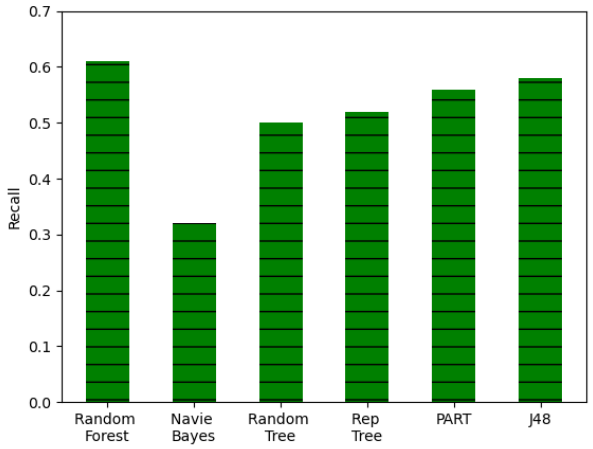

Fig. 8. Various Recall Algorithms based on Baseline Features.

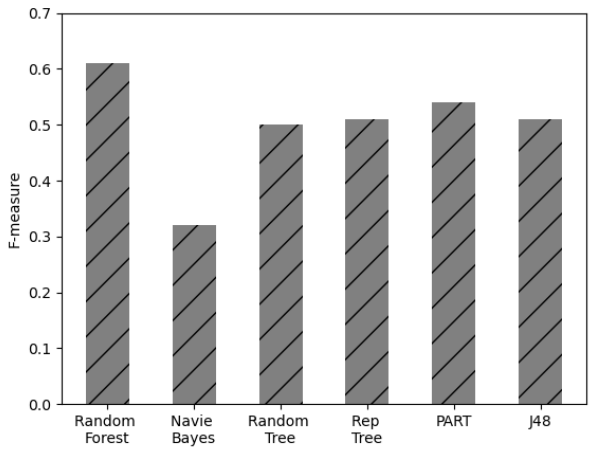

Fig. 9. F-Measure in Different Algorithms based on Baseline Feature.

Partial Tree, J48, Random Tree, Rep Tree, Random Forest and Naive Bayes is shown in **Fig. 7 to 9**, and baseline feature sets are used respectively. **Fig. 10 to 12** shows the comprehensive comparison of accuracy, recall rate and F-measure of Partial Tress, J48, Random Tree, Rep Tree, Random Forest and Naive Bayes, separately employing high-level function union features. It is important to note that the most state-of-the-art methods have baseline characteristics, accuracy, recall rates, and F-measures of less than 60%. For another, with the improvement of advanced feature sets, these methods increase significantly in accuracy, recall rate and F-measure. However, Partial Tress and J48 with 96% accuracy, recall and F-measure will show superior than other schemes. J48 has 60% F-Measure, but its performance is significantly improved through the advanced feature set, as shown in Fig. 10 to 12. Therefore, the function of distinct machine learning models should be better with advanced feature sets.

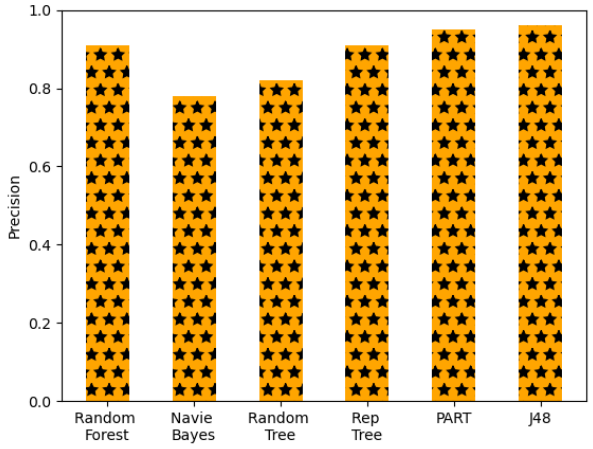

Fig. 10. Accuracy of Various Algorithms based on Advanced Feature Sets.

VI. Conclusion

With the emergence of the BDD_FFS system in the medical field, there have been many security risks in big data medical equipment. However, the most serious security threat facing the healthcare field is brain tumors. Brain tumors are irregular growths of cell tissue in the brain, which may lead to life-threatening. In a safe environment, the use of BDD_FFS-based system applications to detect early brain tumors is important to reduce mortality. The conventional techniques used to detect brain tumors are biopsy and MRI or CT scanning by human experts. Biopsies are very unbearable for patients, and a large number of MRI and CT scans is a complex task that is impractical for limited specialists.

Therefore, it is necessary to adopt safe and automatic technology to accurately detect brain tumors. In this work, firstly, a secure PART_T-based computational approach is employed to correctly identify the lesion grade of brain tumors. Secondly, this work introduces a high-ranking feature union not formerly involved for the proper recognition of brain tumors. Finally, The experimental results show that the designed PART_T technology with advanced feature group is superior to other subsistent technologies for instance Rep Tree, Random Tree, Random Forest and Naive Bayes in correctness and computational overhead.

The future work is as follows: expert automation technology system is very necessary to determine brain tumors in the early period, so that they can be more treated with drugs, so as to avoid a series of processes of surgical pain. Firstly, Applying techniques such as compounded machine learning models or neural networks to improve brain tumor diagnostic procedures is an inevitable need for active academic attention. Secondly,, some further modern functions can also be applied to make better medical effects. BDD_FFS combines active metadata, semantics, knowledge mapping, data virtualization, AI and other technologies to enable accurate, agile, and efficient matching between users and data to achieve optimization for specific medical scenarios. Finally, BDD_FFS is a technical architecture approach that addresses the complexity of data and metadata in an intelligent way and provides seamless access and sharing for all data consumers.

***Abstract*—Image enhancement is an important method in the process of image processing. This paper proposes an image enhancement method base on an improved fuzzy c-means clustering. The method consists of the following steps: firstly, proposed a fuzzy c-means clustering with a cooperation center(FCM-co). Secondly, using the FCM-co, divide the image pixels into different clusters and marked membership values to those clusters. Thirdly, modify the membership values. Finally, calculate the new pixel gray levels. This enhancement method can overcome the disadvantage of overexposure and better retain image details. Through the experiment, the test results show that the proposed enhancement method could achieve better performance.**

***Keywords*—Image enhancement; fuzzy clustering; fuzzy c-means clustering; membership; objective function**

I. Introduction

Image enhancement plays a significant role in digital image processing. Low contrast in digital images can result from many circumstances, including lack of sunlight or indoor lighting, and inadequacy of the device. There are many methods to enhance images. Histogram equalization (HE) is the simplest image enhancement method. It stretches the histogram of the image, based on the probability probability density function and cumulative distribution function values of the pixels, leading to enhancement in the contrast of the image [1], [2], [3], [4], [5]. The gamma correction-based method is an automatic transformation technique that improves the brightness of dimmed images via the gamma correction and probability distribution of luminance pixels, this method uses temporal information regarding the differences between each frame to reduce computational complexity [6], [7], [8]. Fuzzy sets can deal with some uncertain factors better than classical mathematics. Fuzzy technology is also increasingly used for image processing [9], [10], [11].

In 2000, H.D. Cheng et.al proposed a novel adaptive direct fuzzy contrast enhancement method based on the fuzzy entropy principle and fuzzy set theory [12]. In 2009, M. Hanmandlu et.al presented a new approach for the enhancement of color images using the fuzzy logic technique [13]. In 2011, G. Li et.al proposed an image enhancement operation that used the value of grey entropy in the neighborhood window as parameters to measure the level of the current pixel being edge point [14]. In 2012, K. Hasikin et.al presented a fuzzy gray scale enhancement technique for low contrast image [15]. In 2016, A. K. Gupta et.al presented a fuzzy based enhancement technique for low contrast gray scale image [16]. In 2017, V. Magudeeswaran et.al presented a Contrast limited fuzzy adaptive histogram equalization to improve the contrast of MRI Brain images [17]. In 2019, S. Zenian et.al implemented an intuitionistic fuzzy set and fuzzy set, respectively, in the fEEG image by using intensification operator in enhancing the contrast of the image [18], [19].

The fuzzy c-means (FCM) clustering algorithm was first introduced by Dunn [20] and later extended by Bezdek [21]. FCM clustering algorithm is often used to deal with data classification problems. In recent years, it has been applied to image processing [22]. The main idea of the algorithm is to divide the data set into different categories by calculating the difference between gray values and clustering center iteration, so as to optimize the criterion function for evaluating clustering performance.The algorithm is an iterative clustering method that produces an optimal partition by minimizing the weighted within group sum of the squared error objective function.

This paper proposed an image enhancement method base on an improved fuzzy c-means clustering (FCM-co). Compared with the traditional fuzzy C-means clustering, FCM-co has a cooperation center. The data used in cooperation center calculate is a cooperation matrix of the same size as the image. The cooperation matrix element value is the average of the gray values of the pixel at the corresponding image position and the pixels around it. This means that FCM-co also considers the image pixels' location information. In the clustering process, the cooperation center is always updated synchronously with the clustering center. After the FCM-co divides the image pixels into different clusters and marks pixels' membership value, we modify the pixels' membership value again and calculate the pixels' new gray levels. The paper's contribution is to propose a new clustering method(FCM-co) and a new function to modify the membership value. In the last section, the test results show that this paper proposed an enhancement method that could achieve better performance.

II. Methodology

A. Improve Fuzzy C-Means Clustering

Compared with traditional clustering methods, in order to better use the position information of pixels in the image, this paper proposes a fuzzy c-means clustering with a cooperation center (FCM-co). The FCM-co's objective function as follows:

$$J_m = \sum_{i=1}^{c} \sum_{j=1}^{N} u_{ij}^{m} \left(\|x_j - v_i\|^2 + \alpha \left\|x_j^* - v_i^*\right\|^2 \right). \quad (1)$$

Image $I = \{x_{k,p}|k = 1, 2, 3, \cdots, m, p = 1, 2, 3, \cdots, n\}$, where $x_{k,p}$ is the gray scale of the pixel in row k and column p of the image. $I^* = \{x^*_{k,p}|x^*_{k,p} = mean(x_{k,p}$ and around $x_{k,p})\}$ is the cooperation matrix of Image I. In the Eq. (1), $X = \{x_j|x_j = x_{k,p}, j = (k-1)n+p$, 1 ≤ k ≤ m, 1 ≤ p ≤ n, $x_{k,p} \in I\}$, similarly, $X^* = \{x^*_j|x^*_j = x^*_{k,p}, j = (k-1)n+p$, 1 ≤ k ≤ m, 1 ≤ p ≤ n, $x^*_{k,p} \in I^*\}$, $N = mn$. c is the number of clusters. u_{ij} is the degree of membership of x_j and x^*_j in ith cluster, m is the weighting exponent on each fuzzy membership, v_i and v^*_i are the prototype of the center of cluster i, $\|x_j - v_i\|^2$ is a distance measure between object x_j and cluster center v_i, $\left\|x^*_j - v^*_i\right\|^2$ is a distance measure between object x^*_j and cluster center v^*_i. The parameter α is a constant. By definition, each point x_j satisfies the constraint that $\sum_i^c u_{ij} = 1$. The object function J_m can be obtained through an iterative as follows:

Step A : Initialize the membership values u_{ij}.

Step B : Calculate the v_i and v^*_i by

$$v_i = \frac{\sum_{j=1}^N u_{ij}^m x_j}{\sum_{j=1}^N u_{ij}^m}, \tag{2}$$

and

$$v^*_i = \frac{\sum_{j=1}^N u_{ij}^m x^*_j}{\sum_{j=1}^N u_{ij}^m}. \tag{3}$$

Step C : Update u_{ij}

$$u_{ij} = \sum_{k=1}^{c} \left(\frac{\|x_j - v_i\|^2 + \alpha \left\|x^*_j - v^*_i\right\|^2}{\|x_j - v_k\|^2 + \alpha \left\|x^*_j - v^*_k\right\|^2} \right)^{-\frac{1}{m-1}}. \tag{4}$$

Step D : Compute the value of the objective function $J_m^{(t)}$

$$J_m^{(t)} = \sum_{i=1}^{c} \sum_{j=1}^{N} u_{ij}^m \left(\|x_j - v_i\|^2 + \alpha \left\|x^*_j - v^*_i\right\|^2 \right). \tag{5}$$

Step E : If $\left|J_m^{(t)} - J_m^{(t-1)}\right| < \epsilon$, then stop. Otherwise, $t = t + 1$, return to step B.

B. Modify Membership and Calculate New Gray Scale Level

After FCM-co marks the membership value for pixels, for further adjust pixels' the membership value, we propose the following adjustment function:

$$u^*_{ij}(x_j) = \begin{cases} u_{ij}(x_j), & x_j \le \hat{v}_{i=1,2,\cdots,c} \\ 1 + \frac{1-u_{ij}(x_j)}{2}, & x_j > \hat{v}_{i=1,2,\cdots,c} \end{cases}. \tag{6}$$

In the Eq.(6), $j = 1, 2, 3, \cdots, N$. $u^*_{ij}(x)$ is the modified membership of the jth pixel in the ith cluster. $\hat{v}_i$ is the cluster, $\hat{v}_i$=max(v_i, v^*_i).

For calculation of the new gray scale level of the pixel, the original image gray scale levels are updated and mapped to compute the enhanced image by given formulations:

$$y_j = \frac{1}{c} \sum_{i=1}^{c} u^*_{ij}(x_j) x_j, \quad j = 1, 2, \cdots, N. \tag{7}$$

Where y_j is the new gray scale level of the jth pixel.

C. Algorithm

This paper uses the algorithm to process the test images as follows:

Step 1: Initialize the parameters: m, c, α, and ϵ.

Step 2: Calculate the cluster centers and pixels' membership value using FCM-co, Eqs.(2)-(5).

Step 3: Modify the membership values using Eq.(6).

Step 4: Calculate the new pixels' gray scale level using Eq.(7).

III. Experimental Results and Analysis

In this section, when we use the algorithm in the experiment, set the the parameters $m = 2, c = 2, \alpha = 1$, and $\epsilon = 0.00001$.

A. Subjective Analysis

There show the effect of the proposed method on image enhancement (see Fig. 1). To analyze the performance, the proposed method is compared with methods in [23], [24], and [25] (see Fig. 2).

Fig. 1. Original and Result Images.(a) Original, (b) Enhanced by Proposed Method.

Fig. 1 shows that the proposed method can enhance the image. In Fig. 2(b), and Fig. 2(d), the layered highland, signage, door inside the courtyard wall, and house in the distance are not visible. It overexposed the image and lost some image details. Although Fig. 2(c) retains more image details, it also has the disadvantage of insufficient enhancement. The image details retained by Fig. 2(e) are similar to those of Fig. 2(c), such as layered highland, signage, door inside the courtyard wall, and house. But the image contrast of Fig.

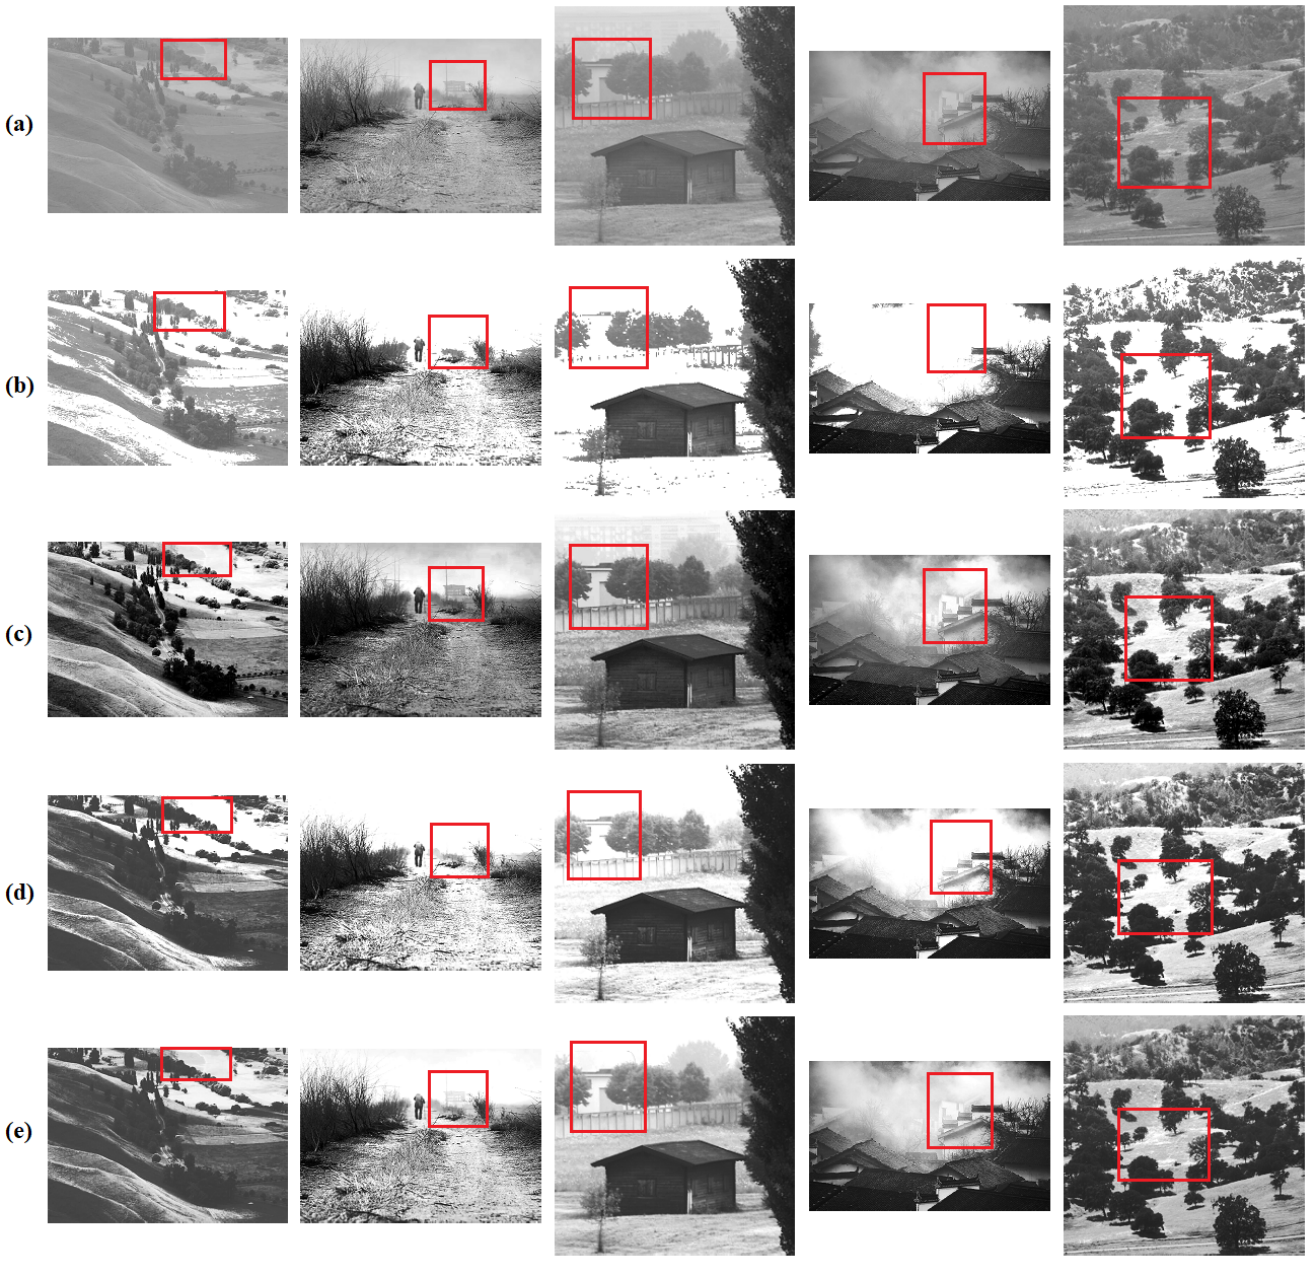

Fig. 2. Original and Result Images. (a) Original, (b), (c) and (d) are Enhanced by Methods in [23], [24], and [25], Respectively, (e) Enhanced by Proposed Method.

2(e) is higher than that of Fig. 2(c). Through visual contrast, Fig. 2(e) (processed by the proposed method) can increase the image contrast, be fully exposed, and also retain some obvious image details.

B. Objective Analysis

For image enhancement effect evaluation, this paper used algorithms include mean squared error(MSE), peak signal-noise ratio(PSNR), structural similarity(SSIM), average gradient(AG), Linear index of fuzziness(IOF) and entropy[26], [27]. The lower MSE(IOF) or the higher PSNR(SSIM, AG, entropy) indicates a better enhancement effect.

$$MSE = \frac{1}{M \times N} \sum_{i=1}^{M} \sum_{j=1}^{N} (x_{i,j} - y_{i,j})^2. \tag{8}$$

$$PSNR = 10 \times \log_{10} \frac{(2^n - 1)^2}{MSE} dB. \tag{9}$$

$$SSIM(x, y) = \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)(\sigma_x^2 + \sigma_y^2 + c_2)}. \tag{10}$$

Truck	0.8096	**0.6486**	6.0274	**6.6620**

'Aerial', 'Airplane', and 'Stream and bridge', the proposed method achieves a lower MSE value, and a higher PSNR and SSIM value. Table IV shows that in more than half of the test images, the proposed method obtained a higher PSNR value. In Table V, compared to the original test images, all the result images have a lower IOF value, and More than half of the result images achieve a higher entropy value. The above experimental results show that the proposed method has a good enhancement effect.

IV. Conclusion

This paper proposed an image enhancement method base on an improved fuzzy c-means clustering(FCM-co). The FCM-co has a cooperation center and it could consider image pixels' location information. The paper introduces a new function to modify the membership value. Through comparative experiments, the results show that the proposed method has a good enhancement effect. In the following work, we intend to try to change the value of parameters c and α for further research. We also plan to apply FCM-co to other areas, such as image segmentation.

Acknowledgment

The authors would like to express their appreciation and gratitude to the Research Management Centre, Universiti Malaysia Sabah for granting this research study under Skim UMSGreat (GUG0540-2/2020).

***Abstract*—Hate speech often spreads on social media and harms individuals and the community. Machine learning models have been proposed to detect hate speech in social media; however, several issues presently limit the performance of current approaches. One challenge is the issue of having diverse comprehensions of hate speech constructs which will lead to many speech categories and different interpretations. In addition, certain language-specific features, and short text issues, such as Twitter, exacerbate the problem. Moreover, current machine learning approaches lack universality due to small datasets and the adoption of a few features of hateful speech. This paper develops and builds new feature sets based on frequencies of textual tokens and psychological characteristics. Then, the study evaluates several machine learning methods over a large dataset. Results showed that the Random Forest and BERT methods are the most valuable for detecting hate speech content. Furthermore, the most dominant features that are helpful for hate speech detection methods combine psychological features and Term-Frequency Inverse Document-Frequency (TFIDF) features. Therefore, the proposed approach could identify hate speech on social media platforms like Twitter.**

Keywords*—Hate speech detection; hate speech classification; hate speech features; hate speech methods

I. INTRODUCTION

As the number of users of social media increases, the impact of hate speech is drastic due to the ease of posting hate speech without geographical boundaries and user anonymity. The uncontrolled spread of hate can damage our society gravely and severely harm marginalized people or groups [1]. The effect of hate crimes is widely spread due to the users' anonymity[2] and the wide use of social media. Twitter, as social media, was studied by 54.81% of researchers; primarily, textual analysis was the prevalent method with 33% compared to other methods [3].

Hate speech detection is a challenging research problem due to many issues, including competing definitions, limited feature sets, small-sized datasets, and the current design of current models. Competing hate speech definitions capture different information with different interpretations by proposed models. For example, racist and homophobic tweets are more likely to be classified as hate speech. However, some definitions are debatable [4]. Therefore, the nonexistence of a universally accepted definition is due to whether offensive conveys hate or not [5]. The critical aspect is separating hate speech language from other offensive languages [6]. The problem of competing definitions would result in a poor feature detection set that could not help identifying hate speech. The problem posed by ungrammatical text has mainly been used to mitigate the difficulty of automatically detecting hateful speech, particularly when users intentionally change keywords' spelling or avoid automatic content [7], [8].

The issue of feature detection becomes more challenging as some words are contextual dependent on users and groups and are not inherently offensive [9], [10]. Small-sized datasets are not enough to generalize results or capture compelling hate speech detection features. For example, Cervero's method [11] employs 200 tweets and yet achieves a good result. Obstacles also include partially labeled data, which makes comparing the performance of many datasets hard to validate. Therefore, many machine learning models do not generalize any hate speech content as it is limited to specific keywords or dictionaries [11]. For example, it was shown that the Yin and Zubiaga model's performance[12] drops down by 10% when tested on another dataset outside the same group of datasets. As a result, the feature sets of datasets do not necessarily represent real-life cases, despite reported performance[11]. Therefore, several machine learning models cannot scale well in practice or models that are not robust due to dataset bias.

This paper develops several machine learning models that are helpful in detecting hate speech based on textual tweets on Twitter. The paper uses the Twitter dataset of 150k tweets [13], called the MMHS150K benchmark dataset. The images were removed from the dataset, and the dataset was converted from the JSON to a tabular format. Three textual features were extracted from the dataset: the frequency of user mentions, hashtags, and emojis; TFIDF of 3-grams; and psychological features extracted by the Linguistic Inquiry and Word Count (LIWC) [14]. Linguistic Inquiry and Word Count is a software application for counting words that references a lexicon of grammatical, psychological, and content word categories. LIWC has been used to categorize texts effectively along psychological dimensions (such as users' personality traits and emotions). The proposed approach was tested on Naïve Bayes, Gradient Boosting, XGBoost, Random Forest, KNN, and Decision Trees algorithms. This study aims to present a model that could be used to automate hate speech detection on any social media platform such as Twitter. We also aim to find the best features that work well with the best-performing algorithm.

The proposed method has several contributions aside from using existing machine learning models from conventional and deep learning methods. This study has extensively studied

the effect of three different groups of feature sets on the results of hate speech detection. We have shown that combining more than one feature set provides a good performance model. Moreover, the proposed method studies the multilabel classification problem and delivers results at the label level, which was lacking in previous studies. Additionally, the proposed model could be integrated with social media platforms to instantly detect and block hate speech.

Our research objectives include identifying textual features that were effective in the classification. For example, the model should be able to detect hate speech fine-grained at the label level given a short text (Tweet).

The paper is outlined as follows. Related works are summarized in Section II. Section III illustrates the proposed machine learning approach. Results and discussions are explained in Section IV and V. The paper is concluded in Section VI.

II. Related Work

Hate Speech and Offensive Content Identification in Indo-European Languages (HASOC) is a new track to detect hate speech detection in the research community. The HASOC track intends to provide a platform to develop and optimize Hate Speech detection algorithms for Hindi, German and English [15]. The best result on the English language dataset of HASOC was based on Long Short-Term Memory (LSTM), which used GloVe embeddings as input. The best system achieved a performance of f1-measure of 0.52; however, the dataset has only 3,708 records for the English dataset. The International Workshop on Semantic Evaluation (SemEval) organizes the OffensEval series of shared tasks on offensive language identification using the hierarchical annotation of the type and target of offensive content [16] [17]. However, robust datasets survive in many classification tasks of hate speech and are reusable and easy to update.

Furthermore, it was reported that robust datasets are required to allow comparability of features and methods [18]. Therefore, as posts of hate speech can also be implicit, few lexical features could be used for machine learning models. Although there are many approaches and features, the current list of models cannot be generalized due to dataset size, credibility, low precision, or imbalanced datasets.

The literature reported various features of hate speech that include shallow lexical features [19], dictionaries [20], sentiment analysis [21], linguistic characteristics [22], knowledge-based features [23], and meta-information [24] of social media content. Readers may refer to a comprehensive study of hate speech detection methods and datasets published recently [25]. However, the literature showed that shallow lexical detection methods have low precision [19]. The literature reported that identifying hate speech on a large scale is still an unsolved problem [26]. For example, the DeepHate method [16] is based on many features: word embeddings, sentiment, and topic information. Recently, aggressive and gendered identification are getting attention [27]. It was found that stylometric (such as function words) and emotion-based features are robust indicators of hate speech[28]. Markov *et al.* [28] provided a model based on encoded emotion information of 14,182 emotion words and their association with emotions and sentiments from the emotion lexicon [29]. Furthermore, the Linguistic Inquiry and Word Count (LIWC) of Pennebaker *et al.* [14] and profanity [30] (especially anger) are good indicators of hate speech in the Indian language context [31]. The LIWC categories include linguistic statistics such as counts and summary variables: analytic, clout, authenticity, and emotional tone. In addition, the LIWC could reveal feelings, personality, and psychological motivations [14]. However, it was shown that the features relating to users' personality traits and emotions in text achieved an accuracy result of 0.7 in English text [32].

Therefore, current methods lack a suitable set of features for hate speech; are either based on small datasets or have low performance when tested over multiclassification hate speech problems. The overall issue is related to the nonexistence of a universally accepted definition of hate speech which results in whether offensive tweets convey hate or not [5].

III. Proposed Framework

In this study, the proposed framework is a machine learning model with an input of a hate speech dataset and trained binary classification output. The framework (Fig. 1) has four steps: data preparation, feature extraction, model learning, and classification output.

A. Data Preparation

It was found that datasets target multiple hate speech categories; however, only 60% of dataset builders reported an inter-annotator agreement [33]. Moreover, it is common for many datasets to overlap between class labels, as Waseem [34] showed an overlap of 2,876 tweets with the Waseem and Hovy datasets [35]. Therefore, relevant and no obsolete datasets are essential to a useful predictive hate speech model. However, creating large and varied hate or abusive datasets that minimize potential bias is laborious and requires specialized experts [36]. Therefore, this study uses a large benchmark dataset taken from a previous Twitter dataset of 150k tweets [13], the MMHS150K dataset. The dataset has an average tweet length of 91 characters, a minimal length of 15, and a maximum length of 193, including the URLs. The dataset has images and textual data of tweets and image captions from Twitter in a python dictionary inside a JSON file. The key of each entry in the JSON file is the tweet ID. The other fields include three different fields, which are the image URL, tweet URL, tweet text, and class labels. The dataset has six classes, shown in Table. I.

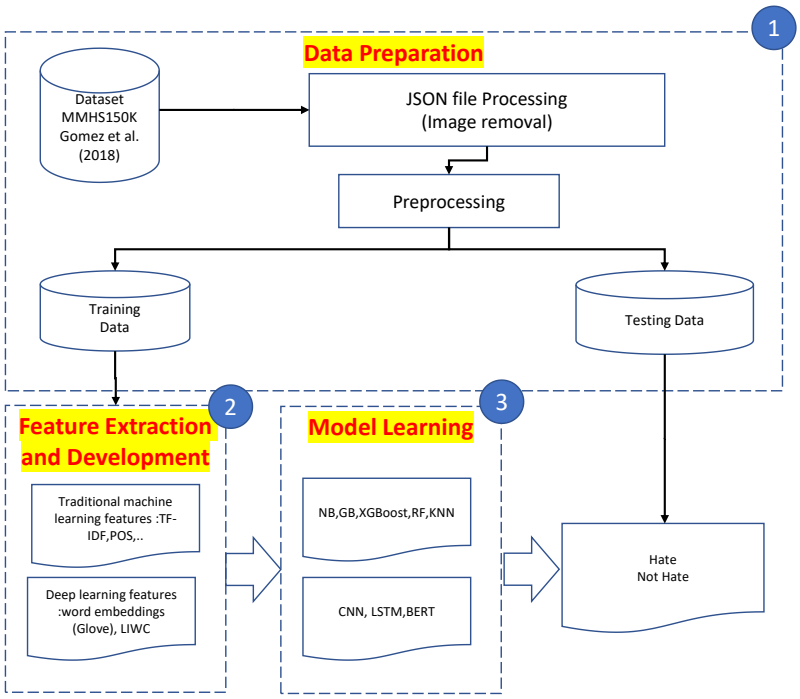

Fig. 1. Proposed Framework.

TABLE I. DISTRIBUTION OF CLASS LABELS IN THE BENCHMARK DATASET*

Class	Total Instances
Not Hate	131,081
Racist	44,535
Sexist	19,509
Homophobe	10,554
Religion	2,119
Other Hate	21,217
Total	143,277

* Further details about extracting and preparing the original dataset are found here https://gombru.github.io/2019/10/09/MMHS/

B. Data Preprocessing

The following are the text preprocessing actions carried out in this study.

1) Removal of images and keeping only textual content in the dataset. This step involves converting the dataset into a tabular format for further preprocessing.

2) Stop words removal.

3) Convert text to lowercase after counting the number of capital letter words.

4) Removal of user mention after checking if a tweet has a mentioned user.

5) Emotions extraction using the UNICODE_EMOJI library from the emot.emo_unicode package.

6) Convert emojis to placeholders so that they will be part of the 3-grams.

7) Tokenization.

8) Lemmatization.

9) 3-grams Extraction.

*10)*Convert text to TF-IDF vector.

C. Feature Extraction and Development

Based on previous literature, this study selects several feature sets such as frequency of tokens (e.g., hashtags) or TFIDF and word embeddings. We follow the following criteria for selecting the sets of features: (1) features must be used in prior hate speech detection models with evidence of acceptable results, (2) the feature must be textual and in line with the current dataset characteristics, and (3) the feature should be used by at least two related studies. Therefore, following these criteria, the features are explained in Table II.

Notably, the selection of feature set 3 is used by only one related study; however, such feature set (LIWC) was evident in other studies related to human sentiments. Therefore, different combinations of the three groups will be used with various machine learning algorithms.

D. Model Learning

This study examines the performance of traditional and deep learning methods on the benchmark dataset. A good model must use the minimum number of features; therefore, this study finds the best features that maximize performance. Consequently, the following methods were selected from machine learning: Naïve Bayes, Gradient Boosting, XGBoost, Random Forest, KNN, and Decision Trees. The benchmark dataset was split into training and testing (80% training and 20% for testing). Stratified sampling is used to ensure proper sampling for each class label. The dataset is imbalanced; therefore, the dataset is balanced using oversampling techniques of SMOTE, where BorderlineSMOTE was the best.

TABLE II. THE FEATURE SET FOR HATE SPEECH DETECTION

Category	Name	Description	Rationale	Related Studies
Feature Set 1 (Counts)	Username Mention	Checks if a tweet mentioned any other user. The preprocessing uses '1' if a username is mentioned, '0' otherwise	Mentioning a person could indicate hate toward that person.	[37]
	Capital Letter	Count of words with Capitals letters.	Tweets that have capital letters may indicate hate or stress in speech.	[38]
	Hashtags	Count of hashtags	Similar to the user mention	[37] [39] [40]
	Emojis	Count of emojis in the tweets	Could indicate a negative attitude of users	[26]
Feature Set 2 (TFIDF)	TFIDF Or Word Embeddings	Cleaned TFIDF vector. It includes tokenization, stemming, and 3-grams. Word embeddings (Glove) is used with Deep learning models.	The semantic structure of tweets	[41] [42] [37] [43] [44] [45]
Feature Set 3 (LIWC)	Summary Language Variables	analytic, clout, authentic, and tone	Analytical thinking, clout, authenticity, emotional tone	Proposed by this study
	Linguistic Dimensions	i, we, you, shehe, they, and ipron	It was shown that the hate speech features relating to users' personality traits and emotions in text achieved an accuracy result of 0.7 in English text [32].	Proposed by this study
	Psychological Processes	Affect variables posemo, negemo, anx, anger, and sad		[46]
	social	family, friend, female, and male		Proposed by this study
	bio	body, health, sexual, and ingest		Proposed by this study
	drives	affiliation, achieve, power, reward, and risk		Proposed by this study

The results that predict hate speech are anlayzed following the standards of machine learning. The precision, recall, f1-measure, and ROC standard performance metrics. The analysis also includes a comparison with other methods in hate speech detection. The analysis also includes identifying the most predictable features for each model.

IV. EXPERIMENTS, RESULTS AND DISCUSSION

Following the selected features in Table II and after preprocessing the dataset, each feature set was created using the python scikit-learn library. Each feature set was prepared alone, allowing different feature sets to be combined with various machine learning algorithms. For example, the first feature sets were processed as follows:

1) If a Tweet includes a usernames, add another feature that is '0' has does not include a username and and '1' has mentioned any user name.

2) If the Tweet has capital letter words, add a new feature and place the total number of capitalized words.

3) Keep hashtags as they might be informative.

4) Replacing URLs, mentions, emojis, Retweets, and capital letters as placeholders.

For example, the tweet

'@Mr Rodie94 Nigga was in the store like 😂 https://t.co/dSEb83kIhm'.

becomes

'mention placeholder nigga was in the store like face_with_tears_of_joy url_placeholder'.

The second feature set is the TFIDF with 3-grams, which was carried out using python; the top trigrams are shown in Fig. 2. Samples of preprocessing steps are shown in Fig. 3. Finally, the third feature set was extracted with LIWC software, which in turn was exported to excel and preprocessed with python.

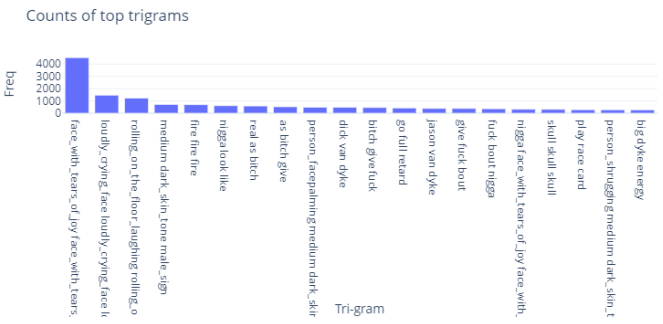

Fig. 2. Top Trigrams.

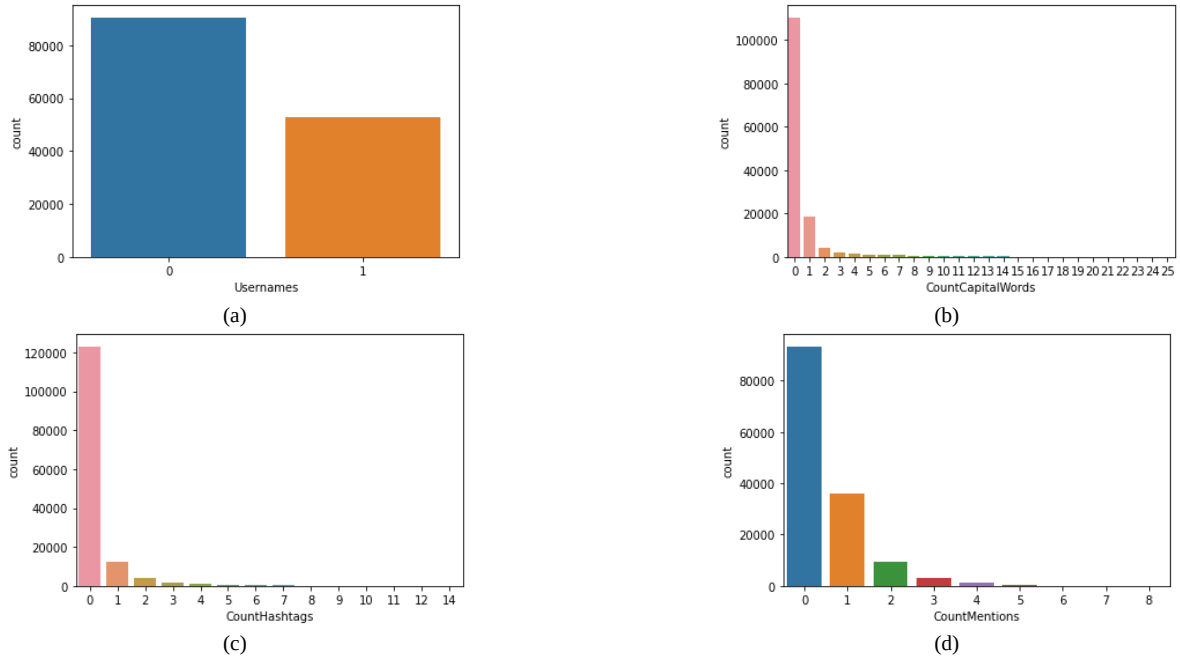

Fig. 3. Preprocessing Steps. Showing Usernames for Both Negative and Positive Example (a), Counting of Capital Words (b), Counting of Hashtags(c), and Count of Mentioned (d).

E. Application of the Proposed Methods (Model Learning)

The classification of this research is a binary classification where each machine learning algorithm is tested on the dataset (hate/not hate). The adopted methods are explained in Table III. On the other hand, the deep learning structure for binary classification of hate speech is shown in Appendix A. The parameters were deduced as per many experiments considering that the nature of machine learning is multiclassification. Each feature set was first to run alone with a specific method, and then the features were combined together.

TABLE III. TRADITIONAL MACHINE LEARNING METHODS FOR BINARY CLASSIFICATION OF HATE SPEECH

Algorithm	**Settings**
Naïve Bayes	naive_classifier = MultinomialNB()
Gradient Boosting	criterion='friedman_mse', init=None, learning_rate=0.1, loss='deviance', max_depth=3, max_features='log2', max_leaf_nodes=None, min_impurity_decrease=0.0, min_impurity_split=None, min_samples_leaf=1, min_samples_split=2, min_weight_fraction_leaf=0.0, n_estimators=80, n_iter_no_change=None, random_state=None, subsample=1.0, tol=0.0001,
	validation_fraction=0.1

LSTM	Structure varies based on feature sets, as explained in A ppendix A
BERT	Structure varies based on feature sets, as explained in A ppendix A

F. Classification Output Analysis

Following the machine learning Table III, Appendix A, and the proposed set of features in Table II, the results are depicted in Fig. 4-6 and discussed here. As shown in Fig. 4, the first feature set is the lowest-performing feature set, indicating that such features are not performing well. However, the second and the third feature sets provide promising results with the most studied algorithms. The highest performance was for the BERT, with a 0.974 f1-score measure on the second feature set and 0.956 on both the first and the third feature sets. The f1-measure for positive and negative examples of the selected machine learning models is shown in Fig. 5. The figure shows that models provide high performance for positive examples (hate=1) and low performance for negative examples. This finding is consistent with previous works [19] and shows that negative examples are still challenging due to the use of similar keywords, as illustrated earlier [6] [5]. Therefore, the nonexistence of a universally accepted definition is due to whether offensive conveys hate or not [5]. Overall, the proposed model provided higher performance in binary classification, 0.98 compared to the original model of a maximum of 0.734 [47].

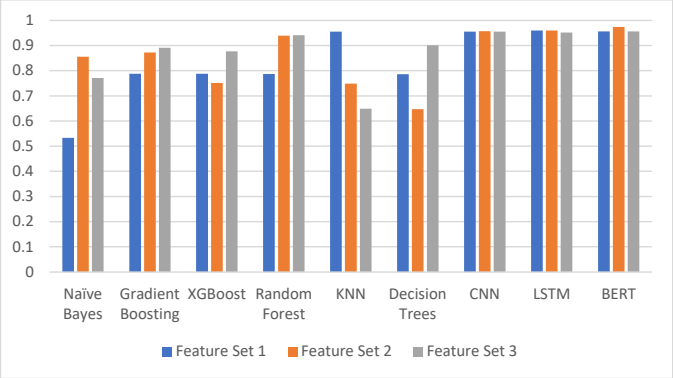

Fig. 4. Traditional and Deep Machine Learning Algorithms F1-Measure against Feature Sets.

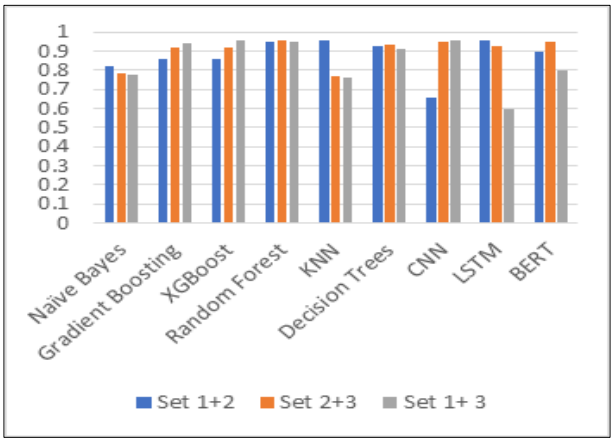

Fig. 5. Selected Algorithms Average F1-Measure (Binary Classification Feature Combinations).

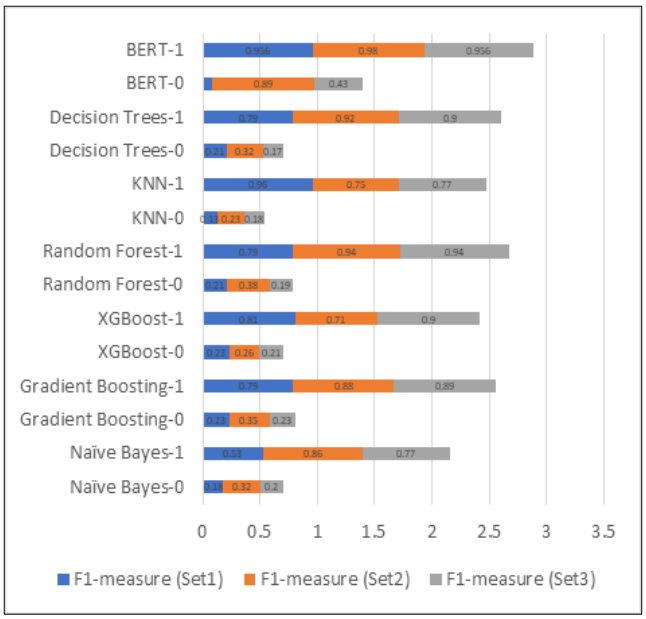

Fig. 6. Deep Learning Machine Learning Algorithms F1-Measure against Feature Sets.

Next, the performance of LSTM, CNN, and BERT (along with the baseline methods) are shown in Figure 6. For BERT: bert_multi_cased_L-12_H-768_A-12/2 model were used. The f1-measure for the BERT model is the highest among the deep learning models. The structure of these algorithms is shown in Appendix A. As compared with previous methods, BERT is the most promising method. The reported f1-measure for BERT is 0.974. Above all, BERT was the most prominent method that distinguishes the negative examples of hate speech, as shown in Fig. 5. However, in practice, it is essential to select the best performing set of features that provides the optimal model. Fig. 5 shows the list of selected algorithms and their performance when several features are merged. It shows that the LSTM got an f1-measure of 0.96 when combining features (set 1 and set 2). Contrary to our previous finding that BERT is the best, it was not performing as compared to LSTM due to the complexity of integrating feature sets of the original bert_multi_cased model and the new features extracted from text. Nevertheless, the most consistent algorithm for the random forest provides relatively similar results when different feature sets.

Table IV shows a sample of related works on hate speech classification and their performance. Unfortunately, most models are not available to the public and were tested in different datasets. Therefore, careful interpretation of the results in the table should be considered as different datasets will eventually change the model outcomes; this issue is already discussed before.

TABLE IV. TRADITIONAL MACHINE LEARNING METHODS FOR BINARY CLASSIFICATION OF HATE SPEECH

Ref	Dataset	Best Method	Accuracy	F1-measure
[48]	Islamophobic hate speech:100K tweets	One-versus-one SVM	0.77	
[19]	25K tweets	SVM		**0.91**
[49]	5K tweets	Logistic Regression	0.704	
[39]	76 K tweets	MCD + LSTM	0.78	
[50]	6.6K tweets	GRU + CNN		**0.78**
[51]	14 K for SemEval-2019 Task 6 subtask A: Offensive/non-offensive	MCD + LSTM	0.78 F1-score	
[52]	SemEval-2019 Task 6 [154]	GRU + CNN	Task A: classification of tweets into either offensive (OFF) or not offensive (NOT) 0.78 for supervised 0.77 for the unsupervised approach	
[53]	**six datasets and 121 customized list**	**Cat Boost**		**F1-score ranging from 0.85 to 0.89 Best average F1-score 87.74 across all datasets**

V. DISCUSSION

Our research objectives include identifying textual features that were effective in the classification. The research showed that the most dominant features are textual features extracted from TFIDF features, as shown in Fig. 2. The features are focused on emotional features such as face_with_tears_of_joy, which was evident in the dataset with 4,528 frequent items. In addition, other keywords were frequent, such as 'fire,' 'nigaal', 'dick van dyke', and others. Such a finding is consistent with previous studies that showed that sentiments are effective in showing a large number of hate speech contents [37], [38], [54]. In addition, the findings are consistent with works related to LIWC as additional features showing human behavior [46].

The developed machine learning models showed that, as expected, the binary classification was providing acceptable results. The best performing model was BERT with 0.974. LSTM also reported good results with an f1-measure of 0.96. The reason is that these models depend on high-dimensional word embedding, and their design was proved to work well with many textual classification tasks. The combination of feature set 2 and feature set 3 provides good results for LSTM and BERT models. The other models reported lower performance, such as CNN (below 0.66 f1-meaure) for the combination of feature set 1 and feature set 2. A single feature set, such as feature set 2 performed well on most algorithms. The best-performing model reported an f1-score of binary classification f1-score of 0.704 with the Feature Concatenation Model (FCM) [13]. The proposed model reported LSTM with an f1-measure of 0.96 (feature set1+feature set 2) with binary classification and 0.96 on LSM and CNN (feature set 2+feature set 3). However, the proposed model has not reported good performance for each label. The investigations showed the original imbalanced dataset, which does not have enough examples for each label. Due to the complexity of hate speech detection, decision trees and KNN provided high f1-measure performance based on TFIDF feature sets. However, these algorithms did not generalize well at the label level (hate/not hate), indicating that there were standard features between positive and negative examples of the hate speech benchmark dataset.

Consequently, with a wide set of machine learning models, the results indicate that as the number and type of features are added (shown in groups in Table II.), the machine learning model performance increase. The reason is that the additional features add new semantics to the embedded or intended meaning in a particular Tweet. For example, the LIWC features (Feature set 3), have shown relatively good performance in detecting sentiments and user psychological features.

Although the experiments have been run on a single dataset, the dataset is considered one of the largest datasets that are available online. According to a previous study, it was found that current datasets suffer from various aspects, including their size, bias, and authenticity in terms of the annotation process [25]. A comparison of hate speech models was not fully available as many models are not published, or the dataset is private. However, the proposed model was able to provide an acceptable accuracy with a baseline work that used additional non-textual features such as images and their captions [13]. Therefore, given these restrictions, and due to the complexity of hate speech features, the results are considered acceptable but should be interpreted within the context of hate speech categories implied in the adopted benchmark dataset. The new work provides implications to theory with newly adapted machine learning models and could be used on unseen data on Twitter or similar social media platforms.

VI. CONCLUSION

This paper develops three feature sets that could be used for hate speech detection: frequencies of unique tokens, TFIDF, and LIWC features. Then, the paper extensively compares several machine learning models: Naïve Bayes, Gradient Boosting, XGBoost, Random Forest, KNN, Decision Trees, LSTM, CNN, and BERT. The difficulty of hate speech identification was shown by the high f1-measure performance of decision trees and KNN based on TFIDF feature sets. However, these algorithms did not generalize effectively at the label level (hate/not hate), showing that positive and negative samples of the hate speech benchmark dataset shared common

characteristics. Conversely, the results of the BERT model were relatively higher, with an f1-measure of 0.974 on the same feature set (TFIDF). In addition, the LIWC feature sets and their combination with TFIDF provided better results on the LSTM method. However, features among the adopted LIWC could share common information. It is recommended that the adopted approach should be considered in the context of generic hate speech on a short text like Twitter. The model might need retraining due to out-of-vocabulary keywords that users might use over time. Furthermore, the researchers might consider another resource of hate speech aside from Twitter. Therefore, we plan to test the models based on a single sub feature on a leave-out scheme in the future.

***Abstract*—Processing huge and complex data to obtain useful information is challenging, even though several big data processing frameworks have been proposed and further enhanced. One of the prominent big data processing frameworks is MapReduce. The main concept of MapReduce framework relies on distributed and parallel processing. However, MapReduce framework is facing serious performance degradations due to the slow execution of certain tasks type called stragglers. Failing to handle stragglers causes delay and affects the overall job execution time. Meanwhile, several straggler reduction techniques have been proposed to improve the MapReduce performance. This study provides a comprehensive and qualitative review of the different existing straggler mitigation solutions. In addition, a taxonomy of the available straggler mitigation solutions is presented. Critical research issues and future research directions are identified and discussed to guide researchers and scholars.**

Keywords*—Big data; blacklisting execution; Hadoop; MapReduce; spark; speculative execution; straggler

I. Introduction

Due to the accelerated expansion of structured and unstructured data generated by the internet of things (IoT), social media, multimedia, etc., it is becoming increasingly difficult to analyse the information and data that is being generated. Applications like MapReduce, a fault-tolerant, scalable, and user-friendly framework for data processing, allow their users to efficiently process these enormous volumes of data [1], [2] . The preparation and generation of a large amount of data can be accomplished using the MapReduce approach. This is because it provides a user-friendly environment and provides solutions for a variety of ad hoc and misses, including data sorting and web indexing, among others. Bigger businesses, including Yahoo and Google, among others, use MapReduce in their large information applications.

The variety in accessibility in the CPU, I/O conflict, or network traffic is what causes stragglers. The MapReduce Framework is complete once map and reduce have been finished [3], [4]. The job is not finished in the MapReduce framework until the very reduce and map tasks are finished. Additionally, when the range of time employment increases [5-8], the number of stragglers decreases. Some compute nodes are quicker than others in a diverse environment. Faster compute nodes will finish their work ahead of schedule and wait for the stragglers to complete. Slower compute nodes are known as stragglers (Fig. 1). Nodes can occasionally fail owing to hardware or software issues. To prevent system performance degradation, it is crucial to identify stragglers at an early stage.

Traditional database management solutions such as E-R model are no longer suitable for processing and analysing of massive amounts of data generated by today's big enterprises. The bulk processing problem has become a major difficulty, and its analytical tools are evolving quickly because of Google's creation of MapReduce, which enabled millions of users to locate material from millions of pages in less than one tenth of a second. On the other hand, stragglers are widely acknowledged as a significant bottleneck in the processing of large amounts of data and they can have a considerable effect on it. Some stragglers mitigation techniques are evaluated in this paper.

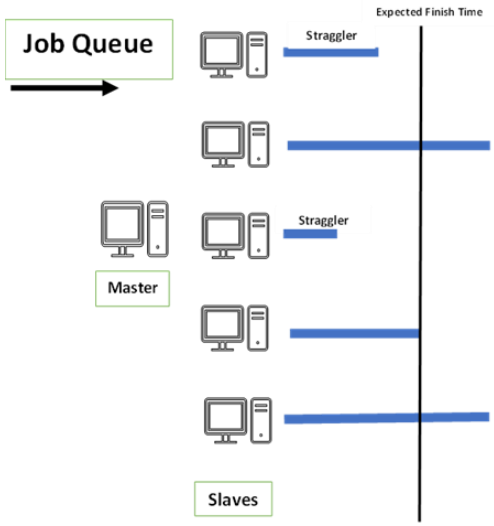

Fig. 1. Straggler Nodes in Parallel Processing.

II. MapReduce Framework and Stragglers

For significant information preparation on bunch-based figure designs, MapReduce is the ideal matching information preparing model that has been suggested [5]. Inside server centres, this system is utilised to support machine learning, data mining, and search applications. Large-scale online search applications must be addressed by the philosophy. Google was the one that originally recommended handling extremely large-scale online search applications.

Programmers are granted licences to extricate themselves from issues like parallelization, booking, and allocating so they may concentrate on creating applications. Processing, storing, visualising, and interpreting big data are the four main components of contemporary businesses and organisations. Applications on a parallel hardware cluster can be automatically run by MapReduce. Terabytes and petabytes of data can also be processed more quickly.

Due to the MapReduce capability to offer a highly effective and efficient framework for the parallel execution of applications, data allocation in distributed database systems, and fault tolerance network connections, it has recently grown in popularity in a variety of applications. Parallel map assignments, as shown in Fig. 1, are carried out as a single input data set consisting of a collection of "key value" sets that are further divided into *fixed produce* and *size blocks* transitional output. Information preparation tools called *map* and *reduce* are included in the MapReduce programming model as depicted in Fig. 2.

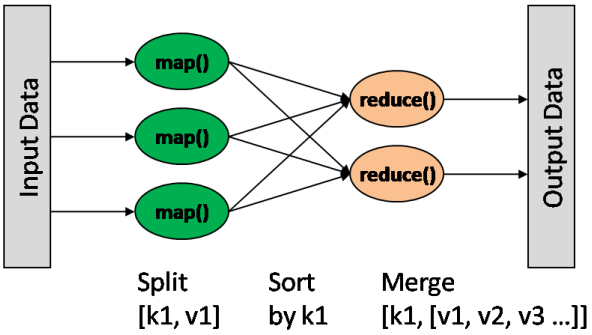

Fig. 2. MapReduce Phases.

When a user submits a job request during the Map-phase, the tasks are mapped to commodity machines for execution. In the Reduce phase, the Combiner lowers the network's data transmission rate. The Reduce-phase includes the Sort or Merging step. The time is utilised to combine the Map outputs from various nodes, and this combining is referred to as the Reduce time. The final stage in running the operation in a MapReduce fashion is the Reduce-part. The impact of each step in this process on runtime varies, so different weights should be used to estimate each job's completion time (the impact of each step on the execution process is determined by the ratio of the time of each step to the overall process's runtime).

The tasks that require more time to complete than comparable tasks are known as stragglers. There are many reasons for delaying the assignment, including the use of inefficient machines, the amount of information to process, framework obstructions, equipment heterogeneity, and competition for the available resources [6], [7].

Additionally, if one task is running slowly on a particular system, it is not important for other upcoming and current tasks to execute slowly on that same machine. Three main mechanisms must be kept in mind when addressing the straggler issue:

- If it is discovered that the anticipated remaining time is longer than the typical runtime, the procedure may be resumed up to three times.
- A speculative duplicate is scheduled if the resource measurement lowers unfavourably. The following procedures estimate the expected remaining time (trem) and the typical runtime (tnew), as shown.
- term = (telapsed * d/dread) + twrapup.
- tnew = processRate∗locationFactor∗d+schedLag.

Stragglers can occur for a variety of reasons, such as load inequality, ineffective scheduling, data localization, communication overheads, and hardware heterogeneity [8], [9]. Additionally, there have been initiatives to address one or more of these worries to lessen the issue [10]–[12]. Even if all these earlier attempts were significant and helpful in solving this issue, more rigorous analytical techniques are required to fully comprehend the effects of stragglers on the performance slowdown in huge data [13], [14].

III. Related Works

For addressing data skew for joins in a MapReduce system and avoiding stragglers, the SharesSkew algorithm was suggested by [7]. When data is skewed, the method determines the multi-way join in MapReduce. In essence, the method divides up the work of performing multi-way joins and maximises the amount of information transferred from the Mappers to the Reducers.

The technique uses a modified version of the SharesSkew algorithm to partition and share highly valued records in a distinctive way to minimise communication costs. The algorithm determines the heavy hitter value of an attribute based on the sizes of the relations or the portion of the connection with heavy hitters and how the sizes interact with one another.

In contrast to existing techniques that limit the number of Reducers employed, the SharesSkew approach merely limits the number of tuples of each Reducer. As a result, the number of tuples selected ensures that the data is distributed equally among the Reducers. (For determining the parameters of the proposed approach, both chain and symmetric joins are taken into consideration.).

A dynamic skew mitigation approach called SkewTune in MapReduce applications was proposed by [15]. The SkewTune approach tries to address the following challenges: i) the MapReduce system should not require extra input from user ii) the system should be fully transparent and iii) there should be minimal overhead even when there is no skew. If the node in the cluster is idle, the SkewTune recognizes the task with the highest anticipated remaining processing time. Afterwards, the non-processed input data of the straggling task is proactively re-partitioned such that it fully utilizes the nodes within cluster. It then conserves the ordering of the input data for the original output to be re-built by concatenation. The SkewTune is implemented as an extension to Hadoop and the efficiency is evaluated by employing several actual applications.

In the quest to address the problem of load imbalance due to data skew, a load balancing based on join algorithms in MapReduce systems was proposed by [16]. The load balancing algorithm named Fine-Grained partitioning for Skew Data (FGSD) for reduced tasks. The FGSD employs the properties of both output and input data via a proposed stream sampling algorithm. In addition, FGSD provides an approach that distributes the input data that help in handling efficient redistribution and join product skew.

Consequently, the authors declare that FGSD achieved better balancing of data distribution and minimizes execution time of jobs with different degrees of data skew. FGSD does not need any alteration to the MapReduce configuration and is suitable for handling complex jobs. Similarly, Gavagsaz et al. [17] focus on reducer phase to achieve load balancing in MapReduce system by employing scalable straightforward random sampling. The major problem in reducer phase is data skew, which lead to a significant load imbalance and degradation of performance. Therefore, a sorted balance algorithm was proposed, which is centered on sampling results. The Sorted Balance algorithm using SCalable random sampling (SBaSC). The scalable sampling algorithm is employed for monitoring a more exact approximate distribution of the keys through sampling small fraction of the intermediate data.

In MapReduce, reducer side data skew occurs due to unbalanced allocation of intermediate map-output to reducers. Therefore, [18] proposed an adaptive Learning Automata Hash Partitioning (LAHP) algorithm to address the data skew problem. The LAHP is based on learning automata game for conventional allocation of intermediate key-value pairs to designated reducers. It is achieved by setting a learning automaton on each mapper node to control the allocated load on each reducer. Thus, during execution of job, a learning automata game is enabled.

In addition, the LAHP algorithm partitions the intermediate key value pairs arbitrarily without considering the statistical distribution of pre-processing and input data. A load balancing mechanism that enhances MapReduce in Hadoop was proposed for mitigating negative impact of data skew on the performance of MapReduce [19]. Data skew has become a typical problem in MapReduce processing for handling data intensive applications. The mechanisms integrate Reservoir Sampling and Greedy (RSG) algorithms. It further slots in the concept of data locality in order to properly distribute the workload of each reducer, which is based on priority-based load-balancing mechanism (PLBM).

Wang *et al.* [20] proposed an enhanced Replication Framework of Stragglers over a Large-scale Parallel processing (RFSLP) for addressing the latency Framework of Stragglers encountered due to replication of stragglers. The framework analyzes replication latency-cost tradeoff and determines the best replication strategy. The strategy considers three design ideas including i) how many replicas are required ii) the time to replicate straggling tasks and iii) whether to terminate main copy or not. The framework analysis demonstrates that for specific execution time allocation, a small quantity of task replication can drastically minimize the cost of computing resources and latency. Further, an algorithm that estimates cost and latency based on the empirical allocation of task execution period.

In another aspect, a Framework for Assessing Stragglers Detection (FASD) mechanisms over MapReduce was proposed by [21]. It focuses on detection of stragglers because most of the existing works are centered on mitigating stragglers. In this light, an all-inclusive framework for straggler detection and mitigation was proposed. The detection strategy considers set of metrics that can be employed for characterizing and detecting stragglers. The metrics include fake positive, recall, detection latency, precision, and undetected time. Further, an architectural model was developed in such a way that the metrics can be linked to determine performance. The performance measure includes system energy overhead and execution time. To demonstrate those metrics that are effective in detecting stragglers and predict effectiveness in terms of energy efficiency performance, a number of experiments were conducted.

Similarly, a data partitioning concept, which is based on intermediate node for mitigating skew over a spark computing environment was proposed [22]. The main issue targeted in this work is unbalanced partitioning, which leads to variation in the amount of data processed by each Reducer task. Considering the mentioned issue, a Spark Key Reassigning and Splitting Partitioning (SKRSP) algorithm for handling the partition skew from the source codes of Spark-core 2.11 has been developed. The concept considers two approaches of balancing namely: partition balance for intermediate data and partition balance after shuffle operators. The contribution is in two folds first, a Key Reassigning Harsh-based Partitioning (KRHP) and rang-based Key Splitting Reassigning Partitioning (KSRP) algorithms. These algorithms can create suitable strategy for implementing the skew in the shuffle phase. The KSRP creates a weighted bound for partitioning intermediate data for the kind of sort-based applications. While KRHP stores these reassigned keys, and the new reducers of these keys are from other applications.

A proactive method named Hummer-1 for mitigating stragglers based on partial clones was proposed by [23]. In the existing solutions, different methods have been suggested including speculative execution, blacklisting and proactive mitigation. However, these solutions either waste much resource or consume much time during execution. The Hummer method trigger clones just when jobs are submitted thus, tasks in one job are assigned with clones to reduce stragglers. The initial default number of clones for a single task is three, which has been found to be the best value since there exist variations among nodes in the cluster [23]. To further improve Hummer-1, Hummer-2 was introduced which uses cloning for only tasks with high-risk delay. The authors claim that the Hummer method consumed fewer resources and minimize job delay that is, job completion time is reduced.

A Dynamic Server Blacklisting (DSB) framework was proposed for lessening stragglers to evade Quality of Service violation for time-sensitive applications [24]. The straggler task may occur due to one or more of the following reasons: heterogeneous hardware configuration, resource contention and

so on. Straggler task could become severe due to increased complexity and system scale.

The DSB is developed based on the two prominent concepts namely speculative execution, which is automatic/dynamic and blacklisting, which is manual configuration. DSB considers the previous, which is historical and present behavior of server node to improve straggler mitigation efficiency. The computing servers are ranked at a given time interval according to their present performance in completing jobs instead of their physical facilities. The servers with worst performance are momentarily blacklisted dynamically. Thus, due to the strategy no new replications/tasks are allotted to those straggler-prone nodes in each time window. DSB further offers an alternative API in such a way that the top worst nodes are blacklisted based on their ranking. An optimal node is examined as a trade-off between straggler mitigation efficiency and capacity loss. Table I contains the comparison of existing load balancing solutions.

TABLE I. COMPARISON OF LOAD BALANCING SOLUTIONS FOR STRAGGLER MITIGATION

Existing Solutions	Comparisons						Remark
	Heterogeneity among Network Node	Data Processing Method	Priority-based Scheduling	Mitigatio0n Approaches			
				Speculative	Blacklisting	Proactive	
ShareSkew [7]	No	MapReduce/Hadoop	No	Yes	No	No	Multi-way joins have not been considered to investigate an efficient multi-round MapReduce algorithm.
SkewTune [8]	Yes	MapReduce/Hadoop	No	Yes	No	Yes	SkewTune approach may lead to resource contention due to high computation.
FGSD [9]	No	MapReduce/Spark	No	Yes	No	No	Similarity joins has not been considered in the Fine-grained skew data method
SBaSC [10]	No	MapReduce/Spark	No	Yes	No	No	The query level load balancing and fairness need to be optimized
LAHP [11]	Yes	MapReduce/Hadoop	No	Yes	No	No	Data skew could also occur when the sizes of the keys are different and affect the shuffle time.
PLBM [12]	No	MapReduce/Hadoop	Yes	Yes	No	No	The transfer cost is only based on splitting capability. Which may not be sufficient achieving efficient load balancing.
RFSLP [13]	No	MapReduce/Spark	No	Yes	No	No	Despite the use of scheduling concept, priority has not been assigned some critical tasks.
FASD [14]	Yes	MapReduce/Hadoop	No	Yes	No	No	The metric evaluation has limitation of not able to detect stragglers before occurrence.
SKRSP [15]	No	Hadoop/Spark	No	Yes	No	No	In the intermediate data distribution, the weight of each key is calculated, which could lead to overhead that may result in data processing delay
Hummer-1 [16]	Yes	MapReduce	No	No	No	Yes	Computation time required for deciding which task need to be cloned could also increase the execution time
Hummer-2 [16]	Yes	MapReduce	No	No	No	Yes	The approach could lead to increase in execution time
DSB [17]	Yes	MapReduce/Hadoop	No	Yes	Yes	No	Stragglers due to data skew have not been considered in this framework.
SkewTune [8]	Yes	MapReduce/Hadoop	No	Yes	No	Yes	SkewTune approach may lead to resource contention due to high computation.

IV. Scheduling in Straggler Mitigation

In this subsection, the solutions that employ scheduling concepts considering adaptive, resource allocation and data locality-aware scheduling in MapReduce framework have been analyzed and presented.

A. Adaptive Scheduling

A problem of omission failure due to stragglers has been addressed by proposing a Failure Detector Abstraction (FDA) based on MapReduce system [25]. The omission failure is due to timeout service adjustment, which strongly endangers the workload performance. Various algorithms have been suggested based on detector abstraction for describing the timeout. Therefore, three different levels of failure detector abstractions have been suggested namely, High Relax Failure Detector (HR-FD), Medium Relax Failure Detector (MR-FD) and Low Relax Failure Detector (LR-FD). The HR-FD serves as a non-dynamic alternative to the default timeout. The MRFD acts as non-static detector that modifies the timeout, based on progress score of each workload. While the LR-FD merges the MapReduce, non-static timeout using an exterior monitoring system to enforce accurate failure detection. The LR-FD is considering in case if there are strict deadline bounded user requests. Meanwhile, the authors claim that there is significant improvement in the timeout selection for user request regardless of the failure injection time and workload type. A Task scheduling optimization framework named ET-scheduler was proposed to handle time sensitive jobs and high resource consumption [26]. The existing scheduling technique cannot complete job within the time constraint of the user. Therefore, the ET-scheduler tries to allocate resources to the tasks of job submitted. The scheduler makes sure that jobs are completed within the time specified by user. It minimizes consumption and modifies the time allocation in the process of Map and Reduce.

A Map-Balance-Reduce (MBR) programming model was proposed for improving parallel programming model for load balancing over MapReduce [27]. The problem of load imbalance occurs if the data matching to a specific key or several keys account for majority of the data, then the Reduce node task will create unbalanced load. The MBR model runs on the custom Hadoop framework, which effectively processed the unique data with unbalance data. MBR programming model is designed based on two varied scheduling namely, processing and self-adaptation scheduling. The processing scheduling in MBR tries to find unbalanced task in advance, to compile balance function. Then value/keys are pairs outputted by Map, which are transmitted to balance the function. The values are outputted by Map and can be pre-processed for unbalanced data by calling the balance function process. In the self-adaptation scheduling, if there exists unbalanced load, the present Reduce task is terminated and then the unbalanced load is dynamically split and schedule for distribution to attain dynamic load balancing of the requested task.

Cheng *et al.* [28] proposed an enhanced MapReduce solution using Adaptive task tuning (*Ant*) over a heterogeneous environment. The solution tries to address poor performance due to heterogeneous clusters. In the existing work, there is homogeneous configuration of tasks on heterogeneous nodes, which leads to load imbalance and thus causes poor performance. The *Ant* can automatically determine the optimal configuration for distinctive tasks executed on different nodes. *Ant* algorithm performs better even when the jobs are large with more than one rounds of map task execution. At the beginning task are configured with randomly chosen settings. To evade trapping in local optima and speed-up task tuning, the algorithm employs genetic functions during task configuration.

B. Resource Allocation Scheduling

Huang *et al.* [29] proposed a Workload Alleviation Scheduling Framework (WASF) in order to avoid negative effect of intermediate data skew in small scale over MapReduce cloud. The intermediate data skew is caused due to unevenly allocation of intermediate data between nodes at run time. Thus, the intermediate data skew makes the nodes in the MapReduce cloud idle, which in turn leads to waste of computation resources. This also leads to prolonging of execution time, which gives user a bad experience in cloud computing. The WASF dynamically and smartly used the available computation resources for minimizing the intermediate data skew. A method that employs result analysis of profiling and relation of system parameters was proposed to address the limitation of speculative and clone execution method [30]. The limitation is in terms of performance reduction due to heterogeneous clusters and task stragglers in big data processing. The method tunes the quantity of task slots of nodes dynamically to match the processing capability of the nodes, which is based on present task progress rate and resource consumption. Therefore, a Task Progress Rate-based (TPR) approach has been developed. The tuning process is further optimized to achieve faster convergence. Thus, the method is implemented in the Hadoop MapReduce platform.

In [11], a Root-cause analysis for stragglers in Big data environment named BigRoots was proposed for handling user programs optimization problem. The BigRoots is a general method that incorporates system features and framework for root-cause analysis of stragglers in big data environment. It analyses the stragglers using features from Big data framework including system resource utilization, JVM garbage collection time and shuffle read/write bytes. The system resources include input/output, central processing unit and network, which can detect both external and internal causes of stragglers. The BigRoots is evaluated by injecting high resource utilization over dissimilar system components and different case studies were considered to analyze dissimilar workloads in Hibench to evaluate the performance.

Lakshmi [31] proposed an algorithm for enhancing Map and Shuffle Phases (MSP) over Hadoop MapReduce in Big data environment. In the MapReduce, the shuffle phase uses individual shuffle services component with efficient input/output policy. Meanwhile, the map phase's output serves as an input to the subsequent phase. Thus, map phase requires intermediate checkpoints that regularly observe all splits created by intermediate phase. Therefore, the algorithm is designed as shuffle as a service component for decreasing the total execution time of task, monitoring map phase based on skew handling and improve resource consumption in a cluster.

C. Data Locality-aware Scheduling

A MapReduce concept based on data routing and locality was proposed to handle data imbalance in local and remote machines and to avoid network congestion [32]. A scheduling and routing algorithm named Joint Scheduler was proposed to balance task allocation to local and remote machines and to provide data routing that evade network congestion. The proposed algorithm is centered on bringing data close to computation instead of bringing computation close to data. Hence, it uses both communication network and computing resources efficiently. It is proven that the Joint Scheduler can support any load of jobs as used in the existing algorithm, which achieves the highest capacity region.

In [33], a task scheduling algorithm named rTuner was proposed to improve performance of the MapReduce job. The existing solutions are faced with the limitation of heterogeneity and resource contention, which lead to performance degradation in terms of overall job execution time. Thus, the rTuner consider the key objective to improve the reduce task execution time in both heterogeneous and homogeneous settings. Unlike the map task, the reduce task involves three phases namely, copy, shuffle and reduce phases. If the underlying situation is not analyzed by the scheduling algorithm, re-scheduling a straggler reduce task might negatively impact on the performance of the system.

Therefore, the rTuner study the reduce tasks' straggling causes and then tunes the reduce task. If tasks happen to be a straggler, then the rTuner re-schedules it to a suitable node, which depends on the situation. In summary, Table II presents the comparison of existing scheduling solutions in straggler mitigation.

TABLE II. COMPARISON OF SCHEDULING SOLUTIONS FOR STRAGGLER MITIGATION

Existing Solutions	Comparisons						Remark
	Heterogeneity among Network Node	Data Processing Method	Priority-based Scheduling	Mitigatio0n Approaches			
				Speculative	Blacklisting	Proactive	
FDA [19]	Yes	MapReduce	Yes	Yes	No	No	The failure detector abstraction did not consider data intensive computing systems.
ET-scheduler [20]	No	MapReduce/Hadoop	No	Yes	No	No	The scheduling optimization does not consider prioritization of task
MBR [21]	No	MapReduce/Hadoop	No	Yes	No	No	The pre-processing scheduling of the MBR model does not consider prioritization of the critical task
Ant [22]	Yes	MapReduce	No	Yes	No	No	The multi-tenant MapReduce settings has not been considered
WASF [23]	No	MapReduce/Hadoop	No	Yes	No	No	The scheduling framework does not consider prioritizing smaller or bigger workload
TPR [24]	Yes	MapReduce/Hadoop	Yes	Yes	No	No	This approach does not consider the shuffle phase.
BigRoots [25]	No	Spark/MapReduce	No	Yes	No	No	The relationship between locality and network utilization has not been investigated for the Root cause
MSP [26]	No	Hadoop/MadReduce	Yes	Yes	No	No	Meanwhile, heterogeneity of the network nodes has not been considered, which is important in the case of resource contention
Joint Scheduler [26]	No	MapReduce	Yes	No	No	Yes	Heterogeneity among network nodes has not been considered.
rTuner [27]	Yes	MapReduce/Hadoop	No	Yes	No	No	It is often fuzzy when deciding to declare a task as a straggler. However, the fuzziness has not been considered in rTuner.

Advantages and Disadvantages of Load Balancing Techniques (Algorithms).

Load techniques are either static or dynamic and each one has its own limitations and advantages which includes:

Advantages

- The static load balancing techniques are usually very efficient in stable environment because they do not need to monitor the resources during run-time.
- In a stable environment, operational properties do not change over time and loads are generally uniform and constant at the running time.
- Dynamic load balancing techniques are more flexible in dynamic computing environments.
- Dynamic load balancing techniques usually take into consideration different types of attributes in the environment both prior to and during run-time.
- Dynamic techniques can consider changes and provide better results in heterogeneous and dynamic environments.

Disadvantages

- Static load balancing techniques are not flexible and cannot accept changes of attributes during execution time.
- Static load balancing techniques do not consider continuous monitoring of the nodes hence they cannot consider load changes during run-time.
- When dynamic load balancing considers all changes during runtime it become more complex and dynamic to handle.
- Under certain conditions, dynamic load balancing techniques tend to have decreased performance in services.

V. Open Issues and Research Challenges

In this section, we have highlighted many research issues, which need research attention to attain efficient and effective straggler mitigation in MapReduce framework. The research issues are focused on how to balance the distribution of loads across the machines and how to efficiently schedule tasks to resource of the machines in order minimize slow tasks, which causes delay and negatively affect job completion time. The detailed discussions of the issues are as follows:

- Data Skew Caused by Inefficient Distribution of Data in Reducer Phase.

The main issues that affect the performance of the MapReduce framework is that some task take longer execution time to finish than others. This is due to data skew. The data skew is termed as inequality in the quantity of data allocated to each task or imbalance in the amount of work needed to process such data. These kinds of data are usually skewed in nature. Thus, it causes poor parallel processing, inequality of reducers input and high varied reducer execution time hence, it enlarges the completion time of the MapReduce job. Further, the intermediate data sharing in input data is not known, thus generating a strategy for the data group adjustment is difficult. It leads to the imbalance in the data distribution for a given task, which in turn causes stragglers. In addition, data skew could also occur when the sizes of keys are different and affect the shuffle time, which may cause straggler. Therefore, there is a need to develop a strategy that determines the values and keys for achieving balanced distribution of data, which mitigates the skewness of the data and improve the job completion time.

- Data Replication and Placement Issue.

The MapReduce framework is well known for its ability to handle large task and perform parallel processing during task handling. These strengths have encouraged researcher to employ replication strategy to minimize latency in job completion time. However, the replication concept has caused redundancy in task execution, which causes high resource consumption. Since the replication strategy generate redundant data there is a need for concepts that consider queuing and priority of the replicated data in terms of critical tasks for efficient job completion time. Because when there is large number of tasks that need to be executed, then the replication of these tasks will have impact on the computing resources hence, also affecting the task execution time due to resource constrain, which could cause stragglers.

- Poor Resource Allocation for Computation-Intensive Tasks.

In the existing MapReduce framework, some solutions use computational resources in a loose way on the basis that numerous idle nodes available can be used to collaboratively handle intermediate data skew. However, MapReduce system could be on a small scale and/or the task could be in a large scale. The proper utilization of the resource is very important in the case of a sophisticated system. In the existing solution, they smartly utilize computation resources in nodes and dynamically distribute workload of a node with other nodes by dispatching skewed intermediate data to a resource allocator. In addition, heterogeneity of the network nodes when allocating computation-intensive tasks to machines has not been considered, which is very significant in the case of resource contention. Consequently, the improper resource allocation to task could also lead to creation of straggler, which affect the job completion time of the Map Reduce framework. Therefore, considering the challenges, there is a need to design and develop an improved straggler mitigation solution that considers efficient resource allocation for task distribution.

- Inefficient Task-Resource Matching.

This usually results in sending simple tasks to machines with high computational capabilities and complex tasks to slow machines which may end up increasing the total job completion time.

VI. Conclusions

We have extensively reviewed existing related works and present the most recent research development in straggler mitigation approaches. The straggler issue has become challenging in MapReduce framework. Considering the negative effects of straggler, several solutions have been proposed that focus on load balancing and scheduling of the distributed task. Thus, a comprehensive review of the existing studies has been suggested in this paper. This review classified load balancing solutions into data skew and replication/placement approaches. While the scheduling approaches are classified into adaptive, resource allocation and data locality-aware scheduling. Further, open issues and research challenges are highlighted. The straggler problem degrades the performance of the existing data processing frameworks, specifically MapReduce. Therefore, there is a need to further explore more robust solution on how to effectively mitigate stragglers.

***Abstract*— More and more new health care solutions are born based on the development of science and technology. The subjects who benefit the most, in this case, are not only patients (i.e., shorter healing time, faster recovery) but also medical staff, e.g., doctors/nurses (i.e., easy monitoring of the patient's recovery process, proposing new treatment). However, there are still products that have not found an alternative: blood and blood products. Regardless of how science and technology can affect all aspects of patient treatment as well as medical care, blood still plays an important role in the treatment method. In addition to the above, blood and blood products may only be obtained from volunteers (i.e., blood donors). The preservation process is also very difficult, and no medical facility has enough facilities to preserve them. Therefore, the current process of blood preservation and transportation is done manually and contains many potential risks (e.g., data loss, personal information collection). In addition to the above barriers, developing countries (including Vietnam) also face many difficulties due to limited facilities. It is for this reason that this paper aims at a Blockchain-based technology solution for efficient management and distribution of blood from blood products. On the one hand, the paper contributes to the limitations in the information management process of storing and transporting blood and its products in the traditional database being applied in medical facilities in the cities and provinces in the Mekong Delta (the West-South of Vietnam). On the other hand, the article offers technology-based solutions to increase transparency and reduce the fear of centralized data storage (i.e., security and privacy issues). We also implement a proof-of-concept to evaluate the feasibility of the proposed approach.**

I. Introduction

There is no denying in the contribution of technology in the treatment of diseases today. Specifically, it increases the patient's ability to recover after treatment and reduces the risk of human error. In parallel with those positive aspects, new diseases always appear with more dense frequency and more dangerous toxicity for patients (e.g., Covid-19). For this reason, treatment and health care procedures have changed dramatically from the same time period ten years ago. However, some products cannot be replaced in the treatment process regardless of the development of science and technology [1]. One of the prime examples of this type of product is blood. Indeed, blood and its products are important medical resources in long-term treatment as well as in emergencies [2], e.g. blood is often required for trauma victims, surgery, organ transplants, childbirth and for patients being treated for cancer, leukemia and anemia. Each unit of blood is very precious and gives hope to the patient. For example, a liter of blood can sustain the life of a premature baby for two weeks; 40 or more units of blood may be required for the survival of an accidental blood loss trauma victim, or eight platelets per day are the minimum level for the treatment regimen of blood cancer patients.

In addition to the irreplaceable requirements in the treatment of diseases, the supply of blood is extremely limited because only donated blood is used instead of other substitutes due to a number of medical reasons. Besides, the requirements on time of use are also very strict to ensure the safety of the recipient. Specifically, blood and its products cannot be stored for long periods of time. Red blood cells must be used within 42 days of collection. Meanwhile, platelets have a shelf life of five days of collection. On the other hand, checking blood group similarities between blood donors and recipients is extremely strict. In particular, all blood collected must be rigorously tested to reduce the risk of transmission of infection by blood transfusion (e.g., hepatitis B and C (HBV - HCV) or human immunodeficiency virus (HCV) (HIV)) before transmission to the recipient [3]. All three of the above reasons are the main reasons for the shortage of supply according to Chapman et al. [4]. The above article also shows that the best way to optimize the use of blood and blood products is to save the amount of blood that can be received from the donor.

In addition to the above obstacles affecting the blood supply chain management process, time requirements are also extremely important. Specifically, no one expects blood, but if it's not available when it's needed, the consequences can be deadly. While donors may tell you there's no better feeling than saving a life, only about 5% of eligible donors actually donate [5]. Therefore, maximising the amount of blood stored in the warehouse is imperative.

In addition to the above barriers, one of the main obstacles in blood collection and storage for developing countries is supply (i.e., volunteers still do not have a positive attitude towards blood donation) [6], and infrastructure and database management system (DBMS) for blood and its products' storage [7]. Vietnam is also on the list of developing countries and suffers from a shortage of supply. As far as we know, there is only one hematology hospital that supplies blood to the whole Mekong Delta. This article focuses on the second issue (i.e., infrastructure and DBMS) rather than increasing citizen blood donation behaviour-aware. Therefore, in the scope of this article, we only focus on technology solutions to improve the current management system as well as change from the centralized to the decentralized storage system. In particular, we aim to share donor data in a controlled manner; for

example, reduce the medical declaration time from the second blood donation onwards. Indeed, each user can only donate blood at least 28 days after their previous blood donation (i.e., about a month) [8]. Hence, previously stored information must be stored decentralized, and volunteers can donate blood at a different location without providing the previous information.

In addition, data sharing among the hospitals and blood donation clinics makes donor management easier. Health workers have more options in contacting volunteers for the next blood donation, thereby promoting the blood donation movement in the community. To solve the second problem, we want to verify blood and blood products to achieve transparency-proof. As storage conditions (e.g. temperature, humidity) and storage time vary depending on the blood product collected. The storage and transportation of blood and blood products from storage to hospital (or vice versa) makes it difficult to identify relevant information, including time, location, health notes, and so on. To address the above issues, many methods have proposed blockchain technology to increase the transparency and traceability of information storage. There are several benefits of the blockchain approach proved in the management system. For instance, Cash-on-Delivery (COD) exploited the smart contract to set up the contract compliance among the stakeholders [9], [10], or define the shipper participant role in the marketplace [11], [12]. Moreover, in the Healthcare system, the patient can control the permission to show the necessary information to the authorized partner (e.g., nurse, doctor) [13], [14] or define the emergency between the medical staff and patient's friend or relative [15], [16] Besides, data stored decentralized is also a plus point compared to the current traditional storage model. Where all data is shared and easily traceable to identify the source of blood and blood products, however, current models cannot fully address the requirements for storing different information about blood and its products [17], [18] for proper storage (i.e., shelf-life of usage, temperature, humidity). Furthermore, there has not been an in-depth study to assess the appropriateness of the application of advanced technologies in supply chain management w.r.t. blood and its products in Vietnam. To address these problems, this paper proposes blood and its product management process by applying blockchain technology and decentralized storage for medical facilities in Vietnam.

The contribution of this article is three-fold: i) analyzing the current management mechanism of blood and its products in the provinces and cities in the Mekong Delta (southern Vietnam); ii) proposing a solution to manage the supply chain of blood and blood products based on blockchain technology; iii) implement the proposed model based on Hyperledger Fabric platform and evaluate their feasibility.

Following this introduction, the state-of-the-art is presented in Section II to summarize blockchain-based blood supply chain system approaches as well as that system for blood and its products management in Vietnam. Then, we analyze the current blood and the supply of its products chain system and our architecture before presenting the execution algorithm in Sections III and IV, respectively. Section V focuses on the analysis and evaluation. The following section presents the discussion of this article. Finally, suggestions for future research and conclusion are made in the last section.

II. Related Work

A. Blood Supply Chain Management Systems not Applying the Blockchain Technology

Supply chain management integrates core business processes and information. These processes use a central server to handle visibility and traceability issues. The system combines a very complex process that requires synchronization of different operations, leading to randomness and supply chain risk [19], [20]. For example, Nagurney et al. [21] proposed a model to minimize costs and risks by expressing the breakdown properties of blood as supply coefficients. Armaghan and Pazani [22] proposed a blood supply chain to handle urgent requests from blood units during the Iran earthquake. The authors build a multi-level, multi-objective model to find an optimal route based on the selected routes to transport blood. The main contribution of [22] is to reduce the cost of the blood supply chain network and maximize reliability. In addition, Eskandari-Khanghahi et al. [23] have developed a model that provides a combination of integer mixed linear programming while considering location, allocation, inventory, and distribution. On the other hand, Delen et al. [24] have integrated GIS (geographic information systems) and data mining techniques to build blood supply chain processes. The main purpose of [24] work is to build an optimal blood transport model to be applied in the military environment.

One disadvantage of centralized storage in the above approaches is transparency [25]. To address this issue, Lam et al. [26], [27] demonstrated the implementation of a micro services-oriented software architecture for middleware that collects, stores, and traces data in a centralized manner in order to provide data analysis. To apply these advantages, a centralized blood donation management solution has been proposed in [28]. This approach not only reduces the amount of information collected from blood donors but also improves the efficiency of blood donation management.

B. Blood Supply Chain Management Systems based on Blockchain Technology

Trieu [17], and Nga [18] propose a cold-blooded supply chain system based on Hyperledger Fabric called BloodChain. The proposed system supports the verification of blood-related transactions from donors to recipients. Moreover, BloodChain allows displaying the necessary information during the blood donation process. Specifically, the actors in the system only receive enough information to verify information about donors as well as recipients. Similarly, Lakshminarayanan et al. [29] propose a blood supply chain management system based on Hyperledger Fabric. Similar to BloodChain, it also ensures transparency of donated blood by tracking blood units between donors and recipients. Moreover, Toyoda et al. [30] have integrated the RFIDs into the blood bags using the EPC stored in the tag. This integration helps to ensure reliability and avoid tampering by tracking products and checking their tags.

However, there are some limitations to the aforementioned solutions. For example, the verification of the system proposed in [18], [17] is incomplete due to the lack of evaluation analysis. Moreover, they ignore the mobility role of the blood/its product, which exploits the transportation company [31] or

shipper [32]. In particular, the blood and its product must be received from several mobility resources (e.g., mobile blood collection units, medical clinics) and stored at the blood bank/hematological hospital. Therefore, the role of transporter[33] is vital in blood donation environments. Furthermore, the monitoring solution proposed in [30] is limited to monitoring blood bags only, and it does not guarantee the traceability of blood components (i.e., red blood cells, platelets, white blood cells, platelets and plasma). Since different blood components have different shelf lives and storage temperatures, the order of user preference should also be considered.

III. The Blood Donation Traditional Process

A. The Current Blood Donation Process in Vietnam

To get the most unbiased view of the traditional blood donation and blood handling process, we collected information about the process in hospitals and healthcare facilities in the Mekong Delta, Vietnam. We conducted a short interview with the medical officers working at the hematology hospital in Can Tho, which supplies blood and blood products to hospitals and healthcare facilities not only in Can Tho city but also in neighbouring provinces (e.g., Vinh Long, Ben Tre, Hau Giang).

Fig. 1 presents the current blood donation process. In particular, the donors are able to donate blood through four ways, including medical clinic, mobile blood collection unit, medical facility (e.g., hospital), and hematology hospital. Except for the second blood donation method (i.e., mobile blood collection unit) which is held in public places for a short time (usually 1 day), donors can donate blood at any time at the three remaining medical facilities. For blood donation at the medical clinic and mobile blood collection unit, the collected products are transferred to the storage facility at the hematology hospital. Here, blood is separated into several components including plasma, red blood cells, white blood cells, and platelets, and then stored according to the specific conditions of the blood product (e.g., temperature, humidity, duration). For the two remaining ways of donating blood, the collected blood does not need to go through a transportation step because these medical facilities have the facilities/equipment to conduct separation and storage. Finally, the blood and its products are delivered to the hospital for recipients. All these steps are performed manually and stored locally at each location (e.g., hematology hospital, medical clinic, hospital).

Although the traditional approach is simple and easy to apply to all medical facilities because it does not require high support technology as well as easy to deploy in a practical environment. However, the above approaches face many inherent risks for systems based on centralized management. Verifying the reliability of the data is admissible to this approach. In particular, any data displayed is only taken from the data available in the database, which is provided by the central server. Moreover, the important information that affects the treatment process can be lost if the central server is hacked. This is an extremely dangerous thing for medical/healthcare organizations. Due to these dangerous risks, it is urgent to find a decentralized storage solution as well as increase the authenticity of data. Blockchain technology can fulfil both of these issues. The next sections will detail the blockchain-based management models to address the current blood management model.

B. The Process Requires Blood and its Products

This procedure outlines the basic steps for transferring blood from hematology hospitals to hospitals when blood is in short supply or in an emergency (e.g., platelet request). Fig. 2 shows the procedure for requesting blood when a specific type of blood product (e.g., platelets) is needed. New blood recipients go to hospitals or healthcare centers for treatment as a first step. We assume that the requested amount of blood/its products is a rare blood type or that the treatment site has no corresponding blood/blood product. To solve this request, the medical center/hospital sends a request to the hematology hospital to find the corresponding blood/blood product source. At this point, the medical staff will find candidates based on the previous list of donors. They filter information by matching requests received from lower-level hospitals with information available from donors in the system. As a next step, medical staff at the hematology hospital contact the selected candidates to determine if they can donate blood (with a pre-set time). After selecting potential candidates (at least two people), the medical staff conducts a health assessment and blood tests to rule out those with weak health or blood problems at the time request point. Finally, they selected a single candidate to draw blood and transferred it to the respective treatment facility.

C. Limitations of the Two Traditional Processes

As described in the Introduction (i.e., Section I), all data is stored and managed centrally. The information is easily attacked by malicious users resulting in data loss. In addition, it is difficult to evaluate the stored information because all blood/its products data is displayed from the information stored in the central server. In terms of management processes, health care systems lack linkage, i.e., only supporting the link between hematology hospitals and lower-level hospitals. Hence, it is difficult to take advantage of the available blood volumes in the system. All requests are handled single-line (i.e., send directly to the hematology hospital) when an emergency occurs. Information about donors and recipients is easily stolen.

IV. Approach

A. Blood Donation Process based on Blockchain Technology

The biggest difference between the proposed model based on blockchain technology and the traditional model is that all data and retrieval requests are stored in a distributed ledger. Specifically, Fig. 3 shows the storage process of the stakeholder who has a role in the system, i.e., medical facilities (e.g., hospital, medical clinic or hematology hospital); donors; blood products (e.g., red blood cells, white blood cells, platelets); transportation; and blood bank. All data related to blood/blood products are stored, but also all requests for data retrieval from relevant parties (e.g., healthcare workers, carriers) are stored in a log book. dispersion one. This increases transparency for the whole system. Data owners easily know which users can access their data. As for blood records, all information about donors is stored in a distributed ledger. Information about blood type, time, date, and other preservation information are all stored and processed in a decentralized form. Thereby, medical facilities can retrieve and confirm data related to the treatment process. Besides, the data of medical centers/hospitals is also very

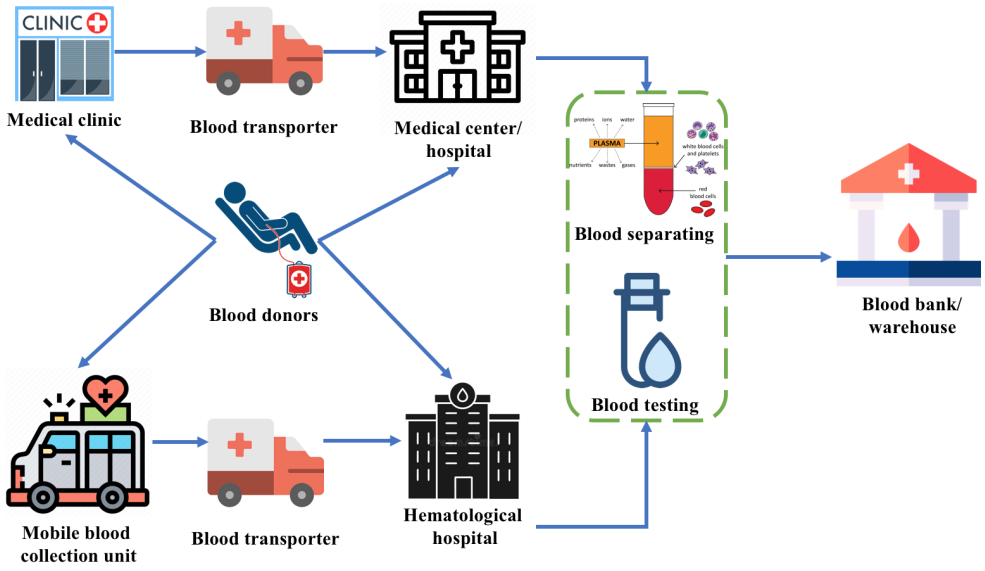

Fig. 1. The Current Blood Donation Process.

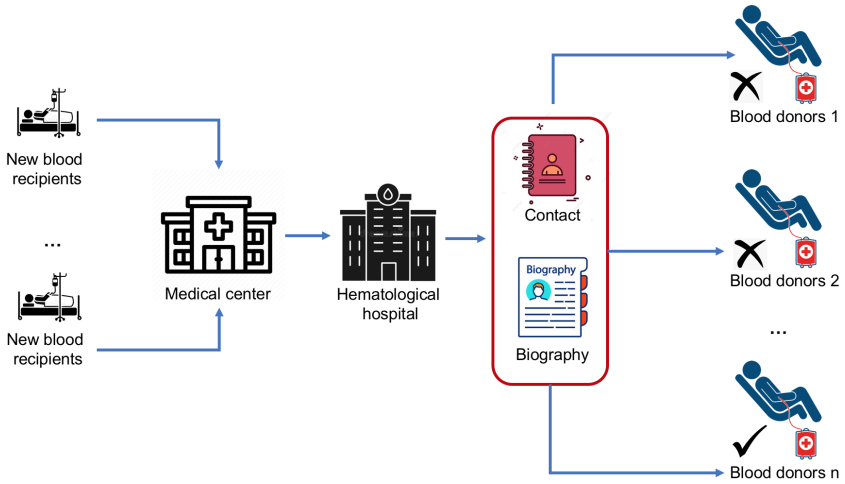

Fig. 2. The Current Blood Request Procedure

important. Instead of local storage, our proposed model is towards a decentralized model, where data can be shared for healthcare purposes. Specifically, medical centers/hospitals can exchange information on blood volume and blood products that can be shared in an emergency, reducing requirements for hematology hospitals. On the other hand, information about donors donated at one medical facility in the past can be easily retrieved by another facility, thereby increasing the quality of treatment for patients.

Fig. 4 details the process of sharing donor data between different health facilities. Specifically, basic information (i.e., biography) about addresses and phone numbers is shared for health care purposes. In addition, information about the amount of blood in stock is shared with other medical facilities. In addition, the conversion process is always up to date if there are any shipping requirements for healthcare purposes. However, the results of donor blood tests are not shared in the current model to limit privacy violations. The information shared by donors is only related to health care needs. In unsatisfactory blood test results, the donor's personal data will be deleted from the distributed ledger. We do not support off-chain executions (i.e., out-of-scope) in the current approach, so data sharers (i.e., medical officers) must secure on-chain data uploads.

B. Algorithms

In the proposed blockchain-based system, we have two main algorithms to control the process. As explained in Section IIB, our methods apply the Hyperledger Fabric platform to conduct the transactions. Moreover, due to these approaches are suitable for a hybrid business environment [32], we exploit JavaScript format for the information structure and the blockchain system for the process structure below::

```
bloodRecords = {
"donorID": donor ID,
```

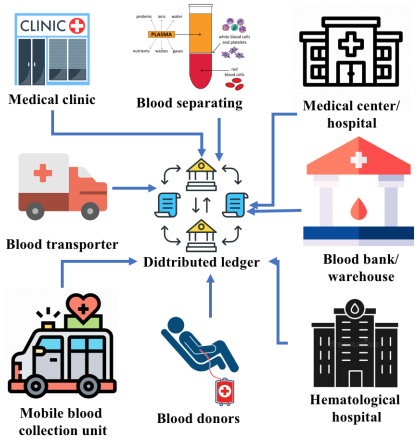

Fig. 3. The Distributed Storage of Blood Donation Process.

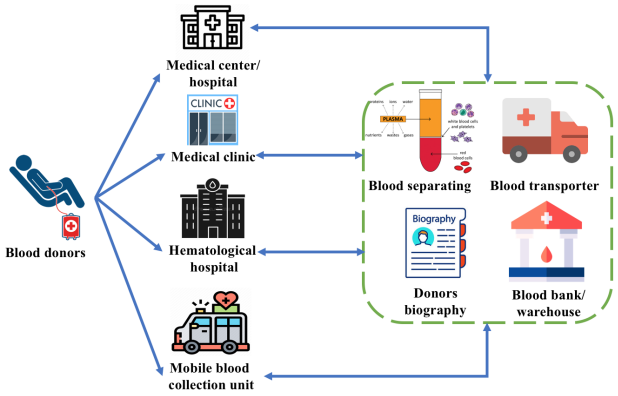

Fig. 4. The Blood Donation Process based on Blockchain Technology.

```
"bloodID": blood and its production ID,
"bloodGroup": blood group,
"bloodProduction": blood production,
"temp": temperature,
"humidity": humidity,
"time": time,
"date": date,
"duration": duration,
"state": 0,
"medicalFacility": locate of medical facility,
"amount of blood unit": 350
};
```

This section targets two main algorithms, including Algorithm 1 describing the data creation to store the blood and its products; whereas Algorithm 2 presents the delivery of blood samples from the donation place to the hematological hospital/medical facility).

Algorithm 1 present all the steps to collect the data relate to donors, blood and its product, storage requirement as well as their metadata (date, time). Blood and its products, once collected, are identified by the donorID of the respective donor. Each blood and its item has a distinct bloodID. This data is unique and not repeated in the ledger; the blood is then stored at the blood bank or the other facility of medical with the identity info being donated. Finally, all the collected data (i.e., blood and its products, their metadata) have updated the status in the ledger.

Algorithm 1 The Blood and its Products Data Creation

```
Input: Donor ID, blood group, blood production, blood donation metadata (i.e., time, date), storage requirements (i.e., temperature, humidity, duration), and blood unit amount
Output: all the related data is stored in the ledger
for blood unit and its metadata do
    storing all the blood unit and its metadata to the ledger;
end for
```

Algorithm 2 shows process of blood and its product delivery from the blood bank or donation place to the recipient (i.e., patient) or clinical center. This process may transfer among the medical facilities in emergency situations. Since the time of storage is limited, they first update the time of remaining usage and then select the oldest one to transfer the destination (i.e., other facilities or recipient). To speed up this process, the shipping company selected and detect the destination address. During the transportation process, the stakeholders are allowed to update the status of the blood units. In particular, the transportation process received several inputs namely, the shipping unit's information, blood units as well as its metadata and the output is the delivery data (time, date, address) and the updated institution of the clinical center (corresponding ID_Center).

Algorithm 2 Delivery of Blood and its Product from Donation Places (e.g., Medical Clinic) to Blood Storage (e.g., Blood Bank)

```
Input: the blood delivery unit's data
Output: the blood delivery' data
for delivery unit do
    for blood and its products do
        Blood_Unit_ID
    end for
    for blood and its products do
        update the new location of the medical center
    end for
end for
return Encrypted hash
```

V. Evaluation

A. Environmental Setting

Our proposed framework is deployed in the Hyperledger Fabric platform. We simulate the environment requirement inside docker containers. This section measures the chaincode's performance of the two scenarios in the algorithms (see Section IV-B), namely initializing and querying data. The experiments are deployed on Ubuntu 20.01 configuration, Core i5 with 2.7Ghz and 8GB RAM.

To collect all information related to the performance, we exploited the Hyperledger Caliper[1]

[1]Hyperledger Caliper deploys the test situations and gathers all the data with respect to the execution. See more related information in this link https://www.hyperledger.org/use/caliper

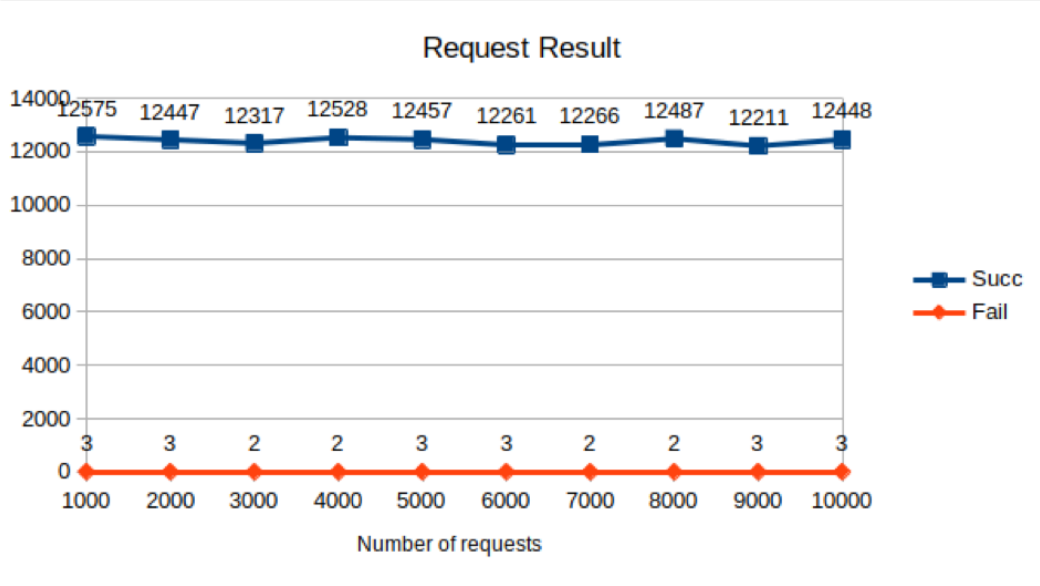

Fig. 5. The Results of the Create Data Functions.

B. Execution Time

In the data creation execution, we measure how long to response time (i.e., seconds) is to create a data request function. In this case, for each worker, they initially created 1000 requests for each second in the system. We stop at 10,000 requests for each second. The #requests are then consistently transferred to the system (i.e., at most 2 minutes of waiting) and slowly rise by 1,000 requests for each performance test until 10,000 requests/s. All the results of these executions are recorded and presented in Fig. 5. From this figure, we are able to detect that the #requests w.r.t successful execution is high compared to the other ones (especially the failed requests are tiny). In fact, the number of successful execution requests is higher than 12,000 request/s; in contrast, this amount of unsuccessful ones is a range of 2-3 requests.

Fig. 6 shows the outcomes of requests measurement that execute the update methods for blood and its products. #Workers rose by 2 in this attribute which is higher than the beginning data creation requests; the number of requests. In the same situation, we start from 1,000 requests/second and increase another 1,000 requests/second until stop at 10,000 requests/second for each worker. The number of successful execution requests increased not noticeably, range 15K to 16K requests for each second. However, compared to the initial process with only one worker, the number of failed requests is higher. To explain this point, we consider the number of workers who creates the request (i.e., the number of workers has increased) and analyse the latency aspect of the system (see more detail in the next subsection). From this point, we can claim that the time of response is longer when the number of users is increased.

For the data query, Fig. 7 describes the outcomes and quantity of requests to query the blood and its products recorded in the distributed ledger. In the last scenario, we increase the number of workers to 10 workers[2]. Similar to the two above scenarios, we start from 1,000 requests/second and increase another 1,000 requests/second until stop at 10,000 requests/second for each worker. According to the outcomes of Fig. 7, we found that the results are still steady. Specifically, #succeeded requests varies from the lowest rank, around 37K, to the highest, approximately 42K requests. Whereas #unsuccessful requests for data query are at most one request (negligible). This further proves the outstanding advantages of the distributed system compared to the traditional centralized ones.

C. Latency

In this second scenario, the article gauges and assesses the latency situation to three functions: data initialization, query, and update.

Fig. 8 indicates the latency of the information initialization function of the blood samples. In which the majority of the three latency levels are steady. Specifically, the highest latency index varies in the range of 500s when the quantity of requests rises from 1000 to 10,000 requests. However, a certain case happens in case 6 with 6000 requests/s; the latency increases significantly at 2240.21s, which may arise when the system has a bottleneck in processing transactions, so arriving transactions take more time to complete processing. Nevertheless, at Min and Avg latency indicators, the processing time for requests is still stable at the level of 363.16s/request and 0.64s/request, respectively.

The latency of data query requests is indicated in Fig. 9. The greatest latency index varies quite importantly from 1.41s/request to 4.64s/request. Nonetheless, the system's processing time progressively diminished and stayed stable when the number of requests rose from 1000 to 10,000. The most noteworthy value is 4.65s for a total of 2000 requests.

[2]We assume that workers are the doctors/nurses/officer in the medical facilities

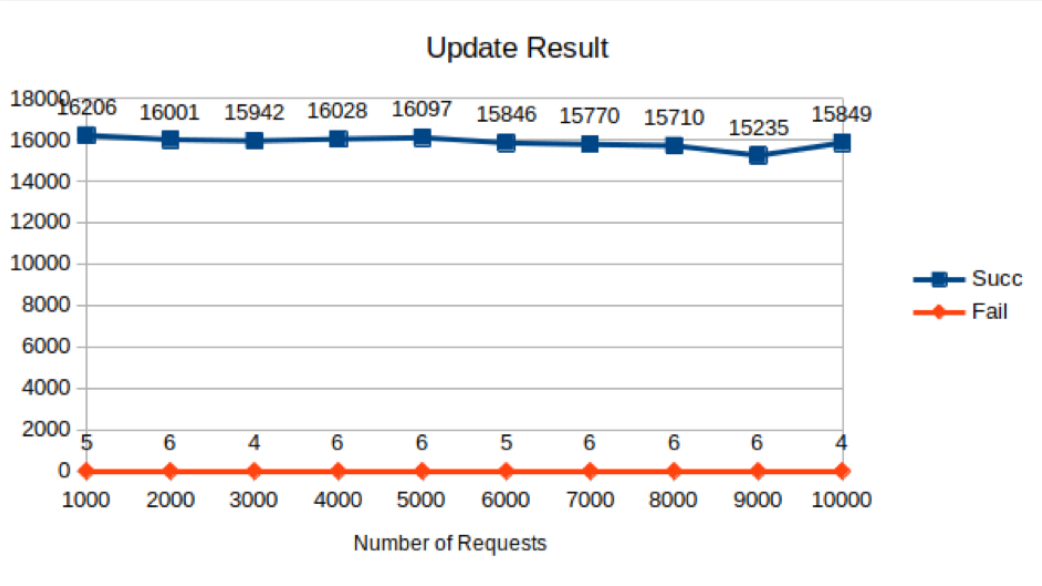

Fig. 6. The Results of the Update Data Functions.

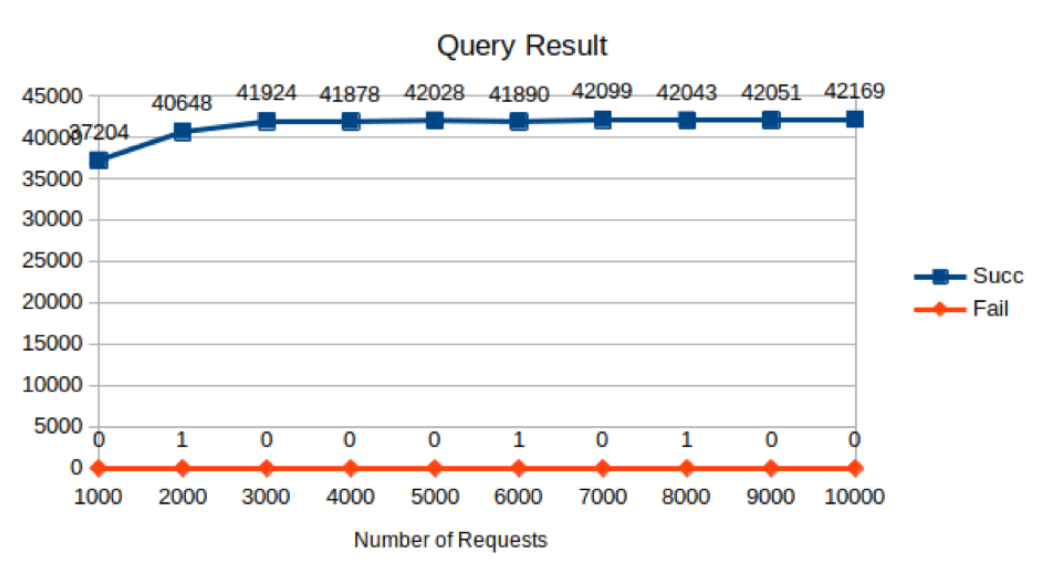

Fig. 7. The Results of the Request Data Functions.

Fig. 9 depicts the latency of requests to query information of all users in the system. The lowest latency 0.01 - 0.02 and average latency 0.19 - 0.82 are negligible even when the quantity of requests rises to 10,000 requests at the same time. The highest value of Max latency is 4.65s, correspondent with the scenario of 10 users delivering 2000 requests to the system at that point.

Ultimately, the latency of the data update function of the blood samples is also depicted in Fig. 10. The latency of the requests is kept stable when the number of requests increases from 1000 to 10,000. However, the processing time is at the most significant rank in comparison with 2 requests: to initiate and query data; this occurs when the system begins to query the information and then upgrade the data fields requesting data and stores new ones. The highest value of Max Latency is 795.4s for 1000 requests; moreover, the other cases are steady with a postponement of over 700s.

VI. Discussion

A. Remarkable

It is easy to see that the execution time of initialization, query and surrogacy requests is quite stable and does not depend on the number of requests sent to the system per second. However, they show the opposite when analyzing the response delay. Specifically, we recorded anomalies in two specific cases (i.e., initialization and query), while the latency of on-chain data updates is quite balanced and does not depend

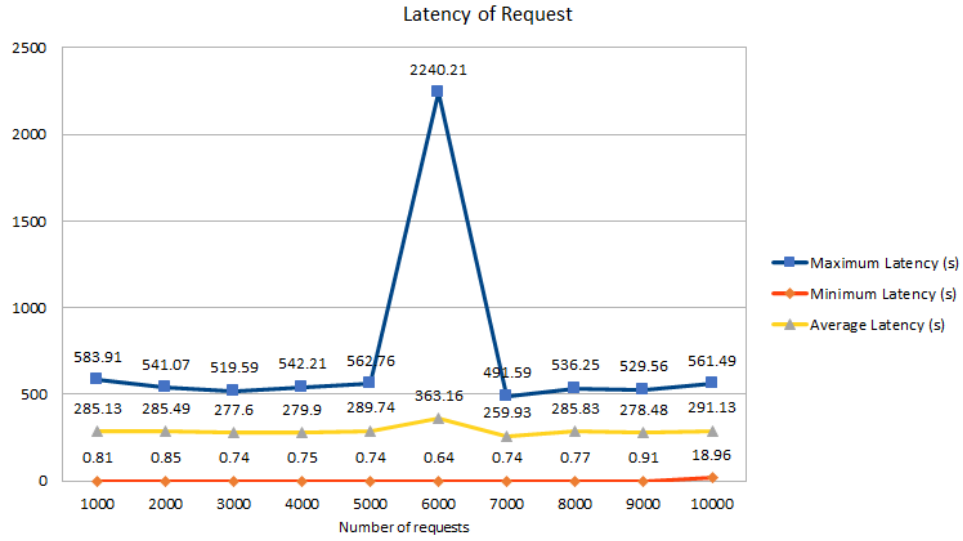

Fig. 8. The Latency of the Data Initialization Functions.

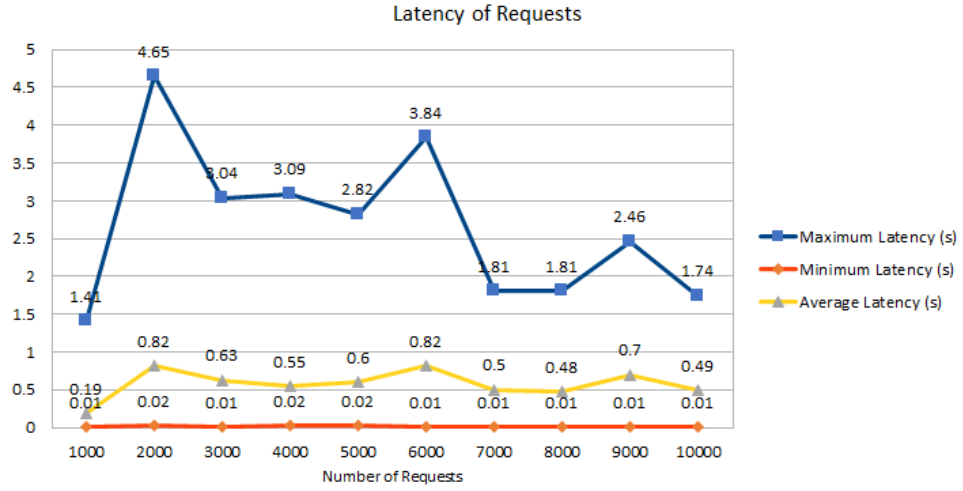

Fig. 9. The Latency of the Request Data Functions.

on the number of responses per second. Specifically, in the case of 6000 requests/second, the latency spikes and drops immediately for the next case. We assume that a problem may occur in the in-chain processing, severely affecting the system's response time. Proof of our claim is that latency tends to be stable from the 7000 requests/second (see Fig. 8). To prove the above statement, we closely observed the peer pairs with transactions during operation and discovered a serious error affecting the whole system. Specifically, when a peer belonging to a specific transaction has not completed the execution request, the whole system must wait until that peer completes, seriously affecting the whole system. We further assume that executing requests on a system that is limited to our hardware equipment is responsible for the above risk.

To answer this question, we continue to observe in the query scenario (i.e., Fig. 9) and update (i.e., Fig. 10) on the data. whether on-chain. Our assumption is not entirely correct for two reasons. The first reason comes from a detailed assessment of client data queries' response time. Specifically, the 2000 milestone is unusually higher than the other observed milestones. This leads to concerns about process interruptions and system-wide effects (since 2000 requests/seconds is not a theoretically alarming milestone). However, when we observed two other anomalies in the same scenario (i.e., 6000 and 9000 requests Fig. 9), we noticed a gradual decrease in latency. This proves the opposite of the assumption above that latency is inversely proportional to the system's processing speed (i.e. the more processing, the more latency increases and vice versa). This proves that the latency of the whole system does not depend on the system configuration but is affected by the sequence processing (i.e., priority).

In the third scenario, we ignore the peers when there is a

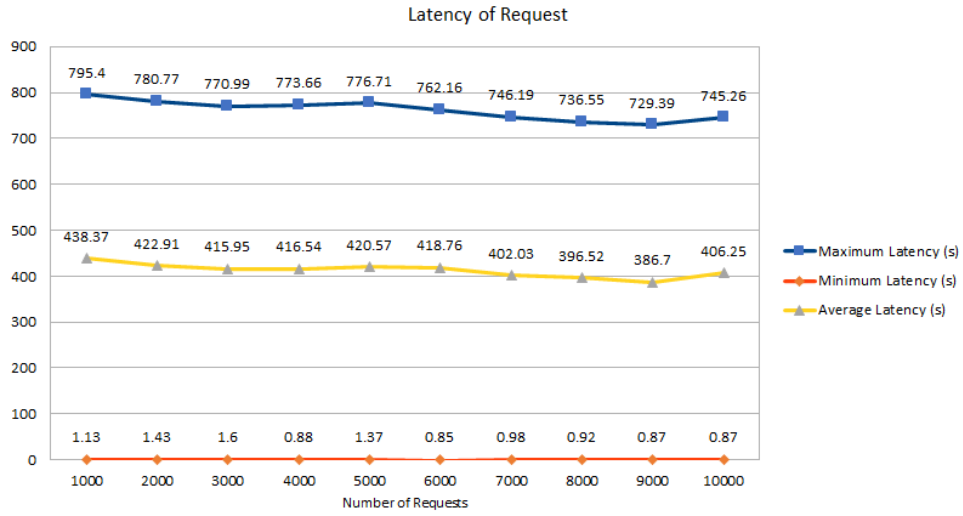

Fig. 10. The Latency of the Update Data Functions.

problem in a corresponding transaction to substantiate these remarks. Fig. 10 proves that our assessment is correct as changes in the number of requests do not affect system latency.

B. Security and Privacy Discussion

The blockchain has a key role in the modern system, which satisfies the transparency and availability conditions for the supply chain [34], [35], [14]. However, the blockchain-based system has some troubles documented in [36], particularly in the security and privacy perspective. To enhance the security and privacy matters in the blockchain-based blood donation system, we consider the authorization for the parties within the same transaction and the flexibility in the clinical environment.

For the authorization factor, we will take the advantage of attribute-based access control (ABAC) [37], [38] to handle the access control process. The primary advantage of this model is that only accepted users can get to the released data. Moreover, the query rewriting can be utilised for a complicated context where the released data is disseminated to numerous users [39], [40]. Eventually, a few methodologies split the original policy into sub-policy [41], [42] (i.e., public and private policy) to assure that the information is only accessed through permission even the parties in the same transaction.

Finally, comparing to the previous papers, this is the first approach supplying the proof-of-idea to target blood donation management. In other words, several papers pay attention to the general problems in the healthcare system instead of focusing on the specific concern, i.e., blood management. This paper underlined BloodChain as a technology to manage the benefits of this system. We also show the outcome of our suggested model derived from some experiments.

VII. Conclusion

The article applies the benefits of Blockchain technology (i.e., transparency, decentralized storage) to propose a blood and blood product processing process based on the limitations of the current traditional process in Vietnam. Vietnam. The paper provides a proof-of-concepts based on the Hyperledger Fabric platform, which stores information about blood and its products during the storage and transport processes. The information is stored transparently for easy verification in transit and storage. This is an initial effort in applying the benefits of blockchain technology in designing and managing the supply chain of blood and its products for Vietnam in particular and developing countries in general.

In future work, we aim to manage stakeholders based on constraints defined in the form of Smart Contracts. Moreover, this research result is only the first step to build a system based on blockchain technology in a real environment. Therefore, we aim to deploy the proposed model for exporting in more complex scenarios where there are multiple-role of users and off-chain executions (i.e., out of scope for current version) processes of the medical facilities.

***Abstract*— The exchange of goods between countries is growing, contributing to the promotion of logistics-related technologies. More and more systems are adopting advances in science and engineering to reduce manual handling steps, thereby reducing transit time. Letter-of-Credit (LOC) is a standard method where the parties involved will enter into agreements for the sale and exchange of goods. Specifically, each party will receive a set of original documents and does not need to meet face-to-face under the bank's witness. The process brings many benefits in terms of time and reduces records processing. However, the system faces a lot of risks when one of the parties is dishonest. On the other hand, the traditional LOC systems face a lot of risks related to the transparency of information about the goods, and also the supplier may lose the goods (e.g., 4/100 Vietnamese cashew nut containers are lost. stuck in Italy) or deposits in the hands of shipping companies (e.g., GNN Express - Vietnam) and many more. To this end, many research directions have exploited blockchain technology and smart contracts. Specifically, all information related to the transaction between the supplier and the demander including package, time, and delivery location. However, there needs to be a mechanism to ensure the smooth implementation of smart contracts, specifically for sanctioning when there is a conflict between a supplier and a demander. This role should be considered for the transaction manager, who directly designs and is responsible for their smart contracts. Currently, there is no mechanism to guarantee all interests of the parties involved in non-bank transactions. To increase the processing capacity and integrate with the Blockchain system, we propose the Letter-of-credit Chain that defines the agreements between the parties in international trade. We also deploy the proof-of-concept of the Letter-of-credit Chain on the three EVM-supported platforms (i.e., under ERC20), namely, Ethereum, Binance Smart Chain, and Fantom. By evaluating the actual execution of Gas for each platform, we found that our proposed model had the cheapest fee when deployed on the Fantom platform. Finally, we share the deployment/implementation of these platforms' proof-of-concept to encourage further future research.**

***Keywords*—Letter-of-Credit; blockchain; smart contract; authorization; Ethereum; Fantom; Binance smart chain**

I. Introduction

It is undeniable that the development of technology has changed almost completely the approach to a business organization as well as a management strategy to meet customer requirements [1]. The exchange of goods no longer takes place in a narrow area limited in area, but instead, companies can transport and export/import goods from all over the world. Traditional international trade models were originally built on trust. Specifically, in the first stage, the supplier will bring the goods to another city or country to find a demander. It is clear that this model is very risky for both the supplier and the demander. In particular, demanders may purchase inferior products because all constraints are not controlled; on the supplier's part, they may lose the entire goods if the demander refuses to pay or the product is past its expiry date due to the time-consuming shipping process [2]. In order to solve the risks of transporting the goods, the supplier will authorize the transport company when transporting the goods to the demander (i.e., minimizing risks in transportation and transit time), i.e. that the parties can communicate indirectly through intermediaries instead of having to meet face-to-face - this also reduces the costs incurred. Due to the growing and expanding trade, where the need to transport goods increases and the transit time decreases. Therefore, both parties will authorize a trusted third party called a transaction manager (e.g. a bank). All contractual requirements and constraints must be accepted by all three parties (i.e. supplier, demander and third party). The role of the intermediary is assigned to the Bank (called Letter-of-Credit - LOC). Specifically, the demander is provided with an economic guarantee from the bank that grants credit to the exporter of the goods [3]. The supplier receives the money only if and only when the demander receives the goods and provides all statements related to the shipment confirmed by the transaction manager. An important disadvantage of the traditional LOC model is that it is easy for suppliers to lose goods if they work with the untrusted transaction manager and malicious demanders. One of the most examples of this problem is introduced in Section IV, which present the cashew nut export from Vietnam to Italy in 2022[1].

E-commerce has enhanced the process of transporting goods across borders thanks to the exchange of routes through e-commerce platforms. This process is made faster and brings many benefits to both the supplier and the demander. A series of e-commerce platforms (e.g., Amazon, Alibaba) have largely changed users' shopping habits, while shipping companies (e.g., FedEx, ASL) have also accelerated the conversion process. goods. The freight conversion process is based on a Cash-on-Delivery (COD) shipping company, where the carrier will play an extremely important role in delivering and receiving the demander's funds. Payment to the supplier is the responsibility of the carrier. Most shipping companies will keep the demander's money before handing it over to the supplier. If the shipping company goes bankrupt or refuses to pay, the supplier will lose money [4]. In fact, a series of shipping companies have appropriated the supplier's money (e.g., GNN Express).

[1]https://english.vov.vn/en/economy/vietnam-requests-italy-to-investigate-suspected\ \-cashew-nut-export-scam-post931226.vov

To solve these challenges, several Blockchain-based approaches have been developed to replace the traditional LOC model. These new systems provide a secure platform for both suppliers and demanders, aka decentralized marketplaces/exchanges [5]. These protocols focus on dealing with issues related to suppliers, demanders, and carriers (see details in the III section). However, these models still do not meet the requirements of international trade, where the role of the transaction manager is extremely important [6]. To solve this problem, we introduce Letter-of-Credit Chain, a system based on Blockchain and smart contracts to solve the insurance problem for cross-border exchange. Letter-of-Credit Chain builds three main user groups, including suppliers, demanders and transaction manager. This model consists of eight main steps, from the supplier creating the package/goods to the order being delivered to the demander and the order arrival. Besides, we develop a role-based access control model (i.e., authorization) to define logical constraints in smart contracts to maintain the stable operation of the system. To define the logical binding between stakeholders on smart contracts, we also exploit the Solidity. To evaluate the Chain of Credit, we deployed a test model for our proof-of-concept on all three of the most popular platforms that currently support the Ethereum Virtual Machine (EVM) environments, including Ethereum, BNB Smart Chain, and Fantom (see [7] for further info). To support the current letter-of-credit system (i.e., International Trade), we share our proof-of-concept implemented on all three platforms.

Following this section, we present the background of blockchain technology and its platform in Section II. Whereas, Section III describes the summary, limitations and challenges of the current approaches. Then, the two next sections define the problem statement of the traditional model of the Letter-of-Credit approach and also introduce the architecture of Letter-of-Credit Chain Architecture based on the blockchain and smart contract in Sections IV and V, respectively. Section VI describes the proof-of-concept of the Letter-of-Credit Chain, i.e., data structure, execution algorithm, and authorization. Last but not least, Section VII focuses on the effectiveness proof via the evaluation process based on deploying Letter-of-Credit Chain in the ETH, BNB, and Fantom platforms. Finally, we continue with the conclusion and the future work of the article in the last section.

II. Background

A. Blockchain Technology

Blockchain was popular after the introduction of Bitcoin by Nakamoto in 2008 [8] and is usually represented as a transparent, trusted, and decentralized ledger. The blockchain-based system manages transaction data on multiple computers simultaneously on a peer-to-peer network. Therefore, it creates a secure connection between the transacting parties (i.e., receiver and money transmitter) without the need for a traditional third party (e.g., a bank) [9].

The most popular types of blockchains today include Public, Private, and Hybrid (Called Consortium). In the first type, the two best-known examples of public blockchains currently are Bitcoin and Ethereum. Any users (including hidden ones) could join to Blockchain network to view content, execute a new transaction, or check the integrity of the existing blocks. For private blockchains, some common examples of this type include GemOS, MultiChain, Ripple, and Eris. Unlike the Public type, they only support authorized users who can join the network as well as execute, check transactions to the block or create a new block [10]. Combining the two, a semi-private (called Consortium) blockchain is defined as the boundary between public and private ones. It strives to achieve outstanding characteristics in each category - specifically, Consortium blockchains are often deployed for enterprises to ensure their security and interact with their partners for better business. Two famous examples of hybrid blockchains are Hyperledger Fabric [11] and Ethereum [12] (i.e., which allows the creation of Golang-based federated blockchains).

B. Blockchain Platform

1) Ethereum: Ethereum [13] is a decentralized blockchain platform for running smart contracts with the support of the Solidity programming language. Similar to other high-level languages (e.g., Java), Ethereum is executed by the Ethereum Virtual Machine (EVM). Ethereum supports decentralized finance (DeFi) protocols where smart contract-based constraints are provided.

2) Hyperledger Fabric: Hyperledger Fabric [11] is open-source enterprise-grade permission designed for large-scale commerce. This platform is designed based on distributed hyper-ledger mechanism and supports both public and private blockchain platforms simultaneously. Hyperledger Fabric and Ethereum together perfect Turing. However, instead of executing smart contracts on the EVM virtual machine like Ethereum, Hyperledger code is executed in Docker containers called ChainCode. It allows developer applications to deploy smart contracts with minimal overhead. Another advantage over Ethereum is that it supports high-level programming languages (i.e., Java and Go) instead of relying on Solidity. With this advantage, Fabric has facilitated the development and maintenance of the platform. By not having to switch to a new language, Fabric has helped to reduce operating costs (e.g., system maintenance, information storage and querying within the blockchain).

C. Smart Contracts

A smart contract (Ethereum) or chaincode (Hyperledger Fabric) is a term that describes a set of protocols that assist developers in defining terms and agreements in transactions between the parties to the contract. The entire process of smart contracts is not dependent on external interference and is performed automatically based on the support of Blockchain technology. In a Dapp, the terms and constraints of a smart contract are recorded in the language of a computer and are equivalent to a legal contract.

1) Characteristics: The Smart Contract routine has the following characteristics:

- **Distributed**: Replicated and distributed in all nodes of the Ethereum network. This is one difference from other solutions based on centralized servers.
- **Deterministic**: Only take actions that they are designed to perform if the conditions are satisfied. Be-

sides, the results of Smart Contracts remain the same no matter who the executor is.

- **Automate**: Able to automate all kinds of tasks, and it works like a self-executing program. However, in most cases, if the Smart Contract is not activated, it will remain "inactive" and will not perform any action.
- **Non-modifiable**: Smart Contract cannot be modified after deployment. They can only be "deleted" if this function has been added before. Therefore, it can be said that Smart Contract is like an anti-forgery code.
- **Customizable**: Before deployment, Smart Contracts can be encoded in different ways. So, they can be used to create many types of decentralized applications (Dapps). Ethereum is a blockchain that can be used to solve any computational problem (Turing complete).
- **No need to rely on trust**: Two or more parties in a contract can interact through a Smart Contract without knowing or trusting each other. In addition, blockchain technology ensures the accuracy of data.
- **Transparency**: Since Smart Contracts are based on a public blockchain, no one can change their source code, although anyone can view it.

2) How Smart Contracts Work: The working principle of a smart contract can be compared to a vending machine. It only automatically executes pre-programmed commands.

First, assets and contract terms are both encrypted and transferred into a block on the Blockchain. Then this smart contract will be distributed and copied by the nodes working on that platform. After receiving the deployment order, the contract will be deployed according to the predetermined terms. Simultaneously, the smart contract will also automatically check the implementation of the commitments stated in the agreement.

- Cost savings: Pay a minimal fee to the blockchain network, saving fees.
- Flexibility: The terms in the contract are handled flexibly and efficiently for the user.
- Transparency, clarity: all payment transactions can be traced, but payment transactions will not be reversed at all, and all transactions will be recorded on the blockchain with extreme clarity.
- High Reliability: Once the contract is completed, no one or a party can interfere in the execution and negotiation of the contract.
- Fast, convenient: can set up and execute a contract in seconds, install for many people simultaneously, and use it many times.

3) Solidity: Solidity is an object-oriented, high-level language for implementing smart contracts. Smart contracts are programs that oversee the conduct of records inside the Ethereum state. Solidity was influenced by JavaScript, C++, and Python and is intended to focus on the Ethereum Virtual Machine (EVM).

Solidity is statically composed and upholds inheritance, libraries, and complex client-characterized types, among different highlights. With Solidity, you can make contracts for utilizations like democratic, crowdfunding, dazzle barters, and multi-signature wallets.

4) Web3.js: Main steps in creating blockchain applications with Ethereum:

- Innovative contract development - composing code that gets sent to the blockchain with the Solidity programming language.
- It is creating sites or customers that cooperate with the blockchain - composing code that peruses and contains information from the blockchain with smart contracts.

Web3.js empowers you to satisfy the following duty: creating customers that communicate with The Ethereum Blockchain. An assortment of libraries permits you to perform activities like sending Ether starting with one record and then onto the next, peruse and compose information from shrewd agreements, make smart contracts, and thus significantly more.

If you have a web advancement foundation, you may have utilized jQuery to settle on Ajax decisions to a web worker. That is a decent beginning stage for understanding the capacity of Web3.js. Rather than using jQuery to peruse and compose information from a web worker, you can utilize Web3.js to peruse and keep in touch with The Ethereum Blockchain.

Web3.js converses with The Ethereum Blockchain with JSON RPC, which means "Remote Procedure Call" convention. Ethereum is a distributed organization of hubs that stores a duplicate of all the information and code on the blockchain. Web3.js permits us to make solicitations to an individual Ethereum hub with JSON RPC to peruse and compose information for the organization. It's similar to utilizing jQuery with a JSON API to peruse and manage data with a web worker.

5) Remix: The remix is a Solidity IDE used for writing, compiling, and debugging Solidity code. Solidity is a high-level, contract-orientated programming language for writing clever contracts. It is affected by popular languages such as C++, Python, and JavaScript.

Ethereum is a general-purpose blockchain, which is more suitable for using advanced scripts (also known as smart contracts) to describe business logic. Ethereum is developing as a decentralized or global computer that combines blockchain functions with a broader perspective. As a reliable machine with a complete Turing contract engine.

Benefits of using remixed IDE to compile and deploy smart contracts:

- Compile the contract in Remix IDE.
- See a few warnings issued with the help of using a compiler while high-quality practice is not followed.
- Contract implementation on JavaScript EVM (Ethereum Virtual Machine).
- Make transactions with the implemented contracts.
- See example reading and writing in the IDE terminal.

D. Our Selection Platform

As mentioned in the Introduction section, this article deploys the proof-of-concept of the Letter-of-credit Chain on three platforms, namely, Ethereum, Binance Smart Chain, and Fantom[2].

1) Binance Smart Chain: Binance Smart Chain (BSC) is an enhanced version of the original Binance Chain version. BSC is designed to be a parallel platform to the first version. Similar to Ethereum, BSC offers Dapp developers options to support smart contracts and can be deployed on other Blockchain platforms that support EVM.

2) How does Binance Smart Chain Work?: BSC applies a hybrid model of Proof of Authority and Proof of Stake - called Proof of Staked Authority (PoSA). Validators for the BNB system will put a certain amount of BNB into the system and receive a bonus after each successful validation.

Binance Chain and Binance Smart Chain are cross-chain compatible and designed to be completely in sync. With BSC, assets can be moved between blocks thanks to the fast transaction capabilities of the original version and smart contracts of the improved version (i.e., EVM integration). Specifically, Binance Chain supports two tokens (BEP-2 and BEP-8). In addition, Binance Chain can also be swapped with Smart Chain BEP-20 tickets. So, thanks to ERC-20 contract compatibility, DApp developers on other EVM-enabled platforms can switch to Binance Smart Chain relatively quickly.

III. Related Work

Several protocols exploited the blockchain system's advantage to improve their transaction among the peers or components. Some of them considered Cash-on-Delivery (COD) model [14], [15] (i.e., suppliers, demanders), the medical care system [16], [17], [18] (i.e., doctors and patients), health care emergency situation [19], [20] (i.e., medical staff and the patients' friends or relatives), or blood donation - humanitarian blood transfusion (donors and recipients) [21], [22] and much more.

To prove the improvement of Blockchain for traditional shipping (i.e., Letter-of-Credit shipping (called LOC) or COD) Ha et al. [6] described the current shipping system faced the massive drawback (e.g., dependence on trusted third parties, goods/order management, complicated payment processes among the parties in the same peer or ecosystem, losing the package and deposit for supplier and demander, respectively. To this end, Le et al. [23] suggested that blockchain technology could fill these gaps via the usage of smart contracts and decentralized management in COD general and LOC special. For instance, the Ethereum ecosystem proposed a method called `localEthereum` which is introduced to support the transaction or DeFi Dapp between the suppliers and demanders [24]. Similarly, `OpenBazaar` [25] developed based on the `localEthereum` extension, in which this protocol defined the demander and supplier-sponsored. However, compared to `localEthereum`, the main difference between `OpenBazaar` was that the `OpenBazaar` involved the three parties: the supplier, the demander, and the moderator (i.e., a new role in control).

Moreover, a new protocol targeted at helping transport products from suppliers to demanders [26] exploited the ETH-based transaction to propose a COD/LOC mechanism. In particular, this tool considers the new actor (i.e., shipper) rather than focusing on only the transaction between the demander and supplier as in the previous approaches above. However, this approach still has the main drawback is that it required trusted behavior from the shipper (i.e., new role) not only in this task but also the interaction between the supplier and demander (i.e., how can be proof of this level is still the open question). Furthermore, there are impossible to assume that the stakeholders are trusted for all their behavior in the system/network. Hence, this is the main limitation of these approaches.

To increase the shipper's role in the blockchain-based approaches, some studies (e.g., [27] and [28]) introduced carriers in the decentralized marketplace, rather than focusing only on demanders and suppliers. These works developed the transportation processes as well as provided the mechanisms to promote and ensure the benefit of the stakeholders. These models also penalized any parties who intentionally commit fraud; therefore, the demanders' and suppliers' interests are enhanced. However, the scope of these models' application has limited to the distance of shipping where the transaction occurs in the same city or at most in the same country. Last but not least, they have not considered the conflict issues among the parties in the same transaction, for instance, suppliers and demanders.

Compared to the existing works, our proposed model (i.e., Letter-of-Credit Chain) introduces a trusted international trade channel that connects all the suppliers and demanders around the World (among the different countries). We aim to reduce the conflict among the parties in the system to solve the two case studies, namely, GNN Express as well as cashew nut export problems as present in the Introduction section.

IV. Problem Statement

Fig. 1 describes the problem of the cashew nut export from Vietnam to Italy in 2022.

The Vietnamese enterprise (Exporter) first signs a contract with the Italian importer to specify the contract's bank and port of destination. The Exporters then deliver goods to shipping lines and receive "original documents". Apter that, the Exporter receive the original documents and bring them to a bank in Vietnam (a.k.a Exporter's bank) to ask this bank to collect money. The Exporter's bank next send this set of original documents to the importer's bank in Italy. At this point, the Italian importer's bank will pay the exporter's bank and give this original document to the Italian importer for them to receive the goods.

However, the problem with this is that the importer's bank in Italy did not receive the original set of documents, but they get photocopies instead. Thus, this bank refuses to transfer money.

[2]Since selected platforms supporting the EVM are similar in the execution process (BNB Smart Chain and Fantom), this section gives summarize of the Binance Smart Chain in a nutshell.

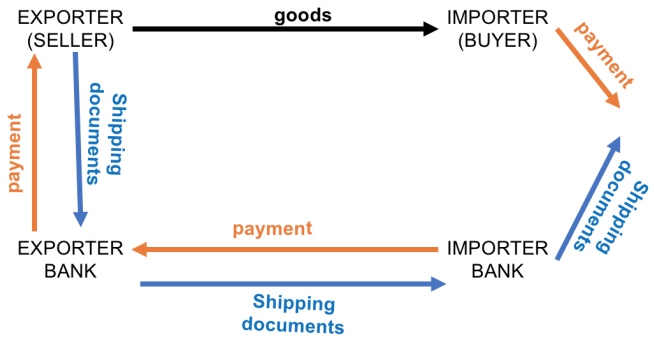

Fig. 1. The Problem Statement of the Cashew Nut from Vietnam to Italy in 2022.

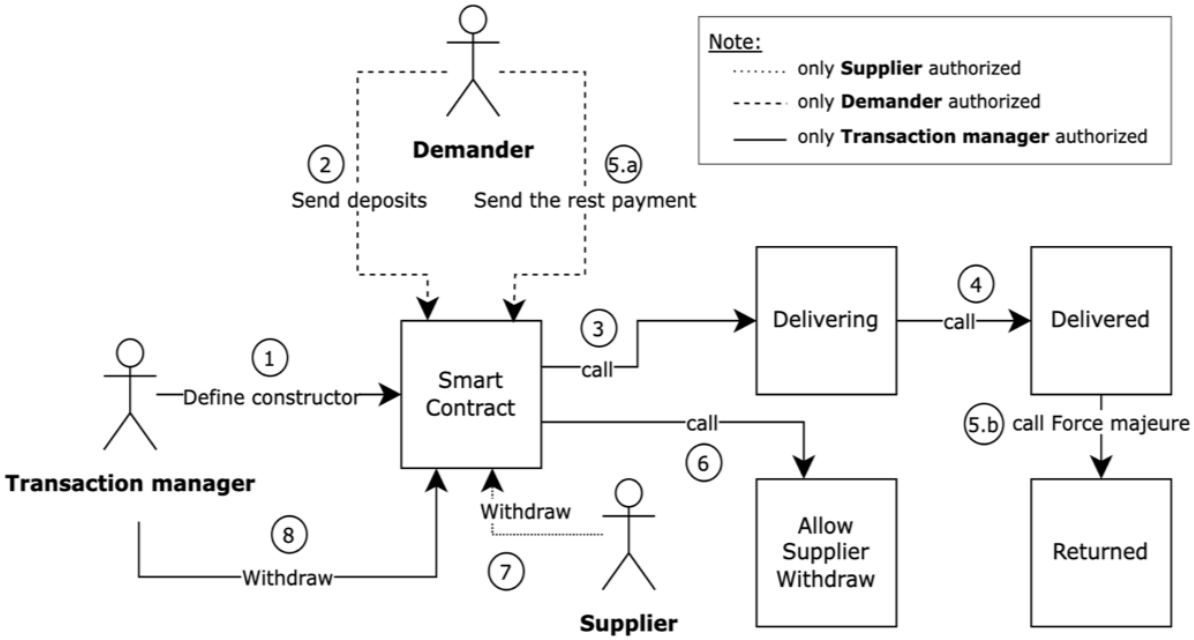

Fig. 2. Letter-of-Credit Chain Architecture.

V. Letter-of-Credit Chain Architecture

Fig. 2[3] shows Letter-of-Credit Chain architecture including three main components, namely supplier, demander, and transaction manager.

- *supplier*: The party who provides goods or services to another organization. In Letter-of-Credit Chain architecture, the Supplier can withdraw the money after the goods are delivered to Demander via the smart contract.
- *demander*: Who makes requests for an item or service in the platform economy. In this architecture, the Demander must send the amount of deposit as well as the remaining money to the Suppier via smart contract. In the case that Demander won't send the remaining amount, their deposit is lost. We also consider this point in our experiments (see Section VII).
- *transaction manager or Trustee*: the third party who manages both traditional contracts and smart contracts. *TransactionManager* controls the two flows i.e., the order to Demander and the money to Supplier.

The TransactionManager define the smart contract (a.k.a. the tradition contract) and upload this on the Letter-of-Credit Chain [Step 1]. This can identity the address on the corresponding blockchain network. The second step show that the must be send the deposit to certain smart contract defined by the TransactionManager. In our approach rather than one-time-transfer the Demander can split this as multiple amount; however the sum of these amounts must be higher than 50% of the order's price. The order status is changed to Delivering in the third step, whenever the *TransactionManager* confirm that the shipping function is called. In the next step (i.e., the order delivered) we deploy this as off-chain. In the current version, we do not focus on the off-chain tasks in the whole transportation process. Step 4 calls the delivered function if and only if the order has arrived. We have two cases in this point,

[3]In this model architecture, we do not refer to off-chain tasks.

i.e., the Demander transfer the remaining amount in Step 5(a) or does not transfer in Step 5(b). Regarding to the behavior of the Demander we have two corresponding solutions that are i) if they transfer the remaining, the Supplier can withdraw their money for the goods/order via Allow Supplier Withdraw function in Step 6; otherwise the Demander lost their deposit and this amount automatically send to Supplier as shown in Step 7. Finally, the *TransactionManager* withdraw their amount based on the smart contract fee execution in Step 8 and does not depend on the Demander decision.

VI. Implementation

A. Data Structure

Fig. 3 describes the Letter-of-Credit Chain framework' data structure. We only consider the key information (i.e., Order or Goods) in this paper. The remaining ones are described in our code. Please follow the deployment of our implementation in the three platforms (see Section VII for more detail).

B. Algorithm

Letter-of-Credit Chain framework (i.e., Algorithm 1) executes from top to bottom. First, the TransactionManager add the smart contract code to the blockchain network. This point is created by the TransactionManager, but we can easily to detect the meaning of their requirement. In the next step we set up current_State; State.Created; and balance_Received = 0. When the Supplier uploads their orders to the network and finds the corresponding Demander (see lines 4 to 15) the Demander must sends deposit money to the smart contract. At this point, Algorithm 1 updates balance_Received as well as the smart contract also logs the history of the transaction into payment_Histories parameter. If the order on the delivering (current_State = State.Hold or State.Complete_Payment), the state of current order current_State equal to State.Delivering value (see the if command lines 16 - 19). For the next If condition, the order has delivered, we update current_State = State.Delivered (lines 19-21)

The while command to verify whether the Demander send the remaining or not (see V for more details). Lines 30 and 31 show the Demander paying the remaining amount of money and our process; otherwise, please follow lines 32 and 33. Finally, the Supplier receives their amount (see lines 35-37) as well as the TransactionManager (see lines 38 - 40)

Moreover, the Letter-of-Credit Chain also provides the RBAC service for the three actors in the system. In this service, we allow the authorized partner can call the corresponding function/method. The list of functions is presented in our paper public in [7]. However, the data and meta data of the transaction is still public for all the stakeholders. Please follow our analysis w.r.t security and privacy which describes in Section VII-D

Algorithm 1 Letter-of-Credit Chain Execution

```
1: Input: contract_Name, Transaction_Manager, Demander, Supplier, order_Amount, tax_Amount, deposit_Amount
2: current_State = State.Manager_Withdrawm
3: Begin: set balance_Received = 0; set current_State = State.Created
4: while Demander transfers deposit>=deposit_Amount do do
5:    update balance_Received
6:    storing payment transaction to payment_Histories
7:    if balance_Received<deposit_Amount then
8:       update current_State = State.DEPOSIT
9:    else if balance_Received>=deposit_Amount && balance_Received<order_Amount then
10:      update current_State = State.HOLD
11:   else
12:      update current_State = State.COMPLETE_PAYMENT
13:   end if
14:   storing order's status to orderStatus
15: end while
16: if current_State == State.HOLD or current_State == State.COMPLETE_PAYMENT then
17:   manual update current_State = State.SHIPPING
18: end if
19: if current_State == State.SHIPPING then
20:   manual update current_State = State.SHIPPED
21: end if
22: while receiving the rest payment until the deadline do
23:   if balance_Received == order_Amount then
24:      update current_State = State.COMPLETE_PAYMENT
25:      manual update current_State = State.CAN_WITHDRAW
26:   else
27:      manual update current_State = State.NONPAYMENT
28:   end if
29: end while
30: if current_State == State.CAN_WITHDRAW then
31:   set amount_Withdraw = balance_Received - tax_Amount
32: else if current_State == State.NONPAYMENT then
33:   set amount_Withdraw = balance_Received - 2*tax_Amount
34: end if
35: while Supplier withdrew money do
36:   current_State = State.WITHDRAWN
37: end while
38: while TransactionManager withdrew money do
39:   current_State equal to State.MWITHDRAWN
40: end while
```

VII. Evaluation

A. Environmental Setting

The setting of our environment is shown below:

- Blockchain platform: Binance Smart Chain, ETH, Fantom

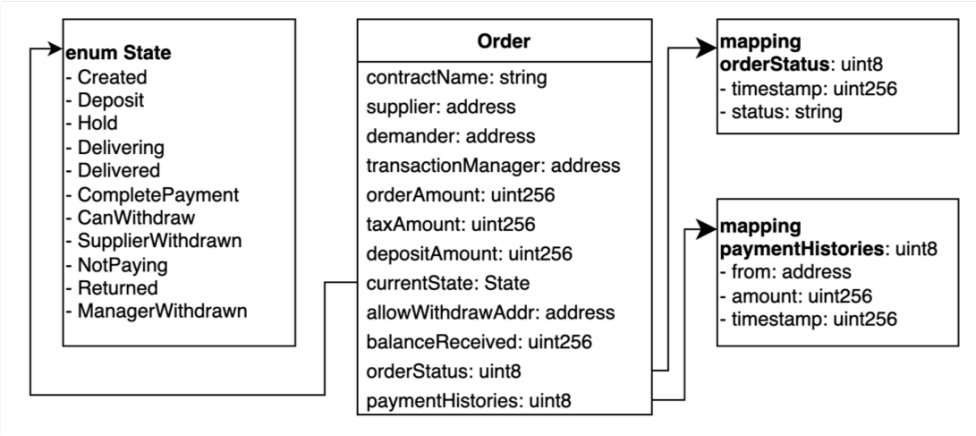

Fig. 3. Data Structure.

- Language: Solidity
- IDE: Remix
- Compiler: 0.8.16+commit.e07a7930a
- Evm version: default
- Gas limit: 3000000
- Optimization: yes
- Open Source License Type: MIT License

B. Results

To prove the effectiveness of Letter-of-Credit Chain, we set up two scenarios (i.e., Supplier pays and not pays the rest of payment) in the three most common EVM Blockchain platforms, namely, Fantom, Ethereum, and Binance Smart Chain. We also provide the source code and installation for the further extension in this topic[4]. We consider the two scenarios (i.e., Demander pay the full payment and Demander does not pay the rest of the payment).

1) Scenario 1: Supplier pays full payment: This scenario will sequentially trigger the states as State.Created, State.Hold, State.Delivering, State.Delivered, State.CompletePayment, State.Can_Withdraw, State.Supplier_Withdrawn, and State.ManagerWithdrawn.[5] In this scenario, the Supplier transferred the payments remaining within the validation time. The result of the first scenario is shown in Table I:

2) Scenario 2: Supplier does not Pay the Rest of Payment: This scenario will trigger the states sequentially as State.Created, State.Hold, State.Delivering, State.Delivered, State.NotPaying, State.Returned, State.Can_Withdraw,State.Supplier_Withdrawn, and State.ManagerWithdrawn. In this scenario, the TransactionManager and the Supplier do not transfer the rest of the payment to the smart contract within the validation time.[6]. The result of the second scenario is shown in Table II.

C. Discussion

Tables I and II present the gas fees for the deployment and execution on the three platforms, i.e., Fantom, Ethereum, and Binance Smart Chain of the Letter-of-Credit Chain[7]. We can easily see that Fantom's smart contract execution fee is the cheapest compared to the other two (i.e., on average 0.08 FTM with $0.02665366). Specifically, the most expensive method is executed with approximately 0.5 FTM ($0.13); whereas the cheapest one is $0.0045 with 0.017 FTM for the two scenarios. On the other hand, ETH is the most expensive, with $8.87 for the most and $0.1 for the least for the two scenarios. Following the ETH is the BSC execution fee of $6.6 to deploy the contract on BSC, which is approximately 17 times higher than Fantom's ones and $0.35 for the cheapest ones for the two scenarios. On average, the gas for all eight functions/methods in the two scenarios is $1.49 and $1.29 for the deployment on Ethereum and Binance Smart Chain, respectively.

D. Security and Privacy Discussion

In this article, we just provide the Letter-of-Credit chain based on the blockchain, which focuses on the decentralize and transparency rather than security and privacy (S&P) issues. In these aspects, we support the basic authorization via the role base access control, in which the right party can be called the corresponding functions. However, the main drawback of the RBAC is that on large-scale systems, RBAC is limited at the #roles. These systems might conflict with or redundancy the new policy; thus, the malicious might attack the system [29]. To this end, we will exploit the attribute-based access control (ABAC) approach, which is introduced by [30] to manage the access control process. In particular, Son et al. [14] define the two-layer of policy for the on-chain and off-chain, respectively. Similarly, some approaches split the original policy into sub-policy (e.g., [31]), i.e., public and private policies to ensure

the data is only accessed via permission even by the parties in the same transaction. Besides, the query rewriting can apply to the complex context where the released data is shared with multiple parties and dynamic context [32], [33]. In particular, the authors proposed the dynamic query VII, which responds the difference value (i.e., details level) based on the user attribute.

VIII. CONCLUSION

This article introduced Letter-of-Credit Chain, which replaces the traditional international trade process based on Letter-of-Credit transactions with edge-cutting ones. Specifically, Letter-of-Credit Chain harnesses the benefits of Blockchain technology and smart contracts to build three user groups: transaction manager, supplier, and demander. Letter-of-Credit Chain's execution process is based on eight steps, from the supplier initiating the order to passing the order on to the demander. Compared to the traditional model of depending on a trusted third party (i.e., a bank), Letter-of-Credit Chain is aimed at decentralized storage, where users can view relevant information regarding their order. If a dispute arises, the role of the transaction manager emerges as the one who decides who should be penalized. Specifically, in the current version, the sanction requirements are all public in the smart contract previously defined by the transaction manager. To demonstrate the effectiveness of the Letter-of-Credit Chain, we implement proof-of-concept on all three popular EVM-enabled platforms today, Fantom, Binance Smart Chain, and Ethereum. The performance comparison section proved that Fantom is a viable platform to deploy for further studies.

Regarding future research directions, we plan to develop the current RBAC model that supports more attributes with the application of ABAC. In addition, the privacy scalability of the Letter-of-Credit Chain is also considered by designing a dynamic request mechanism where the return result depends on the requester's role. On the other hand, Letter-of-Credit Chain does not yet include a shipper role, so a serious consideration to extending the current model is urgently needed.

Enhanced Security: Implementation of Hybrid Image Steganography Technique using Low-Contrast LSB and AES-CBC Cryptography

Edwar Jacinto G, Holman Montiel A, Fredy H. Martínez S
Facultad Tecnológica, Universidad Distrital Francisco José de Caldas, Bogotá, Colombia

***Abstract*—Now-a-days, sensitive and confidential information needs to be exchanged over open, public, and not secure networks such as the Internet. For this purpose, some information security techniques combine cryptographic and steganographic algorithms and image processing techniques to exchange information securely. Therefore, this research presents the implementation of an algorithm that combines the AES-CBC cryptographic technique with the LSB steganographic technique, which is statistically enhanced by image processing by looking for low-contrast areas where the encrypted information will be stored. This hybrid algorithm was developed to send a plaintext file hidden in an image in BMP format, so the changes in the image are invisible to the human eye and undetectable in possible steganographic analysis. The implementation was performed using Python and its libraries PyCryptodome for encryption and CV2 for image processing. As a result, it was found that the hybrid algorithm implemented has three layers of security over a plaintext encrypted and hidden in a digital image, which makes it difficult to break the secrecy of the information exchanged in a stego-image file. Additionally, the execution times of the hybrid algorithm were evaluated for different sizes of plaintext and digital image files.**

Keywords*—Steganography; cryptography; LSB; low contrast areas; AES-CBC algorithm

I. Introduction

When sensitive or confidential information needs to be sent securely between two parties communicating over media with a high probability of attack, e.g., public, open, or unsecured networks such as the Internet, it is necessary to employ information security techniques to perform this exchange. Some techniques can be used for information hiding and others for information encryption [1]. In the case of information concealment, steganographic techniques allow hiding a secret message in a cover message in such a way that its existence is not detectable to others but only to the receiver of the information. In the case of information encryption, cryptographic techniques allow exchanging secret information between sender and receiver through the encryption and decryption of coded messages.

Additionally, when the information traffic on the Internet today is analyzed, it is evident that the conventional type of communication is based mainly on sending images and video, which is how images have come to be selected as a means to communicate secret information securely. Nowadays, there is literature on different image steganographic techniques for information concealment [2] [3], and different cryptographic techniques for information encryption [4]. Such studies classify the existing algorithms, indicate the performance parameters, and show the advantages, possible applications, and attacks or security problems they may present [5] [6].

Thus, some of these studies have concluded that one way to improve information security, increasing the reliability, robustness, and solidity in the exchange of information is to combine steganographic techniques with cryptographic techniques [1] [7]. One way to do this is to take the sensitive or confidential information to be transmitted to perform an encryption process by implementing some cryptographic technique, and then take the encrypted message to perform a mixing process with a cover image using some steganographic technique [8].

Some examples of this are: [9] where the message to be transmitted is encrypted in two stages, the first by Caesar cipher and the second by chaos theory; the encrypted message is embedded in the cover image using the Least Significant Bit (LSB) substitution steganographic algorithm. [10] where the message to be transmitted is encrypted using Advance Encryption Standard (AES) encryption; at the same time, the cover image is preprocessed to resize it and identify the areas where the LSB substitution process was performed using inverse Wavelet Transform and Artificial Neural Networks (ANN). The author in [11] where the message to be transmitted is encrypted using AES encryption, including a hash process; this hash encrypted text is embedded in a cover image through Dynamic Octa Pixel Value Differencing (DOPVD) embedding algorithm that includes LSB + PVD approach. The author in [12] where the image to be transmitted is encrypted using a large secret key through XOR operation; the encrypted image is embedded in a cover image by LSB obtained a stego-image; finally, the stego-image is watermarked in time domain and frequency.

For this reason, this research aims to implement an algorithm that combines cryptographic and statistically enhanced steganography techniques for sending plain text files over a digital image in BMP format. That algorithm develops using Python and the OpenCV libraries as the base implementation language, considering the size restrictions of such information to be hidden as well as the resolution of the cover image [13].

In the case of cryptographic technique, it was decided to use Advanced Encryption Standard (AES) as the encryption

method. Because it is the standard cipher [14] [15] [16], given its security level, information encryption speed (capacity), and current availability in the internal architecture of processors as a dedicated hardware block [17] [18] [19], making it native in any application [20]. The only configurable parameter on AES is the cipher operation mode, which is associated with the order in which the keys and the initialization vector are combined with the information to be encrypted. Therefore, in this case, the Cipher Block Chaining (CBC) operation mode was chosen.

In the case of the statistically enhanced steganographic technique, it was decided to use the Least Significant Bit (LSB) substitution as a base method [21] [22] [23], enhanced in terms of selecting the information hiding areas. Such enhancement is achieved by using image processing techniques to choose a low contrast area [24], where the image entropy is less affected [25], offering a robust solution in terms of a possible stego-analysis. The image processing technique uses applied statistics concepts as mathematical criteria for locating the hidden and encrypted information. For this purpose, it is based on the characteristics of the analyzed images as a random variable, where the histogram's high dispersion can measure an image's high contrast. That is, the higher the contrast of the stego-image, the higher the security level given by this extra layer based on the processing and analysis of digital images (PAID).

Therefore, this paper presents the implementation and validation of a hybrid crypto-steganographic system. Section II describes the structure proposed to implement the hybrid system highlighting the three main elements. Section III explains the development of the software application step by step, showing: how the user key is entered, how the information encryption process, how the area where the encrypted message will be hidden is chosen, and how the execution of the LSB algorithm to reach the output stego-file. Section IV presents the validation of the implemented hybrid system and performs a performance analysis of the complete application's processing time. Finally, in Section V the conclusions according to these results are shown.

II. Methodology

The proposed structure is a hybrid technique that combines the AES-CBC cryptographic technique with enhanced LSB steganography to hide the information in the lower contrast area of the image, as shown in Fig. 1. The upper part of the graph shows the plaintext encryption process corresponding to the sensitive or confidential information to be transmitted. The lower part shows the processing of the cover image to determine the low contrast area. The right side of the figure shows the embedded process of the cipher text using a classical LSB technique to conceal it in the low contrast area, obtaining a stego-file containing the encrypted information immersed in the image (called Stego-Image).

This proposed structure complies with the philosophy of Feistel networks, which is none other than having the same architecture of the solution for the encryption and decryption of the information. It is a reversible structure where it is only necessary to reverse the order of the blocks to carry out the decryption process.

For the implementation, an application was made in Python 3.X, using the OpenCV libraries for image processing, in addition to using Numpy to work with vectors and matrices and MatplotLib to visualize the partial and final results. In this case, the information to be encrypted and hidden is a plain text encoded in UTF-8, to which a data type change process must be performed to be encrypted with AES in a CBC operation mode, always working with a pure binary string or in 64 bits format. Finally, the Cryptodome library was used, which has every one of the cryptographic functions necessary to encrypt the information.

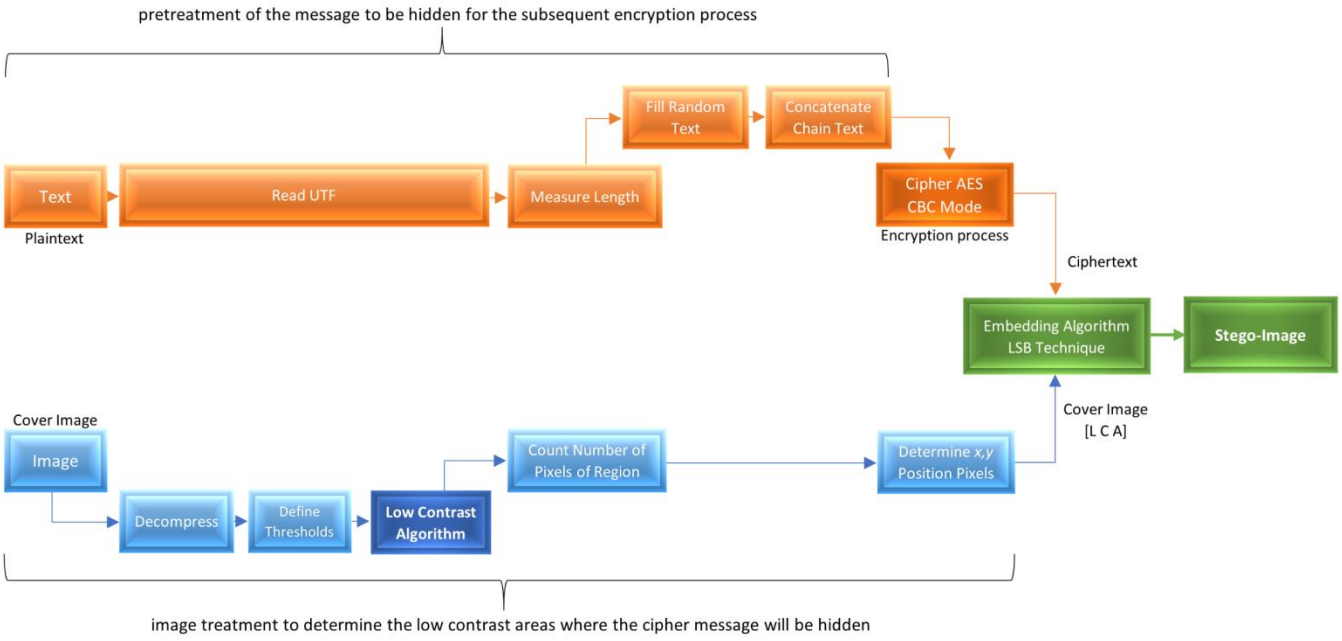

Fig. 1. General Block Diagram Implementation.

A. User Key Expansion

The aim is to encrypt the plain text using a standard block cipher such as AES-CBC; this algorithm requires a key and an initialization vector. For that, a key expansion process must be performed, and then the encryption of this key with an asymmetric algorithm [26].

Since block ciphers must have a key size equal to the block's size to be encrypted, a minimum procedure is required to ensure that the size of the session key is entered by the person or entity that will perform the steganography process complies with this characteristic. For this purpose, a key expansion procedure is performed, using the functions of the Cryptodome library developed for Python in its version 3.0 or higher, employing the PKCS #5 key expansion process, shown in the pseudo-code of Fig. 2.

This block cipher algorithm generates a series of subkeys to increase the entropy of the encrypted information; this process of generation and mixing of the subkeys with the information to be encrypted corresponds to the CBC mode of operation. This mode of operation generates high entropy since, in each of the cipher rounds, the K-th subkey is mixed with the information, obtaining at the end of the encryption process a new key that is mixed with the initialization vector. This process is automated and standardized, achieving greater security in the encryption of the information.

B. Encryption Process of the Plaintext Message

Once the operation mode of the encryptor, its working mode, the key of the indicated size, and the implicit generation of the initialization vector are clear, the information encryption process must be clearly understood to achieve its compatibility with the image file. In this case, the size of the plaintext file must be clear to be encrypted, what type of data is necessary to achieve the encryption process, and generate empty vectors where the encrypted information will be returned. For this process, it must have some of the tools offered by the NumPy library.

Next, the process of reading the text size to be encrypted is performed and compared with the number of pixels chosen to blend the ciphertext with the image. It must be guaranteed that the number of characters of the input text will never be the same as the number of pixels; therefore, a random filler text must be generated so that no empty spaces are created in the output stego-file. This process is done to avoid the simple detection of hidden information. Fig. 3 shows in a simple pseudo-code this programming scheme.

Once the character string is ready to perform the information encryption process, taking into account the dimensions and type of data required, an algorithm is applied that selects the low contrast areas where it is more difficult to detect the hidden information.

C. Statistical Method: Choice of the Low Contrast Area

The aim is the cover image file processing using applied statistics concepts to identify the areas of lower contrast in the image, areas where the encrypted information will be placed. In other words, a process of selecting in which part of the image to place the hidden information is made. This task requires using image processing functions available in the OpenCV (CV2) libraries.

According to [24], an algorithm is used to detect some pixels with low contrast, complying with the following criteria to detect the areas where the human eye does not detect any change:

The criterion for detecting dark areas is in the image. This criterion is described in (1). It requires determining a working window, the number of pixels of the convolution matrix. For establishing a series of local medians $m_{s_{xy}}$, which will be compared with the global median of the entire image m_G using a weighting constant k_0, where the value of this constant depends on the gray level that will be given as "dark."

$$m_{s_{xy}} \leq k_0 \cdot m_G \quad (1)$$

```

2.  SizeText = len(PlainText*8) //8 bits per character  // calculate length per char to pixel
3.  ImgPixels = CountPixels (rows*columns)  //measure length of the image
4.  Bits_Array = zeros(ImgPixels) // create an empty array
5.  Len_Random_str = round (ImgPixels - SizeText / 8) //calculate length of the fill text
6.  For I in range (0, len_random_str):
7.          Random_str[i] = random('a','z') //generate random char
8.  End
9.  Plain_text_fill = plain_text +random_chain //create the final char array
10. Plain_Text_Bytes = str.encode.bytes(plain_text_fill) // To Cypher plaint text in bytes only
```

Fig. 3. Pseudo-code for Encryption Process of the Plaintext Message.

The possible selection criterion is for finding low contrast areas. This criterion is described in (2). It compares the local standard deviation in a certain pixel window $\sigma_{s_{xy}}$ with the global standard deviation σ_G of the whole image by taking as a weighting factor or comparison criterion a factor k_2. This factor is determined by the experience of how scattered are the grayscale values in the low contrast regions to be detected.

$$\sigma_{s_{xy}} \leq k_2 \cdot \sigma_G \quad (2)$$

On the other hand, a possible error is generated in the selection criterion that [24] describes as enhancing a constant area, where the standard deviation would be zero evidently. Such a problem must be applied depending on the characteristics of the chosen image and is described by (3).

$$K_1 \cdot \sigma_G \leq \sigma_{s_{xy}} \quad (3)$$

This equation describes the way to compare a minimum local standard deviation in a certain pixel window $\sigma_{s_{xy}}$ with the global standard deviation σ_G with a factor K_1, avoiding enhancing or selecting constant zones. In other words, it becomes undesirable to select a pixel from a zone with the same gray level as a candidate for the LSB algorithm.

The algorithm applying the above mathematical criteria in practice was implemented through a pseudo-code, shown in Fig. 4. As a result, a binary matrix is obtained, which clearly identifies the low contrast zones where the LSB information mixing algorithm will be used to obtain the stego-image with the concealed information in these specific zones.

D. LSB Method (Least Significant Bit)

It is a method that seeks to place a binary string with the information to be hidden in the stego-file. In this case, having encrypted information, the binary string will be in a pure binary format or base64; these types of data result from the encryption process. Then, mixing or embedding this information in the cover image is performed through a simple binary mask. Fig. 5 shows the pseudo-code that mixes or embeds the encrypted information in the least significant bit of the cover image in the areas chosen by the statistical algorithm (low contrast areas).

It is necessary to ensure the correct functioning of the LSB algorithm that an image with large low-contrast areas compared to the total image size should be chosen. On the other hand, it is recommended to work with images of a size larger than the possible size of the plaintext to be encrypted and hidden in the digital image. In other words, the size of the stego-image of the input image should be much larger than the stego-message, which should be cipher using an encryption algorithm.

For this case, it was chosen only to hide plaintext files since it requires less processing than applying such processing to multimedia files. However, if the application requires it, the same technique can be applied to other types of files or combinations.

```
1.  Img = cv2.read(ImFile.Imext) //read the image
2.  ImgGray = cv2.cvtColor(Img, cv2.COLOR_BRG2GRAY) //Convert to only one matrix
3.  GlobalMedian = np.mean(ImgGray)  // calculate global median
4.  GlobalDevStd = np.std(ImgGray) // calculate global standard deviation
5.  Pix = NWin
6.  Dim = (pix,pix)
7.  MConv = np.ones(Dim) * 1/(pix**2)  // create convolution matrix
8.  LocalMedian = conv2(ImgGray,Mconv) // calculate local median
9.  LocalDevStd = conv2((ImgGray - LocalMedian) .^2 , MConv))  // calculate local standard deviation
10. ImgOut1 = LocalMedia <= K0*GlobalMedian  // compare to create binary matrix of dark regon
11. ImgOut2 = LocalDesvStd <= k2* GlobalDesvStd // compare to create binary matrix of low contrast
12. ImgOut = BitAND(ImgOut1, ImgOut2) // Binary matrix of the choose pixels
```

Fig. 4. Pseudo-code for Statistical Method - Choice of Low-contrast Area.

```
1.  Def Func_LSB(msg): // define LSB function
2.      for CharIn in(msg):
3.          o = CharIn  //// read the encrypted message
4.          for Column in (Img):  // traverse the columns
5.              for Row in (Img): // traverse the rows
6.                  if ImgOut(Row,Column) == (TRUE) // check if the pixel is choose to lsb
7.                      for in range (8)
8.                          O & lsb(Img) // put the information in the 8 pixels
```

Fig. 5. Pseudo-code for LSB Method.

III. Results

The first step to verify the algorithm's effectiveness is to verify that the statistical algorithm effectively identifies the areas with low contrast. Fig. 6 shows in part (a) the original image with an area of low contrast and in part (b) a black and white image, where the white parts are the areas of the pixels chosen to perform the information hiding process using the LSB algorithm. For this part, it was only necessary to follow the steps of equations (1) and (2).

As a result, the stego-image does not look the same in its least significant bits as the original cover image, although this is not as visible to the human eye. The image loses its natural entropy, i.e., the bright part of the image is removed. This characteristic serves as an indication to discover whether a stego-image has hidden information in a steganalysis process.

The information encryption and hiding process were tested using the AES-CBC algorithm for encryption and the enhanced LSB algorithm that mixes o embeds information in the low contrast areas; this test was made using different sizes of plaintext files. Fig. 7 shows a bar graph that presents the execution time depending on the size of the information to be encrypted and hidden. The tests were performed on a PC with an 8-core Core i7 with 16 Gigabytes of RAM and a Geforce GTX 610 video card.

It can be seen how the application can store files of different sizes in the stego-image, up to a limit of one Megabyte, the size of the book Don Quixote in plaintext format, for which the processing time was approximately one minute. On the other hand, the time for information smaller than 200 kilobytes is less than 10 seconds, so it could be said that the process is agile for small texts.

IV. Conclusion

It was verified that the step-by-step implementation of a hybrid algorithm that combines cryptographic and steganography techniques for sending plaintext files over a digital image in BMP format gives a double layer of security. So, if the stego-image is revealed to have hidden information, it is impossible for the person or entity intercepting the message to know plaintext content because it is encrypted.

On the other hand, it was determined that using a statistically enhanced steganography technique to choose the lower contrast areas to hide the encrypted information only in these zones gives the hybrid algorithm an extra layer of security, making the entire algorithm more robust. The choosing lower contrast areas algorithm makes that the entropy of the image is only affected in the areas chosen by it. This feature makes it difficult to detect concealed information. It adds an extra layer of security since, besides having the session key to decrypt the ciphertext, the value of two constants, k_0 and k_2, must be present so that when performing the decryption process, the information only is taken from these areas. Therefore, it is verified that only modifying the least significant bit does not affect the statistical selection criteria with which the pixels in which the encrypted information was hidden were chosen.

Regarding the cryptographic technique implemented to encrypt the information before hiding it, the standardized AES-CBC algorithm was used, which was automated using the Cryptodome library, achieving greater security in the encryption of the information. However, it became evident that it would be possible to experiment with different combinations of standardized modes for AES in the Cryptodome library for future work. Seeking to maximize the entropy in the information and therefore generate fewer possible patterns in the LSB algorithm, as well as specifying how the key and the comparison constants would be exchanged.

Finally, the algorithm's performance was analyzed regarding the time used for the encryption and embedded process, resulting in fast usability for small plaintext files below 200 kilobytes. It is a good performance considering that a 100 kilobytes text is the entire chapter of any chapter literature text.

Acknowledgment

The Universidad Distrital Francisco José de Caldas supports this work through the research group SIE -Embedded Informatics Security- which belongs to the Technological Faculty. SIE has dedicated to working in cryptography and applied steganography. Currently, the bases are being generated to implement this type of algorithm in stand-alone applications, which is the final purpose of the workgroup.

***Abstract*—Implicit certificates own the shorter public key validation data. This property makes them appealing in resource-constrained IoT systems where public-key authentication is performed very often, which is common in Host Identity Protocol (HIP). However, it is still a critical challenge in IoT how to guarantee the security and efficiency of implicit certificates. This article presents a forgery attack for the Privacy-aware HIP (P-HIP), and then propose a Secure and Efficient Implicit Certificate (SEIC) scheme that can improve the security of the P-HIP and the efficiency of elliptic-curve point multiplications for IoT devices. For a fix-point multiplication, the proposed approach is about 1.5 times faster than the method in SIMPL scheme. Furthermore, we improve the performance of SEIC with the butterfly key expansion process, and then construct an improved P-HIP. Experimental results show that compare to the existing schemes, the improved scheme makes a user/device have both the smallest computation cost and the smallest communication cost.**

***Keywords*—Authentication; privacy; implicit certificates; internet of things (IoT); host identity; security**

I. Introduction

Public-key authentication is a critical issue for any IoT system. Many current IoT devices rely on the Public Key Infrastructure (PKI) to achieve public-key authentication [1]. One of the differences between IoT devices and conventional devices is how their public-keys are authenticated. Traditional devices rely basically on X.509 certificates [2] whereas IoT devices use implicit certificates [3]. It is a known fact that besides the device's public key and the signature generated by a trusted Certificate Authority (CA), an X.509 certificate also contains information about the certificate subject, the supported encryption and/or digital signing algorithms and information to determine the revocation and validity status of the certificate. For instance, for the authentication and key exchange of HIP shown in Fig. 1, the certificates $cert_r$ and $cert_r$ are carried in the messages R_1 and I_2, respectively. Digital signatures of the parties are applied for this situation. In order to verify the correctness of a message signed by the private key of the sender, a receiver first needs to validate the corresponding public-key via its certificate. When IoT devices use implicit certificates instead of explicit certificates, they will reduce the amount of information required for authenticating public keys. Hence, public-key authentication in IoT encourages the use of implicit certificates.

This work focuses on a specific yet important problem: how to attain fast public-key authentication in IoT through the use of Elliptic Curve (EC) implicit certificates. Allowing one IoT device to achieve public key validation remains a challenging problem [1]. This is because certificate verification involves expensive public key operations and communication cost transmitting the authentication data. From Table I, we notice that the certificate size is much larger than the public key size, and their ratio is greater than 5. Here, the certificates are self-signed and created using the OpenSSL library [2]. Some authors [3, 4] explored how to reduce the communication overhead for public-key authentication through the use of EC implicit certificates. However, the scheme in [3] suffers from a forge attack (see Section II-B). This paper will propose a secure scheme to further improve the efficiency of public key authentication by using EC implicit certificates. That is, by designing a table-and-optimality-based technique for EC fixed-point multiplication, we improve the computational efficiency of public key authentication. In addition, by integrating the proposed scheme with butterfly key expansion process, we also reduce the communication cost of public key authentication.

Fast public-key revocation validation seems to be a dilemma on IoT devices. In PKI, public-key revocation is achieved through the certificate revocation. The unexpired

* Corresponding author

certificates are revoked by using Certificate Revocation Lists (CRLs) or the Online Certificate Status Protocol (OCSP). The CRL introduces substantial communication overhead since the CRL size is proportional to the number of revoked certificates. The OCSP increases certificate revocation verification latency and the risk of leaking user privacy (such as accessing history of the device). Hence none of the above methods is desired for IoT. In order to reduce both the communication overhead and the latency, based on Nyberg's one-way accumulator, this paper designs a credential revocation mechanism which is significantly efficient in the verifier's side.

With the applications of IoT technology, security and privacy concerns have also emerged. Especially, tracking of devices' activities is a threat to their privacy. HIP is a suitable solution for IoT devices considering the security and privacy requirements of IoT systems [3]. In the HIP, an IoT device is issued a public key as host identifier and a 128-bits hash of the public key as Host Identity Tag (HIT). A mobile IoT device uses the same public key and HIT to authenticate to its peers when it moves from one network to another network. By learning the public key and HIT, an attacker can track the mobile IoT device. This paper improves the security of P-HIP in [3] such that devices can avoid tracking by changing the short-lived implicit certificates.

In general, the different implementations of public-key authentication in IoT should at least fulfill the following requirements: (1)Security: The CA can not be compromised or coerced to assign a public key to a malicious attacker. (2)Accuracy: A device should accurately determine a certificate revocation status. (3)User privacy: The protocol should not leak the identities of the accessing devices. (4)Efficiency: The protocol should cost small memory, computation, and network resource on IoT devices. (5)Compatibility: The protocol is required to be compatible with current certificate standards and existing certificates.

Our Contribution: In this paper, we first present a forgery attack for P-HIP scheme [3], and then propose a secure and efficient implicit certificate (SEIC) scheme to overcome its weaknesses. Specifically, the SEIC scheme runs the signature algorithm to output a signature by hashing the public key validation data, the timestamp and the CA's public key. A table-and-optimality-based technique is designed for EC fixed-point multiplication such that it's achievement is about 1.5 times faster than the method [4]. In addition, SEIC contains a credential revocation mechanism which is significantly efficient in the verifier's side. That is, the verifier achieves the revocation verification of a public key by performing one Nyberg one-way accumulator operation while keeping only one $\mathbb{Z}_p$ symbol. Furthermore, we improve SEIC via the butterfly key expansion process, and then construct an improved P-HIP. Experimental results show that the improved P-HIP can achieve performance gains during credential issuance and mutual authentication, while preserving the user privacy.

The rest of this paper is organized as follows: Section II analyzes the security of the implicit certificate scheme in P-HIP [3] after an overview of the scheme, and then introduces related work. Section III explains the basics notations as well as the primitives of proposed scheme. Section IV introduces SEIC scheme and discusses its security and performance. Section V shows that SEIC can be improved via the butterfly key expansion process, and then an improved P-HIP is constructed. Section VI formally analyzes the privacy of the improved P-HIP and the corresponding performance gains is shown in Section VII. Finally, Section VIII concludes the discussion.

Fig. 2. The Implicit Certificate Scheme in P-HIP [3].

II. Analysis of the Implicit Certificate Scheme in P-HIP and Related Work

A. The Implicit Certificate Scheme in P-HIP

Consider an additive cyclic group $\mathcal{G}$ generated by a point G on the elliptic curve $y^2 = x^3 + ax + b$ over a finite field $\mathbb{F}_q$, where q is a large prime and $4a^3 + 27b^2 \neq 0 (\mathrm{mod} q)$, and n is the order of generator G. We assume that Q_{ca} and $Q_{\overline{ca}}$ in $\mathcal{G}$ are the public keys of CA and $\overline{\mathrm{CA}}$, respectively.

As shown in Fig. 2, an implicit certificate scheme was proposed recently to design a P-HIP [3]. We review the scheme as follows. The basic goal of the scheme was to bind a public key Q_u to its owner u via the public-key authentication data V_u. To compute the private key construction data s_u, the scheme is different from the conventional ECQV implicit certificate schemes. That is, the CA does not issue a certificate ($cert_u$) to the user. The scheme computed s_u as $s_u = k_u + d_{ca}(modn)$, which did not multiply h_u=$Hash(cert_u)$ with k_u or d_{ca} to compute s_u (see the steps 23 of Fig. 2). Then, s_u and δ_u were encrypted and then sent to the user. Upon receiving a new ECQV-based credential s_u and δ_u, the user computed a unique public key Q_u=$d_u * G$ and HIT HIT_u=$Hash(Q_u)$ for a network that it would join without communicating with the CA.

A user device provided its ECQV public key Q_u and the public-key authentication parameter V_u to a verifier device. The verifier computed a public key Q'_u as Q'_u=$V_u + Q_{ca}$. If Q'_u=Q_u, then the verifier ensured that the public key was genuine and issued by the CA.

B. Security Weaknesses of the Implicit Certificate Scheme in P-HIP

We have observed weaknesses of the implicit certificate scheme in P-HIP [3]. First, the scheme suffered from a forgery attack. This is because a malicious user holding the implicit certificate issued by a CA is able to forge an implicit certificate issued by another CA, precluding the use of any digital signature scheme. In the case, as shown in Fig. 2, the CA whose public key is Q_{ca} had issued an implicit certificate (V_u, d_u, Q_u) to u. Assume that an adversary either is u

himself or colluding with him. Let $\overline{\text{CA}}$ be compromised by the adversary who knows its public key $Q_{\overline{\text{CA}}} = (\overline{x}, \overline{y})$. The adversary disguising as $\overline{\text{CA}}$ can mount a forge attack such that a forged $(\overline{V}_u, d_u, Q_u)$ passes in the public key verification. Here, $\overline{V}_u = V_u + Q_{ca} + (-Q_{\overline{ca}})$, and $-Q_{\overline{ca}} = (\overline{x}, -\overline{y} \bmod n)$. This is because in the scheme [3], $\overline{\text{CA}}$ had issued the public key Q_u to u if and only if its implicit certificate satisfied the equation $Q_u = \overline{V}_u + Q_{\overline{ca}}$. It is easy to see that the equation holds under the condition that $Q_u = V_u + Q_{\underline{ca}}$. This means that the forged implicit certificate under the $\overline{\text{CA}}$ is valid to u. Therefore, the implicit certificate scheme in P-HIP [3] is insecure.

In addition, we deplore implicit certificate schemes in [3, 4] lack of a revocation mechanism. Thus, there is a risk that a malicious attacker might try to use the relevant credential that it is no longer valid while the credential itself has not expired. Instead of CRLs and OCSP, we propose a certificate revocation mechanism that uses only one Z_p-symbol as the authentication information to achieve the revocation validation of implicit certificates.

C. Related Work

Public-key authentication is emerged as a popular tool in IoT applications. In PKI, the CA issues and manages public keys of users by using digital certificates. In the traditional explicit certification model,a user's digital certificate $cert_u = (meta, Q_u, sig_u)$ is issued by a trusted CA. The signature sig_u on $cert_u$ implies that the owner of $cert_u$ knows the private key d_u of public key Q_u. In the implicit certification model, the key pair (d_u, Q_u) is computed by the user u in collaboration with the CA. Implicit certificates were introduced in the work of Günther [5] and Girault [6]. Brown et al. [7] defined a general notion of security for implicit certificates, and proved that optimal mail certificates were secure under this definition. However, it has various drawbacks in terms of security and efficiency. In 2013, Campagna [8] presented an implicit certification solution in the Elliptic Curve Qu-Vanstone (ECQV) protocol. Unfortunately, this approach suffered from certificate misbinding attacks. Recently, Barreto et al. [4] proposed an improvement for its security weaknesses and computational efficiency.

The authenticated key establishment between two IoT devices was achieved via HIP [9]. Fig. 1 shows that the host identifiers (public keys and HITs) were validated by the HIP peers exchanging X.509 certificates. However, the size of the certificate is much larger than both that of its public key (see Table I) and the maximum transmission unit of the IEEE 802.15.4 link [10] in IoT networks. Recently, Hossain and Hasan [3] proposed P-HIP in which the ECQV implicit certification scheme was able to reduce the public-key authentication data for mutual authentication while protecting the user privacy. In this work,we shows that the ECQV implicit certificate in P-HIP suffered from a forgery attack, that is, a malicious user holding the implicit certificate issued by a CA was able to forge an implicit certificate issued by another CA. Then, a new scheme SEIC is proposed to resist the forge attacks.

III. Preliminaries

In this section, we introduce some notations and Nyberg's one-way accumulator needed later.

A. Notations

We shall use the following notations throughout the paper. A set with integers $1, 2, \cdots, n-1$, is written either $\mathbb{Z}_n^*$ or simply $[n-1]$. We denote by $|x|$ the length of the binary string corresponding to x, and $\lceil x \rceil$ the least integer that is greater than or equal to the given number x. Let $\mathbb{F}_q$ be a finite fields, $\mathbb{Z}_n$ be a addition group, and $\mathbb{Z}_n^* = \mathbb{Z}_q \setminus \{0\}$, where q and n are two prims, $q \geq n+1$, and n is the size of a signature (see step 24 in Fig. 3 and 5). We let $H : \{0,1\}^r \times \{0,1\}^* \to \{0,1\}^r$ denote a Nyberg one-way accumulator, $Hash : \{0,1\}^* \to \mathbb{Z}_n$ and $h : \{0,1\}^* \to \{0,1\}^{rd}$ be two one-way hash functions, where h is used to construct the required H. Let p is a prime number satisfying r=$|p|$, where $A_{\sqcup} \in \mathbb{Z}_p$ (see Section IV-B2)).

B. Nyberg's One-Way Accumulator

Here, the concept of the Nyberg One-Way Accumulator (NOWA) in [11] is reviewed. Let $H(\cdot,\cdot)$ denote NOWA from $\{0,1\}^r \times \{0,1\}^*$ to $\{0,1\}^r$, and $\odot$ be the bitwise operation AND. The NOWA was constructed by a one-way hash function $h : \{0,1\}^* \to \{0,1\}^{rd}$. Here, $N = 2^d$ is an upper-bound to the number of items to be accumulated, and $r = |q|$ is an integer. All that was required to specify an NOWA was hashing process and AND operation.

Let $h_1, h_2, \cdots, h_n$, $n \leq N$ be the items to be accumulated, and $h(h_i) = y_i$, $i = 1, \cdots, m$ be their hash values. Each hash value is a string of length rd bits. The heart of NOWA was the hashing process. The hashing process applied a hash function h to the input to produce a r-bit output. The hashing process was composed of the following operations: (1)Hashing operation: Hash accumulated item h_i of the input and output a rd bits binary string v_i=$h(h_i)$. (2)Transfer α: NOWA did a transfer operation on the binary string v_i which was divided into r blocks, $(v_{i,1}, \cdots, v_{i,r})$, of length d. The transfer of a block from a d-bit input to a bit output was performed as follows: If $v_{i,j}$ was a string of zero bits, it was replaced by 0; otherwise, $v_{i,j}$ was replaced by 1. That is, $\alpha(v_i)$ =$(b_{i,1}, \cdots, b_{i,r})$, where $b_{i,j} \in \{0,1\}$, j=$1, \cdots, r$. In this way, we can transfer an accumulated item h_i to a bit string, b_i=$\alpha(h(h_i)) \in \{0,1\}^r$, which can be considered as a value of r independent binary random variable if h is an ideal hash function.

In practice, the NOWA is effectively implemented by using the generic symmetry-based hash function and simple bit-wise operations. The NOWA on an accumulated item $h_i \in S$ with an accumulated key $k \in \{0,1\}^r$ was able to be implemented using the AND operation described as $H(k, h_i) = k \odot \alpha(v_i) = k \odot \alpha(h(h_i))$. And it also could be represented as $A = H(k, h_i) = k \odot \alpha(v_i) = k \odot \alpha(h(h_i))$ $(i \in [n])$ if S was a set of accumulated items $S = \{s_1, s_2, \cdots, s_n\}$. $H(\cdot,\cdot)$ has the following properties: (1) Quasi-commutativity: $H(H(k, h_1), h_2) = H(H(k, h_2), h_1)$. (2) Absorbency: $H(H(k, h_i), h_i) = k \odot \alpha(h(h_i)) = H(k, h_i)$. (3) An item h_i within the accumulated value A can be verified by $H(A, h_i) = A \odot \alpha(h(h_i)) = A$.

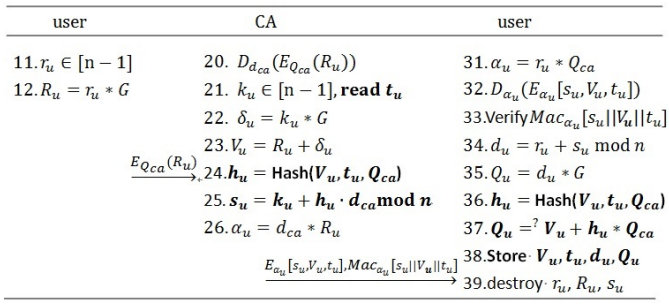

Fig. 3. The Proposed Secure and Efficient Implicit Certificate (SEIC) Scheme.

IV. The Proposed Scheme

In the section, we propose a secure and efficient implicit certificate (SEIC) scheme to overcome the P-HIP's weaknesses in Section II-A. In order to make the signature s_u prevent the forgery attack, the SEIC scheme constructs a secure digital signature algorithm by hashing the public key validation data V_u, the time-stamp t_u and the CA's public key Q_{ca}. The scheme also presents a table-and-optimality-based technique that makes the fixed-point multiplication in [4] more computationally efficient. Then, a certificate revocation mechanism is proposed. Finally, a formal proof for the security of SEIC is provided.

A. Proposed SEIC

The user sends a request R_u to the CA via a secure way (i.e.,public key encryption), by choosing a random integer $r_u \in [n-1]$ and then calculating $R_u = r_u * G$. Upon receiving the request, the CA obtains R_u. Then, by picking a random integer $k_u \in [n-1]$ and computing $V_u = R_u + k_u * G$ and s_u=$k_u + h_u \times d_{ca} \bmod n$, the CA issues a public key construction data s_u and a unique public-key authentication data V_u to the user, where h_u=$Hash(V_u, t_u, Q_{ca})$, t_u is the current time-stamp of the CA. Before sending (s_u, V_u, t_u) to the user, the CA uses the shared session key, $\alpha_u = d_{ca} * R_u$, to encrypt them and compute their Message Authentication Code (MAC). Upon receiving the messages from CA, the user computes α_u to decrypt $E_{\alpha_u}[s_u, V_u, t_u]$, and verifies $MAC_{\alpha_u}[s_u||V_u||t_u]$. Then, the user generates a private key d_u = r_u+$s_u \bmod n$ and public key $Q_u = d_u$*G. The user validates the result using the equality Q_u=V_u+$Hash(V_u, t_u, Q_{ca})$*Q_{ca}. The details of the proposed implicit certificate protocol are shown in Fig. 3.

The proposed SEIC can prevent the forged attacks in Section II-A. Since $Hash(\cdot)$ is one-way and collision-resistant, it is hard to compute a pre-image of a given value. That is, given a randomly chosen $h_u = Hash(V_u, t_u, Q_{ca})$, it is computationally infeasible to find a tuple $(\overline{V}_u, t_u, Q_{\overline{ca}})$ such that $Hash(\overline{V}_u, t_u, Q_{\overline{ca}}) = h_u$. Thus, based on (V_u, t_u, Q_{ca}), it is hard to forge an $\overline{V}_u$ satisfying Q_u=$\overline{V}_u + h_u * Q_{\overline{ca}}$. In other word, in the proposed SEIC, it is computationally infeasible for a malicious user holding the implicit certificate issued by the CA to forge an implicit certificate issued by another CA.

B. Performance Considerations

Assume that all the users know the system parameter pas=$\{\mathcal{G}, G, n, Hash(\cdot)\}$. The proposed SEIC can be very efficient since it allows a certain amount of precomputation.

1) Precomputation for $h_u * Q_{ca}$: Assume that b_m (bits) is the memory size used to the precomputation for $h_u * Q_{ca}$. Notice that the binary length of the output of $Hash$ is $|n|$, and the elliptic curve is on the finite field $\mathbb{F}_q$. We observe that the computational efficiency of $\hat{h} * Q_{ca}$ is significantly improved when $\hat{h}$ is restricted to a sufficiently small range. Note that the CA's public key Q_{ca} is commonly a fixed point for each user. Therefore, $h_u * Q_{ca}$ is amenable to optimization methods typical of fixed-point EC multiplications [4]. For a larger integer $h_u \in \{0,1\}^{|n|}$, we select a suitable base B and obtain its expansion (1) on the base B, so that each term $(c_l \cdot B^l) * Q_{ca}$ can be calculated efficiently.

$$h_u = c_\kappa \cdot B^\kappa + c_{\kappa-1} \cdot B^{\kappa-1} + \cdots + c_1 \cdot B + c_0. \quad (1)$$

Here, $0 \le c_l < B$, $l = 0, 1, \cdots, \kappa$, and $\kappa = \lceil |n|/(log_2 B)) \rceil$ is the number of substrings of length $log_2 B$ in h_u.

Given b_m, q and n, we design a table-and-optimality-based technique: how to choose an optimal base B such that the operation $h * Q_{ca}$ is accelerated. The specific operations are as follows:

(1) Define allowed values $AV = \{B = 2^\theta : 2|q|\lceil |n|/\theta \rceil 2^\theta < b_M\}$. This is because that there are $\kappa \cdot B$ intermediate results $(c_l \cdot B^l) * Q_{ca}$ to be stored, and $x, y \in \mathbb{F}_q$ for a point Q_{ca}=(x, y).

(2) It is recommended to select the largest $B = 2^\theta$ in AV. We notice that $\kappa = \lceil |n|/\theta \rceil$ decreases as $B = 2^\theta$ increases.

(3) By pre-computing $\hat{T}[l][c_l] = (c_l \cdot B^l) * Q_{ca}$ $(0 \le c_l < B, 0 \le l < \kappa)$and then storing them in the memory of the device, the h_u*Q_{ca} operation can be implemented via table look-ups as follows:

$$\begin{aligned} & h_u * Q_{ca} \\ &= (c_{\kappa-1} \cdot B^{\kappa-1} + \cdots + c_1 \cdot B + c_0) * Q_{ca} \\ &= (c_{\kappa-1} \cdot B^{\kappa-1}) * Q_{ca} + \cdots + (c_1 \cdot B^1) * Q_{ca} + c_0 * Q_{ca} \\ &= \hat{T}[\kappa-1][c_{\kappa-1}] + \cdots + \hat{T}[1][c_1] + \hat{T}[0][c_0]. \end{aligned}$$

This means that h_u*Q_{ca} operation can be attained through $(\kappa - 1)$ point additions.

For example, assuming that $|n|$=256, $|q|$=512, and b_m=512KBs=4194304 bits (IoT devices have a few megabytes of memory (8–32 KB of RAM and 48–512 KB of ROM), e.g., eZ1-Mote [12] has 32 KB of RAM and 512 KB of ROM). In the case, the allowed values is $AV = \{8, 16, 32, 64\}$. We choose B=64, and then κ=$\lceil 256/(log_2 64) \rceil$=43. Ignoring the (usually small) cost of table look-ups, this approach would take only 42 point additions. The size of the memory block storing the intermediate results is $43 \times 64 \times (512 + 512)$ bits =344 KBs.

In comparison, the method in SIMPL [4] using B=16 would require 63 point additions and 128 KBs memory. Thus,

the table-and-optimality-based technique is expected to be about 1.5 times faster than the method [4].

2) Implicit Certificate Revocation: Let $HIP^{(\sqcup)}$ be the set of revoked implicit certificates in time slot $\sqcup$. Based on the NOWA H, the revocation manager (RM) compute a NOWA value in $\mathbb{Z}_p$ by accumulating the hash values of implicit certificates in $HIP^{(\sqcup)}$. Then, the RM distributes the value in $\mathbb{Z}_p$ to all users in advance. Keeping just one $\mathbb{Z}_p$-symbol for the revocation verification reduces the storage and communication costs of each user. Specifically, when a user u requests to revoke her/his implicit certificate, the RM can revoke the implicit certificate as follows.

(1) The user u sends the implicit certificate (V_u, t_u, d_u, Q_u) and the CA's ID to the RM. The RM first determines the implicit certificate to be unexpired and correct by using the steps 36-37 in Fig. 3.

(2) The RM revokes the unexpired and correct implicit certificate by updating the previous $A_{\sqcup}$ with the new $A_{\sqcup'}$ for the time epoch $\sqcup'$, where $A_{\sqcup'} = H(A_{\sqcup}, \text{HIT}_u)$, and $\text{HIT}_u = Hash(Q_u)$. The RM then sends the value $A_{\sqcup'}$ to all users via the block chain or a tamper-proof electronic bulletin board.

(3) Each verifier downloads timely the new $A_{\sqcup'}$. The verifier then checks if $H(A_{\sqcup'}, \text{HIT}_u) \neq A_{\sqcup'}$ for the valid public key Q_u, where $\text{HIT}_u = Hash(Q_u)$. If the inequality holds, (V_u, t_u, Q_u) is valid; otherwise, it has been revoked.

C. Security Analysis

Under the assumption that the elliptic curve discrete logarithm problem (ECDLP) is hard on $\mathcal{G}$, we provide the security proof of SEIC as follows.

As shown in Fig. 3, the corresponding digital signature scheme DS=$(Gen, \mathcal{K}, \mathcal{S}, \mathcal{V})$ is defined as follows:

- $pas = \{\mathcal{G}, G, n, Hash(\cdot), H\} \leftarrow Gen(1^{\kappa})$: On inputting the security parameter κ, the probabilistic algorithm Gen outputs an array of system parameters pas.
- $(d_{ca}, Q_{ca}) \leftarrow \mathcal{K}(pas)$: On inputting the system parameters pas, the probabilistic algorithm $\mathcal{K}$ generates a pair of public and private keys (d_{ca}, Q_{ca}) for a CA.
- $(R_u, (V_u, t_u, s_u)) \leftarrow \mathcal{S}(d_{ca}, R_u)$: On inputting a private key d_{ca} and a message $R_u \in < G >$, the CA runs the probabilistic algorithm $\mathcal{S}$ to produce a signature σ = (V_u, t_u, s_u).
- $\{0, 1\} \leftarrow \mathcal{V}(Q_{ca}, R_u, \sigma)$: On inputting the CA's public key Q_{ca}, a message R_u and a signature σ, anyone can run the deterministic algorithm $\mathcal{V}$ to check whether σ is a valid signature. That is, σ is a valid signature if Q_u =$V_u + Hash(V_u, t_u, Q_{ca}) * Q_{ca}$, where Q_u = $R_u + s_u * G$.

The Lemma 1 in Appendix proves the unforgeability of DS in the proposed SEIC against adaptive chosen-message attacks.

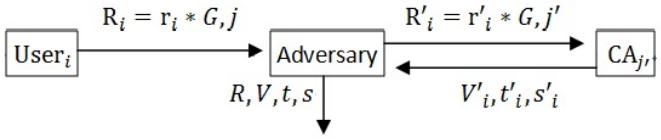

Fig. 4. Security Model for Implicit Certificate Adapted from [[7]].

Assume a scenario with n_{usr} legitimate users, denoted usr_i for $1 \leq i \leq n_{usr}$, and with n_{ca} CAs, denoted CA_j for $1 \leq j \leq n_{ca}$. Let $(R_i = r_i * G, j)$ denote usr_i's implicit certificate request for CA_j, and let (V_i, t_i, s_i) be the response sent by that CA. Also, let Q_i and d_i denote, respectively, the public and the private keys reconstructed by usr_i from CA_j's response, using that CA's public key Q_j. There are no restrictions on the number of credential requests that can be sent by usr_i to CA_j.

Definition 1. *A (τ', ϵ)-adversary $\mathcal{A}$ (of an implicit certificate scheme) is a probabilistic Turing machine that runs in time at most τ, interacting with legitimate users and CAs by performing each of the following operations any number of times:*

(1) *receive a request $(R_i = r_i * G, j)$ from usr_i for an implicit certificate from CA_j; and*

(2) *send a request $(R_{i'} = r_{i'} * G, j')$ to $CA_{j'}$, and receive response $(s_{i'}, V_{i'}, mac_{i'})$ from $CA_{j'}$.*

With probability at least ϵ, $\mathcal{A}$ outputs a triple (r, V, t, s) such that d=$r + s$ is the private key associated with the public key Q reconstructed from V and some Q_z (that is, $d * G$ = $V + Hash(V, t, Q_z) * Q_z$) such that either

(1) *[Forgery attack against CA_z]: (V, t, s) was never part of a response of CA_z for the request $(r * G, z)$; or*

(2) *[Key compromise against usr_i]: (V, t, s) was included in a response of CA_j to some request $(r * G, j)$ originally from usr_i, where $j \neq z$.*

A (τ', ϵ)-adversary is considered successful if ϵ is non-negligible for a polynomial time τ'.

In summary, as shown in Fig. 4, this model covers a scenario where the adversary $\mathcal{A}$ acts as proxy for requests from users and responses from CAs. Hence, $\mathcal{A}$ can: simply relay the request to the correct CA; modify the value of R_i =$r_i * G$ in the request; modify the user identifier i in the request, thus affecting the value of V in the credential; and/or forward the request to a different CA.

Under the security model of Definition 1(see Fig. 4) and the random oracle model, Theorem 3 in Appendix proves the security of the proposed SEIC.

V. Application to HIP in IoT

Public key validation can ensure the authenticity of an HIT in HIP. HIP is based on the Diffie-Hellman key exchange, using public key identifiers from a new host identity name-space for mutual peer authentication. The device uses a 128-bits hash of the public key as HIT.

An important challenge in HIP environments is to build a privacy-preserving HIP where authorized devices cannot be tracked, either by eavesdroppers or by the system itself [3]. One common approach for this issue is to provide a IoT device with multiple short-lived public keys. Then, IoT devices can avoid tracking by changing the public keys employed to sign its messages while it move from one network to another one. Hence, messages broadcast from different locations and using distinct public keys cannot be easily linked to any given IoT device. However, the total number of public keys valid simultaneously should be limited [4]. Among the existing solutions, the Secure Credential Management System (SCMS)[13] is one of the most relevant. The approach in SCMS combines privacy and scalability in the so-called butterfly key expansion process. Essentially, this process can issue multiple implicit certificates with a single request from a user. Furthermore, in the proposed SEIC, it reduces the amount of data exchanged and also the number of operations performed by the user.

In this section, we improve SEIC via the butterfly key expansion process, and then construct an improved P-HIP, We also formally analyze the privacy of the improved P-HIP.

A. Performance Improvement for SEIC

The implicit certificate issuance and revocation in the improved SEIC involves mainly four entities: User, Registration Authority (RA), CA and RM. Assume that there is no CA-RA collusion. They are respectively responsible for the following operations:

- User: the entity that requests credentials from a registration authority (RA). For better efficiency, each request leads to the provisioning of a batch containing β implicit certificates.
- RA: the entity that creates β implicit certificate requests to the CA from a single request of a user (called butterfly key expansion process). Those requests are individually forwarded to the CA, in such a manner that requests associated to different users are shuffled together.
- Credential Authority (CA): responsible for issuing credentials upon the requests by the RA. The credentials are then individually signed and encrypted by the CA before being sent back to the RA, from which they are delivered to the requesting user.
- Revocation Manager (RM): the entity that identifies the implicit certificates of users/devices and, whenever necessary, revokes them by accumulating their hash values to generate a value $A_{\sqcup}$ in $\mathbb{Z}_p$ (see Section IV-B2). Then, the RM distributes timely $A_{\sqcup}$ to all users in advance.

In the improved P-HIP, Fig. 5 presents the message exchange in the implicit certificate issuance phase, where the revocation operations are the same as that of the SEIC in Section IV-B2). All communications are made via secure ways, using standard protocols (e.g., Transport Layer Security-TLS) or public key encryption. The user first sends (R_u, f) to the RA. In response to the request of the user, the RA expands the point R_u into β points $\hat{R}_u^{(l)} = R_u + f(l) * G$. Note that f is shared only between the user and the RA. The RA then sends each individual $\hat{R}_u^{(l)}$ to the CA, while shuffling together requests from different batches to ensure their unlinkability.

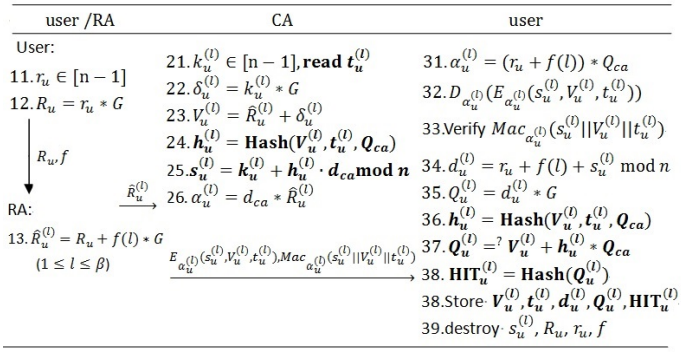

Fig. 5. The Implicit Certificate Issuance Phase in the Improved P-HIP.

The CA, in turn, randomizes $\hat{R}_u^{(l)}$ by picking randomly an integer $k_u^{(l)}$ and adding $k_u^{(l)} * G$ to it. The randomized point is used as the butterfly public key validation data $V_u^{(l)}$. Then, according to the procedure in Sections IV-A, the CA generates the hash value for $(V_u^{(l)}, t_u^{(l)}, Q_{ca})$, and outputs its signature $s_u^{(l)}$. The resulting credential is encrypted and verified with the Diffie-Hellman-key $\alpha_u^{(l)} = d_{ca} * \hat{R}_u^{(l)}$ and sent back to the RA. The RA, unable to decrypt the CA's response $\overline{pkg}$, forwards it back to the requesting user, in batch.

Finally, the user computes $\alpha_u^{(l)}$ to decrypt $\overline{pkg}$. It then verifies that the retrieved credential is indeed valid via $Mac_{\alpha_u^{(l)}}[s_u^{(l)} || V_u^{(l)}]$ and $Q_u^{(l)} = V_u^{(l)} + h_u^{(l)} Q_{ca}^{(l)}$, aiming to ensure there is no Man-in-the-Middle attack by the RA. If the verification is successful, the obtained keys, $(V_u^{(l)}, t_u^{(l)}, d_u^{(l)}, Q_u^{(l)})$, can be used for signing messages.

B. Performance Improvement for P-HIP

1) Host Identity and Host Identity Tag: Suppose that $u \in \{i, r\}$ is an authorized user as an initiator i or a responder r. Then, β implicit certificates $\{V_u^{(l)}, t_u^{(l)}, d_u^{(l)}, Q_u^{(l)}\}$ are first obtained via the process in Section V-A, l=1, $\cdots$, β. For each implicit certificate $\{V_u^{(l)}, t_u^{(l)}, d_u^{(l)}, Q_u^{(l)}\}$, its host identity is the public key $Q_u^{(l)}$. The corresponding HIT can be computed by the user u as $\text{HIP}_u^{(l)} = Hash(Q_u^{(l)})$. Hence, the mobile user u can use a new host identity $Q_u^{(l)}$ and its $\text{HIP}_u^{(l)}$ to avoid identity tracking when she/he moves from one network to another network.

2) Host Identity Validation: Here, we present the procedure to validate host identifiers, such as public keys and HITs. Without loss of generality, assume that a prover is the user u who holds an implicit certificate $\{V_u^{(l)}, t_u^{(l)}, d_u^{(l)}, Q_u^{(l)}\}$ and $\text{HIP}_u^{(l)}$. Now, the prover provides its host identity $Q_u^{(l)}$, $\text{HIP}_u^{(l)}$, the public-key authentication data $(V_u^{(l)}, t_u^{(l)})$ and the CA's identity to a verifier. The verifier validates u's implicit certificate by running Algorithm 1 in Fig. 6 as $PubKeyValid(pas, Q_{ca}, A_{\sqcup}, (V_u, t_u, Q_u, HIP_u))$.

Algorithm 1 : Public kry validation
$\{0,1\} \leftarrow PubKeyValid(pas, Q_{ca}, A_{\sqcup}, (V_u, t_u, Q_u, HIP_u))$: It takes pas,Q_{ca}, $A_{\sqcup}$ and (V_u, t_u, Q_u, HIP_u) as the input, and outputs 1 if (Q_u, HIP_u) is authentic or 0 if either the public-key or HIT is forged.
(1) t_u is unexpired.
(2) Q_u is unrevoked by computing $HIT_u^{(l)} = Hash(Q_u)$ and then check if $H(A_{\sqcup}, HIT_u^{(l)}) \neq A_{\sqcup}$.
(3) Q_u is correct and issued by CA if $Q_u^{(l)}$=$V_u^{(l)} + h_u^{(l)} * Q_{ca}$ holds.
(4) If the above checks are true, it returns 1; otherwise, it return 0.

Algorithm 2 : Keying material generation
$null$ or $((d_{pu}, Q_{pu}), V_{pu}) \leftarrow KeyMatGen(HIT_u, d_u, PuzSol)$: It takes the initiator/responder host identifier HIT_u, her/his private key d_u and puzzle/solution $PuzSol$ as the input, and outputs $null$ or a message $((d_{pu}, Q_{pu}), V_{pu})$ as follows:
If HIT_u equals $null$ or HIT_u is revoked or $PuzSol$ equals $null$, it returns $null$; otherwise, it returns $((d_{pu}, Q_{pu}), V_{pu})$ by the following operations.
(1) Choose a random integer $r_{pu} \in [n-1]$ and generate a random point V_{pu} = $r_{pu} * G$.
(2) Compute the hash value h_{pu} = $Hash(HIT_u || PuzSol || V_{pu})$.
(3) Use the private key d_u to generate V_{pu}'s validation data Q_{pu} = $d_{pu} * G$, where d_{pu}=$h_{pu} \times d_u + r_{pu} \mod n$.

Algorithm 3 : Keying material validation
$null$ or $\{0,1\} \leftarrow KeyMatValid(HIT_u, Q_u, PuzSol, Q_{pu}, V_{pu})$: It takes the initiator/responder host identifier HIT_u, her/his public key Q_u, puzzle/solution $PuzSol$, the random point V_{pu}, and the validation data Q_{pu} as the input, and outputs $null$ or 1 if V_{pu} is authentic or 0 if the random point is forged. Specifically, if HIT_u equals $null$ or $PuzSol$ equals $null$, it returns $null$; otherwise, it returns $\{0,1\}$ by the following operations.
(1) Compute the hash value h_{pu} = $Hash(HIT_u || PuzSol || V_{pu})$.
(2) Generate the point Q'_{pu} = $h_{pu} * Q_u + V_{pu}$.
(3) If Q'_{pu} = Q_{pu}, it returns 1; otherwise, it returns 0.

Fig. 6. The Algorithms in the Improved HIP

The correctness of the host identity $Q_u^{(l)}$ can be seen as follows. $Q_u^{(l)} = d_u^{(l)} * G = (r_u + f(l) + s_u^{(l)}) * G = (r_u + f(l) + k_u^{(l)} + h_u^{(l)} \cdot d_{ca}) * G = \hat{R}_u^{(l)} + \delta^{(l)} + (h_u^{(l)} \cdot d_{ca}) * G = V_u^{(l)} + h_u^{(l)} * Q_{ca}$.

3) Mutual Authentication: Let the CA issue $(V_i^{(l)}, t_i^{(l)}, d_i^{(l)}, Q_i^{(l)})$ and $(V_r^{(\iota)}, t_r^{(\iota)}, d_r^{(\iota)}, Q_r^{(\iota)})$ to the initiator and responder, respectively. Assume that CA's public key Q_{ca} and RM's authentication information $A_{\sqcup}$ are correctly sent to all users in advance. The initiator and responder compute $\text{HIT}_i^{(l)}$ and $\text{HIT}_r^{(\iota)}$ as Section V-B1), respectively. For the improved P-HIP, the mutual authentication procedure is shown in Fig. 7.

In the improved P-HIP,the operations in the first step and the last step are the same to the common HIP. We will omit the statement of these two steps, and will describe the other intermediate steps and operations in detail.

Upon receiving the message I_1, the responder then creates a message R_1 that contains $\text{HIT}_i^{(l)}$, $\text{HIT}_r^{(\iota)}$, a puzzle, its keying material (Q_{pr}, V_{pr}), its host identity $Q_r^{(\iota)}$ and the corresponding validation data $(V_r^{(\iota)}, t_r^{(\iota)})$. The keying material is generated by the responder running the Algorithm 2 in Fig. 6 as $((d_{pr}, Q_{pr}), V_{pr}) \leftarrow KeyMaterialGen(HIT_r^{(\iota)}, d_r^{(\iota)}, puzzle)$.

After receiving the message R_1, the initiator first validates

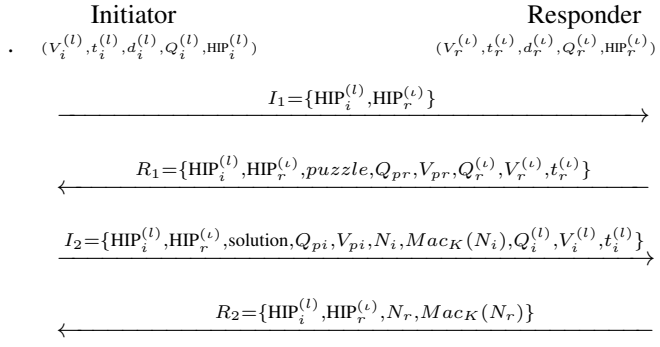

Fig. 7. The Mutual Authentication in the Improved P-HIP.

the host identity $Q_r^{(\iota)}$ and $\text{HIT}_r^{(\iota)}$ by using the Algorithm 1 in Fig. 6 to ensure that the keying material (Q_{pr}, V_{pr}) is generated by an authorized user. Next, the initiator solves the puzzle to get its solution, and then verifies the keying material (Q_{pr}, V_{pr}) in R_1 by running the Algorithm 3 in Fig. 6, this is, $\{0,1\} \leftarrow KeyMatValid(HIT_r^{(\iota)}, Q_r^{(\iota)}, puzzle, Q_{pr}, V_{pr})$. The initiator generates the keying material by using the Algorithm 2 in Fig. 6 as $((d_{pi}, Q_{pi}), V_{pi}) \leftarrow KeyMatGen(HIT_i^{(l)}, d_i^{(l)}, solution)$. Finally, the initiator computes a session key K=$d_{pi} * Q_{pr}$, and sends the message I_2 to the responder. The message I_2 includes the elements as shown in Fig. 7. If one of the above checks returns false, the initiator exits.

Similar to the initiator's approaches, the responder verifies the authenticity of the host identity $Q_r^{(\iota)}$ and $\text{HIT}_r^{(\iota)}$, validates the keying material (Q_{ir}, V_{ir}) in I_2, and authenticates the initiator. Next, the responder computes the session key using d_{pr} and Q_{ir} as $K = d_{pr} * Q_{ir}$, and then validates the $MAC_K(N_i)$.

Finally, at the last step, the responder sends R_2 and the initiator validates $MAC_K(N_r)$ to ensures that a shared session key K is created successfully. After this point, the communications between them are encrypted using K.

4) User Privacy: In the improved P-HIP, a user may utilize a remaining unused implicit certificate to generate the new host identity while she/he moves to a different network or wants to update its host identity. This way provides a secure interact between different parties without compromising user privacy. Let us suppose, an adversary is provided with the implicit certificates, $\{(V_u^{(l)}, t_u^{(l)}, d_u^{(l)}, Q_u^{(l)})\}_{l=1}^{\varpi}$, of a user u that were used in ϖ number of networks. The goal of the adversary is to infer that the implicit certificates belong the same user. In Section VI-B, we utilize the formal privacy definition [15], to prove that the improved P-HIP gives rigorous, rather than ad-hoc or intuition-based privacy guarantees.

VI. The Security Analysis of the Improved P-HIP

In this section, we analyze the security of the improved SEIC and the privacy of improved P-HIP.

A. The Security Analysis for Improved SEIC

Here, we show that the improved SEIC in Section V-A is secure. Under the attack model in Definition 1, Theorem 3 shows that there is no adversary $\mathcal{A}$ that is successful against the proposed SEIC. Form Lemma 1, we know that SEIC's signature scheme DS is secure against adaptive chosen-message attacks. The improved SCMS in Section is the butterfly key expansion of the proposed SEIC. The attacks in Definition 1 does not invalidate SEIC's security claims for at least three reasons[4]. The first is that in the improved SEIC, one of security assumptions is that there is no CA-RA collusion. Next, SCMS recommends using the ECDSA-signature algorithm [13], for which SEIC's signature scheme DS is a secure ECDSA-signature against the attacks in Definition 1. Finally, the latest version of SCMS already suggests the countermeasure hereby proposed [14], that is, the signer's certificate information is included in the hash computation. Therefore, the improved SEIC remains secure against the forgery in Definition 1.

B. The Formal Privacy Analysis of the Improved P-HIP

We first define the privacy model, and then formally analyze the privacy of the improved P-HIP.

1) Privacy Model: We now consider Ouafi and Phan's privacy model [15]. In this model, attacker $\mathcal{A}$ can eavesdrop on all the channels between two users, and he/she can also perform any active or passive attacks. In this regard, $\mathcal{A}$ needs to model the following queries in polynomial time:

Execute$(\mathcal{P},\mathcal{U},s)$: This query represents the passive attacks. In this context, the attacker can eavesdrop all the transmitted messages between the user $\mathcal{U}$ and a party $\mathcal{P} \in \{CA, RA, \mathcal{V}\}$ in the s-th session, where the user $\mathcal{V}$ satisfies $\mathcal{V} \neq \mathcal{U}$. Consequently, the attacker obtains all the exchanged data between $\mathcal{U}$ and $\mathcal{P}$.

Send$(\mathcal{U},\mathcal{V},m,s)$: This query models the active attacks in the system. In this query, attacker $\mathcal{A}$ has the permission to impersonate a user $\mathcal{U}$ in the s-th session, and forwards a message m to another user $\mathcal{V}$. Besides, the attacker has the permission to block the exchanged message m between $\mathcal{U}$ and $\mathcal{V}$.

Query$(\mathcal{U},m_1,m_2)$: This query models the adversary's ability to investigate a user. For this, $\mathcal{A}$ sends m_1 to $\mathcal{U}$ and receives m_2 from $\mathcal{U}$.

Corrupt$(\mathcal{U},K)$: In this query, the attacker $\mathcal{A}$ has the permission to access secret information K stored in the user $\mathcal{U}$'s memory.

Test$(\mathcal{U}_0,\mathcal{U}_1,s)$: This query is the only query that does not correspond to any of $\mathcal{A}$'s abilities or any real-world event. This query allows to define the indistinguishability-based notion of untraceable privacy.

If the party has accepted and is being asked a Test query, then depending on a randomly chosen bit $b \in \{0,1\}$, $\mathcal{A}$ is given $\mathcal{U}_b$ from the set $\{\mathcal{U}_0,\mathcal{U}_1\}$. Informally, $\mathcal{A}$ succeeds if it can guess the bit b. In order for the notion to be meaningful, a Test session must be fresh in the sense of Definition 3.

Definition 2 (Partnership and Session Completion)**.** *An initiator instance i and a responder instance r are partners if, and only if, both have output Accept(i) and Accept(r), respectively, signifying the completion of the protocol session.*

Definition 3 (Freshness)**.** *A party instance is fresh at the end of execution if, and only if (1) it has output Accept with or without a partner instance and (2) both the instance and its partner instance (if such a partner exists) have not been sent a Corrupt query.*

Definition 4 (Indistinguishable Privacy (INDPriv))**.** *It is defined using the game $\mathcal{G}$ played between a malicious adversary $\mathcal{A}$ and a collection of initiators and responders and RAs and CA instances. $\mathcal{A}$ runs the game $\mathcal{G}$ whose setting is as follows.*

- *Learning phase: $\mathcal{A}$ is able to send any Execute, Send, Query, and Corrupt queries and interact with the RA, the CA and users $\mathcal{U}_0$, $\mathcal{U}_1$ that are chosen randomly.*
- *Challenge phase: The attacker selects two users $\mathcal{U}_0$ and $\mathcal{U}_1$, and forwards a Test query $(\mathcal{U}_0,\mathcal{U}_1,s)$ to challenger $\mathcal{C}$. After that, $\mathcal{C}$ randomly selects $b \in \{0,1\}$ and the attacker determines a user $\mathcal{U}_b \in \{\mathcal{U}_0,\mathcal{U}_1\}$ using Execute, Send and Query queries.*
- *Guess phase: The attacker $\mathcal{A}$ finishes the game $\mathcal{G}$ and outputs a bit $\hat{b} \in \{0,1\}$ as guess of b. The success of attacker $\mathcal{A}$ in the game $\mathcal{G}$ and consequently breaking the security of INDPriv is quantified via $\mathcal{A}$'s advantage in recognizing whether attacker $\mathcal{A}$ received $\mathcal{U}_0$ or $\mathcal{U}_1$, and is denoted by $Adv_{\mathcal{A}}^{INDPriv}(k)$ = $|Pr[\hat{b}=b]-1/2|$, where k is a security parameter.*

Theorem 1. *The improved P-HIP satisfies indistinguishable privacy.*

Proof 1. *In the improved P-HIP, after a successful authentication, the user $\mathcal{U}_0$ update its secret key $d_{\mathcal{U}_0}$. Besides, the host identities $HIP_{\mathcal{U}_0}$ change in each session. Therefore, it will be difficult for an adversary to perform any traceability attack by performing the following phases:*

- *Learning phase: In the μ-th authentication instance, the adversary $\mathcal{A}$ is able to send any Execute$(CA,\mathcal{U}_0,\mu)$ queries and obtains the public key $Q_{\mathcal{U}_0}^{(\mu)}$ and the host identity $HIP_{\mathcal{U}_0}^{(\mu)}$ such that $HIP_{\mathcal{U}_0}^{(\mu)}$=$Hash(Q_{\mathcal{U}_0}^{(\mu)})$ holds.*
- *Challenge phase: The adversary $\mathcal{A}$ selects two fresh users $\mathcal{U}_0$, $\mathcal{U}_1$ and forwards a Test query $(\mathcal{U}_0,\mathcal{U}_1,\mu+1)$ to the challenger $\mathcal{C}$. Next, according to the randomly chosen bit $b \in \{0,1\}$, $\mathcal{A}$ is given a user $\mathcal{U}_b \in \{\mathcal{U}_0,\mathcal{U}_1\}$. After that the adversary $\mathcal{A}$ sends a query Execute$(CA,\mathcal{U}_b,\mu+1)$ and obtains the public key $Q_{\mathcal{U}_b}^{(\mu+1)}$ and the host identity $HIP_{\mathcal{U}_b}^{(\mu+1)}$, where $HIP_{\mathcal{U}_b}^{(\mu+1)}$=$Hash(Q_{\mathcal{U}_b}^{(\mu+1)})$.*
- *Guess phase: In the Learning phase the user $\mathcal{U}_0$ updates its secret $d_{\mathcal{U}_0}$, therefore for the two subsequent sessions μ and $\mu+1$, the public keys $Q_{\mathcal{U}_0}^{(\mu)}$=$d_{\mathcal{U}_0}^{(\mu)} * G$ and $Q_{\mathcal{U}_b}^{(\mu+1)} = d_{\mathcal{U}_b}^{(\mu+1)} * G$ are calculated as follows: $d_{\mathcal{U}_0}^{(\mu)} = [(r_{\mathcal{U}_0} + f(\mu)) + k_{\mathcal{U}_0}^{(\mu)} + Hash((r_{\mathcal{U}_0} + f(\mu)) * G, t_{\mathcal{U}_0}^{(\mu)}, Q_{ca})d_{ca}] \mod n$, $d_{\mathcal{U}_b}^{(\mu+1)} = [(r_{\mathcal{U}_b} + f(\mu+1)) + k_{\mathcal{U}_b}^{(\mu+1)} + Hash((r_{\mathcal{U}_b} + f(\mu+1)) *$*

$G, t_{\mathcal{U}_b}^{(\mu+1)}, Q_{ca})d_{ca}] \mod n$. *Note that* $r_{\mathcal{U}_0}$, $k_{\mathcal{U}_0}^{(\mu)}$, $r_{\mathcal{U}_b}$ *and* $k_{\mathcal{U}_b}^{(\mu+1)}$ *are the random numbers. Assume that the hash function* $Hash$ *is truly random, mapping each data item independently and uniformly to the range* $\{0,1\}^r$, *that is,* $Pr[Hash(x) = Hash(x')] = \frac{1}{2^r}$ *where* $x \neq x'$. *Since* $t_{\mathcal{U}_0}^{(\mu)} \neq t_{\mathcal{U}_b}^{(\mu+1)}$, *therefore* $d_{\mathcal{U}_b}^{(\mu+1)} = d_{\mathcal{U}_b}^{(\mu+1)}$ *with the probability less than* $\frac{1}{2^{r-1}}$. *In other word,* $Q_{\mathcal{U}_0}^{(\mu)} = Q_{\mathcal{U}_b}^{(\mu+1)}$ *holds with the probability less than* $\frac{1}{2^{r-1}}$. *Again,* $HIP_{\mathcal{U}_0}^{(\mu)}$=$Hash(Q_{\mathcal{U}_0}^{(\mu)})$ *and* $HIP_{\mathcal{U}_b}^{(\mu+1)}$=$Hash(Q_{\mathcal{U}_b}^{(\mu+1)})$. *Hence, the adversary needs make a random guess for* $HIP_{\mathcal{U}_b}^{(\mu+1)}$. *In this context, the advantage of the adversary recognizing* $\mathcal{U}_0$ *or* $\mathcal{U}_1$, *can be denoted* $Adv_{\mathcal{A}}^{INDPriv}(k) = |Pr[\hat{b} = b] - 1/2| < \epsilon$, *where* $\epsilon = \frac{1}{2^{r-1}}$ *is negligible when* r *is large enough.*

VII. Performance Analysis and Comparison

In this section, based on the improved scheme in Section V, we compare it with other similar solutions in the literature in terms of the desired security properties, computation cost and communication cost.

A. Performance Comparison

A comparison of the security properties among the improved scheme with other implicit certificate schemes [3, 4, 13] is given in Table II. The improved scheme in Section V is secure against the forger and credential misbinding attacks. The signature algorithm's input (see step 24 Fig. 3 and 5) includes both $(V_u^{(l)}, t_u^{(l)})$ and the signer's public key Q_{ca}. In the P-HIP scenario, enforcing this technique when signing public-key authentication data can avoid forgery attacks that builds upon the properties of butterfly keys. Under the attack model in Definition and Ouafi and Phan's privacy model, the improved scheme provides the rigorous security proof in Section IV-C and VI-A and the formal privacy analysis in Section VI-B, respectively. In addition, the improved scheme achieves the revocation verification of a public key by performing one NOWA operation in Section IV-B2. However, the schemes [3, 4, 13] focused on the informal analysis of user privacy, and did not consider the revocation of unexpired implicit certificates. Note that the formal security proof did not provided in [3].

TABLE II. Performance Comparison based on Security Properties with Respect to Implicit Certificate Schemes

Scheme	SP1	SP2	SP3	SP4	SP5
ECQV [13]	No	formal	informal	No	-
SIMPL [4]	Yes	formal	informal	No	SCMS
P-HIP [3]	No	informal	informal	No	HIP
SEIC	Yes	formal	No	Yes	HIP
improved P-HIP	Yes	formal	formal	Yes	SCMS, HIP
SP1: preventing the credential misbinding attacks and a forgery attack					
SP2: security proof; SP3: user privacy proof;					
SP4:credential revocation; SP5: Compatibility					

B. Effectiveness Analysis

We evaluate the effectiveness of the improved scheme in terms of the computation and communication costs.

1) Experimental Results: To show the effectiveness of the improved scheme with respect to the existing implicit certificate schemes, we conduct simulations of the cryptographic operations used by various schemes on an Intel(R) Core(TM) i7-8550U CPU@1.80 GHz laptop computer with 8.00 GB memory and Windows10 using JDK1.8 (operating as the initiator or the responder as per the scheme). The simulations used the JPBC library jpbc-2.0.0 [16] to evaluate the execution time of different cryptographic operations.

We create an ECC self-signed X.509 certificates using the type A pairings on the curve $y^2 = x^3 + x$ over the finite field $\mathbb{F}_q$. SHA-256 is chosen as the cryptographic hash function $Hash$. In addition, we select SHA-512 for hashing h in NOWA H with a 128 bit output, where $N = 2^4$ is an upper bound to the number of accumulated items. When $N > 2^4$, we do this by selecting $\eta = \lceil N/(2^4) \rceil$ different SHA-512 as Remark 1 in [17]. For the function $Hash$ and the message authentication code (MAC), the SHA-256 is chosen as suggested. Furthermore, the leftmost 128 bits in the output of $Hash(Q_u)$ is taken as a HIT corresponding public key Q_u. With the above parameter settings, we consider the average value of over 100 trials for an operation $o \in \{Hash, H, a(\text{Point addition}), m(\text{Point multiplication}), e(\text{AES encryption}), d(\text{AES decryption})\}$. The results are as follows: T_{Hash} = 1.2828milliseconds(ms), T_H = 53.8039(ms), T_a = 1.3418(ms), T_m = 96.9339(ms), T_e = 13.1607(ms), and T_d = 3.7243(ms). In particular, the average time performing an addition or a multiplication of two numbers is 0.6626ms or 0.7615ms, which is negligible compared to other operations.

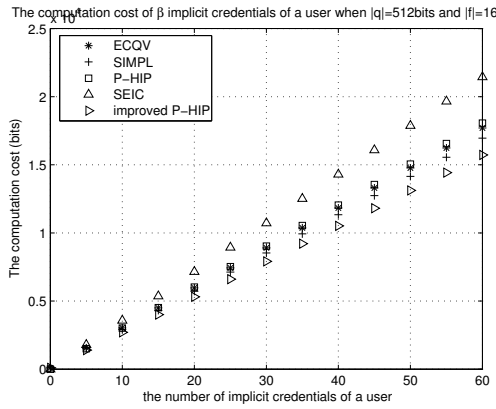
2) Implicit Certificate Issuance:

a) Computation Cost: Computation costs are the principal constraint for IoT users/devices, and we show a reduction in required computation in the improved P-HIP as compared to the existing schemes. Table III shows the computation cost of a user in different schemes. The improved P-HIP is similar to the approach discussed in [4], the key difference is that instead of 63 point addition, $h * Q_{ca}$ is computed by using 42 point addition. In both schemes, the user generates the request $(R_u = r_u * G, f)$, and then obtains an implicit certificate the β by computing $\alpha_u^{(l)}$, $d_u^{(l)} * G$ and $h_u^{(l)} * Q_{ca}$. It means that in the improved P-HIP, the computation cost of the user is $\beta(2\text{T}_m + 44\text{T}_a + T_d + 3\text{T}_{Hash}) + \text{T}_m$. In addition, the verifier performs only one H operation to check whether the unexpired implicit certificates is unrevoked. From Fig. 8 (a), it is evident that the computation cost of a user increases with the number of implicit certificate, but it grows relatively slowly in the improved scheme. In particular, the improved P-HIP makes a user has the smallest computation cost.

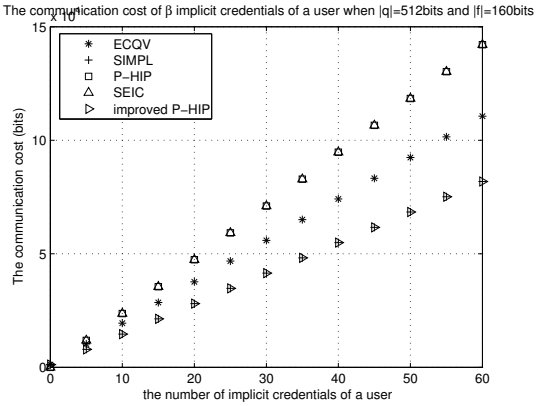
TABLE III. The Cost Comparison of Different Schemes in the Implicit Certificate Issuance Phase

Scheme	Computation cost	Communication cost
ECQV[13]	$\beta(3\text{T}_m + \text{T}_a + \text{T}_{Hash}) + \text{T}_m$	$\geq \beta(2\|q\| + 800) + 2\|q\| + \|f\|$
SIMPL[4]	$\beta(2\text{T}_m + 64\text{T}_a + \text{T}_{Hash}) + \text{T}_m$	$\geq \beta(2\|q\| + 320) + 2\|q\| + \|f\|$
P-HIP [3]	$\beta(3\text{T}_m + 2\text{T}_a + \text{T}_d + 2\text{T}_{Hash})$	$\beta(4\|q\| + 320)$
SEIC	$\beta(3\text{T}_m + 44\text{T}_a + \text{T}_d + 3\text{T}_{Hash})$	$\beta(4\|q\| + 320)$
Improved P-HIP	$\beta(2\text{T}_m + 44\text{T}_a + \text{T}_d + 3\text{T}_{Hash}) + \text{T}_m$	$\beta(2\|q\| + 320) + 2\|q\| + \|f\|$

b) Communication Cost: The advantage of the improved scheme is that the communication cost is low for IoT users/devices in the implicit certificate issuance. The communication cost comparison of these schemes [3, 4, 13] is



(a) The Computation Cost of β Implicit Certificates of a User



(b) the Communication Cost of β Implicit Certificates of a User

Fig. 8. The Computation and Communication Costs of β Implicit Certificates of a User in the Improved P-HIP

shown in Table III. To give a detailed quantitative analysis, we create a ECC self-signed X.509 certificates using the OpenSSL library [2], and choose n = 160 bits and q = 512 bits. The sizes of an identity and a time-stamp are recommended to be 20 bytes [14]. In the improved P-HIP, the communication cost at the user is as follows: The size of β responses from the CA $(c_u^{(l)}, Mac_u^{(l)})$ are $\beta(2|q|+n+320)$ bits, and the size of a request is $|R_u|+|f|$=2$|q|$+f bits. The total communication cost of a user is $(2\beta+2)|q|+320\beta+|f|$ bits. We notice that the size of $meta$ in [4, 13] is not less than 160 bits since $meta$ contains at least a time-stamp. The ECDSA-based signature outputs at least two numbers in $\mathbb{F}_q$. The length of $sig_u^{(l)}$ in ECQV[13] is $2|q|$. However, the size of $|sig_u^{(l)}|$ is $|q|$ since $sig_u^{(l)}$ is a number in $\mathbb{Z}_n^*$. Fig. 8 (a) and (b) shows that the improved scheme makes a user have both the smallest computation cost and the smallest communication cost.

3) Mutual Authentication: Implicit Credential Validation: We also evaluate the benefits of the improved P-HIP when users perform mutual authentication. The gains in this case originate from the following observations.

In Section V-B2), the cost of validating a public key and its HIT is T_H+ $\hat{T}_m$+ T_a+2T_{Hash}, where $h_u^{(l)} * Q_{ca}$ can be accelerated at cost $\hat{T}_m$ = 42T_a< T_m. In addition, the costs for keying material generation and keying material validation (see Algorithm 2 and 3 in Fig. 6) are 2T_m+ T_a+ T_{Hash}) and T_m+ T_a+ T_{Hash}, respectively. However, the generation/validation of a MAC requires one hash operation. Therefore, the total computational cost of an initiator or a responder is T_H +3T_m+ 40T_a+ 6 T_{Hash} $\approx$ 411.3416ms.

The improved HIP has stronger capabilities (such as public key revocation verification) than P-HIP [3], with an approximate computational cost and the same communication cost. In P-HIP, an initiator or a responder takes the total computational cost to be 4T_m+ 3T_a+ 6 T_{Hash} $\approx$ 399.4578ms. This value is close to the computational cost of the user in the improved P-HIP. On the other hand, the time for the device to perform a public key revocation verification operation is 53.8039(ms). Since $A_{\sqcup}$ is sent to all users in advance, both schemes have the same communication cost. The result gives a glimpse of SEIC's potential to speed up both signature verification and public-key authentication in HIP environments.

VIII. Conclusion

In this article, we propose SEIC that can improve the security of the P-HIP and the efficiency of EC point multiplications for IoT devices. For fix-point multiplication, the proposed method is about 1.5 times faster than the method in SIMPL scheme. At the same time, by making use of the butterfly key expansion process, we constructs an improved P-HIP by reducing the amount of data exchanged and the number of operations performed by user. Our evaluation shows that the improved P-HIP helps to achieve all the important security properties and ensures the user privacy with reasonable computation cost. However, one limitation is that for the solution to become a reality, the revocation verification information $A_{\sqcup}$ must be updated timely and sent to all users in advance, which can be costly. A potential future direction of this research is how to effectively implement the update and release for $A_{\sqcup}$. Note that the proposed scheme has minimized the revocation verification information because $A_{\sqcup}$ is just a $\mathbb{Z}_p$ symbol. Hence, for a IoT network with a small number of users, the update of $A_{\sqcup}$ can be effectively implemented. How to achieve the update of $A_{\sqcup}$ for all users in the large and medium-sized IoT networks is still a challenge problem.

APPENDIX

Lemma 1. *Assuming* (1) *ECDLP is hard for* $\mathcal{G}$ *and* (2) $Hash$ *is a random oracle, the Schnorr signature scheme* DS *in Fig. 3 is secure against adaptive chosen-message attacks.*

Proof 2. *Let* $Adv^{cma}_{DS,\mathcal{A}}(\kappa)$ *be the probability that* $\mathcal{A}$ *breaks the above Schnorr signature scheme* DS *and achieve a forgery. Assume that* $Adv^{cma}_{DS,\mathcal{A}}(\kappa)$ *is nonnegligible. We will construct an algorithm* $\mathcal{B}$ *which can solve the ECDLP in* $\mathcal{G}$*.*

Let G *be a generator of* $\mathcal{G}$*. Given a point* Q_{ca}=$d_{ca} * G \in <G>$ *as a challenge to* $\mathcal{B}$*, it aims to output such a value* $d_{ca} \in Z^*_q$*. The hash function* $Hash$ *behaves as a random oracle.*

$\mathcal{B}$ *starts* $\mathcal{A}$ *on input* 1^κ*. Let* $T_1(\kappa)$ *denote the bound of the number of CAs.* $\mathcal{B}$ *picks at random a* $i \in \{1, \cdots, T_1(\kappa)\}$*, guessing that* $\mathcal{A}$ *will succeed against the entity* i*.* $\mathcal{B}$ *runs* $\mathcal{K}(pas)$ *to generate for each entity its private/public pair, except* i*.* i *is given a public key* Q_{ca} *, while the corresponding private key* d_{ca} *is unknown to* $\mathcal{B}$*. A* i*'s signature on a message can be generated by querying the signing oracle* $\mathcal{S}(d_{ca}, \cdot)$*.*

$\mathcal{B}$ *can simulate the entity* i *to respond messages to via the following oracles:*

Hash Queries: *At any time,* $\mathcal{A}$ *can query* $Hash$*.* $\mathcal{B}$ *maintains a list* H_{list} *of tuples* (R, V, t, k, Q_{ca}) *which is initially empty, and a query counter* μ *which is initially set to* 0*.* $\mathcal{A}$ *provides a new pair* (R, V, t, Q_{ca}) *for hash query by first choosing a message* R *and then computing* $V = R + k * G$*, where* k *is a random number in* Z^*_n*. Upon a hash query* (R, V, t, Q_{ca}) *for which there exists a record* (R, V, t, Q_{ca}, h) *in* H_{list}*,* $\mathcal{B}$ *return* h *to* $\mathcal{A}$*; otherwise,* $\mathcal{B}$ *uniformly chooses a random number* $h \in Z^*_n$ *as the value of* $H(V, t, Q_{ca})$*, places* (R, V, t, Q_{ca}, h) *into* H_{list}*, and returns* h *to* $\mathcal{A}$*.*

Signature Queries:*Proceeding adaptively, the adversary* $\mathcal{B}$ *answers* $\mathcal{A}$*'s queries for signing oracle* $\mathcal{S}(d_{ca}, \cdot)$*. When* $\mathcal{A}$ *provides a query message* R*,* $\mathcal{B}$ *works as follows:*

(1) *Randomly choose two numbers* $u, v \in Z^*_q$*, and compute* $V = R + u * G + (-v * Q_{ca})$*;*
(2) *Set* $s = u$*,* $H(V, t, Q_{ca}) = v$*, and place* (R, V, t, Q_{ca}, v) *into* H_{list}*;*
(3) *Returns* (v, s) *as a signature on message* R *to* $\mathcal{A}$*.*

After $\mathcal{A}$ *makes* H*-hash query on* (R, V, t, Q_{ca}) *to get* $v = H(V, t, Q_{ca})$*, it can verify that* (V, s) *satisfies* $R + s * G = V + v * Q$*. Therefore,* (V, s) *is a valid signature on message* R *with respect to* j*'s public key* Q_{ca}*. Since* V *and* s *follows the uniform distribution, and* $Hash$ *behaves as a random oracle,* $\mathcal{A}$ *cannot distinguish between* $\mathcal{B}$*'s response and the real life.*

Output: *Eventually, suppose* $\mathcal{A}$ *returns a forgery* (R^*, V^*, t^*, s^*)*, where* (V^*, t^*, s^*) *is a valid forgery distinct from any previously given signature on message* R^* *with respect to the public key* Q_{ca}*.*

According to the above proof, $\mathcal{A}$ *can find a valid signature with non-negligible probability* $Adv^{cma}_{DS,\mathcal{A}}(\kappa)$*. Then, by using the forming lemma,* $\mathcal{A}$ *can outputs a new forgery* $(V^*, t^*, \hat{s}^*)$ *on the same message* R^* *and a different oracle* $\hat{Hash}(\cdot)$*, with non-negligible probability, such that* $Hash(V^*, t^*, Q^*_{ca}) \neq \hat{Hash}(V^*, t^*, Q^*_{ca})$ *and* $s^* \neq \hat{s}^*$*. From this, we get*

$$s^* = k + d_{ca} Hash(V^*, t^*, Q^*_{ca}) \bmod n$$
$$\hat{s}^* = k + d_{ca} \hat{Hash}(V^*, t^*, Q^*_{ca}) \bmod n$$

Thus, $\mathcal{B}$ *can solve out the private key*

$$d_{ca} = \frac{s^* - \hat{s}^*}{Hash(V^*, t^*, Q^*_{ca}) - \hat{Hash}(V^*, t^*, Q^*_{ca})} \bmod n \quad (2)$$

which is just $\mathcal{B}$*'s challenge* d_{ca}*. The choices of* i *in algorithm* $\mathcal{B}$ *imply that with probability at least* $\frac{1}{T_1(\kappa)}$ *he can 'hit' the correct value of* $\mathcal{A}$*. Thus,* $Adv^{ecdl}_{\mathcal{G},\mathcal{B}}(\kappa) \geq \frac{Adv^{cma}_{DS,\mathcal{A}}(k)}{T_1(\kappa)}$*, where* $Adv^{ecdl}_{\mathcal{G},\mathcal{B}}(\kappa) = Pr[pas \leftarrow Gen(1^\kappa); Q_{ca} \leftarrow \mathcal{G}; d_{ca} \leftarrow \mathcal{B}(pas, Q_{ca}) : d_{ca} * G = Q_{ca}]$*. Since the ECDLP is assumed to be hard in* $\mathcal{G}$*, then* $Adv^{ecdl}_{\mathcal{G},\mathcal{B}}(\kappa)$ *must be negligible. This contradicts the assumption that* $Adv^{cma}_{DS,\mathcal{A}}(\kappa)$ *is nonnegligible. Thus, we conclude that* $Adv^{cma}_{DS,\mathcal{A}}(\kappa)$ *is negligible for all adversaries* $\mathcal{A}$*.*

Theorem 2. *Assuming* (1) *ECDLP is hard for* $\mathcal{G}$ *and* (2) $Hash$ *is a random oracle, there is no adversary* A *that is successful against the proposed scheme SEIC.*

Theorem 3. *Assuming* (1) *ECDLP is hard for* $\mathcal{G}$ *and* (2) $Hash$ *is a random oracle, there is no adversary* A *that is successful against the proposed scheme SEIC.*

Proof 3. *Using Lemma 1, the proof can be obtained similar to the proof of Theorem 2 in [7]. So, we shall omit this proof.*
