We involved eleven Agile team members: a leader, a scrum master, and nine team members. In the internal evaluation process, one-to-one interviews were conducted with the team leader. Besides, a questionnaire was filled out by all Agile team members regarding appropriate practices. Each proposed practice was asked for confirmation using a Likert scale. The question was, "Are the principles of practice <practice name> applicable?". The results of distributing the questionnaires are shown in Fig. 8.

B. External Evaluation

Five experts with experience in Agile implementation participated in the external evaluation using a one-to-one interview and filling out a questionnaire. The experts' profiles participating in the expert judgment process are described in Table III.

The results of internal and external evaluations were carried out by analyzing the interviews and questionnaires. The transcripts from interview data were analyzed using the Dedoose tool, while the Likert scale questionnaire data were analyzed with Microsoft Excel.

C. Internal Questionnaire Data Analysis and Processing

Results from the questionnaires distributed to the Agile team and the experts are demonstrated in Table IV. An average calculation was carried out, and the overall evaluation value was obtained. It was agreed that the practice value was above 3 to apply.

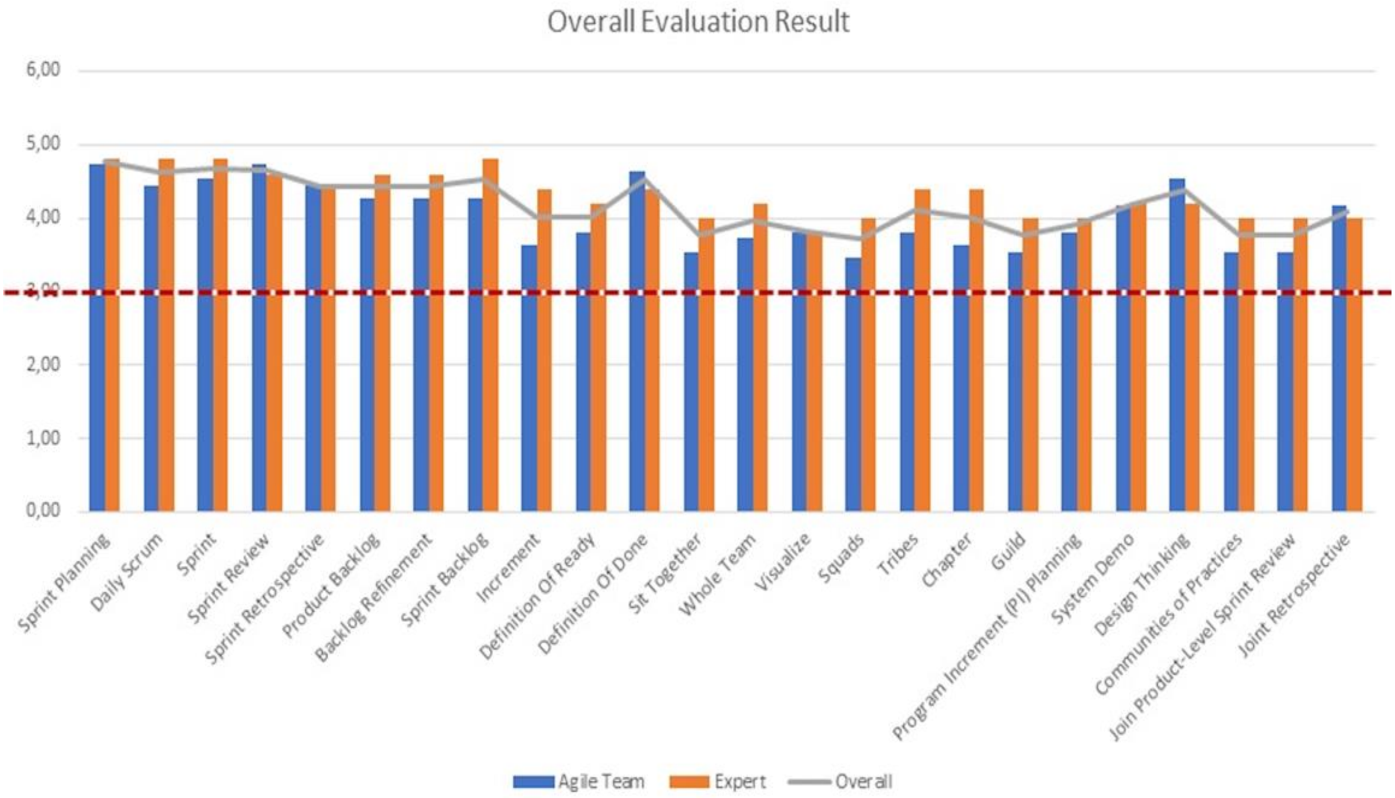

Fig. 8. Evaluation result.

TABLE III. THE PROFILES OF THE EXPERTS

Code	Profession	Experience	Specialization	Certification
N1	Consultant	25 Years	Agile Software Development, Agile DevOps, Project Management, IT Governance	COBIT 5 Foundation certification, Certified Information Systems Auditor, Scrum Master, Professional Agile Coaching, Certified DevOps Foundation, ITIL Foundation - Intermediate Banking Risk Management Certified Level 1-3, dll
N2	Consultant	17 Years	Project Management, Agile Software Development, DevOps	Certified DevOps, ITIL, Certified Agile Coach, Scaled Agile (SAFe) Agilist v5.1, SCRUM Master (CSM), Certified SCRUM Professional (CSP), Certified Kanban System Design (KMP-1), COBIT 5 Foundation, dll
N3	Senior Manager	17 Years	Project Management, Agile Software Development, Business Analyst	Scrum Master Certified (SMC), Project Management Professional (PMP)
N4	Assistant Manager	9 Years	Agile DevOps, Quality Assurance, Agile Software Development	Scrum Master, DevOps Foundation, Quality Management System (ISO 9001:2015)
N5	Senior Manager	13 Years	Quality Assurance, Agile Sofware Development, Agile DevOps	Certified Agile Tester By International Software Quality Institute (ISTQB) Certified Data Management Professional (CDMP)

TABLE IV. THE QUESTIONNAIRES RESULTS

No	Selected Practice	Agile Team	Experts	Overall
1.	*Sprint Planning*	4,73	4,75	4,74
2.	*Daily Scrum*	4,45	4,75	4,60
3.	*Sprint*	4,55	4,75	4,65
4.	*Sprint Review*	4,73	4,75	4,74

D. Internal Analysis and Processing of Interview Data

Interview data was processed by compiling transcripts of recorded interviews or FGDs with the Agile team and one-to-one interviews with experts into a text file. Files containing interview transcripts were uploaded to the Dedoose software. Next, a coding process was carried out for the 24 elections by marking the code from the results of the interview transcription in the relevant section. Excerpts of the codes revealed practices and methods mostly emerge from interviews. Next, a new Software Development Methodology Design was created from the selected practices, proposed practices, and methods.

The selection of these practices has been adapted through one product development sprint cycle, with the outputs of each stage described in Table V. A retrospective process was continued to review the practices and make continuous improvements. Therefore, the team can develop even better methods.

TABLE V. PRODUCT DEVELOPMENT CYCLE AND PRACTICES

No	Phase	Practice	Origin Method	Output
1.	Agile Discovery Session	Program Increment Planning	SAFe	Business Model Canvas (BMC), Product Backlog
		Product Backlog	Scrum	
		Visualize	Kanban	
2.	Agile Sprint Planning	Sprint Planning	Scrum	Sprint Backlog, Kanban board

7.	During coordination		Scrum of Scrums	Sprint Backlog

VII. CONCLUSION

This study aims to develop a model for Agile methods based on the Essence of software engineering framework. The resulting model is a significant outcome of this research, as it encompasses the common ground or shared understanding of scaling Agile practices from well-known methods such as SAFe, LeSS, Nexus, Disciplined Agile, Spotify Agile, and Scrum of Scrums. The intended scope of this Agile method is up to scaling Agile, as it already encompasses the Agile method within it. The common ground includes the principle, business requirement, process, work product, organization, and implementation approach. By following this model, organizations can benefit from valuable guidance in developing their Agile methods, as outlined below:

- Organization can define their initial practices from the current Agile methods
- The common ground can classify the practices to group the practices for more manageable to maintain
- The sample implementation was demonstrated in the case study

The model was implemented in the Agile product development in a national bank in Indonesia. Agile experts participated in reviewing the model. The selected practices, as based on the model, were evaluated during the focus group discussion and interview with the relevant stakeholder in the case study. The model of this study and the common ground can be implemented in the other organization to develop their methods in their Agile development project.

This study has significant implications for both academic research and practical applications. In terms of academic research, it introduces new literature concerning the scaling of Agile methods. A notable contribution is the Essence-based model, which establishes a shared foundation in the realm of scaling Agile. For practitioners, this study enhances their understanding through relevant case studies. The model can serve as a valuable reference for practitioners to make informed decisions, customize, and adapt Agile methods to suit their organizational needs.

Further research can be explored to enhance the model into a more detailed framework. Another study to build the framework can be performed with extensive expert judgment and more case studies. The framework can include more practices and specifications as supporting references.

As the model was derived from the content analysis from relevant references, it may have limitations in actual practices. The grounded theory may complement this model. Other studies in the same field may have different perspectives for building the model.

Acknowledgment

***Abstract*—Human face is the major characteristic for identifying a person and it helps to differentiate each person. Face recognition methods are mainly useful for determining a person's identity with the help of biometric techniques. Face recognition methods are used in many practical applications like criminal identification, the phone unlocks systems and home security systems. It does not need any key and card, and it only requires facial images to provide high security over several applications. The interdependencies of the encryption methods are highly reduced in the deep learning-enabled face recognition models. Conventional methods did not satisfy the present demand due to poor recognition accuracy. Therefore, an advanced deep learning-based face recognition framework is implemented to authenticate the identity of individuals with high accuracy by using facial images. The required facial images are taken from the standard databases. The collected images are preprocessed using median filtering. The preprocessed facial images are subjected to spatial feature extraction, where the Local Binary patterns (LBP) and Local Vector Patterns (LVP) are utilized to extract the relevant optimal patterns from the facial images. Here, optimal pattern extraction is done with the Improved Rat Swarm Optimization Algorithm (IRSO). Then, the facial recognition is done over the extracted optimal features with the usage of the implemented Adaptive Multi-scale transformer-based Resnet (AMT-ResNet), where the parameters in the recognition network are optimized by using the IRSO. The efficiency of the developed deep learning adopted face recognition model is validated through different heuristics algorithms, and baseline face recognition approaches.**

Keywords*—Face recognition; facial images; optimal pattern extraction rate; local binary patterns; local vector patterns; improved rat swarm optimization algorithm; adaptive multi-scale transformer-based Resnet

I. INTRODUCTION

The individuals have been recognized with the help of emerging biometric-based methodologies in the current situation. These biometric-based techniques compute the behavioral and individual's physiological characteristics to ascertain and determine their identity [17]. It exactly identifies the individuals instead of performing people authentication and giving permission for those particular individuals to access the physical domains with the support of utilizing smart cards, plastic cards, PINs, keys, passwords, and tokens [15]. But, it is hard to remember the PINs and passwords, and also, it is a possibility to guess and steal tokens, keys, and cards very easily [7]. In most cases, the magnetic cards of the individuals are missed, and then it can be misplaced, duplicated, purloined, and forgotten by intruders; hence, it becomes unreadable and corrupted [24]. Using biometric-based techniques, an individual's biological traits cannot be stolen, forgotten, forged, or misplaced [2]. When compared to other biometric approaches, face detection is one of the fastest biometric approaches and the least intrusive technique that includes iris recognition, fingerprint recognition, and face recognition [16]. Consider an example, instead of placing an individual's hands in a reader in surveillance systems, the people are requested to place their eyes in front of a scanner, which technique is generally known as iris recognition [30]. But, the face recognition systems unobtrusively capture images of individuals' faces when they are reached in a predefined area. In these face recognition systems, there is no capture delay and intrusion, and the subjects in the face recognition systems are entirely unaware of the process [18].

Face recognition approaches are accomplished several substantial attentions from the market and research communities that are the capability of dealing with real-world problems related to facial images [33]. In general, the face recognition approach is formulated as follows: from a given image or video of a scene, a person is verified and identified from a stored database of faces [29]. Before the detection process, the verification and identification were made by taking the similarity measure among two face images and calculating non-match or match pixel coefficients [6]. Moreover, during the identification process, the similarity measure between the collected face image and face images in the original database is examined to reduce the misclassification to determine the person's identity [21]. Face recognition is natural, convenient, and nonintrusive then it is helpful in a wide range of applications. But, several face recognition approaches encounter great challenges when recognizing the person's identity from spatial images due to the variations in illumination, background clutter, facial pose, image resolutions, and expressions [25]. Then, several artificial intelligence-based face recognition approaches are introduced that have accomplished great success over face recognition.

Deep learning techniques are assumed as the greatest breakthrough over face image recognition because of their powerful learning capacity. The hand-crafted features and the discriminative features are effectively learned through deep learning techniques [13]. The deep face-related face recognition techniques improved the recognition accuracy, but it slightly suffered from degradation in performance when encountering the large-scale dataset. To support effective face recognition in real-world scenarios, fine-tuning the pre-trained models are important [38]. Moreover, the labeling of large-scale datasets is difficult while using these deep learning-based face recognition approaches [37]. Furthermore, the existing deep learning-based techniques are well-suitable for limited modalities, but the complementary features present in the much more modalities are not well descriptive [9]. Therefore, an efficient face recognition model with the support of deep learning techniques has been designed to provide extensive results over face recognition. The main contribution of the developed deep intelligence-based face recognition framework is described below.

- To design an intelligent deep learning-based face recognition framework with the help of a heuristic strategy to identify the person's identity using their face and boosting security.

- To implement an IRSO in the developed face recognition model for the selection of optimal patterns and optimizing the hidden neuron count in adaptive multi-scale transformer-based ResNet for increasing the recognition accuracy of the implemented framework.

- To introduce an effective optimal pattern extraction approach from the LBP and LVP patterns by using the developed IRSO in the developed face recognition model to enhance the performance of the developed framework.

- To present an adaptive multi-scale transformer-based ResNet structure with parameter optimization via the developed IRSO for recognizing the faces very sensitively that is helpful to attain a higher recognition rate under varying illumination conditions, expressions, pose, and background.

- To validate the efficacy of the newly suggested face recognition model by comparing the experimental results among several optimization strategies and baseline face recognition approaches following different positive and negative measures.

The remaining sections used to develop the new deep learning-based face recognition approach are explained as follows. Section II gives the recently implemented deep learning-based face recognition approaches with their merits as well as demerits. Section III illustrates the structural description of the newly implemented face recognition model, the function of median filtering in the developed model, and the description of the database. Section IV enumerates the optimal solution obtained using the developed IRSO and the LBP and LVP pattern extraction process. Section V gives a detailed explanation of the developed multi-scale transformer-based ResNet for the detection of faces and its objective function. The comparative analysis and the experimental results are given in Section VI, and the conclusion of the face recognition approach is summarized in Section VII.

II. Literature Survey

A. Related Works

In 2021, Michael *et al.* [12] facial expression identification approach with the help of deep learning algorithm, which utilized Convolutional Neural Network (CNN) for learning the parameters from the face images. Here, the FER2013 dataset has been used to obtain the sample face images. Various patterns from the face images were retrieved from the original images, and the experimental results were compared over various approaches. The computational cost of this method has been highly reduced by using this approach. The recognition accuracy of the implemented model has been highly improved to baseline approaches.

In 2019, Ranjan *et al.* [27] have introduced a simultaneous face detection algorithm for localizing landmarks, recognizing genders, and estimating poses using deep CNN. Here, the multi-task learning algorithm has been implemented to fuse the intermediary layers to provide the fused features in deep CNN from the face images. Hence, the synergy among the tasks has been greatly exploited, and it improved the performance individually. Moreover, the HyperFace-ResNet and Fast-HyperFace network has been demonstrated to enhance the speed of the face identification process. The implementation results of the developed model have the ability to capture the local and global information in faces, and it provided very effective results than the other approaches.

In 2018, Abhijay *et al.* [1] have introduced a robust and efficient method to recognize individual faces in real-time. The filters have been applied to the collected sample images to eliminate unwanted features and noises. From the filtered images, the binary patterns were retrieved, and the resultant patterns were given to the Multilayer Perceptron (MLP) for recognition purposes. The extensive test results were compared over the benchmark datasets like FACES96, FACES95, and FACES94 in terms of expression, rotation, pose, illumination, and head scale. The test results gave better results and showed the developed face recognition model to be more highly efficient than the benchmark datasets.

In 2022, Junaid *et al.* [23] have studied the performance of the recently implemented deep learning-based Disguise Invariant Face Recognition (DIFR) method, which integrated the data augmentation method for removing noises. The individual faces were effectively recognized by the Viola Jones face detector and the classification was done with the support of CNN. The disguise-invariant features have been effectively learned from the facial images for identifying the person from the face images. Finally, the comparative analysis and the comprehensive experiments have been conducted over six different datasets, from that the Resnet-18 has given a good trade-off than the other face recognition approaches in terms of efficiency, accuracy and average execution time.

In 2019, Zhao *et al.* [19] have introduced a face identification method via the Generative Adversarial Network (GAN) with a dual agent system, which identified the unlabeled patterns from the face images, and the fine details of the images were highly preserved by using this model during the realism refinement. The real and face identities were effectively determined by using this dual-agent system. Moreover, the profile face images have been generated with the support of off-the-shelf 3D face models with varying poses. By using the fully convolution approach high-resolution images have been generated. The poses were sensitively preserved, and the stability of the mechanism has been improved by analyzing the experimental results over conventional face recognition datasets.

In 2018, Al-Waisy *et al.* [3] have developed a Deep Belief Network (DBN) for extracting local handcrafted features to address face recognition problems, which has been highly suitable for unconstrained conditions. Initially, the Fractal dimension was merged with the Curvelet transform to represent the main structure of the face that included both curves and edges. Then, the pixel intensity representations were replaced with the local feature representations with the help of the DBN structure for the multi-modal recognition of facial images. At last, the effectiveness of the developed DBN-based facial recognition approach was evaluated by performing several extensive experiments over different datasets such as LFW databases, CAS-PEAL-R1, FERET, and SDUMLA-HMT. The developed DBN-based face recognition approach outperformed well than the other baseline frameworks with respect to recognition accuracy and time complexity.

In 2022, Durga and Rajesh [5] have offered a deep micro-facial emotion recognition approach with the support of CNN. Here, the 2D-ResNet CNN model has been employed to extract the Multi-class features from the collected face images. Moreover, the developed approach efficiently detected the maskable images from the face images via the 2D-ResNet CNN. This developed approach has been evaluated in Python 3.7.0 software tool, and the 2D-ResNet CNN network has been trained using the public dataset. Furthermore, the jsonify python, fastai, mysql, and flask packages were highly feasible and compatible in the developed architecture. The extensive outcome was shown that the developed approach had proven its efficiency concerning the performance metrics like sensitivity, accuracy, F1-score, and recall.

In 2015, Gao *et al.* [28] have proposed a supervised auto encoder for the recognition of individuals from the collected face images. The auto encoder was a type of new deep architecture, and it effectively learned the hidden patterns from the raw images. Initially, the mapping operation was performed between the canonical face of the person and the face variants from the images. An example of this mapping operation was the integration of normal illumination into neutral expressions. Then, the auto encoder retrieved the features that were robust to the variances of the pose, occlusion, expression, and illumination. After, the deep architecture was obtained over the supervised auto encoders, which have been utilized for the extraction of relevant features in image representation. Several experiments have been conducted over the newly implemented auto encoder-based face recognition approach, which has considered the benchmark datasets like Multi-PIE, Extended Yale B, AR, and CMU-PIE to ensure the efficacy of the developed face identification approach. The test results have shown that the stacked supervised auto encoder-based face representation has outperformed well than the other benchmark datasets.

B. Problem Statement

The face recognition approaches are mainly adopted for numerous applications like internet communication, surveillance, and security. The conventional approaches over face recognition provide satisfactory performance only under controlled scenarios. But, in real-world scenarios, the performance of the model is highly degraded under several conditions like occlusion, expressions, pose variations, and illuminations. Therefore, several supervised learning-based face recognition models are employed to provide better results over face recognition. The features and drawbacks of the developed deep learning-enabled face detection approaches are given in Table I. CNN [12] provides better results over the interpretation of facial expressions and facial recognition. And also, it highly decreases the computational cost due to the development of facial detection. But, it slightly suffers with generalization capability. In addition, it increases the instability and internal covariance, and hence the overfitting problem cannot be avoided. DCNN [27] has the capability to capture both local information and global information in faces. Further, the multi-task information is efficiently reduced to enhance the effectiveness of the recognition. Yet, the topological changes due to the viewpoint variations are not captured effectively in this approach. Consequently, it does not identify the discriminative facial information at various illumination conditions. Viola Jones detector with CNN [1] gives high efficiency and robustness in face recognition. Moreover, it captures the most crucial information from the facial images, and hence, the accuracy of the recognition process is increased. Yet, it is computationally expensive and impractical in darkness condition. Nevertheless, it is a very time-consuming process. In 2D-CNN [23], the training loss that occurred in the systems is highly reduced. Furthermore, it is highly robust for noise reduction. But, it does not meet the real-time requirements. In addition, the availability and feasibility of the model are low. GAN [3] needs less training data without the need for any domain information. Moreover, the resolution of the images is getting increased. Yet, it does not solve the generalized Eigenvalue problems. Furthermore, it does not provide any authenticity over face recognition. ResNet [5] utilizes sparse symbolic representation to symbolize the gradients in the direction domain. Consequently, the artifacts present in the model are highly reduced. Nonetheless, it does not give additional information on convergence. For instance, it needs hardware equipment to recognize face patterns. Auto encoder [28] increases the generalization ability under occlusion conditions. Subsequently, it highly reduces the low-rank error during face recognition. However, it requires more training samples to improve the scalability and availability of the face recognition system. Moreover, it has the capability to hold less amount of information. These drawbacks that arise in the deep learning-enabled face recognition approaches are resolved by the newly introduced face recognition model.

TABLE I. FEATURES AND CHALLENGES OF THE CONVENTIONAL DEEP LEARNING-BASED FACE RECOGNITION MODELS

Author [Citation]	Methodology	Features	Challenges
Michael *et al.* [12]	CNN	• It provides better results over the interpretation of facial expressions and facial recognition. • It highly decreases the computational cost due to the implementation of facial recognition.	• It slightly suffers with generalization capability. • It increases the instability and internal covariance, and hence the overfitting problem cannot be avoided.
Ranjan *et al.* [27]	DCNN	• It has the capability to capture both local and global information in faces. • Multi-task information is efficiently reduced to enhance the performance of the recognition.	• The topological changes due to the viewpoint variations are not captured effectively in this approach. • It does not identify the discriminative facial information at various illumination conditions.
Abhijay *et al.* [1]	Viola Jones detector with CNN	• It gives high efficiency and robustness in face recognition. • It captures the most crucial information from the facial images, and hence, the accuracy of the recognition process is increased.	• It is computationally expensive and impractical in darkness conditions. • It is a very time-consuming process.
Junaid *et al.* [23]	2D CNN	• The training loss that occurred in the systems is highly reduced. • It is highly robust for noise reduction.	• It does not meet the real-time requirements. • The availability and feasibility of the model are low.
Zhao *et al.* [19]	GAN	• It needs less training data without the need for any domain information. • The resolution of the images is getting increased.	• It does not provide better results over face recognition due to the factors like various illuminations, same face, aging, and pose variations.
Al-Waisy *et al.* [3]	DBN	• It gives more accuracy and scalability over face recognition. • It effectively captures the shape variations that are irrespective of the illumination variabilities.	• It does not solve the generalized eigenvalue problems. • It does not provide any authenticity over face recognition.
Durga and Rajesh [5]	ResNet	• It utilizes sparse symbolic representation to symbolize the gradients in the direction domain. • The artifacts present in the model are highly reduced.	• It does not give additional information on convergence. • It needs hardware types of equipment for recognizing face patterns.
Gao *et al.* [28]	Auto encoder	• Under occlusion conditions, it increases the generalization ability. • It highly reduces the low-rank error during face recognition.	• It requires more training samples to improve the scalability and availability of the face recognition system. • It has the capability to hold less amount of information.

III. ARCHITECTURAL VIEW OF THE DEVELOPED FACE RECOGNITION MODEL

A. *Dataset Description of Face Recognition*

The face images required for the identification of persons are collected from standard online databases. The detailed descriptions of the databases are given as below.

Dataset 1 (CFPW Dataset): This CFPW dataset is obtained from the publically available online source of "http://www.cfpw.io/ access date: 2022-12-07". This dataset contains celebrity photos from around the world. The images are collected in profile view and frontal view. More images of celebrities are added to the database.

Dataset 2 (Yale Dataset): The Yale dataset is available in the online source of "http://vision.ucsd.edu/content/yale-face-database: access date: 2022-12-07". Total 15 people's face images are there in the Yale dataset. It contains 165 images with various facial expressions of persons that includes sad, surprised, normal, wink, with or without glasses, and center-light, left-light as well as right-light.

The collected face images are indicated as FI_g, where $g = 1,2,3,...,G$, and the term G denotes the total number of sample images. The collected sample face images from two different datasets are given in Fig. 1.

B. Proposed Face Recognition Model

Face detection is one of the most difficult tasks in image retrieval and computer vision. Because the face recognition approaches are mainly applicable in various domains like driving license systems, healthcare systems, railway reservation systems, ATMs, passport authentication, and surveillance operation. While processing through the large-scale dataset, the face recognition approaches lack in their performance for system reliability, scalability, and robustness. During face recognition, the collected face image correlates with the face image from the database. But, if the query image is unavailable in the database, then it evaluates the similarity between the two images. This leads to an increase in the false identification of persons. Therefore, deep learning-based approaches are adopted for face recognition, where the error rate is highly reduced, and the recognition accuracy is improved. But, it faces several difficulties while recognizing the images in motion images, pose variations, and twins. In addition, persons with different hair colors, makeup, light intensity condition, noises, different illumination condition, hair partitions, beards, and other occlusions are difficult to identify the exact person. Hence, a new deep learning-based face recognition model is developed with the optimization algorithm to solve these disadvantages, and the architectural representation of this newly developed model is given in Fig. 2.

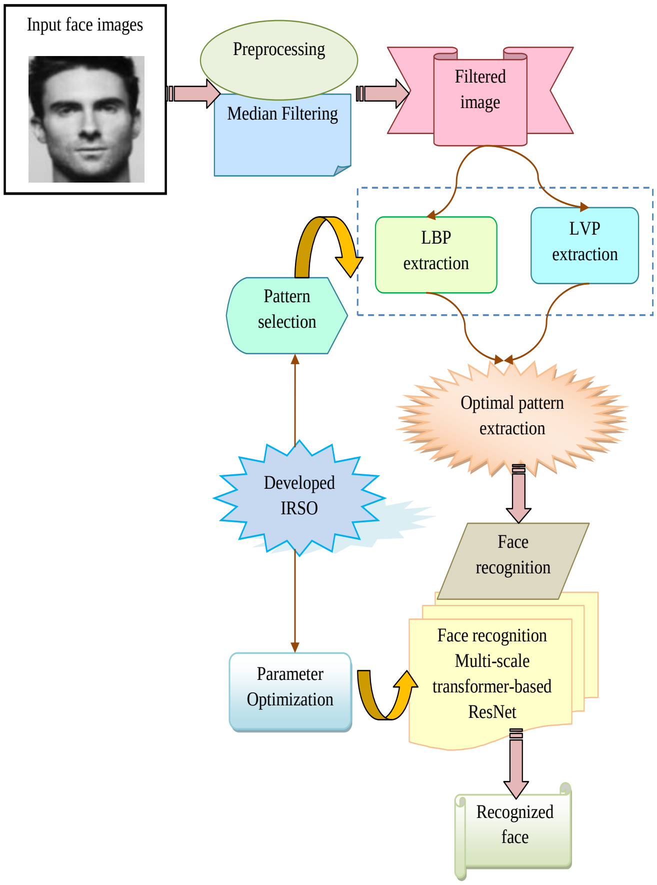

Fig. 2. Architectural illustration of the developed deep learning-based face recognition model.

A new deep learning-based face recognition model is designed with the help of a heuristic algorithm for replenishing the need for security and avoiding present-day crime. The wanted data is gathered from the CFPW and Yale databases. The collected face images are filtered through median filtering to remove the unwanted noises, then subjected to LBP and LVP pattern extraction. The optimal patterns are selected from the retrieved LBP and LVP patterns and placed in a new window. This selection process is carried out with the support of the developed IRSO, increasing the recognition accuracy during face recognition. These extracted optimal patterns are given to the efficient to perform the face recognition. Here, the hidden neuron count in the ResNet is optimized with the utilization of the implemented IRSO for improving the accuracy of the developed face recognition model. The test outcomes obtained from the newly implemented face recognition model are guaranteed with the conventional deep learning-based face recognition model and various heuristic algorithms. The ablation accuracy and convergence analysis in terms of the cost function are carried out in the developed face recognition model for validating the effectiveness of the developed IRSO--AMT-ResNet-based face recognition model.

C. Median Filtering of Input Images

The collected face images FI_g are given to the preprocessing stage for the eradication of noises and unwanted blurs present in the images. In the preprocessing stage, median filtering is used to remove the noises in the images. The median filter is generally a non-linear filtering approach, and it mainly focuses on edge preservation and noise removal over the collected images. Moreover, the errors while processing the images are highly reduced by removing noise present in the images. Fine details preservation may improve the quality of images, and hence the recognition rates are increased. The median filter [20] functioned through the window, and the selection of median intensity was carried out with the help of this window. It takes the average value of the neighborhood pixel values, and then it is named the average filer. The images are processed through pixel-by-pixel values, and the variations in the pixel values are changed with the averaged value obtained over the nearest pixels. This pixel changing related to the nearest neighbor through the window mechanism is named as sliding window mechanism. Through this sliding window, the quality of the images is getting highly increased. The acquired images FI_g are randomly represented as a group of variables $FI_g = FI_1, FI_2, FI_3, ..., FI_G$, and the median value of this image is evaluated using Eq. (1).

$$Med\left(FI_g\right) = \begin{cases} FI_{T+1} = FI_b, & G = 2T+1 \\ \frac{1}{2}\left(FI_{T+1} + FI_T\right), & G = 2T \end{cases} \tag{1}$$

Here, $b = FI_{T+1}$ represents the median rank and the intensity value of the face images are determined by using the 2-D median filter that is given in Eq. (2).

$$Zt_{mh,nh} = \underset{(bn,dn)\in\zeta}{Med}\left(FI_{nh+bn,nh+dn}\right) \tag{2}$$

Here, the sliding window in this approach is indicated as ζ. The finally obtained filtered facial images are represented by the term FI_g^{Mf}, and this high quality with noise-removed images is given to the input of the next level of face recognition approach.

IV. Enhanced Gannet Optimization Algorithm-based Optimal Pattern Extraction for Face Recognition

A. Improved RSO

The suggested IRSO algorithm is used in the newly implemented deep intelligence-based face recognition approach, where the optimal pixels from the LVP and LBP pattern extraction approach are selected using the designed IRSO for maximizing the accuracy of the feature extraction process. Moreover, the hidden neuron count in ResNet is optimized with the support of developed IRSO that helps to improve the recognition accuracy of the designed IRSO-AMT-ResNet-based face recognition model. The RSO algorithm is used in the developed face recognition model because it avoids the local optima problem very effectively, and it highly balances the exploration as well as exploitation phases. Moreover, the computational complexity of this RSO is very less than other algorithms. But, real-world problems are not effectively handled in the RSO. Hence, to solve real-world problems and get best optimal solution in the search space, an improved RSO algorithm is developed. The developed IRSO algorithm has functioned through the parameter M. In the conventional algorithm, the parameter M is evaluated using Eq. (5). But, in the developed IRSO, the parameter M is evaluated using the newly introduced concept that is defined in Eq. (3).

$$\mathrm{M} = 2 * \sqrt{\frac{((k*h)*l)}{IT_{MX}}} \tag{3}$$

Here, the terms k and h represent the random parameters, in which the values are selected at $k=1$ and $h=5$ to get best optimal solution. Furthermore, the term l denotes the iteration count and the term IT_{MX} indicates the maximum number of iterations. By using this modified concept, the best optimal solution is achieved in search space.

RSO: The RSO is inspired by the attacking behaviour as well as the chasing behaviour of the prey. Totally, two different species like, brown and black are there. The female rats and the male rats are named does and bucks. Generally, rats are socially intelligent based on nature. They are involved with various activities like boxing, tumbling, chasing, and jumping. The rats are characterized as the territorial animal that is live with a group of both female rats and male rats. In many cases, the character of rats is very argumentative, which results in the death of some animals. Hence, the RSO algorithm is designed based on the aggressive behaviour of the prey chasing and fighting, and it performs optimization in search space.

Rats chase the prey in a group based on social agnostic behaviour because rats are social animals. The best search agent in the group has knowledge about the position of the target prey. The new position of the search agents is upgraded in regards to the best search agent in the search space. The updated position of the best search agent is given in below Eq. (4).

$$\vec{S} = \mathrm{M} \cdot \vec{S}_t(r) + \mathrm{N} \cdot \left(\vec{S}_b(r) - \vec{S}_t(r)\right) \tag{4}$$

The position of the rat is denoted by the term $\vec{S}_t(r)$ and $\vec{S}_b(r)$ denotes the best optimal solution of the search agent. The formula utilized to estimate the parameters M and N is represented in Eq. (5) and Eq. (6), respectively.

$$\mathrm{M} = L - r \times \left(\frac{L}{IT_{MX}}\right) \quad where, \; r = 0,1,2,\ldots,IT_{MX} \tag{5}$$

$$\mathrm{N} = 2.rd(\;) \tag{6}$$

The parameters N and L are responsible for providing better exploitation and exploration in overall course of iterations, where the parameter L is chosen in the interval of $[1,5]$ and the term $rd(\;)$ denotes the random number and it is selected in the interval between $[0,2]$.

The prey fighting behavior of the rats in search space is given in Eq. (7).

$$\vec{S}_t(r+1) = \left|\vec{S}_b(r) - \vec{S}\right| \tag{7}$$

Here, the updated next position of the rats is given in $\vec{S}_t(r+1)$. The best solution is saved, and the best position of all other search agents is upgraded. The best exploration and exploitation are ensured by using this RSO. Algorithm 1 represents the pseudocode of the developed IRSO.

Algorithm 1: Designed IRSO

```
Initialize the population of RSO
Set the parameters $\mathrm{N}$, $L$ and $\mathrm{M}$
Estimate the fitness value of the search agent
  For $m = 1 \; to S_{pp}$
  For $n = 1 \; to \; IT_{MX}$
    Assume $S_r \leftarrow$ the best search agent
    While $(r < IT_{MX})$
      For all search agents
      Update the parameter $\mathrm{M}$ with a newly developed concept in Eq. (3)
      Update the current search agent position by Eq. (7)
      End For
    Update the parameters $\mathrm{N}$, and $L$
    Find any of the search agent goes beyond the search space
  End For
  End For
      $r = r + 1$
    End while
Go back to the best optimal solution
End procedure
```

B. LBP and LVP Pattern

The input to be given for obtaining LBP and LVP from the preprocessed image is FI_g^{Mf}. The facial images are generally comprised of a composition of micro-patterns that are highly invariant regarding the monotonic transformations in grayscale. Hence, the LBP and LVP pattern retrieval from the facial images are required for recognizing the person with high efficiency.

The LBP [24] operator uses the thresholding approach to label the pixels of an image, where the thresholding operation is performed over the 3×3 nearest of all pixels in accordance with the center value, and the resultant patterns are obtained from the face images are binary numbers. Then, the binary numbers are described as a label presented in the histogram, which can be utilized as a texture descriptor. After completing the thresholding over 3×3 the window, then the window size is extended to use the neighborhood pixels. The bilinear interpolation among circular neighborhoods is used to allow any number of pixels and radius among the neighborhood. The neighborhood pixels are represented as (U,V), where U defines the sampling points, and the term V indicates the radius of the circle. The LBP is known as uniform pattern, because it contains two most transition from 0 to 1 while taking the binary string in the form of a circular. The example of uniform patterns is the 00000000, 00010010 and 10000011. The histogram of the labeled image $FI_g^{Mf}(m,n)$ can be defined in Eq. (8).

$$HS_p = \sum_{m,n} IN\left\{FI_g^{Mf}(m,n) = p\right\},\ p = 0,\ldots,l-1 \tag{8}$$

Here, the term l denotes the number of different labels which can be created by the LBP operator. The distribution of the local micro pattern information is present in the histogram that includes flat areas, spots, and edges. Hence, the whole image is divided into more number of regions $Rn_0, Rn_1,\ldots, Rn_{k-1}$. The spatially enhanced histogram is defined below in Eq. (9).

$$\begin{aligned} HS_{p,q} &= \sum_{m,n} IN\left\{FI_g^{Mf}(m,n) IN(m,n) \in Rn_q\right\}, \\ p &= 0,1,\ldots,l-1, q = 0,1,\ldots,k-1 \end{aligned} \tag{9}$$

Three different levels of locality can be obtained from this enhanced histogram. Moreover, the pixel-level pattern information is contained in the labels of the histogram. The regional-level information is obtained by summing the small regions, and the global description of the face is obtained by combining the regional information from the histogram.

When the whole image is divided into more number of regions, it may await that some region contains more information to differentiate peoples from the extracted patterns. Hence, similarity measure between the patterns are estimated by using the below mentioned formula in Eq. (10).

$$\vartheta^2(A,B) = \sum_p \frac{\left(A_p - B_p\right)^2}{A_p + B_p} \tag{10}$$

This is the formula to calculate the similarity measure and it can be extended to the spatially enhanced histogram by adding over the patterns p and q. Finally obtained LBP patterns from the face images are indicated by LBP_h^{Hs}.

LVP [35] is used to define the local texture in structural information and one dimensional direction by estimating the patterns between the adjacent pixels and referenced pixels in accordance with varying distance and in different directions. The input facial images to be given for extracting the LVP patterns are FI_g^{Mf}. The local sub region of the FI_g^{Mf} images are indicated by the term LS, the direction value of a vector is denoted by $R_{\alpha,Dt}(E_z)$, where the term E_z represents the referenced pixel in the local sub region LS, the distance between the adjacent pixel and the referenced pixel are denoted by the term Dt and the index angle for varying direction is represented by α. The direction value of the vector is estimated using Eq. (11).

$$R_{\alpha,Dt}(E_z) = \left(LS(E_{\alpha,Dt}) - LS(E_z)\right) \tag{11}$$

The LVP is considered as in the α direction of a vector at E_z and the encoding operation of $LVP_\alpha(E_z)$ are given in Eq. (12).

$$\begin{aligned} LVP_\alpha(E_z) &= \sum_{k=1}^{K} g\left(R_{\varpi,Dt}(E_k), R_{\varpi,Dt}(E_z)\right) \\ &\times 2^{k-1} \left| \varpi \in \left\{\alpha, \alpha + 45^\circ\right\}, K = 8 \right. \end{aligned} \tag{12}$$

The mathematical formulation of $g(\cdot,\cdot)$ is indicated in Eq. (13).

$$\begin{aligned} & g\left(R_{\varpi,Dt}(E_k), R_{\varpi,Dt}(E_z)\right) \times 2^{k-1} \\ & \left| \varpi \in \left\{\alpha, \alpha + 45^\circ\right\}, K = 8 = \begin{cases} 1, & \begin{matrix} if\ R_{\alpha+45^\circ,Dt}(E_k, H) \\ -\left(\begin{matrix} \dfrac{R_{\alpha+45^\circ,Dt}(E_z)}{R_{\alpha,Dt}(E_z)} \\ \times R_{\alpha,Dt}(E_{k,H}) \end{matrix}\right) \geq 0 \end{matrix} \\ 0, & else \end{cases} \right. \end{aligned} \tag{13}$$

Finally, the LVP is obtained by integrating the four 8-bit binary patterns of LVPs that is illustrated in Eq. (14).

$$LVP(E_z) = \left\{ LVP_\alpha(E_z) \middle| \alpha = 0^\circ, 45^\circ, 90^\circ, 135^\circ \right\} \tag{14}$$

The resultant LVP patterns from the preprocessed facial images are indicated by the term LVP_b^{Cn}.

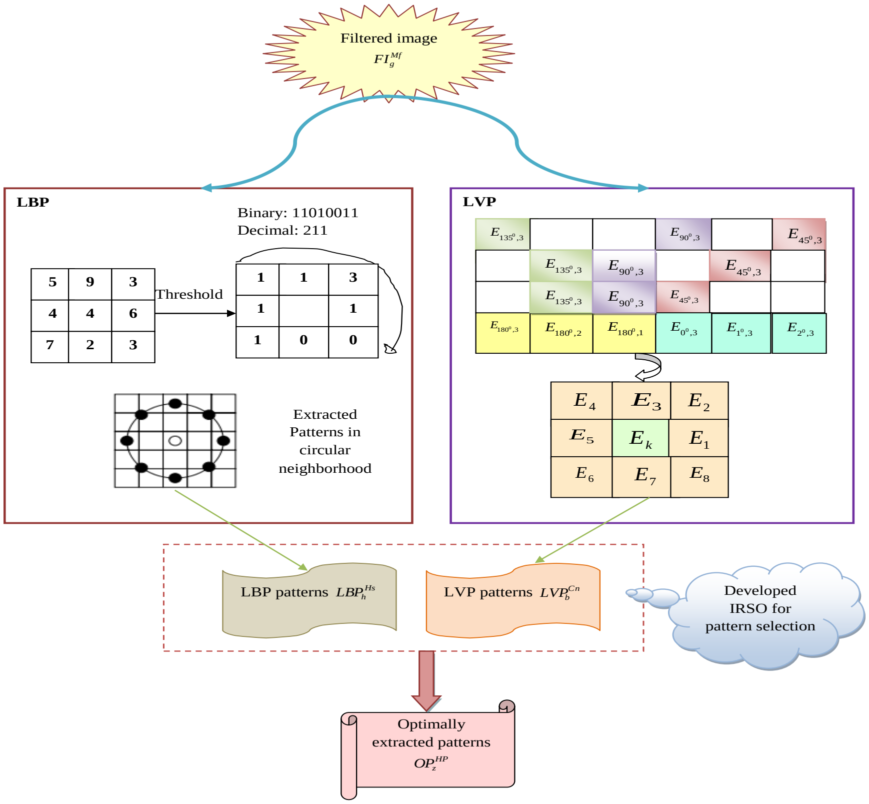

Fig. 3. Optimal pattern selection using developed IRSO from LBP and LVP.

C. Optimal Pattern Extraction

The LBP pattern LBP_h^{Hs} and the LVP pattern LVP_b^{Cn} are extracted from the preprocessed facial images. The size of the LBP pattern image is considered as 128×128, and also the size of the LVP pattern image is considered in the same size of 128×128. Hence, the total pixel of the image should be 16384. From these LBP and LVP patterns, the optimal spatial features are chosen with the help of developed IRSO. The best spatial values are arranged in the new matrix to get a hybrid pattern. The selection of optimal pixel is made with new criteria that is, if the selected pixel number is 1, then get the pixels from LBP output or else, get pixels from the LVP output. At last, a new set of patterns are obtained from the LBP and LVP patterns. The optimally selected patterns, with the help of the developed IRSO are indicated by the term OP_z^{HP}, which is given to the input of the face recognition process. The optimal pattern extraction from LBP and LVP by utilizing the developed IRSO is depicted in Fig. 3.

V. An Advanced Face Recognition using Adaptive Multi-Scale Transformer-based Resnet

A. Multi-scale Transformer-based Resnet

The AMT-ResNet is used in the developed face recognition framework to extract powerful discriminative features from the face images. The learning capacity of the CNN networks is high, and then the ResNet structure is utilized in the developed face recognition model. The input to be passed through the AMT-ResNet model is the resultant optimally extracted patterns OP_z^{HP}.

In AMT-ResNet [8], the encoder and decoder functions are used to detect the changes in the pixels and provide accurate recognition of face images. The encoding and decoding operation may also provide a good trade-off between the effectiveness and efficiency of the developed model. Then the feature-level fusion is also carried out over the query image and the database image. The local receptive field that arises in the network is effectively resolved by the ResNet. The multi-scale transformer divides the whole image into more number of non-overlapping regions that are represented as $P_1, P_2, \ldots, P_n$ and then classifies the pixel points in the facial images very precisely. The loss of information is effectively reduced by using this AMT-ResNet. Moreover, the transformer can find the local receptive fields after extracting features from the face images by using the ResNet model. The ResNet model used in the multi-scale transformer may improve the scalability of the developed face recognition framework. The extracted patterns OP_z^{HP} are given to the transformer, and then the learnable parameter encoding is performed with absolute or relative information about the images.

The attention fusion of the face images are represented by the term Y, and it is expressed in Eq. (15), Eq. (16), Eq. (17), and Eq. (18), respectively.

$$Y = [h^z(P^z) \| h^x(P^x)) \tag{15}$$

$$Ot = Y + MS(Ln(Y)) \tag{16}$$

$$Ot = \left[Ot^{z} \| Ot^{x} \right] \tag{17}$$

$$J^{z} = k^{z}(Ot^{z}) \tag{18}$$

Here, the term P^{z} denotes the pixel points in the given image. Moreover, the terms $h^{z}(\cdot)$ and $k^{z}(\cdot)$ represents the projection as well as the back projection functions that is used to align the dimension of the image.

The pairwise fusion of facial images is represented in Eq. (19).

$$S^{z} = \left[k^{z}\left(\sum_{m\in\{z,x\}} k^{z}\left(P_{CL}^{m}\right) \middle\| k^{z}\left(\sum_{m\in\{z,x\}} k^{z}\left(P_{Patch}^{m}\right)\right)\right)\right] \tag{19}$$

Here, the term P_{Patch}^{m} is the patch information and the term P_{CL}^{m} represents the class information of the face images. The cross attention function is given in Eq. (20).

$$CrAt = At \cdot \vartheta \tag{20}$$

Here, the term At is the attention map and it is estimated using Eq. (21).

$$At = soft\max\left(QL^{t} / \sqrt{\frac{Em}{D}} \right) \tag{21}$$

Here, the term Em denotes the embedding dimension and D gives the number of heads parameter. The values of Q, ϑ and L are estimated using Eq. (22).

$$\vartheta = P_{CL}^{'z}\psi_{\vartheta},\ L = P_{CL}^{'z}\psi_{L},\ Q = P_{CL}^{'z}\psi_{Q} \tag{22}$$

The cross attention of the normalization layer and the residual shortcut are represented in Eq. (23) and Eq. (24), respectively.

$$Y_{CL}^{z} = h^{z}P_{CL}^{z} + MS\left(LN\left(h^{z}\left(P_{CL}^{z}\right)\| P_{Patch}^{z}\right)\right) \tag{23}$$

$$J^{z} = k^{z}\left(P_{CL}^{z}\right)\| P_{Patch}^{z} \tag{24}$$

Here, the term MS defines the multiple heads in the transformer network. The AMT-ResNet structure produces better results over the face recognition, and the accuracy is highly improved. Fig. 4 depicts the basic structure of AMT-ResNet model.

B. Adaptive Multi-scale Transformer-based Resnet

The newly developed AMT-ResNet-based face recognition approach is useful for detecting the person's face from the collected face images under variations in pose, expression, occlusion, and illumination as well as light intensity conditions. The hidden neuron count in the AMT-ResNet is optimized through the developed IRSO for improving the recognition accuracy rate during face recognition. The Multiscale Transformer network is used in the developed face recognition model because it effectively learns the discriminative variations in the face images. It provides better-recognized results over face recognition with highly reduced recognition time and computational complexity. In order to improve the robustness and reliability of face recognition, the adaptive multi-scale transformer-based ResNet is introduced, where the hidden neuron count in the ResNet is optimized with the help of the newly implemented IRSO. The main motive of the parameter optimization in the developed AMT-ResNet is to obtain higher recognition accuracy. The objective function of the developed IRSO-AMT-ResNet-based face recognition approach is given below in Eq. (25).

$$OB = \underset{\left\{Sp_{n}^{LBVP},NH_{m}^{\mathrm{Re}\,sNet}\right\}}{\arg\min}\left(\frac{1}{AR}\right) \tag{25}$$

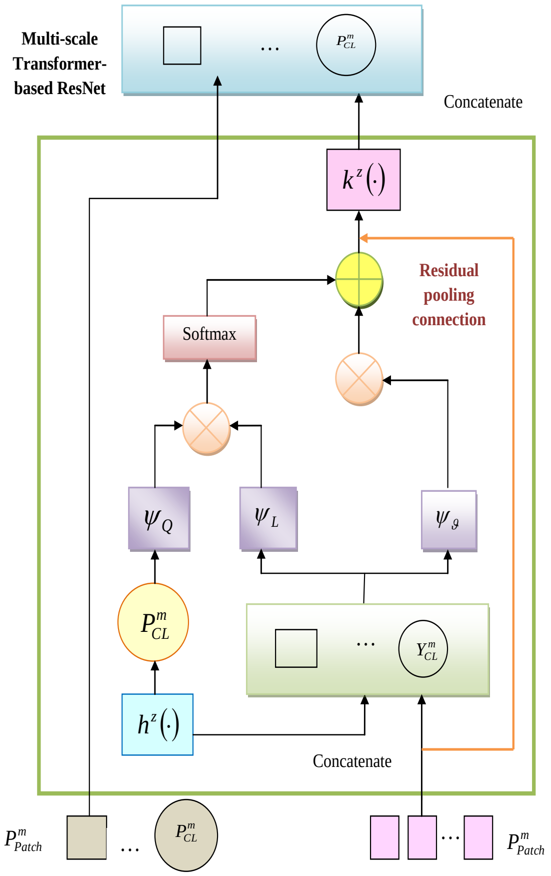

Fig. 4. Basic structure of AMT-ResNet model.

Here, the term Sp_{n}^{LBVP} gives the extracted patterns from LBP and LVP, and the term NH_{m}^{ResNet} indicates the hidden neuron count in the ResNet structure. The extracted patterns Sp_{n}^{LBVP} are optimized in the range of $[1,2]$ and the hidden neuron count is tuned in the range between $[50,100]$. Furthermore, the term AR represents accuracy and it is evaluated by using true and false positive as well as negative observations. The accuracy formula is given in below Eq. (26).

$$AR = \frac{R_P + R_N}{R_P + R_N + L_P + L_N} \tag{26}$$

Here, the term R_P denotes the true positive, L_P is the false positive, R_N is the true negative and L_N is the false negative observation value. The face recognition process using developed AMT-ResNet with parameter optimization is given in Fig. 5.

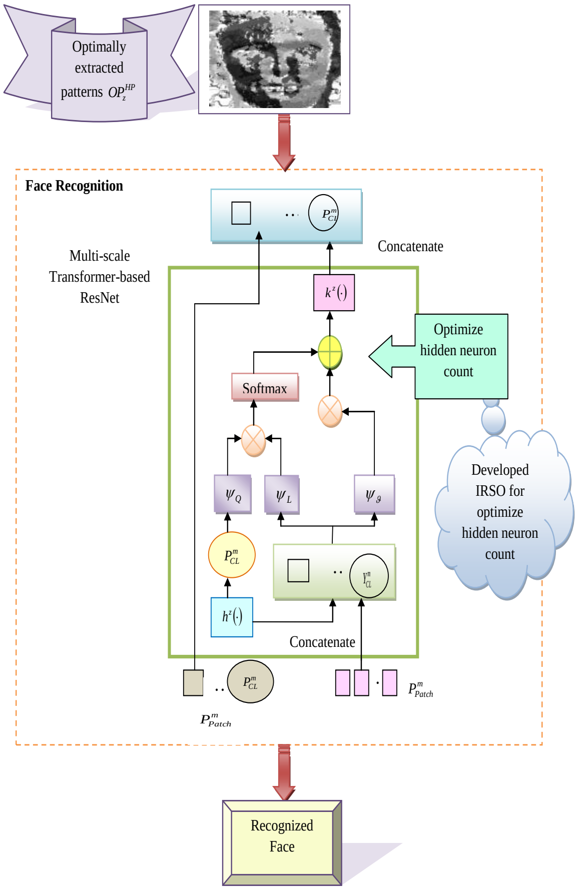

Fig. 5. AMT-ResNet-based face recognition model with parameter optimization.

VI. Results and Discussions

A. Experimental Setup

The newly implemented IRSO-AMT-ResNet-based face recognition approach was designed in Python tool. Moreover, the implementation results of the implemented approach have been analyzed among various heuristic algorithms and conventional face recognition methodologies for validating the efficacy of the developed model. The population count and the maximum number of iterations that should be taken for performing the comparative analysis were 10 and 25, respectively.

The heuristic algorithms to be taken for performing the comparative analysis on the developed IRSO-AMT-ResNet-based face recognition approach were Cat Swarm Optimization (CSO) [32], Cuckoo Optimization Algorithm (COA) [10], Moth Flame Optimization (MFO) [31] and Rat Swarm Optimization (RSO) [14] and the conventional face recognition approaches to be considered for analyzing the performance on the developed model was CNN [12], LSTM [11], VGG16 [4] and ResNet [5]. Various positive, as well as negative measures were used for analyzing the efficiency of the implemented face recognition model.

B. Validation Measures

The performance metrics used to validate the effectiveness of the developed face recognition model are several positive measures such as sensitivity, accuracy, specificity, precision, NPV, MCC, and F1-score, and also negative measures like FDR, FNR, and FPR. The formula used to calculate the positive and negative measures is summarized as below.

$$\Pr ecision = \frac{R_P}{R_P + L_P} \tag{27}$$

$$F1-score = \frac{2R_P}{2R_P + L_P + L_N} \tag{28}$$

$$Sensitivity = \frac{R_P}{R_P + L_N} \tag{29}$$

$$Specificity = \frac{R_N}{R_N + L_P} \tag{30}$$

$$FPR = \frac{L_P}{R_N + L_P} \tag{31}$$

$$FNR = \frac{L_N}{R_P + L_N} \tag{32}$$

$$FDR = \frac{R_P}{R_N + L_N} \tag{33}$$

$$MCC = \frac{R_P + R_N - L_P + L_N}{\sqrt{(R_P + L_P)(R_N + L_P)(R_P + L_N)(R_N + L_N)}} \tag{34}$$

C. Experimental Results

The resultant facial images obtained after the preprocessing, extracting LBP and LVP. The optimal pattern extraction of dataset 1 and dataset 2 are depicted in Fig. 6.

D. Ablation Study on Developed Face Recognition Model Based on the Accuracy

The accuracy of the suggested IRSO-AMT-ResNet-based face recognition approach over the extension of convolutional networks is illustrated in below Fig. 7. This comparative analysis is taken over the two datasets 1 and 2. From the analysis, the developed IRSO-AMT-ResNet-based face recognition approach gained improved accuracy of 8.235%than AlexNet, 6.97% than GoogleNet, 5.74% than ResNet 150, and 4.54 % than ResNet 152 for the learning percentage value of 65 while considering the dataset of 2. The accuracy of the developed IRSO-AMT-ResNet-based face recognition approach is slightly increased than the convolutional networks.

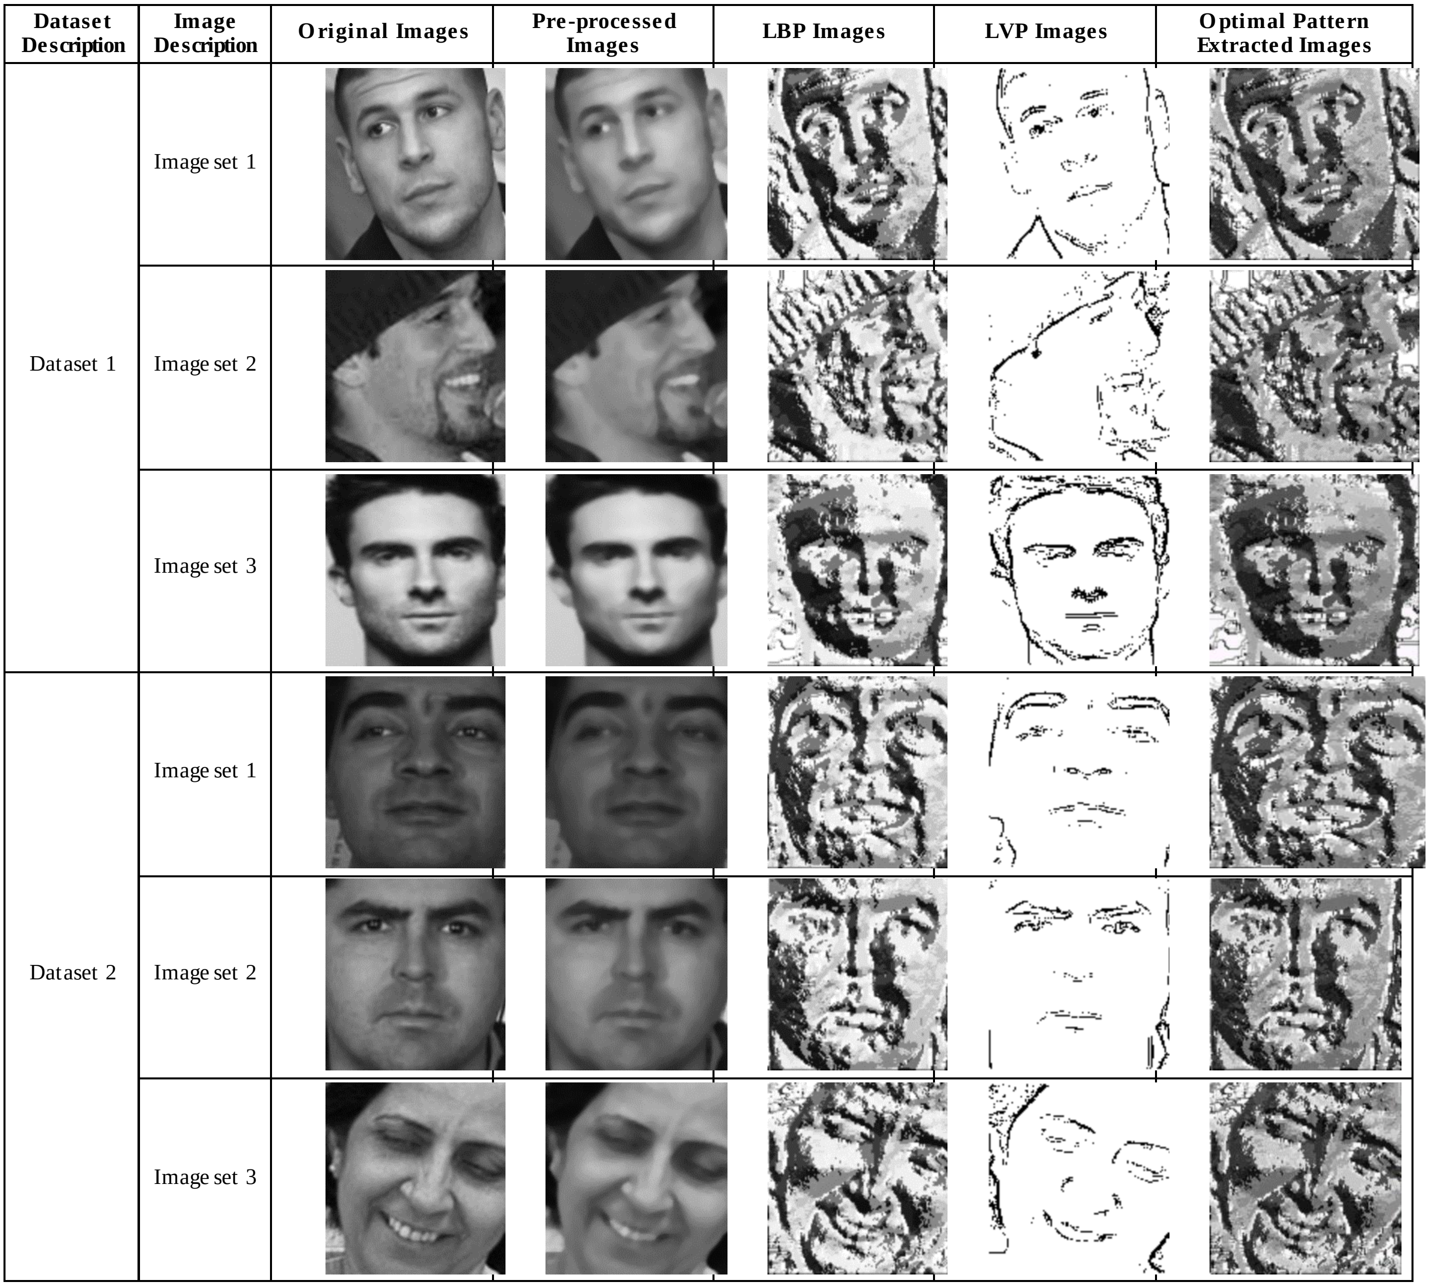

Fig. 6. The resultant facial optimal pattern extracted images from the developed face recognition model.

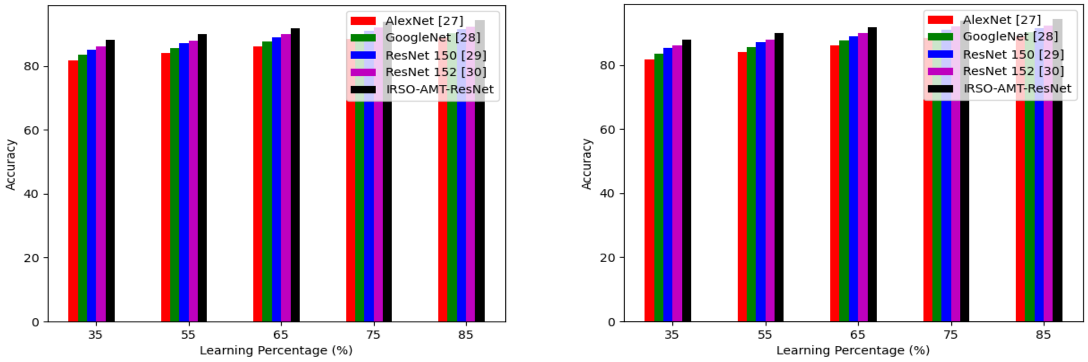

(a)

(b)

Fig. 7. Ablation study on suggested face recognition model over existing networks in regards with (a) Dataset 1 and (b) Dataset 2.

E. Convergence Evaluation on Developed Model

The following Fig. 8 shows the convergence evaluation of the developed IRSO-AMT-ResNet-based face recognition model over dataset 1 and dataset 2. This convergence analysis is carried out over various heuristic algorithms and the developed IRSO-AMT-ResNet-based face recognition model secured with improved cost function rate of 0.29% than MFO-AMT-ResNet, 0.79% than COA-AMT-ResNet, 1.37% than CSO-AMT-ResNet and 2.43% than RSO-AMT-ResNet when considering the iteration number as 20 for dataset 2. Moreover, the cost function is highly decreased in the developed face recognition model rather than the other heuristic algorithms.

F. Accuracy Evaluation on Developed Face Recognition Model

The efficiency estimation of the developed IRSO-AMT-ResNet-based face recognition framework in terms of varying learning percentage value with respect to various heuristic algorithms is given in Fig. 9, and various conventional face recognition approaches is given in Fig. 10. This comparison among heuristic algorithms and conventional approaches are carried out over dataset 1 and dataset 2. The developed model obtained improved accuracy of 5.88%, 4.65%, 2.85%, and 2.27% than the heuristic algorithms CSO-AMT-ResNet, COA-AMT-ResNet, MFO-AMT-ResNet and RSO-AMT-ResNet for dataset 1 with reference to the learning percentage value of 55.

G. K-fold Comparison on Developed Face Recognition Model

The k-fold validation of the implemented IRSO-AMT-ResNet-based face recognition model when compared to various heuristic algorithms is given in Fig. 11, and various baseline face recognition approaches are shown in Fig. 12. The developed model accomplished with improved accuracy of 15.47%, 16.86%, 14.11% and 11.49% than the heuristic algorithms CNN, LSTM, VGG16 and ResNet for dataset 1 with respect to the K-fold value of 3. The developed model secured with high accuracy than the existing face recognition approaches.

H. Comparative Analysis of the Developed Face Recognition Model

The different baseline face recognition approaches are illustrated in Table II. The performance analysis of the implemented IRSO-AMT-ResNet-based face recognition model according to various optimization strategies is depicted in Table III. The developed model obtained with higher recognition sensitivity of 3.95%, 2.80%, 1.70%, and 1.38% than the heuristic algorithms like CSO-AMT-ResNet, COA-AMT-ResNet, MFO-AMT-ResNet and RSO-AMT-ResNet while taking the dataset 1. The recommended face recognition model achieved superior performance than the other optimization strategies in terms of various positive and negative measures.

I. Ablation Study on Different Network Models for Face Recognition

The performance of the developed IRSO-AMT-ResNet-based face recognition model among various face recognition networks is given in below Table IV. The implemented model achieved with improved F1-score of 62.86% than AlexNet, 48.68% than GoogleNet, 33.22% than ResNet 150 and 22.49% than ResNet 152 for dataset 2. The overall performance of the developed face recognition model is greater than the convolutional networks for dataset 1 and dataset 2.

VII. CONCLUSION

A new deep intelligent-based face recognition approach has been presented to identify individuals with high recognition accuracy. This face recognition helped to identify the thieves, and it has been mainly used in forensic applications. The face images were collected from two distinct databases, and median filtering was used to filter the image to eliminate the noises. The LBP and the LVP patterns were extracted from the filtered face images, and the optimal patterns were extracted from this by utilizing the developed IRSO. The optimally selected patterns from the face images were given to the AMT-ResNet, where the hidden neuron count was optimized through the newly implemented IRSO for increasing recognition accuracy. The implementation results obtained from the developed IRSO-AMT-ResNet-based face recognition model have been validated by analyzing the results over the conventional face recognition models according to ablation accuracy and convergence analysis. The developed IRSO-AMT-ResNet-based face recognition model has attained with improved accuracy of 5.94%, 4.59%, 3.15%, and 2.12% than the convolutional networks like AlexNet, GoogleNet, ResNet 150, and ResNet 152. Furthermore, the accuracy of the developed deep intelligence-based face detection approach was highly enhanced than the conventional face recognition techniques and heuristic algorithms.

***Abstract*—Due to financial incentives, the number of malware infections is steadily rising. Accuracy and effectiveness are essential because malware detection systems serve as the first line of defense against harmful attacks. A zero-day vulnerability is a hole in the target operating system, device driver, application, or other tools employing a computer environment that was previously unknown to anybody other than the hacker. Traditional malware detection systems usually use conventional machine learning algorithms, which call for time-consuming and error-prone feature gathering and extraction. Convolutional neural networks (CNNs) have been demonstrated to outperform conventional learning techniques in a number of applications, including the classification of images. This success prompts us to suggest a CNN-based malware categorization architecture. We evaluated our methodology using a bigger dataset made up of 25 families within a corpus of 9342 malware. Last but not least, comparisons are made between the model's measurement and performance with other cutting-edge deep learning techniques. The overall testing accuracy of 98.31% in the provided results attested to the excellent accuracy and robustness of the suggested procedure at a lower computational cost.**

Keywords*—*Malware Classification; zero-day; Convolutional Neural Networks (CNN); grayscale image transformation; Bytehist

I. INTRODUCTION

The quick enhancement of communication and information technologies has had a significant impact on cyber security. Systems and techniques for spotting intrusions and preventing them have significantly advanced. Even with more advanced security measures in place, hackers continue to develop methods to identify weaknesses and seize control of devices and systems. Static analysis approaches, like signature-driven method, pattern-match method, or data mining technology, examine the data inside the file to determine whether an executable portable file contains a programme that shouldn't be launched. The goal of the dynamic analysis method, which involves running the malware itself, is to observe how the portable executable file behaves while it is in use [1][2][3]. Methods for detection and classification were greatly hampered by the attackers' knowledge of infiltration tactics and strategies. Known as zero-day vulnerabilities and zero-day assaults, one of the most popular attack types in use today is malware [1]. The academic community and the security business have employed deep learning, machine learning, and intelligent systems to try and forecast potentially risky conduct. The first quarter of 2021 saw a 68.9% spike in new PowerShell malware and a 41.2% increase in business malware compared to the previous quarter [3]. The aforementioned statistics demonstrate that researchers in information technology disciplines have started to see IT as applying machine learning-based (neural language) detection and classification algorithms and NL processing to sort through the ever-increasing volume of malware and cunning escape strategies being deployed [3][4]. Due to the frequent requirement for traditional malware research approaches to design crucial traits, which costs money and time, machine learning has been found to be more effective [5]. Malware categorization has also been effectively accomplished using (CNN). The first stage of this scientific study will involve converting files from a regular image format to binary language, which will then be translated into grayscale images. Second, the files will be grouped into families of harmful programs. Twenty five (25) families of Trojan horses, malware, backdoors, etc. are negatively impacted. The accuracy in the identification and categorization of files into families of healthy files and families of hazardous files that will be used is then calculated by dividing a portion of these files into a portion for learning by 80% and a portion for testing by 20%.

This paper’s primary divides are as follows: Section I presents the introduction; the Section II shows the related work, Section III introduces datasets, Section IV establishes the proposed AI algorithm and Section V introduces the proposed DL architecture; the experiment's results are laid out in Section VI, along with discussions; the conclusion is given in Section VII.

These are this paper's significant contributions:

1) Using a number of pre-learned CNN algorithms based on image modification, we suggest a supervised learning-deep technique to categorize malware.

2) Check files in the initial phase to verify whether hashing, signature, or encryption modifications have been made, and use the modified metric to create byte-usage-histograms for whole sorts of codes with an emphasis on binary executables in aportable executable (PE) presentation.

3) Utilize thedeveloped tool to transform any executable or binary file into a greyscale PNG image that can be seen in the range [0,255]. We offered a useful paradigm for handling data from an imbalanced dataset.

4) We conducted numerous tests to contrast our approach for classifying malware with a number of existing techniques;

the findings show that our approach works better than these other approaches.

5) In order to classify malware, we created a regularized strategy that performs better than competing models despite learning from a tiny dataset.

II. Comparable Works

The most common malicious attempts on biometric technology are probably those on records with pattern data. The model contains a user's biometric details that might be abused in an assault. The confidentiality of the user is put at risk by the availability of patterns across multiple programmes [27]. Therefore, a strong technique is needed to protect the forms kept in the database. The following specifications [8] through [10][29] ought to be met by the most suitable pattern safety solution.

A. Strategies for Analyzing Malware

Malware analysis comes in two sorts: static and dynamic. Malware analysis aims to comprehend the composition and operation of malware [3]. Malware samples must be examined in order to ascertain their nature and mode of operation [6]. Static and dynamic analysis are the dual basic techniques utilized to detect malware. This is so that malware can be identified during analysis, which enables the resolution of a number of issues, including the presentation of the harmful architecture, the detection of infections and propagation techniques, and the assessment of the specific harm to the victim's devices [6]. The dual chief methods of malware analysis are static and dynamic. While studying malware, basic static analysis is done first, followed by advanced dynamic analysis [7].

B. Static Analysis

In order to do static analysis on Windows portable executable (PE) records, either the binary file or the malware program that has been disassembled must be used. The most popular programs for opening PE files are IDA Pro and Radar. This kind of reverse engineering can be applied to them.

Without running the malware code, static analysis can reveal the structure of a malware sample [8]. The two parts are fundamental static analysis and enhanced static analysis. Without going deeper, elementary static analysis inspects the programs, assessing file content, header information, and functions [6]. Among the tools that be able to utilize to abstract that information are PEiD, Bin Text, MD5deep, and PE view [7]. The first step in malware analysis is basic static analysis; advanced static analysis should be carried out to learn more about malware. The advanced static analysis does a complete study of the program directives.

To accomplish this, assembly codes are generated from machine codes using a disassembler [6] [9]. For thorough static analysis, researchers typically utilize the IDA Pro packet splitter and the supplemental Hex-Rays de-compiler. The investigation is thoroughly scrutinized to look for signs of malice in the procedures for assembling. With the use of sophisticated static analysis and inverse compilation, specific malware functionality may be retrieved. The advanced static analysis offers an in-depth understanding of the functionality and intent of malware. However, a thorough understanding of operating system principles and assembly code instructions is required for this subject [6][11].

C. Dynamic Analysis

Allows us to monitor its behavior and gather all of the virus's traces as we perform the dynamic analysis. This study is often utilized as a secondary analysis to have additional parameters or if we were unable to gather significant information by Employing static analysis, the malware infection developer's considerable obfuscation. This scan should be carried out in a totally isolated setting to prevent damaging our system. There are several habitats to pick from, with Cuckoo Sandbox being the most well-known. They provide an overview of both the methods used for each type of study and the data that was extracted [1].

Due to the dynamic analysis’ use of program execution, malware behavior analysis was done. To prevent infection of the devices, the analysis is done in enclosed environments like sandboxes or virtual PCs. Examining the execution of functions, arguments, data transfers, modifications to the file database, and network usage are all part of the process. When describing the actual operation of malware, static analysis is less accurate than dynamic analysis. There are two different kinds of dynamic analysis: basic and advanced. Basic dynamic analysis is used to examine the behavior of malware [10]. Utilizing Sandboxes, Regshot, ApateDNS, Procedure Explorer, API observe, and Procedure Monitor. The extensive dynamic analysis employs tools for debugging like WinDbg and OllyDbg. Experts who study malware can use debuggers to examine and modify the outcomes of individual commands.

D. Analysis of Statistics and Dynamics

The static analysis makes it simple and quick to evaluate earlier detected malware and gain a quick summary of the software [35]. Unfortunately, it is incredibly difficult to analyze malware that employs obfuscation, packing, polymorphism, and other techniques. Because dynamic analysis involves computer programs, malicious software may be employed. Obfuscation techniques used by malicious software can be recognized. Certain malware variants, however, might be aware that they are being tested in sandboxes and virtual environments, which would conceal their genuine behavior. Dynamic analysis is more efficient when dealing with unknown malware, despite the fact that static analysis is quicker and more precise when dealing with already identified malware [12].

E. Machine Learning Techniques

The two methods utilized in ML are unsupervised learning, which involves identifying hidden patterns or internal frameworks in incoming data, and supervised learning. To be able to forecast future outcomes, supervised learning requires training an algorithm utilizing available data for both input and output.

F. Supervised Learning

An algorithm that generates forecasts using data in the presence of unpredictability is created through supervised ML. A technique for supervised learning employs a set of predetermined input data to predict results. A supervised learning approach teaches the model to produce accurate forecasts in response to new data using a well-known collection of input data and identified reactions to data (output data). If the outcomes you are attempting to forecast have known data, use supervised learning. To build ML frameworks, supervised learning uses regression and classification techniques. Classification techniques predict specific outcomes, such as if an email is real or spam, or if a tumor is malignant or not. The given data are categorized by Common uses including speech recognition, credit scoring, and medical visualization. When you can tag, classify, or divide your data into distinct groups or classes, use classification. For instance, categorization is used by a handwriting recognition program to identify letters and digits [14][15]. Unsupervised pattern recognition algorithms are used in image processing for object recognition and image segmentation. Some commonly popular classification techniques include (SVMs), KNN, nave bays, differential analysis, logistic regression, and NN [17]. Techniques for regression forecast continuous responses like variations in electricity consumption and temperature. Forecasting electricity load and algorithm trading are examples of common applications. Nonlinear models, linear models, progressive organization, regression, reinforced and packed decision trees, adaptive neuro-fuzzy learning, and neural networks are examples of common regression techniques [18].

G. Unsupervised Learning

Data is scanned for underlying structures or hidden patterns using unsupervised learning. From datasets without any marked responses, it is utilized to draw conclusions. Clustering is the technique used most often in unsupervised learning. To find undiscovered patterns or groupings in the data, it is employed in exploratory data analysis. Object recognition and DNA arrangement analysis are a few instances for use for cluster analysis. For instance, a smartphone provider can use machine learning to determine how many different groups of people rely on its towers in order to optimize where it places its cell towers [19]. Because mobile phones can only communicate to one station at a time, the crew used a clustering approach to identify the best locations for cell sites to improve the reception of signals for their customer sets or clusters. Typical clustering methods include clustering based on hierarchy, GM systems, self-organizing maps, HMM, subtractive clustering, fuzzy c-means clustering, and k-medoids and k-means [20].

H. Deep Learning Approaches

DL models are from time to time referred to as DNN since the majority of deep learning methods employ NN architectures. DNNs are simply neural networks that have a lot of hidden layers. While DNN can have up to 150 hidden layers, conventional NN is limited to two or three. Large volumes of categorized data and NN topologies that acquire parameters from the data before learning them are employed for building algorithms for DL [21].

CNN or ConvNet are among the most popular DNN kinds. Specifically, a CNN is well suited for analyzing 2D data, such as photographs, because it mixes learned features with incoming data and makes use of 2D convolutional layers. You won't have to figure out what characteristics are used to classify photos because CNNs do manner with the need for non-automatic parameter extraction. CNN uses direct feature extraction from images to run its business. The necessary features are not pre-trained; rather, they emerge when the network trains on a batch of images. For computer vision applications like object categorization, deep learning models are especially accurate [22].

CNNs are taught to recognize various features of a picture using considerable hidden layers. The complexity of the learned visual elements increases with each buried layer [16]. For instance, the initial hidden layer might train to recognize edges, while the final layer might learn to recognize more intricate forms that are particular to the form of the object, we're able to recognize. In conclusion, because they typically identify and extract a set of parameters in advance and are not built to handle vast volumes of data, conventional ML algorithms have a great complex cost. The technique of DL on the contrary, performs the extraction of features and selection, cutting down on considerable computational costs. Yet, studies have shown that DL is superior to ML in terms of effectiveness and accuracy.

III. Dataset

We assessed our method on a big dataset containing 25 families in malware groups of 9,342. Nataraj et al. contributed MalImg collection [28]. The assessment outcomes display that our technique presents high precision with less computational cost. Moore's details are demonstrated in Fig. 1.

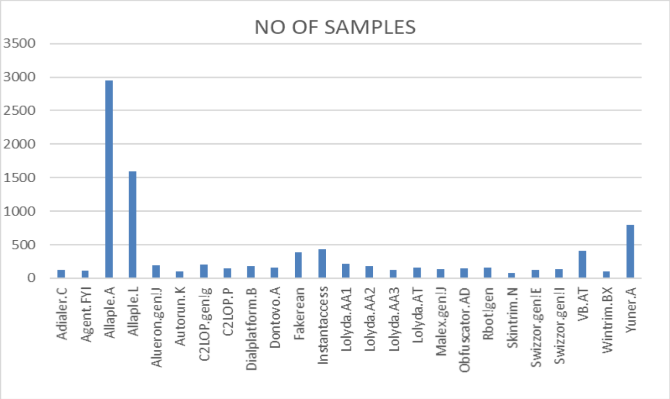

Fig. 1. Malware families found in the MalImg dataset.

IV. Algorithms

We discuss the dataset processing and implementation specifics for the proposed mathematical frameworks in this part of the article. We use the Bytehist software to generate byte-usage histograms for a variety of records, including binary executables in (PE) presentation. Using the Bytehist tool [23], we check files in the initial phase to see if hashing, signature, or encryption changes have been applied. We have divided malware from the MalImg Dataset into a variety of classifications. We use CNN to train and test the DL system for identifying and classifying malware in 25 families of images, and families of grayscale images.

A. Modified Binary File Detection

Static analysis frequently encounters problems while analyzing compressed or encrypted executables. AI algorithms regularly identify harmful executables as safe, despite the fact that many of them are updated to fulfill business or intellectual property objectives. This is understandable given that these modifications would significantly change the executable's entropy and byte spread. When creating a performance-improving technique for detection models, take the likelihood of binary file modifications into account. The tool ByteHist may produce byte-usage histograms for a variety of file formats, with a concentration on binary executables in the PE format. For instance, ByteHist [23] offers information into the nature of data before an examination. We can look at how bytes are distributed within a program that runs using ByteHist.

The distribution gets extra even with each executable compression. Examples of both negative and positive analogs are shown in Fig. 2, together with unpacked and UPX-transformed byte distributions. As shown, UPX alters the byte spread of the binary file, especially when malware is present. It is also a widely used packer and binary unpacking is straightforward, in contrast to neutral le, which has more altered cations [24]. UPX generates less. But a lot of malware comes with more sophisticated software, which complicates the investigation. Statistics could be a useful tool for locating encrypted or compressed data.

Bytes in the data are dispersed quite uniformly as a result of this type of alteration. Typical data typically consists of specific bytes that are constantly in use due to any type of structure. The byte distributions of database files, executable binaries, and plain text that haven't been encrypted or compressed differ significantly from those of those that have. This "phenomenon" is displayed using histograms, which make it easy to distinguish between the two.

B. Employing Images to represent Malware

The objective of this research is to visualize malware using a technique created by Nataraj et al. (2011) that enables a malware binary to be read as a stream of 8-bit integers without signs before being structured into a 2-dimensional matrix. Our tool transforms any executable or binary file into a greyscale PNG image that can be seen in the domain [0,255] (0: black, 255: white) [14]. Malware presentation as a grayscale picture process is shown in Fig. 3 Due to the method's reliance on binary code, a new infection might be created by a malware producer by updating the code of an existing virus, which would result in a very similar image being used to display the new infection. Then, we may use our classification model (CNN), which will be illustrated later, to put it all into one family.

C. Using Transfer Learning to Classify Malware

DL is a branch of ML that includes algorithms designed to mimic the operation of neural networks or the human brain. These structures go by the term neural networks. It trains the computer to perform actions that come naturally to people. Some of the models used in deep learning include autoencoders, recurrent neural networks (RNN), (ANN), and reinforcement learning. Convolutional Neural Networks (CNN) or ConvNet, in particular, have significantly advanced the areas of computer vision and image analysis [13]. CNNs, a subcategory of DNN, are often utilized for image analysis as they able recognize and categorize certain structures in frames. They have a variety of uses. Only a few of their applications include picture and video recognition, image classification and NLP. Fig. 4 concludes the convolutional neural networks' historical development.

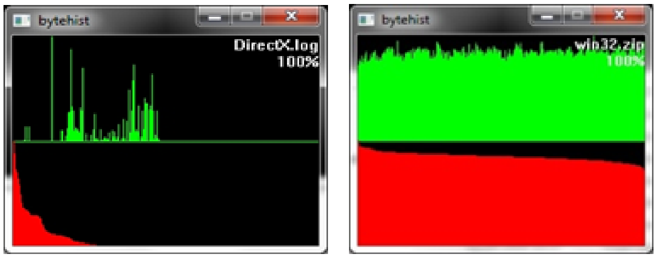
D. CNN'S Principal Architecture

According to Fig. 5, there are two parts to CNN architecture [25].

- Feature Extraction: A convolution tool isolates and classifies the distinctive features of an image for examination throughout the feature extraction process.
- Fully connected: A completely connected layer that predicts the frame's group applying the data collected in earlier steps and the convolution procedure's output.

E. Convolution Layers

The CNN is consisted of three distinct kinds of layers: completely connected (FC), convolutional, and pooling layers. The CNN architecture will be built by stacking these layers. Additionally, to these three layers, there are two more crucial necessities: the dropout layer and the activation function.



(a) File unpacked. (b) File packed.

Fig. 2. Using ByteHist, compare the byte spread of normal and malicious programs.

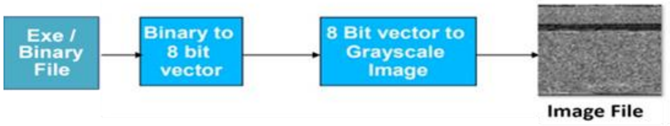


Fig. 3. Malware as a procedure for grayscale representations.

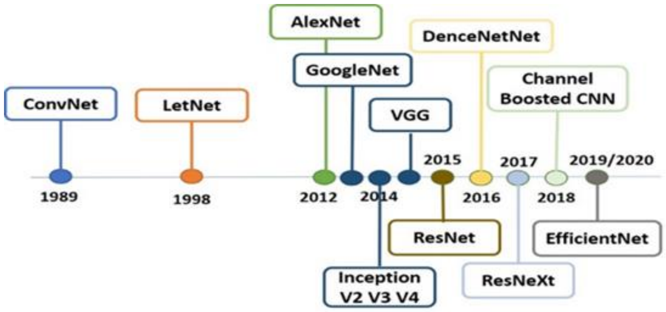

Fig. 4. A brief history of convolutional neural network.

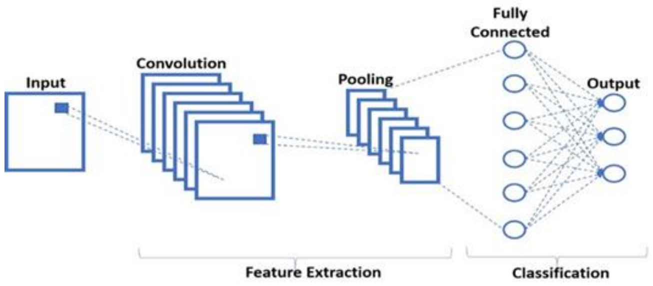

Fig. 5. CNN’s elementary architecture.

F. Convolutional Layer

This is the first layer separating the many structures from the entrance frame. In this layer, the beginning picture is mathematically convolutional using a filter of a certain size MxM. The number of dots that exist across the filter and various areas of the given picture can be calculated according to the filter's size (MxM) by moving the filter through the frame. The final outcome, also referred to as the feature map, contains information about the picture, such as its contours and borders. Then, further layers receive this feature map, which they use to pick up additional features from the input image.

G. Pooling Layer

A Pooling Layer is frequently used after a Convolutional Layer. This layer's primary goal is to scale down the convolved feature map in order to save processing expenses. This is accomplished by minimising the connections within layers and working independently on every element map. There are multiple sorts of pooling techniques based on the technology employed.

The Max Pooling feature map is used to determine the largest element. With middling pooling, the elements within an image segment of a specific size are averaged. The cumulative total of the elements in the pre-known segment is estimated using totality pooling. Connecting the Convolutional Layer and the FC Layer is frequently done via the Pooling Layer.

H. Complete Layer Connectivity

Weights and biases are included in the Fully Connected (FC) layer, which connects the neurons amongst layers. The resulting layer is frequently positioned before the last few layers in a CNN architecture. The input pictures from the layers above are now smoothed and sent to the FC layer. The standard theoretical useful procedures are then performed on the flattened vector via a few additional FC levels. The classifying procedure officially starts at this point.

I. Dropout

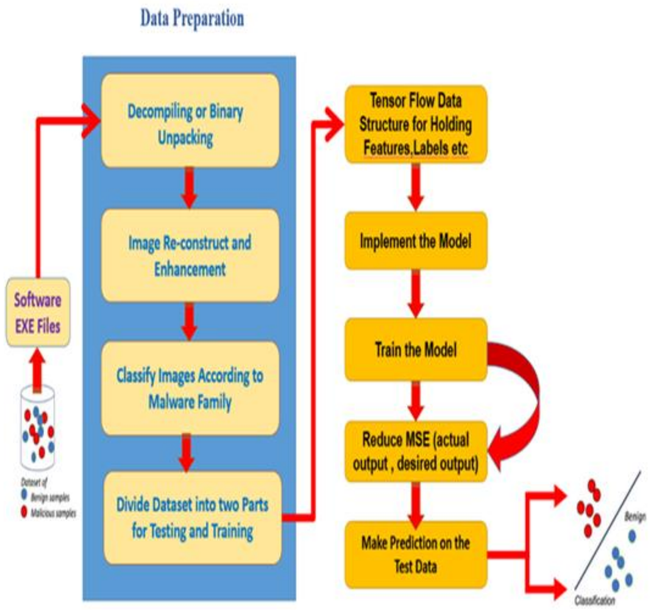
When all of the characteristics are linked to the FC layer, the learning dataset is susceptible to excessive fitting. Overfitting is the process of an algorithm doing such well on data used for training that it has a detrimental impact on how well it works on fresh data. In order to tackle this issue, a dropout layer is implemented, which results in a smaller model by eliminating a limited neurons from the NN throughout learning. After achieving a dropout of 0.3, 30% of the nodes in the NN discontinue arbitrarily.

J. Activation Functions

To summarize, the activation function of the CNN framework is one of its most crucial elements. Any kind of persistent and complicated network variable-to-variable linkage is learned and approximated using them. It decides which design data the network terminal ought to convey as well as which ought not to, to put it simply. The network gains linearity as a result. The ReLU, Softmax, tanH, and sigmoid process are some of the most frequently utilized activation functions. Each of these functions has a unique use. While softmax is frequently employed for a variety of classes sigmoid and softmax functions are chosen for a CNN algorithm for binary classification [26].

K. Proposed Malware Classification Algorithm

The analytical pipeline of the suggested architecture is introduced in Fig. 6 and includes various processing phases. The first step involves preparation of along with information enhancement, which involves changing files from a common picture format to binary language and then back again to grayscale images. Following this, the established CNN framework is described along with its details, including learning through transfer, learning models, variable adjustment, and ultimately categorization. The specifics of those phases are then extensively explained.



Data Preparation
Software EXE Files
Dataset of
Benign samples
Malicious samples
Decompiling or Binary Unpacking
Image Re-construct and Enhancement
Classify Images According to Malware Family
Divide Dataset into two Parts for Testing and Training
Tensor Flow Data Structure for Holding Features,Labels etc
Implement the Model
Train the Model
Reduce MSE (actual output , desired output)
Make Prediction on the Test Data
Benign
Classification

V. Speculated Deep Learning Framework

The proposed DL architecture comprises many steps in which, following preprocessing, the pictures are provided to the suggested CNN for testing and learning in a 64 × 64 array dimension. The proposed CNN structure consists of a source of input, an amount of intended layers, and an output. In this research, five 2D layers of convolution were specifically used, each of which had a 2D max-pooling layer [33]. Convolution is a linear procedure between the input and a kernel (or filter) that acts as an operational monitor. The filters are designed to extract certain information from photos and have a constrained response region. The convolution layer is identified as follows:

$$\mathrm{X}_{\mathrm{n}}^{\mathrm{r}} = \alpha\left(\sum_{m=1}^{k} \mathrm{X}_{\mathrm{m}}^{\mathrm{r-1}} * {w^{r}}_{mn} + \overset{r}{b}_{m}\right) \quad (1)$$

The current layer's ($\mathrm{r}^{\mathrm{tfi}}$) activation map is characterized by X_n^r, the previous layer's (r-1)^τh activation map is represented by X_m^(r-1), and how many enter activation maps are there, is indicated by k. The weight and bias vectors are (w^r)_mn and b$^{\mathrm{r}}$_m, respectively. Convolution is performed using the * operator, and (α) stands for the function of activation.

After each generated activation pattern has been activated by the function of activation, it is subsequently transported to the layer of pooling. The layer of pooling produces a transformation constant by reducing the overall quality of the activation maps and the layer of pooling activations is produced by the convolution layer's dxd (for example, d=2) structure of activation maps. The pooling technique that is most frequently employed is max pooling. The fully connected layer uses the data from all of the activation maps from the layer before it to create a categorization map. The optimizer is essential in learning the DCNN algorithm since it continually modifies the network's layer settings.

To attempt to reduce the effect of the loss function ($\mathbb{i}\cdot e\cdot$∇_θ L(θ)), the settings are modified in the contrary orientation of the variation of the loss function (i.e., L(θ) compared to the variables). Following every repetition, the intended and forecast outputs are contrasted, and the mistake is back propagated. One of the greatest commonly employed evaluation of performance measures is cross-entropy. The basic objective of any optimisation technique is to have a cross-entropy score that is almost zero while the desired and predicted results are the same.

These models will locally identify patterns as CNNs operate internally using convolutions in several sliding windows, enabling a robust differentiation between how every category is represented. The layer of dropouts has been modified to 0.25 for the first and succeeding layers of convolution and to 0.3 for the following layer of convolution. Reformed Linear Units, or ReLUs, serve as the activation function for every layer of convolution. The framework may identify patterns in the provided data and transfer those patterns onto subsequent levels. Following adjusting, the outcome of the preceding convolution is sent to the final dual layers, a full connectivity (FC) layer with 0.2 dropouts and a softmax layer with four neurons. The layer of networks responsible for categorizing determines the likelihood that a data source will fit into a certain classification. For analysis of time-series data employing pooling and expanding filter dimensions ranging this type of multi-layer architecture has shown to be effective. [25][26].

The outcome patterns are y= y1, y2... ym, while the given input patterns for the model are x= x1, x2... xn. The result of the last layer of the network was improved by means of the cost array (xi). If y is the result of every specific method, (L) is the value of the loss function, ($\partial\mathbb{i}$) is the result after the following adjustments and (₵) is the desired class, then (y) is the result.

$$\partial^{i} = \mathrm{L}(\xi¢, \mathrm{y}\square), : \partial\square¢ \geqslant \partial_{\mathrm{j}}\square\forall j \neq ₵ \quad (2)$$

The loss function has been changed to:

$$\mathrm{L} = \sum_{n} \mathrm{t}_{\mathrm{n}} \log(\partial_{\mathrm{n}}) \quad (3)$$

Where ∂_{n} contains the cost that is class-dependent (ξ) and is associated with the result on (y_{n}).

$$\partial_{\mathrm{n}} = \frac{\xi¢,_{\mathrm{n}} exp(y_{\mathrm{n}})}{\Sigma_{\mathrm{k}}\xi¢,_{\mathrm{k}} \exp(y_{\mathrm{k}})} \quad (4)$$

The quantity of samples in a class determines how much weight it has. If class Ŋ has t times extra trials than class p, making one trial from class p as significant as t samples from class Ŋ is the goal. Therefore, the class weight of p is t times more than the class weight of Ŋ. We employ 2D convolutional layers in our model, which is depicted in Fig. 7, using 3x3 kernels for each of the subsequent blocks and 5x5 kernels for the initial block. Moreover, we employ 2x2 for the final two blocks. Every block's second layer of convolution used the ReLU activation function while down-sampled with a stride of two. The first block contained 64 filters, and every block after which included double number of filters. A layer of dropouts (p = 0.3) was added after the last convolutional layer had been applied and connected to one FC-dense layer with ReLU activation scores of 1024.

There was also a layer of dropouts (p = 0.3) sandwiched in among those thick layers. Finally, the algorithm result was provided by a softmax-activated multi-dense neuron. The Adam optimizer was used to learn the algorithm for up to 100 epochs at a rate of learning of 0.001, utilizing a batch dimension of 40. Additionally utilized was the class cross-entropy process of loss that is often employed for several classes' problems with categorization. The class cross-entropy is described as follows, using p standing for the actual distribution and q for the calculated distribution:

$$\mathrm{H(p,q)} = -\sum_{x} p(x)\log\big(q(x)\big) \quad (5)$$

The suggested deep learning pipeline's parameters are recorded in Table I as a whole.

VI. EXPERIMENTAL RESULTS AND DISCUSSIONS

This part goes into considerable depth about both the investigational design and the outcomes. The trial setup includes the framework and code structure training information used in the present study. We conducted separate experiments and compared the outcomes. The experiment's findings are presented and discussed in this part of the paper. We adjusted the hyper-factors for the suggested algorithm's batch size, epochs, and folds in order to get the most effective findings.

Forty (40) batches of data each epoch from a total of 100 epochs are used to learn the network. For every experiment, data is separated into 20%–80% segments for network testing and learning. The set for validation uses 16% of the training set's data. The setup makes use of the Keras platform. The parallel implementation is essential for deep learning training. As a result, we employed Kaggle and the open-source software Python 3.11.0 to perform out the classifier's learning and validation (GPU: NVIDIA TESLA P100 GPUs, 16 GB RAM). The recommended strategy was constructed using the Keras library from Tensor flow applications, and the execution duration was 560.7 seconds. Five series of trials show the changes in how well the suggested solution performs [34].

The framework's assessment establishes how effectively a certain data structure generalizes to new data in order to distinguish among multiple approaches. To do this, we need to assess the effectiveness of multiple algorithms using a method of estimation besides an evaluating approach, such as a learn-test break or cross-validation [27].

A crucial indicator is the accuracy of classification (ACC), which assesses in what way effectively the algorithm foretells a class of instances in the validation set. Further measurements include those defined by terms like sensitivity (SEN), precision, and specificity (SPE) [29][30][31]:

$$\text{Accuracy} = \frac{tn+tp}{tn+tp+fn+fp} \qquad (6)$$

$$\text{Sensitivity (Recall)} = \frac{tp}{tp+fn} \qquad (7)$$

$$\text{Specificity} = \frac{tn}{tn+fp} \qquad (8)$$

$$\text{Precision} = \frac{tp}{tp+fn} \qquad (9)$$

$$\text{F1 Score} = \frac{2*Percision*Recall}{Percision+Recall} \qquad (10)$$

The symbols tp, tn, fp, and fn stand for true positive, true negative, false positive, and false negative, respectively. In order to analyze measurements that are quantitative, the confusion matrix is utilized. The confusion matrix is a table that categorizes forecasts into those that were right and those that were wrong [31][32][35]. A confusion matrix is used in Fig. 8 to show the link between the expected class and the true class. Fig. 8 displays the CNN algorithm's evaluation outcomes for the multinomial categorization of malware groups.

A figure illustrating how intelligent the model is used to identify the family of each malware is shown, and we discover that there was some overlap in identifying some malware families as a result of the limited set of grayscale images on which the model was trained. This is what happened with the family (Autorun. K), which contained a number of images used for only a few grayscale images, and this had an impact on the effectiveness of correctly recognizing the family.

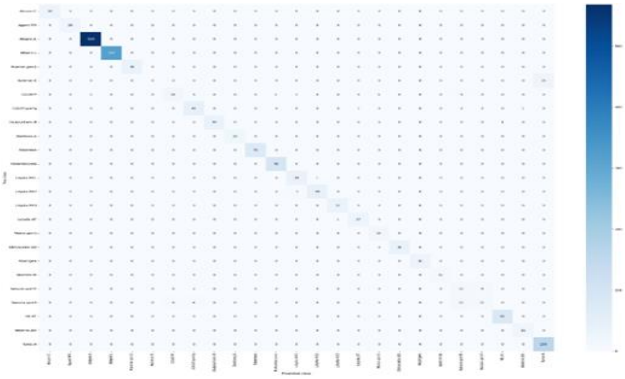

Fig. 8. Results of CNN testing for the Confusion Matrix, showing the accuracy with which it predicted each malware family shown in Fig. 1's list.

Fig. 9. Displays the confusion matrices for the suggested systems.

The produced confusion matrix may be used to create other indices, such as accuracy, precision, F1-score, specificity, and sensitivity (recall). The weighted average of recall and accuracy is the F1 score. The confusion matrix and associated metrics are typically used in conjunction to examine and evaluate categorization methods. Fig. 9 displays the confusion matrices for the suggested systems. Examining which classes, if any, are being misclassified more is quite helpful in determining this. Confusion matrices are helpful for model administration and monitoring in addition to model evaluation. Create confusion matrices for each family class to identify true negatives, false positives, and true positives.

We have employed the criteria already described before to contrast the effectiveness of our methodology. The CNN framework utilizing the basic structure, learned from the beginning via various time-running epochs with the values 20, 40, 50, and 100, achieves an overall classification accuracy of 98.31%. Fig. 10 to 13 show the comparison of accuracy, precision, recall and specificity values for the suggested systems at different epochs respectively. The stated algorithm had a precision of 97.59% as shown in Fig. 10 while Fig. 11 presents a Precision of 97.59 %. Fig. 12 demonstrates a Recall of 90.06% where Fig. 13 introduces Specificity of 99.87% and a F1 score of 99%. Table II introduces the contrasts of the results of accuracy performance by different techniques with the proposed system. According to the findings, our suggested method can provide a reliable algorithm to have an optimum performance to reduce the error and offer an overall accuracy of about 98.31 %. By enhancing the CNN model's architectural design with additional hidden layers, improved nonlinearities, and/or an optimized dropout, it may be possible to get a greater understanding of how to apply it to the categorization of malware. These insights may provide information on the architecture that will work best for creating an intelligent anti-malware system.

VII. CONCLUSION

In the current research, we develop an advanced (DL) image classification algorithm that was previously trained on the MalImg dataset to classify malware based on images. (CNN)-based (DL) methods were contrasted with an extra simple technique created from beginning. We used the same dataset and equal image sizes for our experiments. Since there were no malware zero days in the sample, the model cannot learn and cannot accomplish its objective of identifying zero days and will be considered in the future. Based on transfer learning findings, the model has been demonstrated to be the most effective after accuracy testing. As a result, we can conclude that the transfer learning approach is suitable for classifying malware to categorize. By enhancing the CNN model architecture design with more hidden layers, improved nonlinearities, and/or an optimal dropout, it may be possible to gain more understanding of how well these models apply to the classification of malware. These findings could help in the development of an intelligent anti-malware platform by informing the type of structure to employ. The total testing accuracy of 98.31% in the reported findings attested to the excellent accuracy and robustness of the recommended technique.

Unsupervised Document Binarization of Engineering Drawings via Multi Noise CycleGAN

Luqman Hakim Rosli, Yew Kwang Hooi, Ong Kai Bin
Department of Computer and Information Sciences, Universiti Teknologi PETRONAS, Malaysia

***Abstract*—The task of document binarization of degraded complex documents is tremendously challenging due to the various forms of noise often present in these documents. While the current state-of-the-art deep learning approaches are capable for the removal of various noise types in documents with high accuracy, they employ a supervised learning scheme which requires matching clean and noisy document image pairs which are difficult and costly to obtain for complex documents such as engineering drawings. In this paper, we propose our method for document binarization of engineering drawings using 'Multi Noise CycleGAN'. The method utilizing unsupervised learning using adversarial and cycle-consistency loss is trained on unpaired noisy document images of various noise and image conditions. Experimental results for the removal of various noise types demonstrated that the method is able to reliably produce a clean image for any given noisy image and in certain noisy images achieve significant improvements over existing methods.**

Keywords—Image processing and computer vision; generative adversarial networks; document binarization; deep learning

I. Introduction

In the current Industry Revolution 4.0, images and documents are important methods to acquire information. Specifically, this information is in the form of texts contained within images and documents. Document binarization is a crucial pre-processing step when attempting to analyse and extract the information. The goal of document binarization is to retrieve and extract underlying text from the background of documents. More accurate binarization methods allow for performance improvement of document analysis such as text line and word segmentation and Optical Character Recognition (OCR). Successful and accurate OCR of documents allows for better indexing and searching of documents within document management systems.

Among the many challenges with document images is that they are normally affected by various types of noise and environmental degradation. Examples are uneven illumination, ink or page stain, background colour, shadows, blue and white noise. These noises can come from the state of the document themselves when scanned or bad conditions of digitization. Text extraction from these documents with noisy backgrounds especially those with randomized noise poses a tricky challenge as these noises can obstruct text and possibly not picked up by denoising methods.

In recent years, considerable amount of research pertaining to document image enhancement and recognition has been studied and proposed. Document binarization is an active and ongoing research with steady paper submissions on a yearly basis to Document Image Binarization Competition (DIBCO) which is held by International Conference on Document Analysis and Recognition (ICDAR).

Before the widespread usage of deep learning, popular conventional methods for document binarization are global threshold methods, local threshold methods, statistical-based methods and edge-based. Conventional methods typically focus on a specific noise such as bleed through [1], [2]. The limitation of conventional methods is a reduction in noise removal performance if the document contains various and severe noise and degradation such as a combination of shadow, bleed through and uneven illumination.

Recently deep learning-based document binarization methods have shown significant performance improvement when compared to conventional methods. Built upon the framework Generative Adversarial Networks (GANs), proposed by Goodfellow et al. [12], supervised GANs have been utilized and proven capable to address more challenging noise and multiple degradation and noise. Yun Hsuan Lin [4] uses conditional GANs to remove shadows from complex background colour in documents. Liu et al. [5] utilizes a combination of Recurrent Neural Network with conditional GAN to address complex background noise, colour, and watermarks. Deep learning methods such supervised GAN's are trained in a supervised manner hence matching noisy documents and clean target document pairs are required which are difficult to obtain or generate. Another limitation of supervised GANs and other deep learning methods is that the methods are trained to remove specific noise type which often leads to poor results if the paired training data is not sufficiently many and does not match the noise type.

The ability to denoise and preserve original text and graphics is crucial for accurate OCR and digital document information management. Complex documents such as technical drawings often contain various forms of noise and degradation. Coupled with their irregular text and graphics greatly reduces the performance of an OCR system. The combination of randomized noise and irregular text and graphics results in paired training data for supervised denoising to be difficult or near impossible to obtain. Furthermore, with both the noise and text and graphics in technical drawings being very different from one and another, this results in supervised solutions to be trained multiple times for different combinations of noise, text, and graphics.

Zhu et al. [11] proposed a Cycle-Consistent Adversarial Network (CycleGAN), an unsupervised image to image translation model which does not require paired training data and provides solution to the problems of limited paired datasets. Additionally, CycleGAN has been demonstrated as a capable and flexible denoising method for images with complex noise by Song [14] in denoising complex noisy satellite images into clean satellite images.

Inspired by the framework and capability of CycleGAN, this paper proposes a framework of a modified cycle consistency generative adversarial networks, dubbed 'Multi Noise CycleGAN' for flexible engineering drawing document binarization catering to randomized noise.

The targeted contributions of this paper can be summarized as follows.

- The proposed method focuses on the multi degradation and noise with limited training data availability.
- This framework could be exploited and adjusted to address any complex document degradation problem.
- The proposed hybrid method focuses on addressing current industrial challenge, digitization of historical engineering drawing.

The rest of this paper is organized as follows: Section II reviews associated literature and related works on document binarization and document noise removal. Section III presents the proposed Multi Noise CycleGAN, and the modifications made on the CycleGAN. Section IV presents the experimental results, performance analysis and comparison against other solutions. Section V concludes the paper.

II. RELATED WORK

A. Document Binarization

Research studies covering document image binarization have been conducted and reported in the literature over the past decade. Document Binarization is the process of discarding unnecessary noisy information from documents to preserve meaningful text for text recognition and text extraction. Text in scanned documents is more dense than natural images and contain more contextual information. Emphasis is placed to ensure the text-extracted are similar to the original source. Document image binarization methods are typically categorized into two types: traditional binarization algorithms and deep learning semantic segmentation algorithms. Thresholding is the most basic commonly used method, which sets pixels below a threshold value to 0 and the rest to 1. Global, local and hybrid are among the main types of thresholding. Otsu algorithm [6] is widely regarded as among the most used classical global binarization method.

To drive the progress of document binarization, Document Image Binarization Content (DIBCO) was introduced. Document Image Binarization Content (DIBCO) is a both a document database meant to challenge and serve as a general benchmark for researchers in the field of document binarization with a new document database provided by a specialist every year and a contest of binarization. Chen [7] highlights deep learning models have become the state-of-the-art in document binarization where in 2017, all top six submissions to DIBCO have utilized deep learning model. The document database contains several degradation types that commonly occur in historical documents [7], ranging from stains, bleed through ink, stamps, multiple colour text and border noise.

B. Supervised Deep Learning Document Denoising

Active studies on supervised deep learning document denoising focuses on further improving the accuracy of document binarization alongside covering more degradation and noises within a single document. Souibgui [8] proposes Document Enhancement Generative Adversarial Networks (DE-GAN) to clean and restore severely degraded document images. The DE-GAN reported successful and accurate in addressing blurriness, watermark and ink stain among other noises as well. Most recently, Suh [9] proposes a two stage GAN architecture, addressing document binarization with coloured background, watermark and ink bleed achieving higher results than most state-of-the-art solutions. The architecture proved successful and accurate for shipping labels as well. Both methods are tested on DIBCO datasets for standardization; results at the time of paper publish showcased improvement over other state-of-the-art methods.

Furthermore, Chung [10] proposed a CNN-based binarization for historically degraded drawing maps. Over the years, there have not been many studies and research covering complex documents such as historical drawing maps. Chung [10] CNN based binarization method is an improvement over existing works covering the same document domain, binarization of complex documents consisting of yellowing noise, folded noises and preserving components. Recent works in supervised deep learning document denoising showcases the maturity of methods and algorithms in tackling standardized document binarization test. However, few works address document binarization for complex documents.

C. Cycle consistency Generative Adversarial Network (CycleGAN)

To eliminate the reliance on paired data for training, several unsupervised learning-based methods have been developed for image enhancement inclusive of image denoising. Among them, is a general-purpose method, unsupervised image to image to translation model, cycle consistency generative adversarial network (CycleGAN) proposed by Zhu [11]. CycleGAN allows for the generated image to be as close as target image without paired data and supervision. CycleGAN is derived from generative adversarial networks [12] which utilizes adversarial training, pitting two neural networks against one another. The study of GAN has gained a lot of traction and many variations have been developed to address different problems in the field of computer vision and image processing.

D. Application of GAN and CycleGAN in Image Denoising

The utility of GANs and CycleGAN as an image denoiser has been researched and tested across different industry. Xiong [13] has developed a two stage GAN for low light image enhancement.

In the medical field, due to the intense difficulty of obtaining paired images, modifications were made to cycleGAN as a means to obtain higher resolution and cleaner images to aid doctors in receiving more details from the pictures and increase the diagnostic accuracy. Khan [15] opt for optimal transport cycleGAN to reconstruct high resolution MR images while Lee [16] utilizes attention guided – β CycleGAN to remove metal artifacts from CT images. The works above shares the common goals in removing random noise while preserving the original image through unsupervised image denoising and with limited training data. In the next subsection, past works incorporating CycleGAN ability as an image denoiser at the domain of document binarization is reviewed.

E. Application of cycleGAN in Document Binarization

In the areas of document denoising and binarization, Sharma [17] has applied CycleGAN to the denoising of scanned documents focusing on the removal of watermark, blurriness and background noise removal. Utilizing the design of CycleGAN, Kumar [18] addresses the works of Bhunia [19] for text extraction from documents as the original works of Bhunia [19] requires paired training data, through the development of UDBNET architecture which adds another layer unto the architecture of Bhunia [19] and merging them with a joint discriminator to allow for accurate text extraction without paired data. Tensmeyer [20] extends the CycleGAN model to trained on ground truth binarization masks to produce realistic synthetic data for document binarization of DIBCO datasets.

From recent works, unsupervised document denoising has been tested and refined on standardized degraded documents. However, there exist a research gap in document binarization of complex documents such as technical drawing.

F. Conceptual Research Framework

Fig. 1 provides the framework for a disciplined research approach to the factors affecting OCR performance.

The conceptual framework above highlights the factors and their weightage that contributes to the overall OCR engine performance. Realistically every document requires a certain level of denoising to allow the OCR to accurately extract the underlying text. While there are four main variables affecting the denoising layer, 2 of them, noise type & amount and training data availability has a higher weightage because these are not easily controlled by the user. Commonly used metrics to evaluate OCR performance are Character Error Rate (CER) and Word Error Rate (WER) [24]. [25]. CER and WER indicate the amount of character for CER and word for WER that the applied OCR did not read or generate correctly.

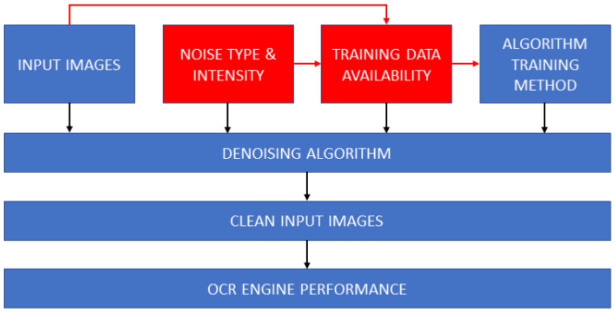

Fig. 1. Overview of OCR performance conceptual framework.

Noise in images can be present due to many factors, environmental, condition of the digital capture device and the condition of the source item. The randomness of the noise has a direct effect unto the training data availability as rarer and more complicated noise generally do not occur often and a sufficient number of data is required to effectively train the denoising algorithm.

The availability of training data is second factor with higher weightage with direct impact to the selection of algorithm training method. In an ideal scenario, even with rare noise type, so long as paired training is available, supervised deep learning denoising method can be utilized. However, that is not often the case. While more mainstream and widespread documents or images have high volumes of data available, certain images especially those in technical areas, engineering, manufacturing or medicine, paired training data are difficult and sometimes impossible to obtain.

As a summary, the critical point for good OCR engine performance lies in the training data. There are very few works that have addressed lack of training data for complex documents. Failure to successfully binarize and conduct text extraction on these documents will result in loss of information as there are enormous number of complex documents from before the digital era.

III. Proposed Method

Image denoising targets to restore a clean image from a noisy one to improve the overall quality of the image for better OCR result. The problems of engineering drawing binarization is treated as an image-to-image translation task where the objective is to produce and generate clean document images and preserve the original content from its noisy counterpart.

CycleGAN has shown to be capable in addressing image to image translation problems in situations there is a lack of paired training dataset. With CycleGAN specific capability of able to work without the constraint of one-to-one mapping between the input image and target image whilst keeping its ability to learn such image-to-image translations, has convinced us to investigate and modify the framework accordingly as a denoising layer for engineering drawings as it is extremely difficult and limited to obtain clean engineering drawings alongside its corresponding noisy counterpart. In Fig. 2 the overview the proposed framework is highlighted.

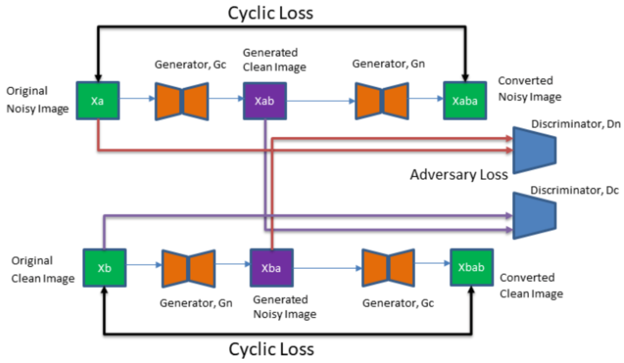

Fig. 2. Overview of CycleGAN.

CycleGAN leverages cycle-consistency loss to get around the problem of learning meaningful transformations in unpaired datasets. This means that if an image is converted from source distribution to target distribution and back, samples can be acquired from source distribution. The cycle consistency loss is incorporated via CycleGAN two generators and two discriminators.

The first generator, G_c converts an image taken from noisy domain, X_a to produce an output image in the targeted clean domain, X_{ab}. To promote and enforce effective relation between noisy and clean images, CycleGAN must be able to learn the necessary features that can be incorporated to turn back generated clean images to its original noisy counterpart. A similar process but in reverse takes place with the second generator, G_n , to convert clean images, X_b to noisy images.

The responsibility of the discriminator is to be able to identify real and fake images generated by the generators ideally as to defeat the generator via rejecting the images produced by it. The generator and discriminator engage in a competition like manner till the generator is able to produce images that are indistinguishable from the original input images. This is expressed as adversary loss.

The proposed, 'Multi Noise CycleGAN', utilizes a similar network structure to that of the original CycleGAN by Zhu [11] with modification made to the existing network which is as follows:

1) 15 ResNet blocks used to build the Generator Architecture as shown in Fig. 3.

2) Individual learning rate for Generator and Discriminator as opposed to same.

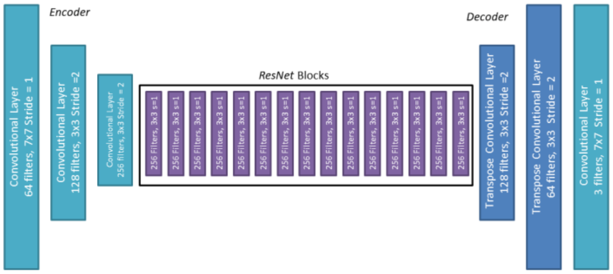

Fig. 3. Overview of modified CycleGAN generator architecture.

Full objective loss is as follows:

$$L\ (G_N, F_L, D_N, D_L) = L^p_{GAN,N}\ (G_N, D_N, X, Y) + L^p_{GAN,L}\ (\ F_L, D_L, Y, X) + \lambda L_{cyc}\ (G, F) +\ L_{IDENTITY}\ (G, F) \quad (1)$$

IV. Experiments and Results

The following subsections describe the experiments that have been conducted using 'Multi Noise CycleGAN'. The proposed dataset, training images and test images alongside the evaluation metrics are described as well.

A. Datasets' Details

In this paper, the experiments are conducted on the noisy engineering drawing dataset type proposed by Chung [10], It consists of 35,960 paired images containing noisy background, yellowed area, and folded lines and their respective clean image. The dirty images are collected and compiled from real degraded as built drawing maps. The noises ae noisy background, yellowed area, and folded lines. The dirty images contain varying degrees of noise level, image clarity and complexity of text and graphics.

For the training phase, 5,083 unpaired dirty images with 256x256 size and 5,063 clean images 256x256 size is used to train 'Multi Noise CycleGAN'.

For the testing phase, to evaluate the overall performance of unsupervised image to image translation, 3,200 pair of images that best represents the structure of engineering drawings containing engineering drawing symbols and diagrams were selected (dirty images and their corresponding clean versions) from the 35,960 paired images and does not include images used during training.

The 3,200 testing datasets are a mixture of four different noises namely as follows:

1) Noisy / Complex background.
2) Less Noisy Background.
3) Noisy Background with discolouration.
4) Noisy Background with poor illumination.

B. Evaluation Metrics

In this paper, to compare and evaluate the performance of unsupervised image denoising with other binarization method, two metrics are used. Structural Similarity Index (SSIM) and Peak Signal to Noise Ratio (PSNR).

The equation for SSIM is as follows:

$$SSIM\ (x, y) = \frac{(2\mu_x\mu_y + c_1)(2\sigma_{xy} + c_2)}{(\mu_x^2 + \mu_y^2 + c_1)((\sigma_x^2 + \sigma_y^2 + c_2)} \quad (2)$$

Where SSIM is the Structural Similarity Index: (x,y) are respective coordinates indicating a nearby NxN window: σ_x , σ_y are the variances of intensities in x,y directions, σ_{xy} is the covariance and μ_x, μ_y are the average intensities in x,y directions.

The equation for SSIM is as follows:

$$PSNR\ (I_{original}\ , I_{clean}) = 10log_{10}\frac{255^2}{MSE} \quad (3)$$

Where MSE is defined as the Mean Square Error. $I_{original}$ is the original image and I_{clean} is the clean, denoised version. MSE is defined as follows:

$$MSE\ = \frac{1}{mn}\sum_{i=0}^{m-1}\sum_{j=0}^{n-1}[I_{original}(i, j) -\ I_{clean}(i, j)]^2 \quad (4)$$

Where m and n respectively are the size of the input images.

For the testing phase, 3,200 pair of images outside of the training data is selected (dirty images and their corresponding clean versions) is used to evaluate the overall performance of unsupervised image to image translation.

C. Experimental Results

Fig. 4 highlights three examples when 'Multi Noise CycleGAN' method is applied unto the test dataset. From the end results, from a visual standpoint, the image is cleaned to a satisfactory level however it is challenging to differentiate a real image from a generated one when the differences between those two are considerably small. As such, quantitative comparison on the proposed method is applied using the aforementioned two metrics: Structural Similarity Index (SSIM) and Peak Signal to Noise Ratio (PSNR).

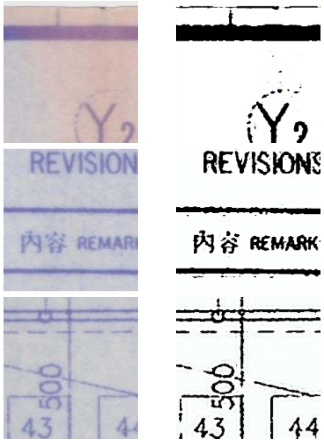

Fig. 4. Multi Noise CycleGAN. From left to right: noisy image, result of Multi Noise CycleGAN.

Guided by the two-evaluation metrics defined above, Table I as shown below summarizes the average results across 3,201 images comparing the performance of Multi Noise CycleGAN against other state-of-the-art methods.

From the results above, 'Multi Noise CycleGAN' on average has achieved PSNR of 15.828 db, and SSIM of 0.806. Therefore, it is shown that the proposed method has achieved comparable results in PSNR and SSIM against state-of-the-art methods with the added advantage of not having to use paired images for the training phase.

Table II highlights few test cases for 1 noise category where the proposed 'Multi Noise CycleGAN' achieves better results in terms of PSNR/SSIM against state-of-the-art method indicating an area of image denoising where it is more advantageous to utilize the proposed 'Multi Noise CycleGAN' method.

It can be observed that the proposed method from a visual perspective as shown in Table II generates a clean image whilst retaining important image details as well without any additional artifacts created.

TABLE I. QUANTITATIVE COMPARISON WITH STATE-OF-THE-ART METHODS ON THE PROPOSED NOISY IMAGE DATASET

Method	**PSNR**	**SSIM**

V. Conclusion

This paper presents a novel model that utilizes Cycle consistent adversarial networks for complex image denoising. The method, dubbed 'Multi Noise CycleGAN' architecture utilizes and modifies CycleGAN to the task of complex image denoising. The method is able to both denoise simple and complex noise due to the inherent property of CycleGAN of cycle-consistency. It is also noteworthy that the method uses unpaired images as training dataset, and therefore does not require ground-truth clean images.

Results show that the proposed method achieves denoising results comparable to state-of-the-art methods. The values of PSNR and SSIM obtained are at same level with state-of-the-art method found in the research literature with some test cases showcasing where the proposed method is overall better.

Future work is targeted to test the feasibility of 'Multi Noise CycleGAN' in tackling additional document binarization problems such as blur and watermark. Improvements to the architecture, to accommodate the addition of blur and watermark noises will allow for even better flexibility of noise removal, improving the accuracy of document binarization of engineering.

***Abstract*—The data driven smart applications, utilize the IoT, Cloud Computing, AI and other digital technologies to create, curate and operate on large amounts of data to provide intelligent solutions for day-to-day problems. Security of Data in the IoT-Cloud systems has become very crucial as there are several attacks such as ransomware, data thieving, and data corruption, causing huge loss to the application users. The basic impediment in providing strong security solutions for the IoT systems, is due the resource limitations of IoT devices. Recently, there is an additional threat of quantum computing being able to break the traditional cryptographic techniques. The objective of this research is to address the bifold challenge and design a light weight quantum secure communication protocol for the IoT Cloud ecosystem. The Ring Learning With Errors (RLWE) lattice based cryptography has emerged as the most popular in the NIST PQC Standardization Program. A light weight Circular Learning Error Algorithm (CELA) has been proposed by optimizing RLWE to make it suitable for IoT-Cloud environment. The CELA inherits the advantages of quantum security and homomorphic encryption from RLWE. It is observed that CELA is light weight in terms of execution time and a slightly bigger cipher text size provides higher security as compared to RLWE. The paper also offers plausible solutions for future quantum secure cryptographic protocols.**

Keywords*—*Quantum secure cryptography; homomorphic encryption; lattice-based cryptography; Learning With Errors (LWE); Ring Learning With Errors (RLWE); Circular Error Learning Algorithm (CELA)

I. Introduction

Smart applications, such as smart traffic management, analyzing customer spending habits, smart homes surveillance, or emergency response for remotely monitored patients, provide intelligent solutions by analysing data from multiple information sources. All these applications are dependent on data. Data is essential for evaluation of performance, prediction of future trends, intelligent decision making and controlling risks. The smart application ecosystem has emerged as a natural confluence of IoT, Cloud Computing, Big Data and AI which provide intelligent automation for various real-life problems [1].

The IoT devices are generating huge amounts of data, but since the sensor-actuator IoT devices have low compute capabilities, the data captured by IoT is sent to Cloud for storage and processing. The IoT-Cloud ecosystem is providing a strong foundation to develop smart applications, in almost all possible domain. Real time processing, underlying infrastructure of servers, storage and communication, and operations, are some key aspects of the IoT-Cloud ecosystem [2].

The amount of data in the world is expanding at a very rapid pace. The survey by Statista [3] shows that the quantity of data created, captured or consumed worldwide in previous decade was at 2 zetabytes (ZB) as on 2010, and in this decade it crossed 64ZB in 2020; and is predicted to reach 180ZB by 2025. And nearly 49% of the world's stored data shall be hosted in public cloud environments. Corrupting the data, data theft and denial of access etc. have become a means of livelihood for hackers. Several attacks are being reported on the data driven systems [4]. Concerns about the safety of data were brought up in [5] and [6]. Data has to be protected against access by any unauthorized persons both during transmission over network and while being stored in any devices. An infrastructure built on the Internet of Things must include standards and services that are necessary for protecting, managing, and connecting the various Internet of Things devices and applications.

Data Security, as defined by NIST (National Institute of Standards and Technology, USA), is the process of maintaining confidentiality, integrity, and availability of an organization's data in a manner consistent with the organization's risk strategy [7]. According to IBM [8], Data Security is the technique to protect digital information from unauthorized access, corruption, or theft, throughout its entire life-cycle from data generation, data transportation over network, data storage and retrieval.

Cryptographic techniques are well established methods for securing data both during transit as well as storage, for a wide range of applications over traditional computers, IoT devices and the Internet. However, there are several challenges encountered while securing the IoT-Cloud ecosystem, such as: (i) resource constraints of IoT devices, (ii) size of crypto keys, i.e. the strength of cryptograhic scheme, (iii) shared access by multiple users, (iv) real time response for the applications, (v) increased threats due to development of Quantum Computing etc. These aspects make traditional protocols vulnerable and impracticable, prodding researchers to develop improved cryptographic techniques.

The most important aspect of any cryptographic technique is to make sure that the encryption cannot be cracked by adversaries. At present, the public key cryptographic algorithms are based on mathematical methods such as discrete logarithm problem (ECC, DHKE) and prime factorization of large integers (RSA), which are difficult to solve in traditional computers.

The RSA public key cryptography is based on modulus arithmetic using very large integers and cycling the data in multiple rounds with the public key; and the decryption is based on finding the prime factors of the very large number. Breaking the RSA-1024 by brute-force would take approximately 2^{1024} comparisons, i.e. a total compute operations of about 10^{264} years, on a single CPU system. However, in 2010, the 768-bit RSA, was cracked in about a week by using the large computational capacity available in a supercomputer cluster [9]. Now, with the emergence of quantum computing Shor's algorithm (which is capable of finding the prime factors of an integer, at an exponentially lesser time), the need to develop quantum resistant cryptographic algorithms has been felt [10].

While several strong cryptographic methods are envisaged, the IoT devices are resource-constrained with limited compute and storage making it impractical to perform encryption and decryption in real-time and also for storing the encrypted data. Hence, light weight cryptographic methods are required. Though conventional encryption techniques, would serve the purpose of protecting the data, the modern IoT-Cloud applications require a multi-user shared, searchable and processable data for quick analytics and control. To cater to these requirements, new methods for encrypted data query and processing have been proposed for the IoT-Cloud systems [11].

Recently, the National Institute of Standards and Technology (NIST) announced the Post Quantum Cyptography (PQC) Standardization Program open call to evaluate and standardize public-key cryptographic algorithms for securing against the emerging quantum attacks. Among the 50 cryptographic proposals that were short-listed, 21 were based on lattice techniques; and in that, the RLWE algorithm turned out to be the most popular with a count of 15 entries. The lattice based crytpo techniques are prime candidates as they have strong security, compute efficiency, wide applicability, homomorphic encryption, and quantum resistance. The NewHope [12] is a fast, memory efficient, and simple scheme that is a suitable replacement of RSA and ECC. It provides homomorphic encryption, reasonable sized key and ciphertexts and significantly resistant to side-channel attacks. Internally it uses the Ring-LWE lattice-based technique.

1) Contribution of this paper: The aim of this research is to propose a highly secure yet light weight protocol for the IoT-Cloud ecosystem. The primary contributions of this paper include:

(i) Lightweight Cryptography: The proposed CELA has lower time complexity on account of modulus switching technique which reduces the polynomial ring order in intermediate computations.

(ii) Improved Security: Enhanced security is provided by increasing the key size to twice that of the base RLWE algorithm and using random noise vector. The ciphertext is of bigger size and more complex.

(iii) Plausible Solutions for Quantum Secure Cryptography: Since, the number theory based cryptographic algorithms are susceptible to be cracked by quantum computers, robust security schemes are suggested towards quantum secure cryptography.

2) Organization of the Paper: Organization of the paper is as follows. The related work is summarized in Section II. A brief description of various cryptographic techniques is presented in Section III. The IoT-Cloud architecture and smart applications are described in Section IV. Section V presents the security challenges in IoT-Cloud ecosystem. The design and implementation of the proposed CELA is presented in Section VI. Plausible solutions for quantum secure cryptography in resource constrained IoT-Cloud ecosystem are provided in Section VII and the conclusion is contained in Section VIII.

II. Related Work

A summary of research papers published over the past five years which focus on the consumer-oriented IoTs clouds applications for the purpose of understanding intelligent IoT-Cloud systems is provided in reference [13], [14]. The authors of [15] investigated the factors that influence the acceptance of Cloud Computing, examined the types of attacks that may be launched against cloud-based environments, and proposed solutions for making cloud-based environments more private and secure. The authors of [16] identified privacy schemes that are usable in cloud-based systems that are based on the internet of things to protect data more thoroughly. In [17], a methodology is presented for the investigation of the privacy and security issues that are prevalent in social networks that are based on cloud platforms. The author in [18] investigates both under-explored and common security vulnerabilities associated with cloud systems from a technical point of view, looking into several types of cyberattacks that could occur in cloud environments.

Improvisations to the Attribute Based Encryption (ABE) schemes have been demonstrated in the following papers by - Li Jiguo et al. [19] based on hidden access structure, Zhao et al. [20] based on hidden policies, Han et al. [21] for Traceable and revocable CP-ABE, Das et al. [22] for Multi-Authority CP-ABE and, Zhang et al.[23] based on lightweight Searchable Attribute Based Encryption(LS-ABE).

Wang et al. [24] proposed FABRIC - a fast and secure unbounded cross-domain Proxy Re-Encryption (PRE) scheme for data sharing in multi-user cloud and Deng et al. [25] proposed transforming identity-based encryption (IBE) ciphertext into an identity-based broadcast encryption (IBBE) ciphertext.

Other recent cryptographic efforts include - Logistics Chaos Model theory based encryption for Big data in cloud environment by Abdel-Kader et al. [26]; Catalan number crypto keys for stronger encryption in IoT systems by Saracevic MH et al. [27]; Boneh-Goh-Nissim (BGN) homomorphic encryption for Shared IoT-Cloud environment by S Halder et al. [11]; Differential levels of encryption security for sensitive and non-sensitive data by Atiewi et al. [28]; and CMAP

(Cryptography and Machine Learning based Authentication protocol) by Singh and Saxena [29].

The more recent efforts in lattice based and LWE schemes provide strong security for light weight devices and PQC. Adaptations and implementation in both hardware and software for the Lattice-based Cryptographic schemes, have been demonstrated by AK Sahu et al. [30], N Hamid et al. [31] and Wai-Kong Lee et al. [32]. While these schemes offered homomorphic encryption resistant to post quantum cryptographic attacks, there is scope for improving their performance for using in real-life IoT-Cloud applications.

A summary of latest research in Learning With Errors Crypto Schemes is available in - Xie et al. [33], Kundi et al. [34], Jose [35], Xiaodan Xi et al. [36], Pengzhou He et al. [37], Shahriar Hadayeghparast et al. [38], and Dongdong Xu et al. [39], have optimized the LWE encryption algorithms and implemented them in hardware. The main aim of these efforts is to develop light weight, low power, low silicon-area * delay, i.e. compact and high speed, yet stronger encryption hardware which can be used inside context devices.

Optimizations and implementation of the RLWE scheme on IoT compatible low power RISC and ARM processors, are presented in Ebrahimi et al. [40], Zhe Liu et al. [41] and Zhang et al. [42].

Various quantum resistant security schemes based on XMSS, HBS, and Quantum-AES for IoT-Cloud ecosystems are offered in the works of WK Lee et al. [43], Santosh Ghosh et al. [44] and Roopa Golchha et al. [45]. The qualifying PKE algorithms of the NIST PQC Standardization program are described in [46].

The comparison of research articles published in the last five years in the area of lattice-based homomorphic post-quantum resistant cryptographic schemes is captured in Table I.

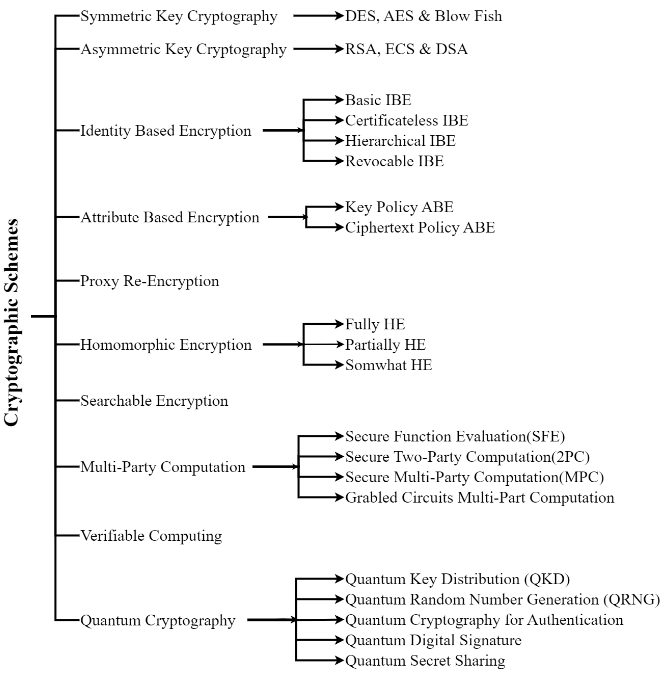
While lattice based schemes like RLWE are found to be quantum resistant and homomorphic, they require to be optimized to be practicable for compact resource-constrained IoT devices. Improving the computational speed and key size may make them amenable for real-world IoT-Cloud applications.

III. Preliminaries

Protecting the data from malicious and inadvertent problems is an important task. The various methods used to protect the Confidentiality, Integrity and Privacy of data include - Authentication and access control, Data Masking, Cryptographic techniques, Steganographic techniques, Differential Privacy techniques and Blockchain.

A. Classification of Cryptographic Schemes

Cryptography is a mature and popular data security mechanism employed for several Internet applications including IoT and Cloud. The variations in cryptography are revealed in the classification [49] shown in Fig. 1.



Cryptographic Schemes
Symmetric Key Cryptography
DES, AES & Blow Fish
Asymmetric Key Cryptography
RSA, ECS & DSA
Identity Based Encryption
Basic IBE
Certificateless IBE
Hierarchical IBE
Revocable IBE
Attribute Based Encryption
Key Policy ABE
Ciphertext Policy ABE
Proxy Re-Encryption
Homomorphic Encryption
Fully HE
Partially HE
Somwhat HE
Searchable Encryption
Multi-Party Computation
Secure Function Evaluation(SFE)
Secure Two-Party Computation(2PC)
Secure Multi-Party Computation(MPC)
Grabled Circuits Multi-Part Computation
Verifiable Computing
Quantum Cryptography
Quantum Key Distribution (QKD)
Quantum Random Number Generation (QRNG)
Quantum Cryptography for Authentication
Quantum Digital Signature
Quantum Secret Sharing

Fig. 1. Classification of cryptographic schemes.

B. Cryptographic Schemes

(i) Symmetric Key Cryptography: This is an encryption system where the sender and receiver have a single common key for enciphering and deciphering the messages. Symmetric Key Systems are simple and fast, but the problem is that sender and receiver have to somehow exchange the key in a secure way. E.g. Data Encryption System (DES).

(ii) Asymmetric Key Cryptography: Under this system the public key of the receiver is used to encrypt the data and send on the channel; and the receiver can only decrypt with his private key. Hence there is no need for key transfer. E.g. RSA, ECC and ElGamal Cryptosystem.

(iii) Key Exchange: The Diffie Hellman Key Exchange (DHKE) provides a mathematical protocol for exchanging the secret key between the sender and the receiver over a potentially non-safe communication channel. The two parties involved in communication, Alice and Bob, start by agreeing on a finite field F_q and a primitive root g, i.e. a generator of the cyclic multiplicative group F_{*_q} where the field F is an algebraic set with two operations (addition and multiplication) and q is the modulus. The pair (q, g) is made public. To obtain the private key, Alice selects an integer a and Bob selects an integer b. Then, Alice sends $g_a\ modulo\ q$ to Bob, who on receiving it, raises it to $b\ modulo\ q$, getting $g_{ab} modulo\ q$. Next, Bob sends $g_b\ modulo\ q$ to Alice, who raises it to a, also obtaining $g_{ab}\ modulo\ q$. Now, even if g is publicly known, the eavesdropper (Eve) cannot obtain $g_{ab}\ modulo\ q$, and hence cannot get a or b secret keys to crack the cipher text.

(iv) Identity Based Encryption: The parties involved in communication identify themselves using a unique identifier such as an email address or user name as their public key. The data is encrypted using the recipient's email address or username. Some popular Identity Based Encryption (IBE)

TABLE I. SUMMARY OF QUANTUM SECURE CRYPTOGRAPHIC RESEARCH WORK

Author	**Algorithm**	**Performance**	**Research Gaps**
Concept/ Model	**Implementation**	**Advantages**	**Future Challenges**
AK Sahu et al. [30], 2021, Lightweight Multi-Party Authentication and Key Agreement for IoT e-Healthcare	Lightweight Multi-Party Authentication and Key Agreement (LMPAKA) based on Lattice-Based IBE	- Lowered Power consumption - Resistant to Replay Attacks, Mutual Authentication attacks, Impersonation, Forward Secrecy, Quantum attacks	Include Privacy of the user data in Cloud server
N Hamid et al. [31], 2020, FPGA implementation of Ring LWE based crypto techniques	NewHope, Kyber, Dilithium, and R.EMBLEM	- Hardware solutions are twice faster and energy efficient. - Generic FPGA kernels are usable by any lattice cryptosystems	Evaluate the accelerator for lattice-based post-quantum algorithms
Wai-Kong Lee et al. [32], 2022, Implemented Lattice NTRU polynomial convolution in GPU Tensor cores	Parallelized algorithm of NTRU polynomial convolution	Tensor-core-based polynomial convolution on NVIDIA RTX3080 GPU improved by over 3 times compared to CPU	Implement on gateway device in IoT
Xie et al. [33], 2020, Hardware implementation for BRLWE	Designed and implemented finite field arithmetic AB + C on Xilinx Vivado series Virtex-7 (XC7V2000) and Kintex-7 (XC7K325) devices	The area-time complexities and area-delay product of this design is superior compared to the existing designs, namely #LUT, #FF, #slice.	Extend the hardware for future applications
Y Chen et al. [47], 2021, On the fly keys generation for LWE based Multi-Key FHE	Dynamic Multi-Key FHE algorithm	- Beforehand fixing of number of keys is not required - Distribution helped to reduce encryption workload on cloud	Presently the MK-FHE is single-bit encryption, plan to extend to multi-bit
Yang Su et al. [48], 2020, FPGA-Based Hardware Accelerator for Leveled RLWE FHE	- BGV FHE - NTT-based modular polynomial multiplier unit - LUT Modular Reduction unit homomorphic evaluation function	- Hardware Area saving of 50% - And 20% speed up compared to existing solutions - Implemented on Virtex UltraScale FPGA	Extend to support wider range of security parameters
Kundi et al. [34], 2022, AxRLWE: Approximate RLWE implementation on FPGA for IoT	Using Approximate Computing (AxC), R-LWE is approximated in a multilevel fashion by replacing the normal Discrete Gaussian (DG) with Binomial Distribution in RLWE multiplier module	- The Xilinx Kintex-7 FPGA based AxRLWE designs provide up to ≈ 64% area saving compared to the accurate R-LWE - And ≈ 3× lower energy consumption against the R-BLWE	Implement PQC within the tight area/energy budgets of the highly resource-constrained IoT devices
S. Ebrahimi et al. [40], 2020, Fault-Resilient Software implementations of binary Ring-LWE on lightweight IoT microcontrollers	Implemented Fault-Resilient Binary Ring-LWE on 8- and 32-b AVR ATxmega128A1 and ARM Cortex-M0 microcontrollers	- 80ms for encryption and 120ms for Decryption - Resistance to first order attacks- randomization, zeroing, skipping faults - Implementation on tiny microcontrollers suitable for IoT	Manage larger key and ciphertext sizes
Zhe Liu et al. [41], 2020, Software Implementation of RLWE on ARM NEON and MSP430	- Vectorized Iterative NTT for ARM NEON - Optimized SWAMS2 reduction technique for MSP430	- The implementation is 7x faster than ECC of the same security level	Practical application in IoT devices
Jose L et al. [35], 2022, Hardware implementation with optimized arithmetic for InvBRLWE	- Inverted Binary Ring-LWE (InvBRLWE) - Linear-Feedback Shift Register (LFSR)	- LFSR optimizes the resource usage for heavy computations - 71.23% less (area x delay) product than recent designs	Deploy for real world application environments
Xiaodan Xi et al. [36], 2023, Hardware implementation of physical unclonable function (PUF)	- ML Resistant LWE decryption module Lattice PUF - implemented on Xilinx Spartan-6 FPGA	- Resistant to ML attacks on both classical and quantum computers - Prototyped with 2136 challenge- response pairs (CRPs)	Validate the prototype Lattice PUF hardware in field applications
Pengzhou He et al. [37], 2022, RBLWE-based PQC accelerators on the FPGA	- RBLWE Encryption - Implemented on Xlinix Virtex-7	Design is balanced between speed and hardware area usage for compact IoT devices	Enhance for side-channel attack resistance
Shahriar Hadayeghparast et al. [38], 2022, Lightweight cryptoprocessor based on RISC-V for InvRBLWE	Optimized Inv Ring-BinLWE	- 51% faster than RBLWE - Implemented on Xilinx FPGA	Prevent side channel attacks like intentional fault injections and Differential Power Analysis
Dongdong Xu et al. [39], 2022, New scheme of ring-BinLWE based on 2's complement ring	Ring-BinLWE based on the 2's complement	- Lightweight implementation on Spartan 6 FPGA - Compact design; less hardware area	Improve resistance to side channel attacks such as Differential Power
Fan Zhang et al.[42], 2020, Side-Channel Analysis and Countermeasure Design on ARM-Based Quantum-Resistant SIKE	Supersingular Isogeny Key Encapsulation(SIKE)	Achieved higher security along with lower time and memory	Eliminate vertical leakages and resist SCA Attacks
WK Lee et al.[43], 2022, The DPCrypto accelerates PQC using Dot-Product Instructions on GPUs	Lattice based KEM FrodoKEM and SaberKEM implemented on NVIDIA V100 and T4 GPUs using Dot-Product instructions for matrix, hash and other operations in the algorithms	- Implementation very useful for Secure Online Transactions and IoT communications - Executing compute-intensive KEM on GPUs reduces the burden for cloud	Execution speed on T4 is less compared to V100 because of the inherent number of cores in each type of GPU
Santosh Ghosh et al. [44], 2018, A Lightweight Post-Quantum Secure Digital Signature Approach for IoT Motes	Hash Based Signature (HBS), XMSS Scheme, Keccak-400 hash function, WOTS+, SHA-3	- Novel XMSS signature scheme has a small memory footprint - FPGA implementation takes 4.8 million clock cycles; 5x faster than software	Extend the novel signature approach as a ultra light weight end-to-end IoT security
Roopa Golchha et al. [45], 2023, Quantum AES for Fog Enabled Cyber-Physical systems	Quantum AES	- Improved security by integrating quantum cryptographic approach and classical AES - About 10 to 21 Qubits are needed for encryption and decryption of messages	Building the quantum circuits is challenging due to noise

algorithms are Boneh–Franklin IBE, Cocks IBE, Gentry IBE and Waters IBE. Conceptually, the different types of IBE include - Basic IBE, Certificateless IBE, Hierarchical IBE, Revocable IBE and Dual-Receiver IBE.

(v) Attribute Based Encryption: The secret keys required to decrypt the cipher text are related to users' attributes such as roles, age, location, etc. The encrypted data can only be decrypted by users who have the specific set of attributes required to access the data. The main types of ABE schemes are - Key-policy ABE (KP-ABE) and Ciphertext-policy ABE (CP-ABE).

(vi) Proxy Re-encryption: Proxy Re-encryption (PRE) is a mechanism to convert the ciphertexts for one key into ciphertexts for another by using a Pproxy. An encrypted data item is stored in the Cloud and the Proxy decides to re-encrypt it and send to legitimate users. This delegation scheme is useful for resource constrained IoT devices as the computationally intensive encryption are outsourced to the proxy server. It is useful for applications such as e-mail forwarding, content distribution and law-enforcement monitoring.

(vii) Homomorphic Encryption: Homomorphic Encryption (HE) encodes data into ciphertext which can be analyzed and worked with as though it were still in its original form. HE will enable users to perform computations on the encrypted data without first decrypting it [50]. HE is expected to play an important role in Cloud based applications (e-voting, health, finance), allowing companies to encrypt and store sensitive data in a Public Clouds and take advantage of the Cloud Provider's analytic services. In 2009, Gentry proposed with proven safety, a fully HE cryptogram technique; this algorithm relies primarily on learning with error (LWE).

(viii) Verifiable Computation: Verifiable computation is a method where a device having limited computing capabilities makes a request to outsource computation services which it is unable to undertake on its own, and receives assistance from another source. The result of using outsourcing is that the results can be delivered in a time- and cost-effective manner [51]. The verifiable computation does not involve interaction between users who have had their identities validated and protects users' privacy by the comparison and verification of the values that are input and output.

(ix) Searchable Encryption: Searchable encryption is designed to boost the efficacy of searching by adding an index for searching specific information whilst still considering the safety of encrypted data. This method consists of - key generation, encryption, generation of trapdoors, and the search test process. During the stage of key generation, the user is generating as well as saving a private key, while also providing other users with a public key. The data are encrypted, and an index is too generated in order to search for keyword information within the data. By using the private key, the user creates a trapdoor for the term. The data supplied by the sender can be located by the receiver by using the trapdoor [50].

(x) Multiparty Computation: Present day collaborative applications in cloud computing desire the ability to exchange encrypted data with other users whilst also protecting their privacy and retaining their confidentiality. Multiparty computing (MPC), is a cryptographic technique that enables multiple parties to jointly perform a computation on their private data without revealing their inputs to each other. The idea is to divide the computation into smaller sub-computations that can be performed separately by each party using their private inputs. These intermediate results generated by the sub-computations are then combined in such a way that the final result can be obtained without any party having access to the private inputs of the other parties.

(xi) Quantum Encryption: This is an extremely secure encryption based on quantum mechanics, but is not yet widely available due to the technical requirements and high cost of quantum computers. Various types of Quantum Cryotography [52] are evolving such as Quantum Random Number Generation (QRNG), Quantum Key Distribution (QKD), Quantum Cryptography for Authentication, Quantum Digital Signatures and Quantum Secret Sharing.

C. Lattice-based Cryptography

In mathematics, Lattice is a multi-dimensional grid of points that are spaced at regular intervals. Since, lattices are flexible, and posses features required for obfuscation, functional encryption and homomorphism, they are being used for encryption and decryption in the lattice based cryptographic algorithms. Two key concepts about lattice are - Vector and Basis. A vector is a tuple of numbers called the coordinates of the vector, indicating the starting and ending points. Basis is a pair of vectors which can produce other points in the lattice, when added with linear integer combinations of these basis vectors.

Mathematical problems related to the lattice are used to obtain the secret from the public key. The Shortest Vector Problem, is to determine a non-zero vector in the given lattice space whose length is minimal over all non-zero lattice vectors. The Closest Vector Problem is a reduction problem to determine a vector in the lattice which is closest to the target vector. Lattice based mathematical techniques and its variations lend themselves to quantum resistant cryptography. This section explains the lattice based methods.

D. Learning With Errors (LWE)

In LWE-based encryption, the data or message is encrypted by adding a random noise (or error) value to it; the resulting ciphertext is sent over an insecure communication channel. The idea is that even if the attacker tries to learn the secret key by solving a set of equations using the ciphertext and the function, the error component makes it difficult to solve the equations and recover the key. LWE can be mathematically stated using the equation:

$$(B[\,] = A[\,] * s + e)$$

where (A) is a random vector $(a = (a_1, \ldots, a_n))$, sampled uniformly over a vector $(Z/Z_q)^n$, and B is the public key based on $b = (a, s) + m + e$, and s is the secret, the error e is drawn from Gaussian Error distribution and all arithmetic is done $modulo\ q$. Breaking the scheme in LWE scheme is based on the hardness of lattice problems.

Without the error term, an attacker could determine the secret key from a polynomial-sized collection of LWE ciphertexts by some method like Gaussian elimination. Hence the plain text is encoded along with the errors. For encoding, we use smaller cleartext space (actual messages) and encode cleartexts by putting the messages in the higher-order bits of the plaintext space. E.g., a 10-bit message can be encoded in the top 10 bits of a 32-bit integer, and leave the remaining 22 bits of the plaintext for the error distribution. Hence size of key is large in LWE scheme. However, the key size can be compressed by changing different parameters such as size of the noise polynomial, size of error, dropping lower-order bits, changing security level etc.

E. Ring Learning With Errors (RLWE)

The RLWE is a specialized form of LWE for polynomial rings over finite fields in which the set of polynomials have coefficients in another ring [53]. In algebra, rings are structures that come with the basic operations of addition and multiplication and a multiplicative identity; addition operation is commutative and the multiplication is associative. The elements in the Ring may be integers, polynomials and matrices etc.

A ring R, denoted by $(R, +, *)$ is a set of elements (integers, polynomials, matrices), with binary operations of addition and multiplication.

For a positive integer q, we define, $Z_q = Z/qZ = \{0, 1, ...(q-1)\}$ as the integer quotient ring, with q as its modulus. The set of polynomials is denoted by $Z_q[x]$ where the coefficients of $Z[x]$ are chosen from Z_q [53]. Any polynomial is uniquely identified by its set of coefficients or the coefficient vector.

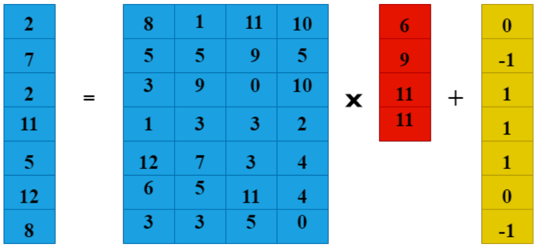
A polynomial ring R_q is any polynomial in $Z_q[x]$, modulus divided by a modular polynomial $f(x) = x^n + 1$. That is $R_q = Z_q[x]/f(x)$ so that no polynomial has higher rank than n.

The RLWE [53], [54], uses ring polynomial and error vectors over Z, sampled with discrete Gaussian Distribution (χ) (σ) with a small standard deviation σ.

$$(B[\ ]_q^{m*1} \ = \ A[\ ]_q^{m*n} \ * \ s[\ ]_q^{n*1} \ + \ e[\ ]_q^{m*1})$$

where $a \in Z_q^n$ are random coefficients, $s \in Z_q^n$ is the secret and $e \in \chi$ and χ is the error distribution with small standard deviation. A typical illustration of RLWE [55] is shown Fig. 2.

$$(B[\ ]_{13}^{7*1} \quad = \quad A[\ ]_{13}^{7*4} \quad * \quad s[\ ]_{13}^{4*1} \quad + \quad e[\ ]_{13}^{7*1})$$



$$\begin{bmatrix} 2 \\ 7 \\ 2 \\ 11 \\ 5 \\ 12 \\ 8 \end{bmatrix} = \begin{bmatrix} 8 & 1 & 11 & 10 \\ 5 & 5 & 9 & 5 \\ 3 & 9 & 0 & 10 \\ 1 & 3 & 3 & 2 \\ 12 & 7 & 3 & 4 \\ 6 & 5 & 11 & 4 \\ 3 & 3 & 5 & 0 \end{bmatrix} \times \begin{bmatrix} 6 \\ 9 \\ 11 \\ 11 \end{bmatrix} + \begin{bmatrix} 0 \\ -1 \\ 1 \\ 1 \\ 1 \\ 0 \\ -1 \end{bmatrix}$$

Fig. 2. A typical example of ring polynomial in RLWE.

The RLWE procedure is shown in Fig. 3. The algorithm takes the following inputs:
1. A positive integer n, which is the dimension of the polynomial used in the RLWE problem.
2. A secret key s, which is a vector of n random elements chosen from the ring.
3. A public parameter A, which is a matrix of n random elements also chosen from the ring.
4. A small error term e, which is a vector of n elements chosen from a Gaussian distribution.
The algorithm outputs the public key matrix B that can be used for encryption and the secret key that can be used for decryption. The security of the RLWE scheme is determined by the degree of polynomial n, ciphertext size $C\ modulus\ q$ and Gaussian Noise Distribution ($\chi\sigma$).

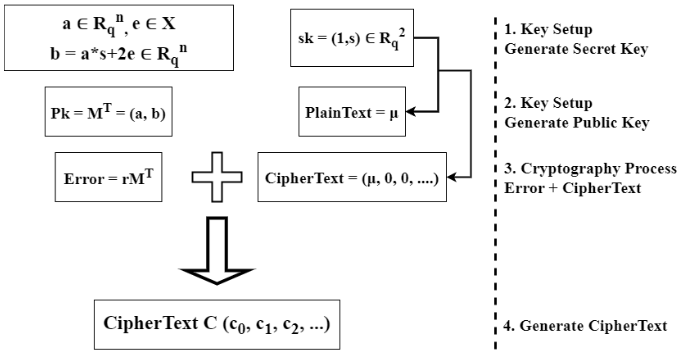


Fig. 3. General RLWE encryption procedure.

In RLWE the keys sizes are much lesser than LWE scheme; RLWE key sizes are almost the square root of LWE key size [56]. If we compare the key sizes for the current security level of 128 bits, the RLWE algorithm would use public keys of 7000 bits in length, whereas the equivalent LWE algorithm requires public keys of 49 million bits. Yet, when compared to the present public key schemes like RSA and ECC which offer public key sizes of only 3072 bits and 256 bits respectively (for a 128-bit security level), the RLWE key sizes are larger.

F. Modulus Switching

In a fully homomporphic encryption, one should be able to add and multiply the ciphertext as if it were in the original plaintext form. The encryption procedure for RLWE-based fully homomorphic encryption is carried out by making use of the elements that are contained within a vector space, and has an Error value in the resulting cryptogram. While performing a homomorphic operation $Eval_{pk}(., c, c)$ of two cryptograms for the multiplication, each having an n-dimension, the encryption expands to n^2.

Adding two homomorphic RLWE ciphertexts produces a resultant ciphertext as the sum of the plaintexts. Homomorphic addition does not increase the size of the ciphertexts. But, homomorphic RLWE multiplication increases the number of components in ciphertexts; that is,

$$(b_1 - a_1.s)(b_2 - a_2.s) = b_1b_2 - (b_1a_2 + b_2a_1)s + a_1a_2s^2$$

Now the ciphertext became larger and has 3 terms. The size of the cryptogram needs to be lessened. The concept of

Modulus Switching [57] can used to contain the growth of ciphertext size.

Modulus switching is based on changing the modulus q to a different prime number q', where q' is smaller than q. By this technique, the size of the polynomial ring can be reduced temporarily during intermediate computations.

The concept of modulus switching is explained with an example. For encoding, smaller cleartext (actual messages) are encode as plaintext by putting the messages in the higher-order bits of the plaintext space. Say, RLWE encodes 10-bit messages in the top 10 bits of a 32-bit integer, and leaves the remaining 22 bits of the plaintext for the error distribution.

In modulus switching, the modulus is changed from q to q', where $q' < q$, and we would like to produce a vector $(a'_1, ..., a'_n, b') \in (Z/q'Z)^{n+1}$, with the new modulus q', that also encrypts message m. In other words, we encrypt $m' = mq'/q$. The operation of $m \to mq'/q$ shifts up by $log_2(q')$ many bits and then shifting down by $log_2(q)$ many bits.

For example, say the number (x=6) requires only top 3 bits of a 32-bit unsigned integer $((q = 2^{32}))$, i.e., (m = 6 · 2^{29}). Let (q'= 2^{10}). Then (mq' / q = 6 · 2^{29} · 2^{10} / 2^{32}) $= 6 \cdot 2^{29+10-32}$) $(= 6 \cdot 2^7)$, which stores the same underlying number (x=6), but in the top three bits of a 10-bit message. By modulus switching, the data (x) is in the same position in the plaintext space, but the plaintext space around it has shrunk, thereby making extra room for error bits in the plaintext space.

The RLWE ciphertext contain a certain amount of noise or error which increases with every multiplication; finally the decryption becomes infeasible if error size passes a certain bound. When modulus switching is incorporated and homomorphic multiplication, is performed, there is space in the plaintext to allow the error term to grow towards the most significant bits of the plaintext.

Modulus switching technique involves changing the modulus of the polynomial ring during intermediate computations to reduce the computational complexity of the algorithm. This technique could significantly reduce the execution time of the algorithm while maintaining the same level of security. The idea behind modulus switching is to reduce the size of the polynomial ring temporarily during intermediate computations to make the computation faster. Then, the size of the polynomial ring shall be increased again to its original size at the end of the computation.

IV. IoT-Cloud Application Ecosystem

The smart application ecosystem shows how data is being used for intelligent automation of various real-life tasks. There is a natural convergence of IoT, Cloud Computing, Big Data and AI to provide smart solutions for many real-world problems [1]. Fig. 4 shows the creation, capture and processing of large volume and variety of data getting ingested into the Cloud at high velocity from the network of heterogeneous devices, computers and users forming Big Data. The IoT data are stored and processed in Cloud Storage and the control decision is sent back to the actuators [1], [58], [59].

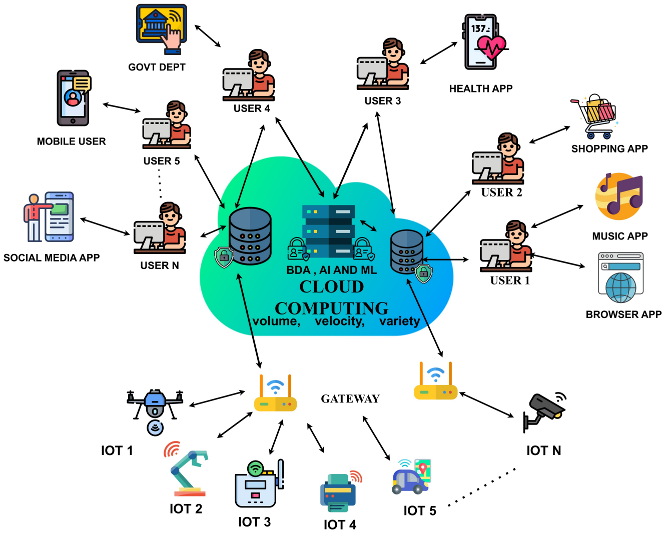

Fig. 4. Architecture of smart applications.

A. Architecture of IoT-Cloud Ecosystem

To meet the needs of real-time processing and control for time critical applications, a multi-layered IoT-Cloud architecture has evolved with intermediate mist, edge and fog layers [46] as seen in Fig. 5. The main difference between the layers is in terms of the compute-storage-communication capacities and where the data is processed and stored.

(i) IoT Device Layer: The bottom layer is the IoT devices with embedded sensors and actuators. This layer contains billions of devices across various IoT networks.

(ii) Mist Layer: On top of the IoT devices is a thin Mist layer which aids to build slightly bigger IoT systems at the local level through virtual communication mechanisms. The Mist allows to execute less computationally intensive tasks, closer to the devices thereby reducing the communication latency (while cloud handles the more computationally intensive tasks).

(iii) Gateway Layer: This is a communication layer having routers for IoT to reach the edge layer.

(iv) Edge Computing: This is composed of small nodes at the edge of the network which are capable of offering routing as well as computing services.

(v) Fog computing: This is an intermediary between the Edge and the Cloud which can carry out functions such as data filtering.

(vi) Cloud Computing: It is the topmost layer. It has large compute-storage capabilities and runs many software applications for multiple users.

B. Applications of IoT-Cloud Ecosystem

The IoT-Cloud system are easily usable and suitable for almost any type of application domain [60]. There are practically hundreds of applications; only a few common ones are listed in this subsection, to provide an understanding to the reader.

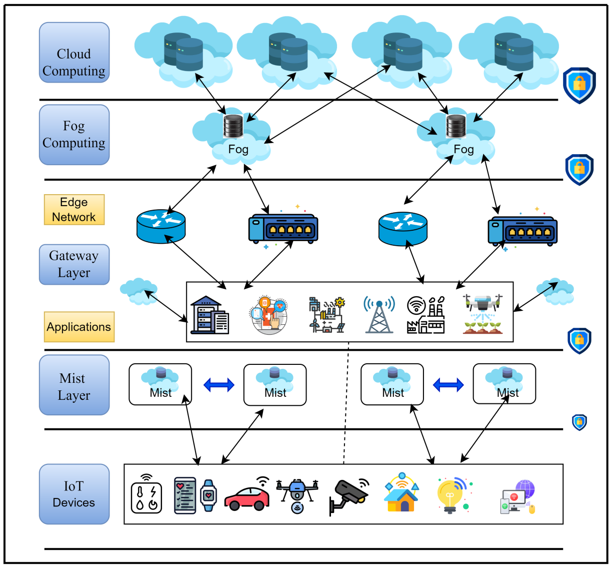

Fig. 5. IoT-Cloud layered architecture.

(i) ***Healthcare***: Simplify healthcare processes by remote patient monitoring and emergency care, ambient assisted living, creation and management of Electronic Health Records, multimedia-based health services.

(ii) ***Smart Cities***: Urban area planning and management, public lighting automation, electricity management, traffic control, water management, law and order, geo-tagging services, device crowdsourcing, etc.

(iii) ***Agriculture***: Automated irrigation, water distribution, improved yield, farm surveillance, crop patterns and agri-analytics.

(iv) ***Manufacturing Industries***: IoT devices on the factory floor monitor critical parameters like temperature and pressure, detect defective components and remove from assembly chain, quality checks for finished products.

(v) ***Wearables***: Body worn smart IoT connected to the internet, such as fitness trackers, cardio monitors, smart glasses, smart watches, virtual reality headsets, etc. having a wide range of day-to-day applications in real-life are becoming the forefront of IoT.

C. Challenges in IoT-Cloud Ecosystem

The main challenges encountered in IoT-Cloud ecosystem are [61]:

(i) ***Heterogeneity***: Wide variety of devices from different vendors and for different application domains, varied operating systems, platforms and services from IoT and Cloud create a disparate environment.

(ii) ***Resource Limitation***: The IoT devices are low capacity, low power units, which cannot afford to process large codes or store huge data.

(iii) ***Performance***: Having fast response time is important for real-world applications for which this ecosystem is utilized.

(iv) ***Reliability***: Reliability is the property of consistently performing well. In the multi-layer IoT-Cloud ecosystem reliability is required at end point devices, data communication network, cloud infrastructure and services, and at the mist, edge, fog and so on. Reliability can be described in terms of number of users affected in unit time or Mean Time to Failure (MTTF).

(v) ***Security***: Non standards hardware and software such as outdated OS, weak factory settings, lack of user awareness etc., create several security loopholes in IoT devices. In the multi-layer IoT to Cloud architecture security is critical for each layer and have diverse security requirements.

(vi) ***Standards***: Unplanned surge of IoT by different vendors has lead to a lack of uniformity and standards.

(vii) ***Scale***: IoT-Cloud systems are becoming very complex with millions of IoT devices getting interconnected and generating huge amounts of data. Monitoring and managing the hardware-software of the complex system is a challenging task.

V. Security Challenges in IoT-Cloud System

Analysis of the evolving IoT-Cloud architectures and recent publications [46], [62] reveal that security of the system is challenged by - technological progress, lack of standardization, IoT resource constraint etc. Broadly, the categories of security problems are - (i) Post Quantum Attacks and (ii) Vulnerabilities due to IoT-Cloud Characteristics.

A. Post Quantum Attacks

(i) ***Emergence of Quantum Computers***: Gartner report indicates that Quantum Computers are rapidly evolving and a reasonable sized quantum computer would be available by 2025. The exceptionally fast computation of prime factors on quantum computers suggest that the popular public key cryptography system like RSA can be cracked down.

(ii) ***Requirement of Larger Key Size***: Evolution of Quantum Computers and High Performance Computers makes it easy to crack even reasonably sized cryptographic schemes such as 1024 bit RSA. A simple remedy is to increase the key size; but it is impractical, especially in the context of resource constrained IoT.

(iii) ***Time-Space-Energy Complexity***: Increasing the key size increases the computational complexity. The encryption and decryption algorithms should not be too complex if they have to run on low power and low capacity IoT and provide near real time response for real world applications. It is desirable to have minimal time-space-energy complexity for the algorithms.

For IoT applications with limited transmission bandwidth, the size of cipherext and the encapsulated key should be minimum for and ensure low communication overheads.

(iv) ***Key Generation - Key Exchange Time***: The unprecedented growth of IoT networks combined with quantum cyber hackers is creating a highly active and complex system. The time for key generation and key exchange should be very fast, for the success of the security scheme.

(v) New Cryptanalysis Techniques: Cryptanalysts are exposing vulnerabilities in several existing crypto systems by using quantum computing algorithms, supercomputers, side channel attacks, guessing attacks, differential power analysis, differential cryptanalysis attacks etc. Rapidly evolving ecosystem, poses new challenges and requirements to develop novel Crypto schemes with higher security which are suitable for IoT and post quantum scenario, optimized algorithms with low footprint, and catering to heterogeneous devices. The concept of crypto-agility (i.e. replacing or adapting cryptographic schemes in software or hardware dynamically without interrupting the flow of a running system) is becoming a requirement for future operational application environments.

B. Vulnerabilities from IoT-Cloud Characteristics

(i) Heterogeneous Ecosystem: Independent manufacturers produce different varieties of IoT devices with varied functionality, that get integrated with different computing systems or Clouds over different networks. The heterogeneity and complexity of the ecosystem makes it very difficult to find a uniform security solution that fits all.

(ii) Lack of Standards: While there are diverse IoT manufacturers and enormous research and academic activities in IoT, there are only few standardization efforts such as from NIST, European Telecommunications Standards Institute (ETSI) and Internet Engineering Task Force (IETF).

(iii) IoT-Cloud Layered Architecture: A hierarchically increasing order of compute-storage capacities from IoT to Cloud to enable real-life applications brings along diverse security requirements at each layer

(iv) Scalability: The scheme should be able to cater for tens-of-thousands of devices and users and for huge volume of data within a reasonable turnaround time.

VI. Proposed Scheme

A. Problem Definition, Objectives and Constraints

The problem is to provide security for data in motion and at rest, for the IoT-Cloud ecosystem, taking cognizance of the emerging quantum computing.

The main constraints for this problem are:

(i) very low capacity of IoT devices and edge computers;

(ii) growing key sizes of the cryptographic schemes;

(iii) possibility of break down of the existing cryotographic schemes by quantum computing algorithms;

(iv) need to support fully homomorphic operations.

Hence, in addition to the basic authentication, confidentiality, integrity and privacy of data, the new cryptographic scheme must provide - low compute footprint and a higher security level. It is desirable to have features of homomorphic encyrption, searchable encryption and verifiable computation which are very useful for big data analytics. Crypto systems should be secure against the imminent quantum computers, which have the ability to solve certain mathematical problems exponentially faster compared to today's supercomputers.

By increasing the size of the key and cipher, we can make it more difficult for attackers to guess the key. This is because the larger the key, the more possible combinations there are, making it harder for an attacker to guess the right one. Similarly, increasing the cipher size also makes it harder for an attacker to break the encryption since the cipher has more bits that need to be decrypted. However, increasing the key and cipher size also increases the computational complexity of the algorithm, which can slow down the encryption and decryption process.

The lattice based, homomorphic and quantum secure, RLWE encryption scheme lends itself to the above requirements, and is also the most popular among the NIST PQC Competition [63]. In order to make it suitable for resource constrained IoT-Edge-Cloud environment, the RLWE should be optimized with respect to the amount of compute, memory and communication bandwidth.

Minor tweaks to the RWLE, can help to increase the security level and reduce the computation. A new algorithm named Circular Error Learning Algorithm (CELA) is proposed which uses modulus switching to improve the execution time and security level of the cryptographic scheme.

B. Circular Error Learning Algorithm (CELA)

In the proposed research, the execution time of the RLWE is reduced and security is improved, by introducing the Circular Error Learning Algorithm (CELA).

To improve security strength, the polynomial ring used in this algorithm shall have a larger dimension to accommodate the larger key size. The size of key is given by:

$KeySize = (RingSize * Log_2(RingSize) + NoiseSize * Log_2(NoiseSize) + SecurityLevel) * 2$

For example, if the security desired is 256 bits, and the ring size is 1024, the noise size is 128, the key size would be 22784 bits. Hence, note that the key size can be adjusted by changing the parameters used in the encryption process.

The execution time is determined by the complex calculations on the polynomial ring. The modulus switching reduces the execution time by reducing the intermediate computations without compromising its security. In modulus switching, the modulus is changed from q to a lower value q', to reduce computational complexity and improve its execution time.

Typically, the cryptographic scheme consists of Key Generation, Encryption and Decryption and the usage method is similar to the Diffie Hellman Key Exchange.

In the setup phase the public key is generated and published and corresponding secret-key generated is securely distributed among the parties. The public key is configured to be in the Hermite normal form of the lattice being examined. The key-holder creates a good basis by selecting P_k as a basis that is composed of short vectors that are 'roughly orthogonal'. The key to unlocking CELA's plan is nothing more than a simple vector. In the lattice based method, a ciphertext is a vector that is located close to the lattice called L. The message that is encrypted in this ciphertext is incorporated in the distance from the nearest lattice vector. In order to encrypt a message denoted by m, the sender must first select a brief 'error vector' denoted by e that encodes m. Next, the sender must compute the ciphertext. We present a lattice-based key agreement mechanism for IoT devices based on CELA problem in order to perform secure data transfer.

The steps for key setup, encryption and decryption in CELA are as follows:

Key Setup:
1: Select public and private keys with a key size of at least $2n$, where n is the desired security level in bits.
2: Generate Private key and distribute among the parties.
3: Generate Public key and publish.
Note: The key size for this algorithm with an alteration is that it is at least twice the desired security level in bits; while the key size for the base RLWE algorithm is typically n.

Encryption:
1: Choose a uniformly random polynomial r with coefficients in Z_q and degree less than n. Choose a uniformly random polynomial r' with coefficients in Z_q and degree less than n.
2: Compute $e = a * r + m + e'$, where m is the message to be encrypted and e' is a small error term.
Compute $e' = b * r' + e''$, where e'' is a very small error term.
3: Return the ciphertext $(e, e' * f)$.
Note: In the encryption step of CELA, modulus switching is applied to reduce the amount of computation and error, while an additional random polynomial r' is used to add randomness to strengthen the ciphertext.

Decryption:
1: Compute $c' = e * b + e' * s \ mod \ q$. Round each coefficient of c' to the nearest integer multiple of $q/2n$.
2: Compute $m' = c' * f^{-1} \ mod \ q$.
3: Return m'.
Note: - In the decryption step of the CELA, the combined term $e' * s$ in the ciphertext makes it more difficult for an attacker to obtain information about the secret key from the ciphertext.

C. CELA Secure Communication Protocol in IoT-Cloud

This scheme uses a variety of available methods in order to conceal from parties the primary data that are not authorised for access. The protocol methodology uses the Registry Service Selection (RSS) security algorithm which has been designed to offer close assistance to the data all the way through the process of distributed computing [64].

The suggested system is divided into four distinct stages. To begin, the stage called - Client Registration to Cloud Specialist Cooperative, is responsible for managing the process through which the client is enrolled with the Cloud Service Provider (CSPs). The second stage (Distributed Storage of Information) will scramble and transfer the data and securely store it on the cloud. This includes data scrambling on the end of the customer and encryption with CELA on the end of the service provider. The third stage is - Client Authentication for Information Recovery Request. The final stage (Information Retrieval) takes the registry information by the confirmed client from the Cloud and gives to the approved client the data back after it has passed across all the security systems. The IoT devices, gateway and CSP are simulated on virtual machines (VMs) for experimentation. The flowchart of secure data communication protocol in IoT-Cloud environment is explained in Fig. 6.

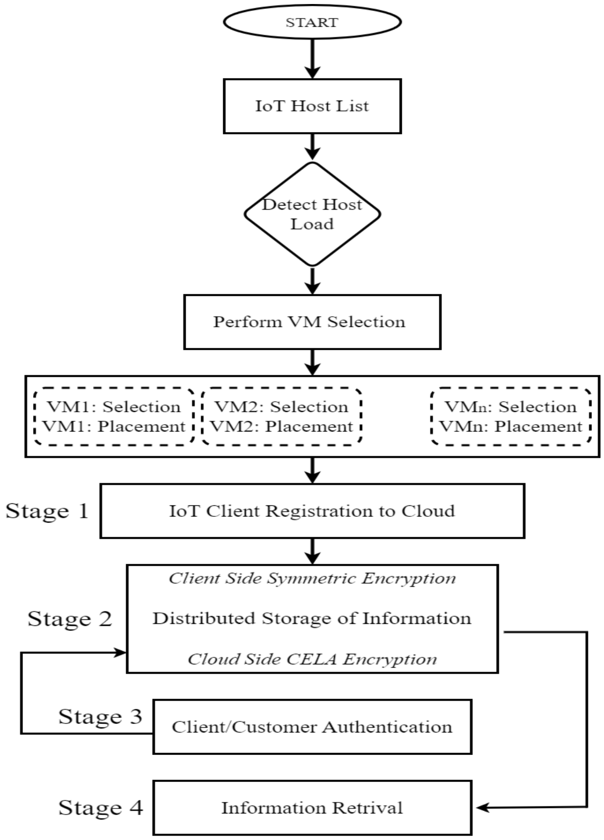

Fig. 6. Flowchart of CELA communication protocol.

D. Results

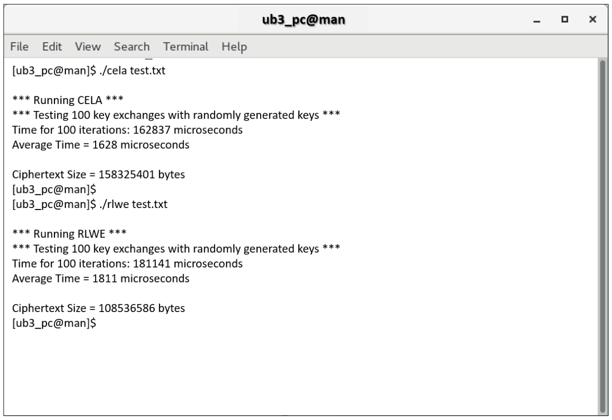
As seen in Fig. 7, the average time required for the CELA algorithm is 1628 microseconds while the average time required for the RLWE algorithm is 1811 microseconds. The ciphertext size for 100 keys in CELA algorithm is 158MB while that for the RLWE algorithm is 108MB.

Fig. 8 represents the comparison of minimum, maximum and average computation time of both RLWE and CELA algorithms. Multiple iterations have been considered for calculating the encryption and decryption time. The packet size transferred during these iterations are in the range of 1KB to 10KB. So for a 1KB packet size considered, the minimum time required is lower for CELA when compared to RLWE. For the highest packet size considered, the maximum time is also lower for CELA.

Typically, the size of the cipher text generated by CELA is slightly higher than that of RLWE as seen in Fig. 9.

E. Discussion

The following are some of the advantages offered by CELA:



```
[ub3_pc@man]$ ./cela test.txt

*** Running CELA ***
*** Testing 100 key exchanges with randomly generated keys ***
Time for 100 iterations: 162837 microseconds
Average Time = 1628 microseconds

Ciphertext Size = 158325401 bytes
[ub3_pc@man]$
[ub3_pc@man]$ ./rlwe test.txt

*** Running RLWE ***
*** Testing 100 key exchanges with randomly generated keys ***
Time for 100 iterations: 181141 microseconds
Average Time = 1811 microseconds

Ciphertext Size = 108536586 bytes
[ub3_pc@man]$
```

Fig. 7. Execution of CELA and RLWE.

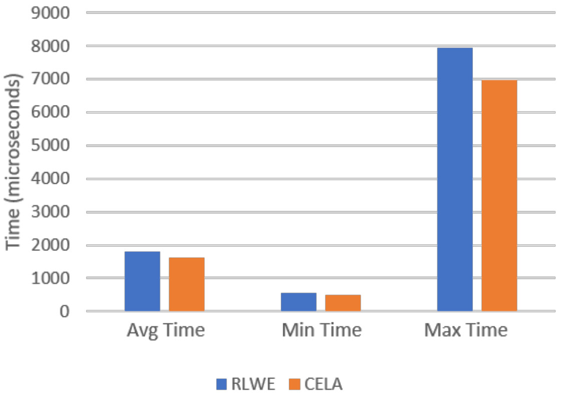


Fig. 8. Performance of CELA and RLWE.

- The proposed scheme offers an optimized lattice RLWE-based key agreement protocol for IoT devices [41], [40].

- The comparative examination of performance demonstrates that the suggested system is efficient in terms of compute and communication overhead.

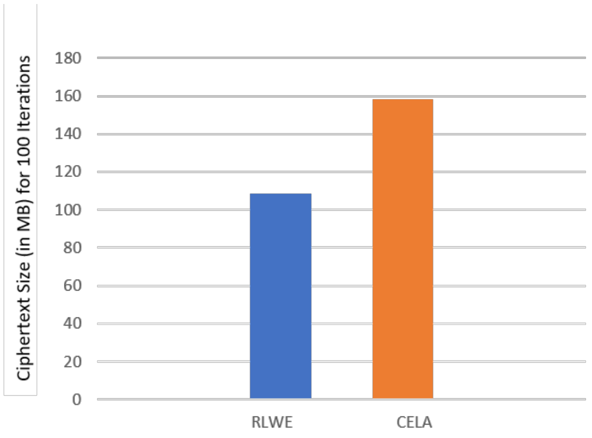

Fig. 9. Ciphertext size in CELA and RLWE.

- The system is provably secure for the longest period of time under the hardness assumption of RLWE, based on the fundamental difficulties of lattice algebraic structures [65]. Security analysis demonstrates that the system is secure against known security threats.

- The technique has been thoroughly researched for homomorphic encryption [66].

- Leveraging the RLWE scheme, CELA is capable of flexibility in dimension choice, and reduced computational requirements.

- The execution speed of CELA is superior in most cases, by virtue of modulus swicthing [57], very small size errors and Hermite Normal Form [67] matrix polynomials.

- The cipher text is more robust due to more randomness and slightly bigger size.

- The execution time of CELA is improved compared to RLWE by about 10%.As the number of IoT devices in the network increases, this can give a significant improvement in the system performance. Overall the CELA execution time being in microseconds is conducive for real-time applications.

- Increase in ciphertext size of CELA makes it computationally challenging for the adversary to break the encryption.

This research designed and demonstrated CELA as an optimized lattice based fully homomorphic cryptographic algorithm and a secure data communication protocol, for the IoT-Cloud converged system.

VII. Plausible Solutions

(i) Resistance to Post Quantum Cryptography: Subsequent to the RSA-768 getting compromised in 2010 due to availability of higher computer power, the key sizes have been increased to RSA-2048, 3072 and 7680 which are said to secure even if the supercomputing power is used to crack them. But with the emergence of Quantum Computers, it is predicted that the Shor's algorithm can calculate prime factors exceptionally fast; again posing a threat to RSA and other public key encryption schemes. While it is anticipated that factorizing the 1024-bit RSA would require about 2000 qubits [46] and the RSA-7680 would require 15362 qubits [68] on a Quantum Computer, it is currently unknown how many qubits would be needed to break 128-bit RLWE encryption as it is based polynomial equations, which is a different type of problem than factoring or discrete logarithms, and it is believed to be resistant to attacks by quantum computers. Presently the best operational quantum computer from IonQ is said to have only 79 qubits. Hence, for guaranteeing security till quantum computers become a reality, it will be sufficient to increase the key sizes.

(ii) Light Weight Cryptography: Increasing key size will improve the security strength, but disproportionately increase the complexity of the crypto system. There will be huge surge in the amount of compute-storage-power complexity, which are unaffordable for IoT-Edge-Cloud type of applications. Light weight cryptography having less computational complexity, faster execution time and low power consumption, less storage space for key and ciphertext, is required to be developed. Complementing with a light weight key exchange mechanism will be highly useful for IoT-Cloud systems.

(iii) Novel Algorithms: Recognizing the need to transition traditional crypto systems as a preparatory for the quantum systems in the next decade, the NIST PQC Standardization Program has researched several Code-Based Techniques, Hash-based and Lattice based techniques. Novel hybrid techniques combining quantum key generation, key distribution with classical cryptography should be developed such as Quantum-AES [45], Quantum-RSA and other Quantum-PKE. Future real-world applications, require crypto-agility (i.e. replacing or adapting cryptographic schemes dynamically without interrupting the running system) to ensure dynamic adaptation in the heterogeneous hyper-connected operational environment.

VIII. Conclusion

The objective of this research was to design a light weight quantum secure communication protocol for the IoT-Cloud ecosystem. Detailed study of the state-of-the-art cyrptographic schemes and the challenges of IoT-Cloud Security in the emergence of Quantum Computing, led to identification of RLWE as a suitable base. RLWE is a homomorphic and quantum-safe cryptographic scheme and has emerged as the most popular in the NIST PQC Standardization Program.

A light weight Circular Learning Error Algorithm (CELA) has been proposed by optimizing RLWE with the modulus switching technique to make it suitable for IoT-Cloud ecosystem. A complete IoT-Cloud communication, including client registration, key generation and exchange, with CELA and RLWE encryption were experimentally compared. The CELA based protocol took 1628 microseconds compared to RLWE based protocol taking 1811 microseconds. This improvement will be significantly rewarding as the number of devices and users in the system increases.

While it may take over a decade for operational quantum computers to be established, the CELA can effectively safeguard the present IoT-Cloud application ecosystem. Meanwhile, agencies such as NIST, are taking cognizance of the threats to data security due to quantum computers. Research is rife for designing novel quantum based public key encryption schemes for the future quantum era; plausible solutions for future quantum secure cyrpto protocols have been presented in this work.

Intelligent Anomaly Detection Method of Gateway Electrical Energy Metering Devices using Deep Learning

Lihua Zhang[1]*, Xu Chen[2], Chao Zhang[3], Lingxuan Zhang[4], Binghang Zou[5]
Marketing Service Center (Metrology Center), State Grid Ningxia Electric Power Co. Ltd, Yinchuan, China[1,2,3]
College of Electrical Engineering, Sichuan University, Chengdu, China[4,5]

***Abstract*—Accurate anomaly detection of gateway electrical energy metering device is important for maintenance and operations in the power systems. Traditionally, anomaly detection was typically performed manually through the analysis of the collected energy information. However, the manual process is time-consuming and labor-intensive. In this condition, this paper proposes a hybrid deep-learning model, which integrates Stacked Autoencoder (SAE) and Long Short-Term Memory (LSTM), for intelligently detecting the abnormal events of gateway electrical energy metering device. The proposed model named SAE-LSTM model, first uses SAE to extract deep latent features of three-phase voltage data collected from the gateway electrical energy metering device, and then adopts LSTM for separating the abnormal events based on the extracted deep latent features. The SAE-LSTM model, can effectively highlight the temporal information of the electrical data, thereby enhancing the accuracy of anomaly detection. The simulation experiments verify the advantages of the SAE-LSTM model in anomaly detection under different signal-to-noise ratios. The experimental results of real datasets demonstrate that it is suitable for anomaly detection of gateway electrical energy metering devices in practical scenarios.**

***Keywords*—Anomaly detection; gateway electric energy metering device; stacked autoencoder; long short-term memory**

I. Introduction

The importance of anomaly detection in gateway electrical energy metering device lies in ensuring the accuracy and reliability of energy measurement. The gateway electrical energy metering devices play a crucial role in power systems as they are utilized to measure and record energy consumption. The significance of anomaly detection in gateway electrical energy metering devices extends to various aspects such as data accuracy, system safety, and energy management. Anomalies occurring in these devices can result in inaccurate energy consumption data, thereby impacting the billing and settlement processes between energy suppliers and consumers. Moreover, anomalies can serve as indicators of underlying issues or faults within the power system, and their timely detection can unveil potential problems. By promptly identifying and addressing anomalies, it becomes possible to ensure the accuracy and reliability of energy measurement, improve energy management efficiency, and guarantee the safe operation of the power system[1]. Presently, the detection of abnormal operating states in gateway electrical energy metering devices heavily relies on manual on-site inspections, which pose safety risks, have lengthy detection cycles, and may not promptly identify faults[2-4]. With the increasing number of gateway electrical energy metering devices, manual inspections necessitate greater human and material resources, making it challenging to fully meet the current requirements for metering device management. Hence, it is imperative to propose and establish a anomaly detection system specifically designed for gateway metering devices. This system should employ suitable anomaly detection algorithms to promptly identify abnormal states.

Currently, methods for anomaly detection can be categorized into three distinct classes. The first class comprises statistical-based detection methods, including Gaussian distribution[5], probability density functions[6], clustering algorithms[7], and Markov models[8]. Although statistical-based methods are grounded in solid theoretical foundations, the task of selecting an appropriate distribution to effectively discriminate normal instances from anomalous ones poses significant challenges. The second class encompasses rule-based detection methods, involving the establishment of thresholds and the utilization of rule engines, among others. Rule-based methods offer ease of implementation and interpretation, but their ability to detect more intricate anomalies may be constrained. The third class encompasses deep learning-based anomaly detection methods, such as those relying on convolutional neural networks[9,10]. These methods extract robust latent features; however, they necessitate the conversion of input data into images, thereby augmenting the data processing burden, while inadequately considering the influence of network structure information on the accuracy of feature extraction[11]. Although variant models based on the support vector machines (SVM)[12] demonstrate commendable performance in non-temporal data processing, their accuracy in handling complex time series data still needs to be improved.

With the rapid developments in artificial intelligence (AI), numerous approaches using machine learning (ML), especially deep learning (DL), have been proposed to overcome these challenges. For example, Lee S et al. used a self-encoder consisting of a graph convolutional network and a bidirectional long short-term memory network to detect anomalies in smart detection data with higher accuracy than a single LSTM network and with reduced power cost and grid power supply[13]. However, the graph convolution operation of the graph convolutional neural network becomes difficult when processing sequential data and suffers from dimensional mismatch. Wang et al. provided a semi-supervised learning based power anomaly detection strategy[14]. Their proposed framework not only detects anomalous power patterns in real time,

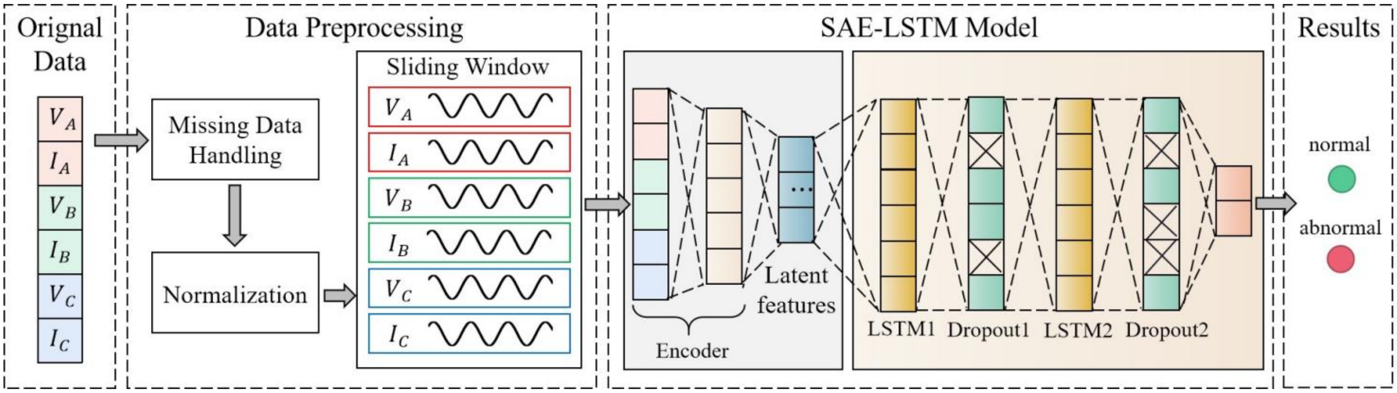

Fig. 1. The flowchart of the intelligent anomaly detection method of gateway electrical energy metering devices using deep learning.

but also identifies suspicious power usage that is inconsistent with customers' lifestyles and typical daily routines, but is not suitable for application to anomaly detection at grid gate metering devices. Hussain et al. have proposed an unsupervised detection approach aimed at identifying power theft behaviors without data labeling costs[15]. Their proposed method is evaluated using accuracy and detection rate.

Although most of the current models perform well, there are several limitations.

First, three-phase voltage data is often noisy and complex, making it difficult to distinguish normal fluctuations from actual anomalies. Second, power systems are dynamic and their operating conditions may change rapidly. Anomaly detection methods must be adaptable and able to evolve with these changes. Finally, many sophisticated machine learning-based techniques can effectively detect anomalies, but often lack interpretability.

To address the above problem, in this paper, we present a novel anomaly detection model that combines the Stacked Autoencoder (SAE) and Long Short-Term Memory (LSTM) networks with elastic network regularization. Initially, the model extracts latent feature representations of the data using SAE and subsequently employs the LSTM algorithm for classification purposes. Following the training of the SAE-LSTM network, elastic network regularization is applied to fine-tune the model using a composite loss function. Bayesian optimization techniques are then utilized to determine optimal hyperparameter values. Lastly, the model is evaluated using a performance assessment metric. Experimental results demonstrate that the proposed model effectively considers the temporal dependencies of the data, leading to improved detection accuracy. It is well-suited for detecting anomalies in gateway power metering devices and effectively assessing their operational state.

The contributions in this paper can be summarized as follows.

(1) This paper presents a novel anomaly detection model that combines the Stacked Autoencoder (SAE) and Long Short-Term Memory (LSTM) networks with elastic network regularization.

(2) Apply the SAE layer for feature extraction. The application of the encode layer allows the proposed model to extract high-level temporal features more efficiently while reducing model performance's dependence on data processing, thus improving the accuracy and efficiency of anomaly detection.

(3) Apply LSTM layer for classification. In the voltage anomaly detection task, the LSTM model can capture the dynamic characteristics of voltage and current signals and is suitable for processing time series data.

(4) The short-term patterns and dependencies in the three-phase voltage and current time series data can be captured using the sliding window technique, and at the same time, by analyzing the sequence within a smaller window, it can help reduce noise in the simulated data and improve the SNR in the data. This further improves the feature extraction efficiency of the proposed model, enabling more accurate anomaly detection.

(5) A real dataset collected from a power grid is applied to evaluate the effectiveness and applicability of the proposed model.

The rest of this paper is organized as follows. Section II describes the Methods. Section III applies the method in a real case and analyzes the results.Section IV discusses the advantages and shortcomings of the proposed method, and the potential future work and concludes the paper.

II. Methods

Accurate anomaly detection of gateway electrical energy metering device is important for maintenance and operations in the power systems. In this paper, a hybrid deep-learning model is proposed to intelligently detecting the abnormal events of gateway electrical energy metering device. The overall process flowchart of the proposed method is shown in Fig. 1.

A. Data Preprocessing

During the data preprocessing stage, three key procedures are utilized to increase the validity of the electrical energy data. These procedures handle missing values, normalize the data, and implement sliding windows on the data.

1) Missing value handling: The data collected from gateway electrical energy metering devices may partial be lost due to various factors, such as human error or equipment issues[16]. In order to address the problem of missing values, several methods exist depending on the data nature and desired outcome. Common strategies involve deletion, imputation, and machine learning techniques. Although direct deletion is a straightforward approach, it may lead to the loss of valuable information, reduction in sample size, and decreased efficiency. Conversely, the utilization of machine learning methods can be excessively intricate. Therefore, Lagrange interpolation is employed to estimate the missing values. The formula for Lagrange interpolation is specified as follows:

$$l_j(x) = \prod_{\substack{i=0 \\ i\neq j}}^{n} \frac{x - x_i}{x_j - x_i} = \frac{x - x_0}{x_j - x_0} \cdots \frac{x - x_{j-1}}{x_j - x_{j-1}} \frac{x - x_{j+1}}{x_j - x_{j+1}} \cdots \frac{x - x_n}{x_j - x_n} \tag{1}$$

$$L(x) = \sum_{j=0}^{n} y_j l_j(x) \tag{2}$$

Equation (1) represents the Lagrange basic polynomial for n+1 data points, while Equation (2) represents the Lagrange interpolation polynomial for n+1 data points[17]. x_i and y_i represent the x-coordinate and y-coordinate, respectively, of the known data points. $l_j\left(x\right)$ denotes the Lagrange basis function, where the index i ranges from 0 to n, representing the i-th basis function. Consequently, $L\left(x\right)$ signifies the estimated value at a given point x, acquired through the employment of the Lagrange interpolation method.

2) Normalization: There are several methods available for data normalization, including min-max scaling, Z-score standardization, and mean normalization. For the purposes of this study, the dataset is normalized using the Z-score standardization method. This approach is chosen due to its simplicity and ease of computation, as well as its ability to effectively normalize data regardless of the scale or presence of extremely large or small values. The Z-score standardization formula utilized is as follows:

$$z = \frac{x - \mu}{\sigma} \tag{3}$$

where x represents the data mean, μ represents the standard deviation, and z represents the standardized score.

3) Sliding window: The sliding window is widely utilized for time series analysis and sequence data processing. It serves as a valuable tool for feature extraction and performing computations on data subsets[18]. With the application of the sliding window, it becomes possible to capture short-term patterns and dependencies presented in the three-phase voltage and current. Moreover, by analyzing sequences within smaller windows, the impact of noise in analog data can be minimized, subsequently improving the signal-to-noise ratio. This aspect proves advantageous for tasks such as anomaly detection and experimental evaluation. Moreover, the mean, median, and variance of the data within the window are extracted as input features.

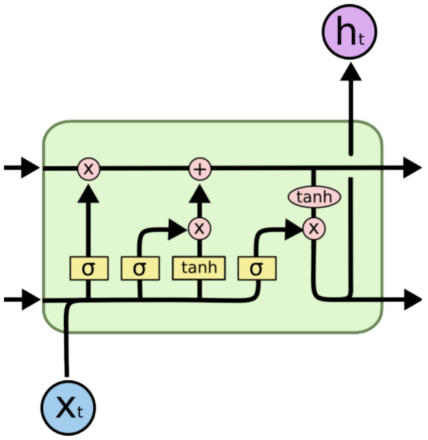

Fig. 2. The structure of the "cell" in the LSTM model[23].

B. The Anomaly Detection Model using Deep Learning

1) Basis of SAE and LSTM: The Stacked Autoencoder (SAE) is a hierarchical neural network comprised of multiple encoders connected layer by layer. It is an unsupervised learning method that follows a layer-wise greedy approach[19]. The Autoencoder (AE), which is a constituent of SAE, employs the backpropagation algorithm to ensure the output values match the input values. Initially, it compresses the input into a latent space representation and then reconstructs the output based on this representation. SAE possesses several advantages, including powerful expressive capability, a straightforward training process, and the ability to construct multiple layers of stacked architecture. It effectively mitigates challenges like "vanishing gradients" and "exploding gradients" that arise with increased depth in autoencoders. Consequently, SAE finds extensive application in target recognition, anomaly detection, anomaly diagnosis, and other domains.

The training process of SAE involves training one layer at a time[20]. Initially, a network with a single hidden layer is trained. After completing the training of this layer, training of a network with two hidden layers is initiated, and so on. Once all the layers have been trained, the encoder weights of each layer are combined to form a complete deep neural network. Subsequently, fine-tuning is performed, where the entire network is fine-tuned using supervised learning methods to optimize network performance. This training approach is known as the greedy layer-wise training algorithm.

Due to its deep structure and layer-wise training strategy, stacked autoencoders can learn higher-level and more abstract feature representations, thereby achieving superior performance across various tasks. In contrast, single-layer autoencoders are limited by their shallow structure and can only capture relatively simple features.

Long Short-Term Memory (LSTM) is a special type of recurrent neural network (RNN) structure[21]. The neurons in an LSTM model consist of four main components: the memory cell, the input gate, the forget gate, and the output gate. The internal structure of an LSTM neuron is illustrated in Fig 2.

$$i_t = \sigma(W_{xi}x_t + W_{hi}h_{t-1} + b_i) \tag{4}$$

$$f_t = \sigma(W_{xf}x_t + W_{hf}h_{t-1} + b_f) \tag{5}$$

$$\tilde{Ct} = \tanh(Wxcx_t + W_{hc}h_{t-1} + b_c) \tag{6}$$

$$C_t = f_t \odot C_{t-1} + i_t \odot \tilde{C}_t \tag{7}$$

$$o_t = \sigma(W_{xo}x_t + W_{ho}h_{t-1} + b_o) \tag{8}$$

$$h_t = o_t \odot \tanh(C_t) \tag{9}$$

The input gate decides whether to include the input feature x_t of the current time step into the state update of the LSTM. W_{xi} and W_{hi} are weight matrices for the linear transformation of the input and the hidden state h_{t-1} of the previous time step, respectively. b_i is the bias term and σ is the sigmoid activation function.The forget gate decides whether to keep the previous state information. W_{xf} and W_{hf} are weight matrices, and b_f is a bias term. The candidate memory unit computes the candidate value at the current time step by applying the hyperbolic tangent activation function. Cell states are updated through multiplication and addition operations. The forget gate determines the proportion of the previous cell state C_{t-1} retained, and the input gate determines the contribution of the candidate memory unit $\tilde{C_t}$ to the cell state. The output gate determines the output of the LSTM cell. W_{xo} and W_{ho} are weight matrices, and b_o is a bias term. The hidden state is the output of the LSTM cell, computed by element-wise multiplication of the cell state C_t with the output of the output gate and application of the hyperbolic tangent activation function.

2) The hybrid model of SAE-LSTM: The architecture of the proposed anomaly detection model, which jointly using SAE-LSTM, is illustrated in Fig. 1. The main steps of the model are described below, with a focus on the SAE-LSTM component.

a) The SAE component is employed to extract the deep latent features from the preprocessed three-phase voltage and current data. To ensure compatibility with the LSTM model, the latent features are further converted into an appropriate format through data type conversion.

b) The SAE network is utilized to extract the hidden features from the data, which are then transformed into time series data suitable for input to the LSTM model. By configuring the hyperparameters of the LSTM model, the model is trained and fine-tuned. Additionally, Bayesian optimization techniques are applied to optimize the model.

c) The optimized SAE-LSTM anomaly detection model is then evaluated using the test set. Various performance metrics, including accuracy and F1 score, are employed to assess the model's predictive capabilities.

3) Fine-tuning and optimization of network parameters: In this study, a composite loss function is employed, incorporating elastic net regression to mitigate overfitting. This technique applies both L1 and L2 regularization to penalize the coefficients in the regression model. By integrating L1 regularization's sparsity and L2 regularization's weight shrinkage, elastic net regression achieves a harmonious balance, leading to improved generalization performance. The combined loss function is calculated using the following formula:

$$LOSS_{com} = \alpha LOSS_{SAE} + (1-\alpha)\, LOSS_{LSTM} + LOSS_1 + LOSS_2 \tag{10}$$

$$LOSS_1 = \lambda\beta\left(W_{en} + W_{de} + W_{ih} + W_{hh} + W_{fc}\right) \tag{11}$$

$$LOSS_2 = \lambda\left(1-\beta\right)\left({W_{en}}^2 + {W_{de}}^2 + {W_{ih}}^2 + {W_{hh}}^2 + {W_{fc}}^2\right) \tag{12}$$

The weight between $LOSS_{SAE}$ and $LOSS_{LSTM}$ is controlled by α. When α is set to 1, only the reconstruction loss is active, and the classification loss has no impact. This means that the model focuses primarily on reconstructing the input data and minimizing reconstruction errors[22]. When α is set to 0, only the classification loss is active, and the reconstruction loss has no impact. This means that the model primarily focuses on the classification task and strives to optimize classification accuracy. When takes an intermediate value, both the reconstruction loss and the classification loss are considered, and the model optimizes between balancing the reconstruction and classification tasks. By adjusting the value of α, the optimal trade-off between reconstruction and classification tasks can be found to meet specific problem requirements and performance demands. λ determines the importance of L1 and L2 regularization, while β controls the weight between L1 and L2 regularization. $LOSS_1$ calculates the L1 regularization term, which penalizes the sum of the absolute values of the model parameters. It measures the sparsity of the parameters by computing the L1 norm of different weight matrices. W_{en} and W_{en} represent the weight matrices of the encoder and decoder in the SAE network, respectively. W_{ih} includes the weights connecting the LSTM layer input to its hidden state, responsible for transforming the input features into hidden state representations within the LSTM unit. W_{hh} is the weight matrix associated with the connections between hidden-to-hidden in the LSTM network, encompassing the weights that link the previous hidden state to the current hidden state within the LSTM layer. W_{fc} is responsible for propagating hidden state information, enabling the LSTM to maintain dependencies across the input time series. It represents the weight matrix of the fully connected layer in the LSTM network. The L1 norm of each weight matrix is the sum of the absolute values of its elements. These norms are summed together, multiplied by λ and β , to weight the L1 regularization term. The purpose of this is to encourage the model to produce sparse parameters, reducing redundancy and improving the model's generalization ability.

TABLE I. Distribution of Normal Data and Abnormal Data

Data type	Substation A	Substation B	Substation C	Substation D
Normal data	2881	375	157	2881
Abnormal data	0	732	1284	0

$LOSS_2$ calculates the L2 regularization term, which penalizes the sum of squared model parameters. It measures the smoothness of the parameters by computing the squared L2 norm of different weight matrices. The squared L2 norm of each weight matrix is the sum of the squares of its elements. These sums are added together, multiplied by λ and $1-\beta$, to weight the L2 regularization term. The purpose of this is to encourage the model to produce smooth parameters, reducing overfitting and improving the model's generalization ability.

By using λ and β multiplied by the regularization terms, an appropriate balance can be found between model complexity, reconstruction task, and classification task. This helps optimize the overall loss function to achieve better model performance and generalization ability.

To obtain the optimal performance of the model, a grid search method is used to search for the optimal model parameters. Grid search (GridSearchCV) is a search technique used to find the optimal parameters of a model. Grid search is a brute force algorithm. This makes a complete search for a given subset of the hyperparameter space[23]. Due to the exhaustive search, grid search consumes significant training time and resources, making its search performance inefficient.

Using Bayesian optimization technique can reduce computational costs and improve efficiency. It is more effective than grid search. It consists of two main components: a Bayesian statistical model for modeling the objective function, and an acquisition function for deciding where to sample next[24]. By using Bayesian optimization technique to find the optimal learning rate and weight in the combined loss function, the accuracy of the model in voltage anomaly detection task can be maximized.

III. Experiments and Results

A. Data acquisition

1) Real Dataset: The real dataset was obtained from the national power grid and consists of secondary load data collected from four 330 kV substations situated in distinct geographical regions. Each substation's data includes measurements of active power, reactive power, three-phase voltage and current, and the total power factor. Specifically, Substations A, C, and D were monitored at 15-minute intervals, while Substation B was recorded at 60-minute intervals. Notably, Substations A and D contain normal data, whereas Substations B and C contain abnormal data. Table I presents the distribution of normal and abnormal data in the dataset.

From Table I, it can be observed that substations B and C have a majority of abnormal data, while substations A and D do not contain any abnormal data. The ratio of normal data to abnormal data in the overall dataset is approximately 4:1. When comparing

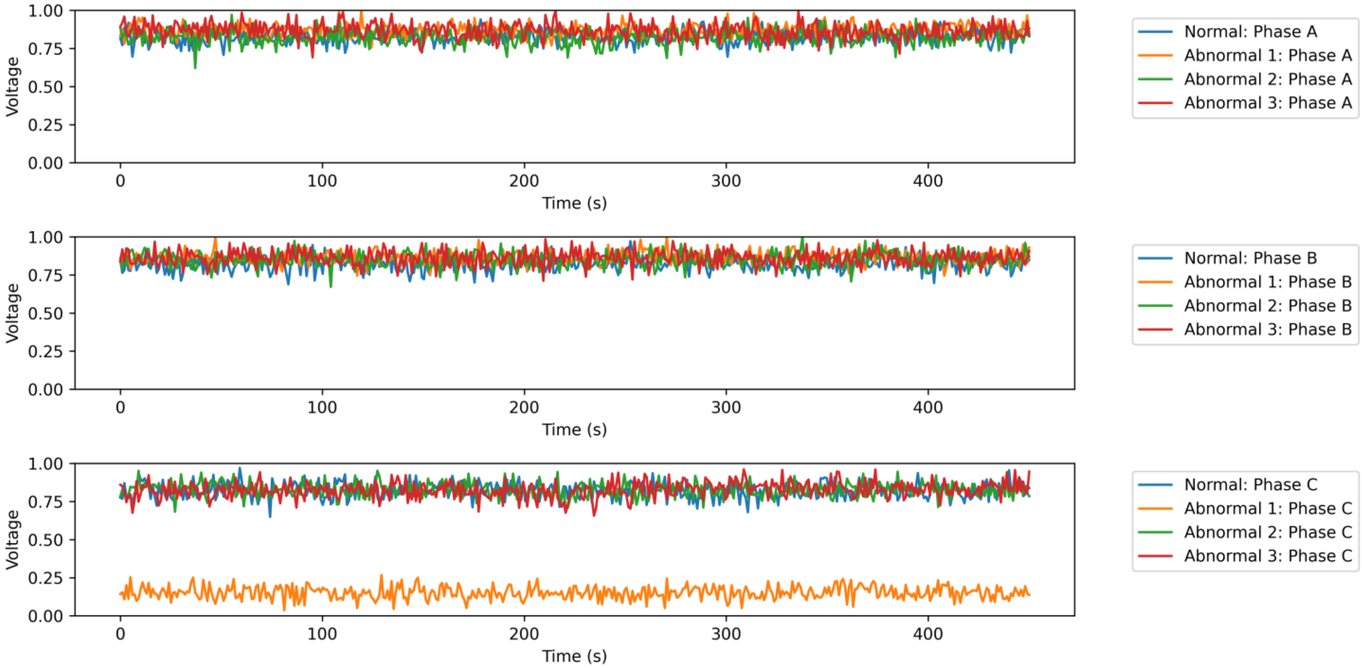

Fig. 3. The SNR is 20dB analog data diagram.

the features of normal and abnormal data, it is found that voltage changes are most pronounced during abnormal occurrences. Although there may be changes in current corresponding to the phase where voltage abnormalities occur, they are not as significant as voltage changes. Therefore, the abnormal data types in this study include voltage overvoltage, undervoltage, and other voltage-related anomalies. Three-phase current is considered as an auxiliary feature to help detect voltage anomalies. Hence, the features extracted for data processing and analysis in this study include three-phase voltage and three-phase current.

2) Computer simulation: The simplicity of the original data does not showcase the advantages of the constructed SAE-LSTM network. Therefore, to facilitate a comparison between the SAE-LSTM network and other networks, a method of generating simulated data by adding noise can be utilized. Signal-to-noise ratio(SNR) generically means the dimensionless ratio of the signal power to the noise power contained in a recording[25]. The parameter settings involve a SNR ranging from -20 dB to 20 dB, with an increment of 4 dB. Consequently, simulated data is generated at 4 dB intervals within the -20 dB to 20 dB range. The simulated data comprises normal and abnormal data, encompassing three types of abnormalities: voltage overvoltage, voltage loss, and low voltage. The figure below depicts the generated simulated data, illustrating SNR of -20 dB and 20 dB.

The Fig. 3 and Fig. 4 illustrate the simulation data with the SNR of 20dB and -20dB respectively, where blue indicates normal data and other colors represent abnormal data. The red color corresponds to phase C undervoltage, green indicates phase B overvoltage, and orange signifies phase C undervoltage. Analysis of the figure reveals that at a SNR of -20 dB, the abnormal data closely overlaps with the original data, indicating a limited ability to distinguish between the signal and noise. Consequently, the detection task becomes highly challenging for the model. However, when the SNR is 20 dB, the distribution of the generated simulated data closely resembles that of the collected system data. Furthermore, the discrimination between the signal and noise significantly improves compared to the -20 dB SNR. This distinction is particularly evident in the case of phase C voltage loss anomalies, where a substantial difference exists between anomaly type 3 and other data types in terms of phase C voltage. Such differentiation is absent when the SNR is -20 dB. Therefore, the detection task becomes relatively simpler when the SNR is 20 dB.

The selection of a SNR ranging from -20 to 20 dB serves specific purposes. Extremely low SNR result in noise intensity surpassing signal intensity, hindering accurate anomaly detection by the model, with consistent accuracy below 50%. Conversely, very high SNR yield simulated data that closely resembles the original data, containing minimal noise. Consequently, the distinction between the signal and noise diminishes. Given the relatively simple and 6-dimensional nature of the original data, different models achieve accuracies exceeding 99%, making it impossible to discern performance differences among them. By setting the SNR between -20 and 20 dB, a range of conditions spanning from high-noise environments to strong-signal environments is encompassed. Conducting experiments within this range enables a more comprehensive analysis of the SAE-LSTM model's performance.

B. Evaluation Index

For model evaluation, more advanced classification metrics from the confusion matrix such as accuracy and F1 score are utilized. As the problem involves multi-label classification with imbalanced data, weighted F1 score is used, assigning different weights to different classes. The formulas for calculating accuracy and weighted F1 score are as follows:

$$Accuary = \frac{TP + TN}{TP + TN + FP + FN} \tag{13}$$

$$Precision = \frac{TP}{TP + FP} \tag{14}$$

$$Recall = \frac{TP}{TP + FN} \tag{15}$$

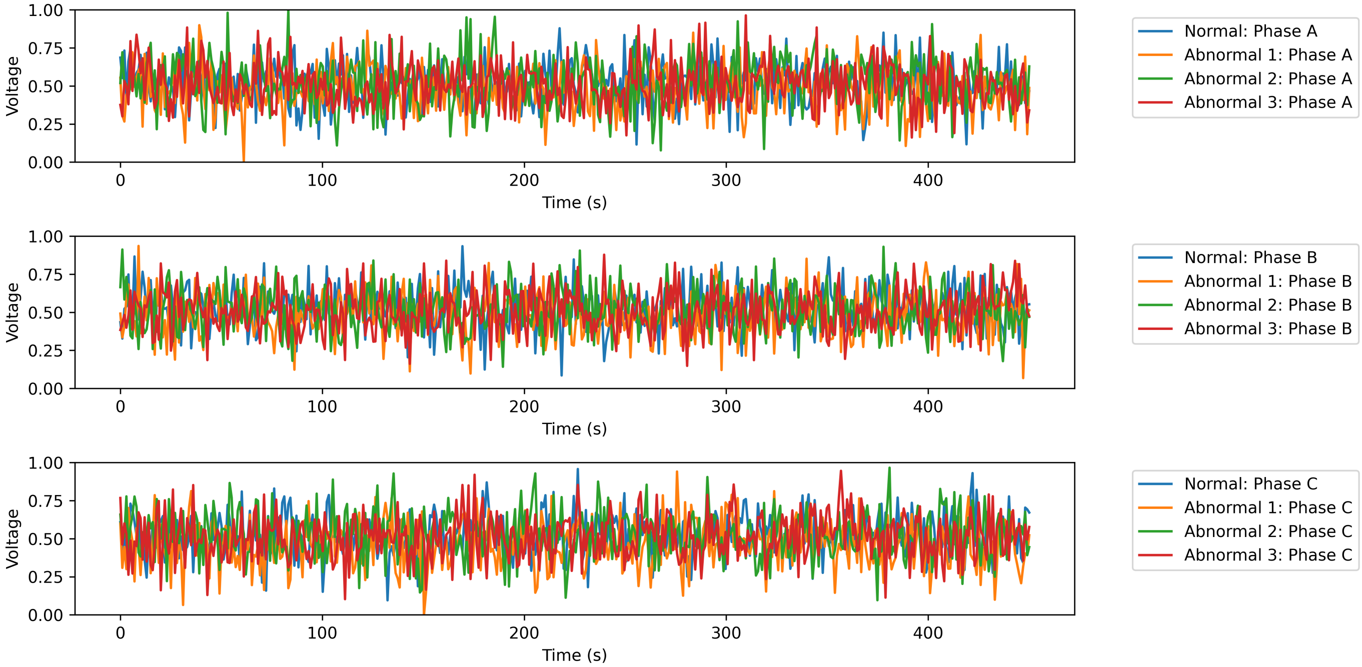

Fig. 4. The SNR is -20dB analog data diagram.

$$F1 = \frac{2PrecisionRecall}{Precision + Recall} \tag{16}$$

where TP represents True Positive. TN represents True Negative. FP represents False Positive. FN represents False Negative.. Recall represents the recall rate, Precision denotes precision.

C. Network Structure Selection

1) Unbalanced data processing: After conducting measurements, it was observed that the dataset exhibits a ratio of approximately 4:1 between normal data and abnormal data[26]. Due to the limited availability of original abnormal data, the SMOTEBoost method is employed to generate synthetic data points in close proximity to the existing abnormal data.

SMOTEBoost is an ensemble method that combines the advantages of SMOTE and Boosting techniques. By integrating multiple weak learners into a robust classifier, it surpasses the performance of the standalone SMOTE method, offering improved accuracy and robustness when dealing with imbalanced datasets.

The fundamental concept of the SMOTEBoost algorithm revolves around augmenting the weight of minority class samples during each iteration of the classification learning process. This emphasis on the minority class allows the weak learners to focus more on these samples. To address the severe class imbalance in the original data, new artificial samples are generated and incorporated into the dataset[27]. The SMOTE algorithm and the update of weak learner weights are described by the following formulas:

$$x_{new} = x + rand\left(0,1\right) * \left(\tilde{x} - x\right) \tag{17}$$

$$\alpha = 0.5 \ln\left(\frac{1-\varepsilon}{\varepsilon}\right) \tag{18}$$

$$\omega_n = \omega_o e^{\alpha} \tag{19}$$

Equation 17 represents the performance calculation of the weak learner, while Equation 19 represents the weight calculation of the weak learner. x represents a selected minority class sample. By applying the principle of nearest neighbors, one sample, denoted as $\tilde{x}$, is randomly chosen from the k nearest neighbor samples of x, where represents a random number ranging from 0 to 1. The newly synthesized sample is denoted as x_{new}. ε denotes the error rate, which represents the cumulative weight of misclassified samples. α represents the weight of the weak learner, while ω_o signifies the weight of each individual sample. Finally, ω_n refers to the updated weights.

2) Ablation experiments with different layers: The neural network comprises an input layer, hidden layers, and an output layer, with the number of hidden layers and hidden units per layer playing a pivotal role in determining the neural network's capacity and complexity. The selection of these hyperparameters significantly influences the model's ability to learn intricate patterns and generalize to unseen data.

In the case of the SAE network, the number of neuron nodes in the input and output layers depends on the dimensionality of the input data. In this study, the extracted and preprocessed dataset exhibits a feature dimensionality of 6. Thus, the SAE network consists of 6 neuron units in both the input and output layers. The purpose of the hidden layers in the neural network is to grasp the complex features inherent in the input data. Augmenting the number of hidden units empowers the network with greater representational capacity, enabling it to capture more intricate and nuanced characteristics of the input data. Nonetheless, an excessive number of hidden layers can lead to prolonged training time, overfitting, and vanishing gradients. In this study, preliminary experiments revealed that exceeding 3 hidden layers in the SAE network resulted in overfitting. Consequently, two optimal combinations of hidden layer units, specifically 64 and 16, were chosen.

Concerning the LSTM network, the extracted hidden features derived from the SAE serve as input features, while the output layer comprises 4 units representing the data labels. Regarding the selection of the number of hidden layers and hidden units, it has been observed that surpassing 3 hidden layers exponentially escalates

TABLE II. Model Parameter Configuration under the SNR from -20dB to 20dB

the network's computational complexity and elevates the risk of overfitting. Consequently, this study concentrates on investigating the range of hidden layers from one to three. To enhance time efficiency, the training iterations were initially set to 100. Given that computers store and process data in binary format, an initial value of 16 was selected for the number of neuron nodes. Subsequently, the program was executed with a progressive increment of neuron nodes by powers of 2 to obtain accuracy values on the test set. The number of hidden units for each of the 1 to 3 hidden layers can be configured from 16 to 256, resulting in numerous possible combinations. Through experimentation, two combinations displaying optimal performance were identified, with the hidden layer units set as 128, 128, and 128, and 128, 128, 128, respectively.

In this study, the optimal number of model layers is initially examined, and the corresponding results are listed in Table II. The comparisons of the results for different models are illustrated in Fig. 5 and Fig. 6.

From the results, it can be observed that the SAE2-LSTM2 and SAE2-LSTM3 models have similar accuracy and F1 scores, but the SAE2-LSTM3 model slightly outperforms the SAE2-LSTM2 model in terms of accuracy and F1 score. This suggests that increasing the number of LSTM hidden layers can improve accuracy. Comparing the SAE1-LSTM2 and SAE2-LSTM2 models, it can be noted that increasing the number of SAE layers does not significantly affect accuracy, indicating that increasing the number of SAE layers has a limited impact on improving model performance. Comparing the four models, it is evident that the SAE2-LSTM3 model achieves the highest accuracy and F1 score, indicating the best model performance. Therefore, the SAE2-LSTM3 anomaly detection model with 2 SAE hidden layers (16, 64 units) and 3 LSTM hidden layers (128, 128, 128 units) exhibits better performance.

D. Comparisons in the Simulation Dataset

To comprehensively evaluate the performance of the SAE-LSTM model, the outcomes achieved through the proposed approach are contrasted with those of SAE, LSTM, as well as other fundamental machine learning models, including Convolutional Neural Network (CNN) and Support Vector Machine (SVM)[28]. The signal-to-noise ratio ranges from -20 to 20 dB, with a step size of 4, enabling an extensive assessment of these models on multi-classification data. score of each model are visualized in the following graph:

From Fig. 7, Fig. 8 and Table IV, it can be concluded that it is evident that the proposed method presented in this study achieves superior evaluation metrics in the task of three-phase voltage anomaly detection, surpassing the other four methods. The LSTM model exhibits comparatively lower recognition performance, with an average accuracy in multi-classification detection that is approximately 10% lower than the other four methods, and a correspondingly lower weighted-F1 score. This discrepancy can be attributed to the introduction of noise in the original data, which affects the temporal nature of the data and consequently hampers the LSTM model's recognition capabilities. The CNN model, primarily designed to capture local spatial correlations, demonstrates inferior performance compared to the SAE and LSTM models. Furthermore, in the case of non-image data, CNN may not fully comprehend the intricate relationship between input features and output predictions[29]. In contrast, both SAE and SVM exhibit superior recognition performance relative

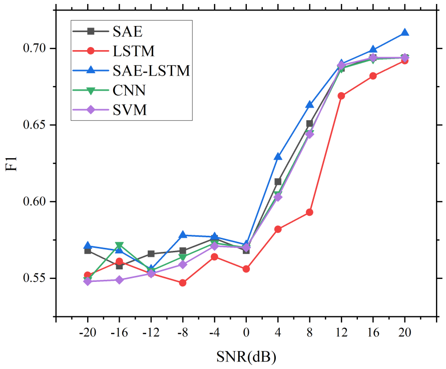

Fig. 8. The F1 diagram of the comparison models under the SNR from -20dB to 20dB.

to CNN and LSTM methodologies. SAE and SVM possess robust feature extraction capabilities and excel in classification tasks.

In addition, the SAE-LSTM hybrid model proposed in this paper has the best detection accuracy with F1 values in all signal-to-noise environments. This can be attributed to the SAE component within the SAE-LSTM model, which compensates for LSTM's limitations in feature extraction, allowing the LSTM component to leverage its strengths in handling sequential problems.

E. *Comparisons in the Real Dataset*

In order to evaluate the model more effectively and reduce experimental bias, k-fold cross-validation is employed. The KCV consists in splitting a dataset into k subsets; then, iteratively, some of them are used to learn the model, while the others are exploited to assess its performance[30].

From the collected data of the substation monitoring system, three-phase voltage and current data along with the label column were extracted. The original data was subjected to anomaly detection, and the experimental results are shown in the Table III.

The analysis of the results indicates that all models exhibit favorable performance when applied to the initial three-phase voltage and current data. The reason for this is that the real data used in this paper is very simple. Not only there are few types of anomalies, but also there is almost no interference, which is very easy to identify. Therefore, traditional machine learning algorithms such as SVM, CNN, etc. can also achieve very good results.

Moreover, although SAE and LSTM do not work perfectly when used alone. However, the SAE-LSTM network proposed in this paper combines the advantages of the two algorithms, which is both very powerful in feature extraction and well adapted to handle such time-series data as power grids. The simulation experiments in the previous paper show that the detection effect is still very good when facing the low signal-to-noise ratio data with great interference.

IV. Conclusion

This paper presents a method that addresses the challenge of delayed anomaly detection in current gateway metering devices by combining Stacked Autoencoders (SAE) and Long Short-Term Memory Neural Networks (LSTM) with elastic network regularization. The advantages of the proposed model are verified by real data experiments and simulated data experiments.

In the experiments utilizing real data, all examined models exhibited satisfactory performance, largely attributed to the dataset's simplicity. To further enrich our investigation, we expanded our research scope to include experiments using simulated data.

These simulated data experiments introduced noise to increase data complexity before comparing the effectiveness of various models.

TABLE IV. The Results of Accuracy and F1 for the Comparison Models in Real Datasets

Model	SVM	CNN	SAE	LSTM	SAE-LSTM
Accuracy	1	1	0.999	0.997	1
F1	1	1	0.999	0.997	1

The findings underscored that the model proposed within this paper demonstrates superior performance in managing complex data.

As delineated in Fig. 8, the F1 score exhibits a gradual ascent when the Signal-to-Noise Ratio (SNR) spans -20dB to 0dB and 12dB to 20dB. In contrast, a brisk rise is observed between 0dB and 12dB. This observation can be attributed to the reduction in noise level as SNR increases, thus facilitating the model's anomaly detection capabilities and consequently leading to the swift enhancement in F1 scores. The sluggish elevation in the F1 score with an increase in SNR might be indicative of the model nearing its maximum performance potential, unable to capitalize fully on the added clarity from higher SNR values. Alternatively, it could imply that the data lacks further valuable information to aid in more distinct anomaly detection, thereby causing the measured F1 score to ascend more slowly.

Power grid data often exhibits specific patterns of variation, making it suitable for analysis using the temporal nature of LSTM networks and the robust feature extraction capabilities of SAE networks. Experimental results have confirmed the high effectiveness of this method for anomaly detection. But fully applying this model to the anomaly detection of the actual substation gateway metering device will have certain shortcomings. In practical applications, there is no corresponding label for the data measured by the metering device. In order to realize the abnormality detection of the metering device more conveniently, it is necessary to increase the learning of unsupervised algorithms; It can also display some parameters measured by the metering device in real time.

Semantic Privacy Inference Preservation Algorithm for Indoor Trajectory

Abdullah Alamri
College of Computer Science and Engineering, University of Jeddah, Saudi Arabia

***Abstract*—Indoor location services have become an increasingly important part of our everyday lives in recent years. Despite the numerous benefits these services offer, serious concerns have arisen about the privacy of users' locations. Adversaries can monitor user-requested locations in order to obtain sensitive information such as shopping patterns. Many users of indoor spaces want their movements and locations to be kept private so as not to reveal their visit to a particular zone inside buildings. Research on semantic indoor trajectory-based human movement data has primarily focused on finding routes without taking into account the protection of privacy. Hence, the servers on which trajectory data is stored are not completely secure. In this paper, we propose a semantic privacy inference preservation algorithm for an indoor trajectory that can issue pathfinding and navigation instructions while achieving good privacy protection of moving entities by generating ambiguous trajectory. The simulation of the proposed semantic indoor privacy algorithm was implemented in MATLAB.**

***Keywords*—Privacy; semantic ontology; indoor space; routing algorithm; spatial databases**

I. Introduction

With the widespread usage of smartphones, mobile crowdsensing is now recognized as a promising means of collecting diverse and heterogeneous trajectory data for moving objects. This is especially useful for modeling human mobility patterns in either indoor or outdoor urban environments. The popularity of mobile positioning devices has resulted in the creation of several location-based services (LBSs) as well as vast volumes of locational data. Location-based services (LBSs) are being used in an increasing number of areas and have become an integral part of modern life [1, 2, 3]. Demand for location-based services is gradually extending from outdoors to indoors. Researchers and enterprises are increasingly interested in "indoor positioning systems (IPS)" and "indoor localization systems (ILS)" because they offer significant commercial opportunities for implementing indoor positioning, mapping, and navigation [4, 5].

Human mobility may be considered as a trajectory across a variety of indoor or outdoor spaces, each with its own distinct characteristics. While many studies have been conducted on outdoor trajectories, research has revealed that people spend more than 87% of their lifetime indoors in places such as shopping malls, airport terminals, and conference offices [6, 7, 8]. However, few studies have been conducted on safeguarding the privacy of indoor user trajectories. Instead, the emphasis has been on ensuring user privacy in outdoor environments despite the fact that most of our time is spent indoors where the same privacy issues apply.

Recognizing the promise of indoor LBSs, large technology corporations, governments, research institutions, and start-ups are making significant investments in this technology. While such technologies promise to make our lives easier, the privacy issues linked with indoor LBSs have raised many concerns, as the data they acquire is often sensitive and needs to be safeguarded. Indeed, misusing location data can result in the revealing of sensitive personal information about a user, such as personal interests and lifestyle habits. For example, users may want to visit stores while keeping their moves private, as an invasion of privacy can be exploited for advertising, spreading rumors, or other unauthorized or malicious purposes. Therefore, the protection of users' trajectories in indoor environments is critical.

Trajectory-based operations involving spatiotemporal data of moving objects are becoming increasingly essential in related research and applications. This is because it provides insight into human movement and has the potential to recognize patterns and predict future behavior. Over the past few years, several researchers have introduced a series of data models for semantic trajectories in indoor environments. However, the studies on semantic indoor trajectory-based human movement data have focused mainly on finding routes without considering the protection of privacy.

In this paper, we propose a solution that enables pathfinding and navigation instructions while achieving good privacy protection for moving entities by generating ambiguous trajectories. Semantic Web technologies provide strong representation tools for ubiquitous applications [9, 10, 11]. With location-based services and Semantic Web standards, trajectories can be linked and semantically annotated more easily, resulting in semantic trajectory descriptions. In this paper, we introduce semantic spatial ontology, which models indoor routing system needs while taking into account the protection of privacy. The contributions of this paper are as follows:

- Integrating semantic ontology/knowledge graphs and semantic privacy inference into indoor location-based services to improve accuracy and enrich navigation instructions with preserving the privacy of the user.
- Generating an ambiguous trajectory achieves privacy protection by safeguarding the actual trajectory of moving objects.

This paper has the following structure. Section II reviews the relevant literature and research on indoor routing and indoor/outdoor spatial privacy. Section III presents an overview of ontology modeling languages for the Semantic Web. Section IV describes the proposed semantic indoor trajectory privacy preservation algorithm. The architecture is comprised of two-level components: a semantic spatial ontology model for indoor routing, and semantic ambiguous trajectory privacy inference preservation. Detailed explanations of each of the architecture's components are provided in Section IV. Section V provides a motivation example and validation experiment for the proposed semantic indoor trajectory privacy preservation algorithm. Section VI summarizes the paper and offers suggestions for future research directions.

II. Literature Review

This section describes the relevant literature and research on indoor routing and spatial privacy in both indoor and outdoor environments. Several studies have explored indoor routing and have conducted studies to determine the algorithms that are most effective for indoor routing and navigation, Fig. 1.

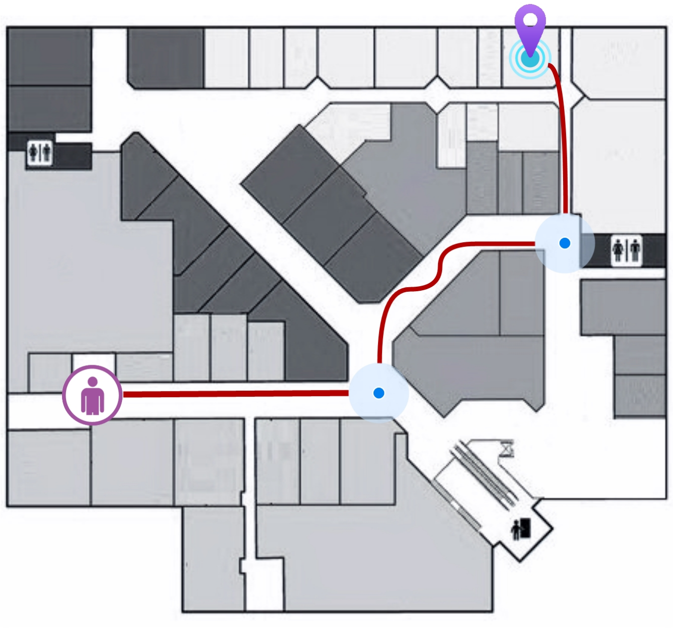

Fig. 1. Example of indoor navigation.

Parulian et al. [12] developed an indoor navigation system with guiding assistance depending on user location and desired destination. Dionti et al. [13] presented a three-dimensional space routing system implementation that represents data as an undirected graph with three-dimensional properties. The study compared four algorithms to determine which offered the shortest path in three dimensions. "The four algorithms are the Dijkstra Algorithm, A* Algorithm, Bellman-Ford Algorithm, and Floyd-Warshall Algorithm".

Alamri et al. [14] proposed an indoor multi-user routing algorithm for social distancing by considering and predicting user locations. The proposed indoor multi-user routing architecture consists of several components, including "indoor data structure, routing selection algorithm, density mechanism algorithm, and predictive routing algorithm". Dionti et al. [15] created a prototype routing system between buildings that combined outdoor and indoor routing systems.

Also, indoor navigation has been studied using semantic ontologies. The IndoorGML and BIGML data model have been applied to model indoor spatial information [16, 17]. Building Topology Ontology (BOT) was proposed to the W3C community group for Linked Building Data as "a simple ontology covering the core concepts of a building" [18].

Ontologies containing semantic representations of navigation path components were presented by Alamri [4] for an indoor navigation system with reasoning functionalities. The proposed system can be employed in navigation systems for route finding and presentation, along with crowd-density monitoring. ONALIN is an indoor routing ontology and algorithm that specifically takes into consideration the American Disability Act (ADA), presented by Doubts et al. [19].

Anagnostopoulos et al. [20] presented a hybrid modeling method for user navigation, called "OntoNav", that incorporates geometric and semantic information, as well as an ontological framework for processing routing requests. Sriharee [21] developed an ontology for indoor navigation based on symbolic information specified in Web Ontology Language (OWL). Wang et al. [22] proposed an ontology for expressing indoor navigation models using semantic location information.

Lee et al. [23] suggested ontology-based semantic queries to investigate indoor activities in a university environment. Yang et al. [24] investigated the use of ontologies for seamless navigation in both indoor and outdoor environments. Kim et al. [25] developed a spatiotemporal context-awareness knowledge model meant to recognize user objectives and help users when several paths are involved, such as hospital tasks.

Zlatanova and Liu [26] developed an indoor navigation space model (INSM) that uses semantic information to create connectivity graphs for buildings and identify several types of building spaces, such as inaccessible obstacles. Park et al. [27] built an expanded data model to assist persons with disabilities with indoor navigation by describing the relevant properties and relationships between PWD mobility and indoor environments. The IndoorGML application is used to support route planning that takes into account information regarding obstacles.

Maheshwari et al. [28] created an ontology for indoor places that considers both semantic and geometric properties. On the basis of this ontology, a space semantic model is developed, which can be used in a variety of applications. Li et al. [29] presented an indoor space dimensional model that allows for barrier-free path-finding by combining geometric, topological, and semantic layers.

All these recent works focus on data models and algorithms for indoor routing to support navigation systems for route finding and presentation. However, the collected data is usually sensitive, so the privacy issues raised by indoor routing are extensive. In fact, misuse of indoor location data can lead to the disclosure of sensitive personal information about users, such as personal interests and lifestyles.

Many works have been developed that focus on the privacy of moving objects' paths in outdoor environments. According to Wu et al. [30], location pair reorganization can be used to protect trajectory privacy. Differential privacy is a new privacy-preserving technology based on data distortion that secures sensitive data while maintaining statistical features by introducing random noise to data [31, 32, 33, 34]. Wang et al. [35] generate dummy trajectories by rotating the user's real trajectory at the specified rotation point. Shaham et al. [36] choose dummy locations that have the same posterior probability as the real places.

Some studies have been concerned about related privacy-preserving methods in indoor positioning systems. Kim et al. [37] proposed a privacy protection strategy for indoor positioning. This approach suggests the usage of an application that changes the phone's MAC address on a regular basis. They choose this approach to protect the user's privacy by not revealing his or her identification to the server. Li et al. [38] introduced noise into user fingerprint data using differential privacy. Furthermore, differential privacy has been applied to data obfuscation approaches to generalize and specialize user fingerprints [39, 40]. Sazdar et al. [41] proposed creating dummy places to safeguard users' location privacy. Zhao et al. [42] presented a paradigm-driven privacy protection framework for indoor localization based on local differential privacy. A comprehensive review was presented in [43] for indoor localization, which analyzes previous studies on user privacy on devices, in data transmission, and on servers.

To the best of our knowledge, the studies on semantic indoor trajectory-based human mobility data have focused mostly on finding routes without taking the privacy issue into account. We are the first to consider user trajectory privacy in a semantic ontology-based indoor spatial information model. This paper incorporates semantic ontology and semantic privacy inference into indoor location-based services to improve accuracy and enrich navigation instructions with preserving the privacy of the user by generating an ambiguous trajectory. Users' sensitive points are identified and use random candidate points to replace them for a pruning process. Consequently, a protected semantic trajectory database is created that preserves semantic consistency and resembles the original semantic route while maintaining various levels of user privacy. In terms of semantic indoor privacy, the proposed algorithm has advantages. An option is provided for users to select whether privacy protection should be activated. The system also can ensure the privacy of moving objects in indoor environments by generating an ambiguous trajectory based on sensitive zones/points, which prevents an attacker from knowing the true route of a user. This can help the user preserve the privacy of his or her movements, as a breach of privacy could be used for advertising, propagating rumors, or other illegal objectives.

III. Semantic Web: The Concept of Ontology

The concept of the Semantic Web indicates the objective of encoding information in a way that both humans and computer systems can understand [44, 45, 46]. This includes creating new ways to represent increasingly complex knowledge for true semantic interoperability. Hence, paradigms for operating the Semantic Web require the formal definition of domain models. These formal models (referred to as ontologies) should contain a clearer and more effective description of the terms used and their relationships than the metadata [47, 48].

Ontologies have brought new ways of representing knowledge, adding the ability to derive new knowledge not explicitly derived from the analysis of existing data. This gives the system a more efficient way of reasoning and a common way of representing knowledge across different systems working towards the same goal. The World Wide Web Consortium (W3C) has established the Resource Description Framework (RDF) as ”the standard paradigm for data exchange on the Web” [45, 46, 49, 50, 51, 52].

These considerations drive our decision to base our knowledge model on semantic web concepts and technology. Our work focuses on semantics in order to improve the proposed system with such capabilities. It serves as a semantic middleware, interlinking, capturing, and providing results. This is shown by the ontology component, in which diverse content is homogenized and stored locally in accordance with RDF triples within a knowledge base. More specifically, the model is employed using RDF edge-labeled graph, Fig. 2. With RDF, heterogeneous data can be integrated with different underlying schemas and distributed graphs can be represented semantically with the relevant reasoning capabilities.

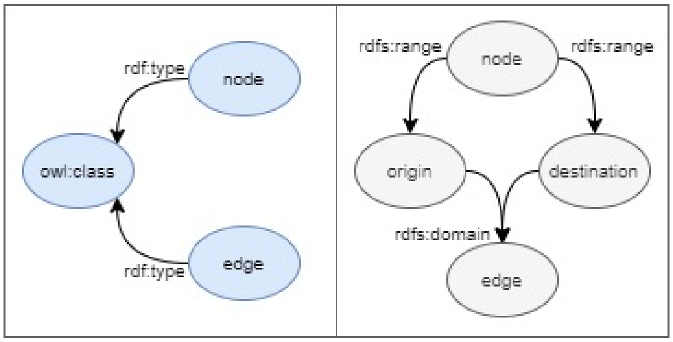

Fig. 2. RDF edge-labeled graph.

IV. Semantic Indoor Trajectory Privacy Preservation Algorithm

The proposed model architecture has been presented in Fig. 3. The architecture is comprised of two-level components: a semantic spatial ontology model for indoor routing, and semantic ambiguous trajectory privacy inference preservation. Each of the architecture's components is explained in more detail as follows:

In the top-level, a spatial ontology model is a routing system implemented in buildings and responsible for selecting the most accessible navigation path for users. The major issue with the spatial ontology routing model is understanding how to create the data structure that describes an indoor environment (Fig. 4). The increasing complexity of indoor spaces demands that the data model for indoor space's semantic division be able to handle efficiently the various features that are likely to be found in complex indoor spaces.

In the indoor space depicted in Fig. 4, it would be straightforward for a user to determine the optimal path from R1 to R2 within a building. However, the computer requires an accurate data structure that can describe corridors, rooms, and staircases. The semantic ontology of indoor space representation is depicted in Fig. 5.

Fig. 3. Proposed system architecture.

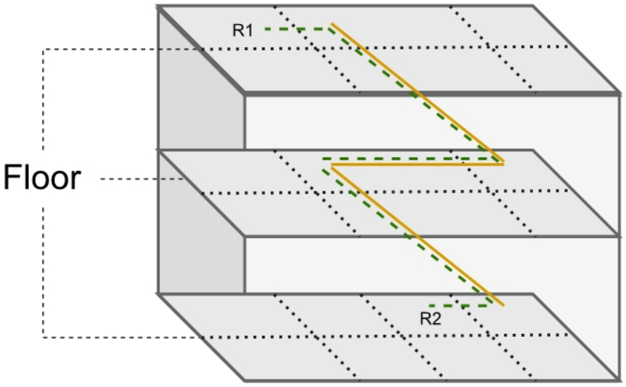

Fig. 4. Indoor space illustration.

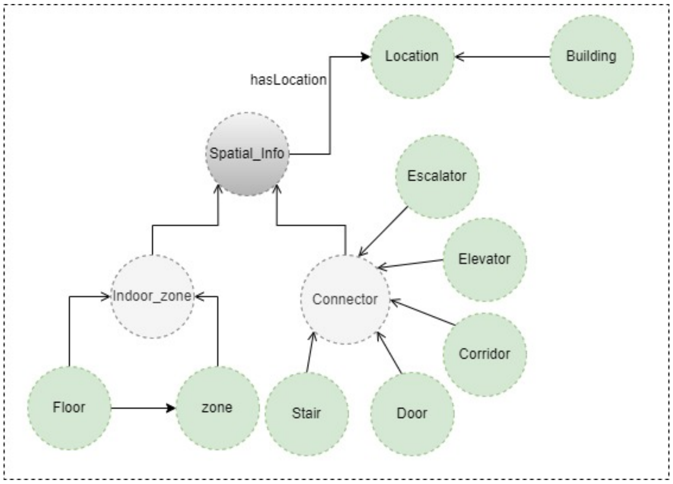

Fig. 5. Semantic ontology of indoor space.

The model presents a semantic model for indoor space that contains both syntactic and semantic information about spaces. In this model, the semantically enhanced representation of indoor space that we propose is a layered multigraph. Its node classes represent indoor spatial spaces symbolically, and its edges provide topological connection information between those spaces. Static semantic information about the indoor space is represented via node classes and attributes that relate to it, as well as node-edge layering. This is determined by the shape of the space, its connectivity with other spaces, and its functional features. We defined two main semantic node classes for the indoor space taxonomy. In order to show the overall hierarchy of floors inside a building, indoor zone space is the primary subclass to which the room and floor. The other is connector space which indicates the connection between the indoor zone and the different floors. The specific semantic partition model is defined as:

- Indoor zone space
  - ○ Room
  - ○ Floor
- Connector space
  - ○ Corridor
  - ○ Stair
  - ○ Door
  - ○ Elevator
  - ○ Escalator

Definition 1 (Taxonomy of Indoor Space): The ontology for indoor space taxonomy consists of two main ontology classes: *"Indoor zone $\wedge$ connector"*,

- *"Indoor zone space"* specifies the major subclass to which the room and floor belong in order to describe the overall hierarchy of floors within a building.
- *"The connector space"* indicates the link between the indoor_zone and the various floors.

Definition 2 (User Route): A user route, which consists of a series of sample points, is usually associated with a specific moving object as Tr_i= (P_s, $\text{cp}_i \cdots \text{cp}_n$, P_d) where:

- P_s identifies the moving object current point/zone location.
- $\text{cp}_i \cdots \text{cp}_n$ represents the obtained trajectory connection points.
- P_d identifies the end point (destination zone).

The system can receive two inputs: the first provides the current point/zone location, and the second contains the location of the endpoint zone of the user's destination. The system then presents the user with routes from the starting point to the destination. An algorithm for building a routing approach for an indoor environment can be summarized as the pseudo-code shown in Algorithm 1. Once the best route has been followed and the user reaches the endpoint, the system will begin protecting privacy if the user requests privacy protection.

In the lower level, semantic ambiguous trajectory privacy inference preservation is employed to safeguard the actual trajectory of moving objects. The result is a protected semantic trajectory database that preserves semantic consistency and a form resembling the original semantic route while meeting various user privacy requirements.

Definition 3. A privacy level is defined as P = Privacy_level, Privacy_level ∈ [high, nil].

Specifically, the privacy level is organized into two levels: Nil privacy (nil), and High privacy (high). Privacy level acts as a confidence level to register path. In the case of nil privacy, the actual trajectory of the moving object is registered. With high privacy, the user achieves privacy protection by safeguarding the actual trajectory of moving objects.

Our goal is to protect the sensitive points while still publishing a trajectory, albeit one consisting of a sequence of ambiguous points. The general idea of semantic ambiguous trajectory privacy is that an adversary with access to the protected semantic trajectories database comes to the same conclusion as whether an individual's trajectory data is included in the database or not. If ambiguous trajectory privacy is achieved in publishing trajectory data, it can assure the user that the released data will not leak his/her privacy whether or not his/her trajectory is in the database. Also, ambiguous trajectory data is published to confuse adversaries due to their similar shape and semantic attributes. When a user wants his or her trajectory's privacy inferences to be protected, the algorithm will collect trajectory data for the user from a data-centric semantic trajectory. First, to protect the privacy of this user's trajectory, we replace two connection points - the starting point and the destination point - with other random points.

Then, in the ambiguous trajectory generation stage, we map these two points by matching them with other random candidate semantic points (from the same or next level) and assume that they have the same semantic attribute. Finally, the algorithm will reconstruct the fake user trajectory by replacing all sensitive points. In this way, the semantic-protected trajectory database that is published will contain a sequence of ambiguous points.

The ambiguous trajectory generation method involves trajectory processing based on sensitive zones/points and other semantic information to prevent an attacker from determining the user's actual trajectory. The most common targets are the start-end points. There are two types of ambiguity-generation methods: trajectory segment pruning and ambiguity trajectory reconstruction. The pruning method eliminates sensitive points from the trajectory segment and uses random candidate points from the semantic bridge category to replace the corresponding start and stop points.

Semantic mappings between different location points are expressed via a semantic bridge category. To formalize this concept, we provide the following definition. Each location point is formalized with a prefix index in order to make it distinct from the others. For example, we use the i prefix to show the original start/end location point. Similarly, we use the j prefix index to signify the candidate location point.

Definition 4 (Semantic Bridge Category): The semantic bridge category can be expressed as: Mapping $\text{P}_{si} \underset{\rightarrow}{\triangleright} \text{P}_{sj} \wedge \text{P}_{di} \underset{\rightarrow}{\triangleright} \text{P}_{dj}$ where:

- P_{si} and P_{di} identify original start and end zones/points.
- P_{sj} and P_{dj} identify random start and end zones/points.
- $\underset{\rightarrow}{\triangleright}$ is the mapping bridge between points.

The proposed trajectory reconstruction algorithm is demonstrated in Algorithm 1. First, we locate a starting point in the trajectory segment P_{si}. Similarly, we locate an end point P_{di} on the segment and generate mapping bridge between these location points based on semantic bridge category $\text{P}_{si} \underset{\rightarrow}{\triangleright} \text{P}_{sj} \wedge \text{P}_{di} \underset{\rightarrow}{\triangleright} \text{P}_{dj}$. We generate a certain number of connection points on the segment (P_{sj}, $\text{cp}_j \cdots \text{cp}_n$, P_{dj}). Various trajectory segments can be obtained. Finally, we utilize the trajectory segment $\text{P}_{sj} \cdots \text{P}_{dj}$ to replace the original trajectory segment. Subsequently, a new trajectory segment is created, thereby protecting user privacy. These trajectories are illustrated in Fig. 6.

V. Experimental Validation

In this section, we use a software engineering strategy and validation experiments to ascertain the effectiveness of the proposed algorithm. The experiment test cases are designed to test ontology-based spatial information and ambiguous trajectory generation for privacy protection. For this experiment, using the indoor space ontology, we created a virtual dataset corresponding to a hypothetical two-floor building.

Assume a user visits a building for the first time and wishes to be directed to a certain zone without disclosing her/his location to the building's manager or any other party. This situation is common in, for example, malls, airports, hospitals, and university campuses. It necessitates the use of an autonomous application running on the user's mobile terminal that can provide the necessary location data as well

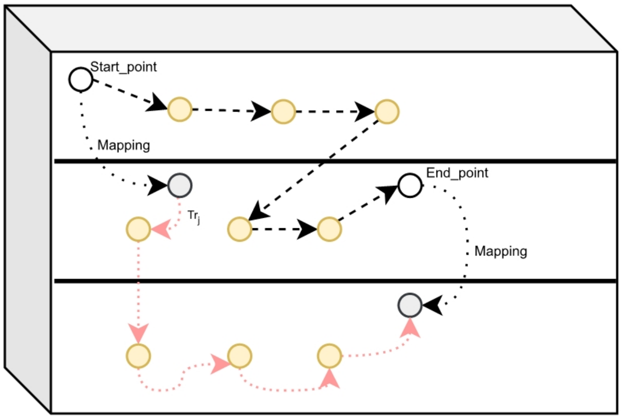

Fig. 6. Deriving a new trajectory segment.

as the information required for the generation of navigation directions.

We give an example of the simulation of the proposed privacy routing algorithm. Examples of the routes are shown in Fig. 7 and 8. Here, moving object o_i wants to visit zone P_{d23} and her/his start position was zone P_{s18}. Based on the trajectory connection points from $P_{s18} \cdots P_{d23}$, the expected route P_{s18}, cp_{12}, cp_{13}, cp_1, cp_2, cp_3, cp_4, zone P_{d23} or P_{s18}, cp_{11}, cp_{10}, cp_9, cp_8, cp_7, cp_6, cp_5, cp_4, zone P_{d23}. The user o_1 can reach the zone by following one of these routes. When the user uses the optimal route and reaches the endpoint, our proposed algorithm is meant to ensure privacy protection.

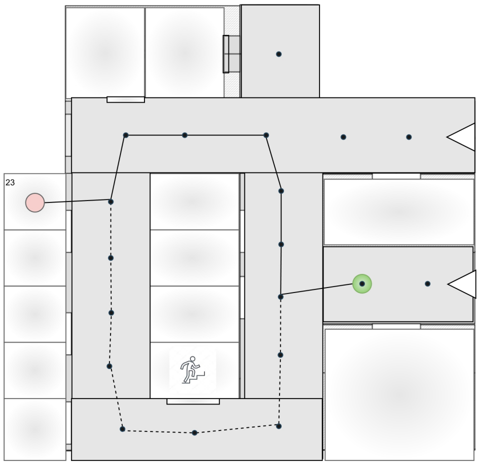

Fig. 7. The route to room/zone d_{23}.

The system generates an ambiguous trajectory and reconstructs it to create new segments of the trajectory for the user. It generates a mapping bridge between start/end location points and computes new traversable routes between two new points. Fig. 9 shows the route of validation on MATLAB, from the current position to zone P_{d23}. Fig. 10 shows a new trajectory segment that has been produced by the system for the user, thereby protecting user privacy.

                  two new points: $P_{sj} \cdots P_{dj}$
                $Tr_j$ = ($P_{sj}$, $cp_j \cdots cp_n$, $P_{dj}$)
                Derive new trajectory segment
            end
        end
end
```

The results demonstrate that the proposed semantic indoor privacy method has advantages. It enables the user to choose whether or not to activate privacy protection. It can also protect the trajectory of moving entities in indoor environments by employing an ambiguous trajectory generation mechanism based on sensitive zones/points and other semantic information to prevent an attacker from determining the user's actual route. This can assist the user to protect the privacy of his or her movements, as a breach of privacy could be exploited for advertising, spreading rumors, or other unauthorized purposes. In the future, more research will be conducted to improve the experiment. A comparison with similar approaches is provided. Furthermore, we would like to assess its effectiveness and performance in recreating user trajectory through real-world usage.

VI. Conclusion and Future Work

In this paper, we proposed an algorithm for safeguarding the semantic privacy inference of entities moving within indoor environments. Previous studies on the privacy of spatial trajectory have focused mostly on outdoor environments, whereas this work focuses exclusively on indoor environments. The proposed algorithm finds the best route for users while preserving their privacy and offering the user the choice to activate privacy protection. The proposed privacy solution involves the generation of an ambiguous trajectory generation based on sensitive zones/points and other semantic information to prevent an attacker from determining the user's actual trajectory in an indoor environment. By means of this algorithm, users can easily find a specific place in a building and achieve adequate privacy protection as the algorithm conceals the user's trajectory.

It is anticipated that future studies will improve on the experiment described in this research and conduct related experiments in an actual indoor space environment. Additionally, several challenges need to be addressed. We intend to evaluate the impact of the overall performance of the proposed algorithm on the reconstruction of user trajectory.

***Abstract*—Patello-femoral joint stability is a complex problem and requires detailed anatomic parametric study for knowing the associated breakdowns of knee cartilage. Osteoarthritis is one of the main disorders, which disrupt the normal bio-mechanics and stability of the patello-femoral joint and for diagnosing osteoarthritis radiologists needs a lot of time to diagnose it. An improved network called PSU-Net is proposed for the automatic segmentation of femoral, tibia, and patella cartilage in knee MR images. The model utilizes a Squeeze and Excitation block with residual connection for effective feature learning that helps in learning imbalance anatomical structure between background, bone areas and cartilage. The severity of knee cartilage is measured through the Kellgren and Lawrence (KL) grading system by radiologists. Also, updated weighted loss function is used during training to optimize the model and improve cartilage segmentation. Results demonstrate that PSU-Net can accurately and quickly identify cartilages compared to the traditional procedures, aiding in the treatment planning in a very short amount of time. Future work will involve the use of augmentation methods and also use this architecture as a generator model for generative adversarial network to improve performance further. The utility of this work will help in analyzing the anatomy of the human knee by the radiologists in short amount of time that may prove helpful to standardize and automate patello-femoral measurements in diverse patient populations.**

***Keywords*—Knee image segmentation; U-Net; loss function; squeeze and excitation**

I. Introduction

Patello-femoral joint stability depend on the knee. The patello-femoral joint is formed between the patella (kneecap) and the femur (thigh bone). It is a complex joint that allows for the movement of the patella during knee flexion and extension. The knee is known as the largest joint in the human body [1]. One of the important components in the knee joint is the cartilage. Cartilage is fine, rubbery, and flexible tissue that covers the surface of bones, which can be found throughout the body. Cartilage helps to reduce friction by acting as a cushion and lubricant between the joints. However, repeated bio-mechanical force or a sudden impact will cause the knee cartilage to experience wears down or tear, leaving the rough bone surface exposed to each other resulting the friction in between the constituent structures making the joint [2]. This situation is called damaged cartilage. Prolonged damage over the time will lead to the happening of Knee Osteoarthritis (KOA) with long-term irreversible effects on normal knee function. Eventually, the disease would lead to permanent physical disability.

KOA is a form of arthritis characterized by inflammation, degradation, and ultimate loss of cartilage in joints, most often affecting the knee's major weight-bearing joint [3]. KOA can be classified according to degradation severity. In 1961, WHO has accepted the Kellgren and Lawrence (KL) grading system as a standardized way to identify and grade the severity of (KOA) [4]. The grading scheme classified KOA into five different levels by assigning a grade from 0 to 4 [5].

Knee osteoarthritis (KOA) can be categorized into different severity levels based on magnetic resonance (MR) images. In the normal knee (KL 0 grade), there is no visible damage. In mild KOA (KL 1 grade), minor loss is observed in the femoral cartilage. Mild KOA (KL 2 grade) shows some loss in bone density in the femoral and patella cartilage. Severe KOA (KL 3 grade) exhibits tearing in the femoral cartilage, while in the most severe stage (KL 4 grade), almost the entire femoral cartilage seems to have worn down, exposing the bone and causing tissue signal inhomogeneity.

Knee cartilage segmentation plays a crucial role in diagnosing KOA. By accurately identifying and delineating the cartilage boundaries from medical imaging such as MRI, segmentation techniques enable quantification and assessment of cartilage health. This information helps in evaluating the severity of osteoarthritis, tracking disease progression, and guiding timely treatment decisions. Additionally, precise cartilage segmentation aids in detecting early cartilage degeneration and monitoring the effectiveness of interventions or therapies. Overall, knee cartilage segmentation plays a vital role in providing objective and quantitative measurements for diagnosing and managing osteoarthritis.

The remaining paper is organized with Section II explaining the related work, Section III describes the methodology, the Experiment work is presented in Section IV. Section V gives evaluation metrics and results and discussions are given in Section VI before Section VII concludes the paper.

II. Related Work

Segmentation of cartilage can be performed manually or by using computational approaches. Computational approaches can be classified into two which is semi-automatic or automatic methods. Manual segmentation of cartilage results usually gives more reliable outcomes compared to computational approaches. In a manual approach, cartilage will be segmented slice by slice from 2D MR images. Although manual segmentation outcome has high accuracy and sensitivity [6] and has been widely used to evaluate the performance of semi-automatic or automatic segmentation methods, it requires extra effort to the user and is time-consuming. This may result in inter and intra observer variability between the experts [7].

The region-based segmentation approaches have been classified under semi-automatic and conventional segmentation approaches. Based on [8], [9] this approach use the concept of exploiting the homogeneity property values of neighboring pixels such as grey-level intensity, texture, and edge [10]. Often, the initialisation point of segmentation or also known as seed points, $S_i = \{S_{1,}, S_2 \ldots, S_n\}$ will be manually placed by a user. After placing the seed points, the algorithm will next begin to search for homogeneous pixels in neighbouring pixels [11] and keep updating the corresponding region's mean and expanding until the similarity requirement is met. In equation (1), let T represent the set of all pixels that adjacent to at least one of the pixels in Si where nb(x) denotes the set of nearest neighbours pixel of x.

$$T = \left\{ x \notin \bigcup_{i=1}^{n} S_i \left| nb(x) \cap \bigcup_{i=1}^{n} S_i \neq \emptyset \right| \right\} \tag{1}$$

This approach has been widely used in the past two decades. However, the traditional region-growing approach is incapable to deal with the inhomogeneous image quality, especially for knee MR images. With this limitation, further research has been conducted by combining this approach with other image-processing approaches to achieve robust segmentation results. The author in [12] proposed a region growth approach by introducing the binary-class intensity-based local clustering to segment knee cartilage from a background image. Binary-class intensity-based local clustering is a voxel labeling of cartilage or non-cartilage. This approach was introduced to differentiate the class of unlabelled areas based on the distance to the knee bone and the contrast of the boundaries area. Finally, a 3D cartilage model was generated to tackle the issue of intensity inhomogeneity. The authors in [13], [14] performed a knee cartilage segmentation model based on a multistage region growth approach. This approach used a median filter to filter the image noise while edge detection and thresholding were used to remove the background image at the pre-processing stage. Next, the pre-segmentation stage by using region growth will take place. Output from this stage was bone and cartilage region mask. Finally, the bone region mask will be removed to leave out the cartilage.

Recently, there have been significant advancements in automatic biomedical image segmentation using deep neural network techniques [15], [16], [17]. In the context of segmenting knee joint structures, Burton et al. [18] initially employed two-dimensional (2D) tri-planar CNNs (axial, coronal, and sagittal planes) to classify pixel labels (background or tibial cartilage) by considering local image patches surrounding each pixel. However, Ronneberger et al. [19] identified two limitations with this approach: excessive redundancy and a trade-off between localization accuracy and the utilization of context. To address these issues, they proposed a dense prediction network called U-Net, which incorporated skip connections. This architecture encompassed both low-level and high-level features for voxel classification and was subsequently employed for knee joint segmentation by Liu et al. [20], Zhao et al. [21], and Ambellan et al. [22]. Generally, the U-Net employed pixel-wise or voxel-wise loss functions such as cross-entropy loss and dice loss. However, the resulting segmentation lacked spatial consistency [23]. The reason is that U-Net consists of only Convolution layers that suffer from the training-related issues of vanishing gradient and dead neurons considered as the main research gap being addressed in this work [24]. The main contribution of this paper is to propose an automatic deep learning segmentation model which can segment knee cartilage in the image efficiently and to do so we have introduced the proposed squeeze and excitation block in U-Net which will work alongside convolution layer of U-Net so that the architecture learning process goes smoothly. Additionally updated loss function is also used, which will help the proposed model to perform the task effectively.

III. Methodology

A. Proposed Squeeze and Excitation Block

The proposed Squeeze and Excitation Block, shown in Fig. 1, is composed of residual connection with Squeeze and Excitation block. The residual connection has been proven to be an effective way to overcome the problem of vanishing gradient when it comes to learning features in deep neural networks [25]. In [26], the authors have proposed SE-Net (Squeeze-and-Excitation networks), which is the ImageNet Challenge winner. The SE-Net adds the Attention mechanism to the feature channel dimension to learn the weight of each dimension through the loss function, and to learn the residual connection according to the importance of each channel feature. The image input after passing from convolution layers, delivers the feature map with size of H x W x C as the output. Then this feature map is passed colorred through Global pooling layer which reduces the size to 1 x 1 x C. Again, the output of global pooling layer is passed through fully connected layer and ReLU activation function thus reducing its channel by r as shown in Fig. 1. This process is known as the Squeeze operation. The output of Squeeze operation is then upsampled to 1 × 1 × C using another fully connected layer followed by sigmoid activation function, which gives weights for each of the channels, a process referred to as Excitation operation. Mathematically the Squeeze and Excitation operation can be expressed as in equations (2) to (5):

$$o_c = F_{sq}(x_c) = \frac{1}{H \times W} \sum_{h}^{H} \sum_{w}^{W} x_c(h, w) \tag{2}$$

Where F_{sq} represents squeezing operation, x_c represents feature map of X_m on the C dimension. H and W denotes the height and width of the feature map, h and w exemplify the abscissa and ordinate of a certain point on the feature map. The correlation between each feature channel is learned through the two fully connected layers and the ReLU activation function, and the correlation between the features is normalized by the Sigmoid function to obtain the weights for each feature channel, then these weights are multiplied by the input feature channel.

$$t_c = F_{\text{ex}}(o_c) = \text{Sigmoid}(W_2(\text{RELU}(W_1(o_c)))) \tag{3}$$

$$\bar{x} = F_{\text{scale}}(x_c * t_c) \tag{4}$$

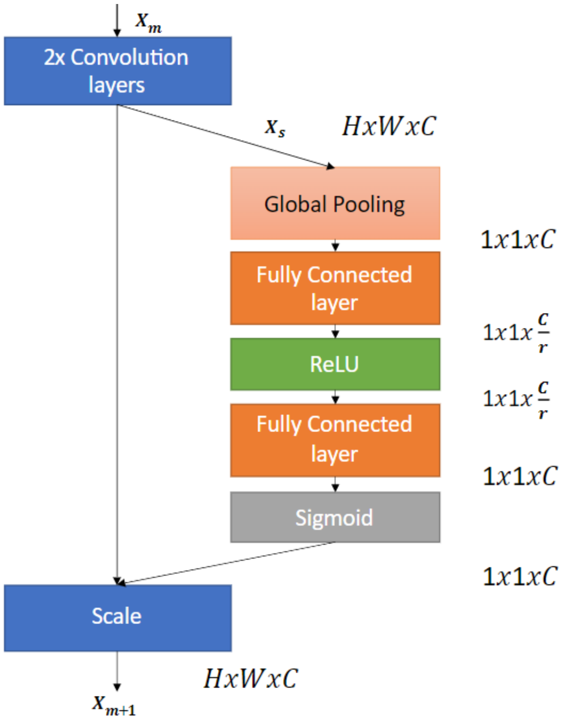

Fig. 1. Proposed squeeze and excitation block.

Where F_{ex} indicates an excitation operation, W_1 and W_2 show weights of two fully connected layers.

$$X_{m+1} = \text{RELU}\left(\bar{x} + X_m\right) \tag{5}$$

X_m signifies the input to the proposed block. Squeeze and Excitation block will then be embedded into the residual connection to improve the residual characteristics of different channels according to the degree of importance that will help in learning ability.

B. PSU-Net

Fig. 2 and Fig. 3 show the U-Net and PSU-Net architecture to segment the knee image data in NRRD format. It has the same architecture as that of the standard U-Net in the Down-convolutional part; each layer is consisting of two convolution layers followed by the activation function and then the input is down-sampled by the Maxpool layer in two-layered step. In the Up-Convolutional part each input coming from bottleneck layer is then upsampled by 2 x 2 in a two-layered step, followed by two 3 x 3 convolution layers and then followed by an activation function. The bottleneck layer connects Down-Convolution part to the Up-Convolution part that helps in stabilizing training and transferring information from Down-Convolutional part to Up-Convolutional part. The last convolution layer helps in reducing the number of labels to three according to number of class in our dataset. The input to the model in our case is 384 x 384 x 1 pixels and our output size is 384 x 384 x 3 pixels in which the digit 3 represents the classes (femoral, tibia and patella). We also used Batch normalization before activation functions.

In PSU-NET the two convolution layers block in the Up-Convolutional part and Down-Convolutional parts are replaced by the proposed Squeeze and Excitation block as shown in Fig. 3. Each unit of Down-convolutional part includes a proposed Squeeze and Excitation Block to extract image features and a down-sampling layer. The down-sampling is done using maxpool layer. The channel size is reduced to half, each unit of Up-Convolutional part includes a proposed Squeeze and Excitation Block and an upsampling layer. Upsampling uses transposed convolution, the channel size is expanded by two times. The last layer consists of convolution layer that helps in reducing the number of class to three - the femoral, tibia and patella in our case.

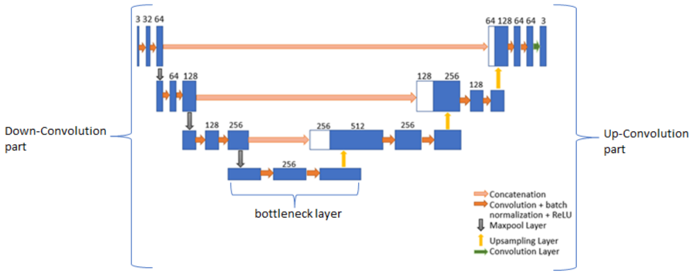

Fig. 2. Standard U-Net architecture.

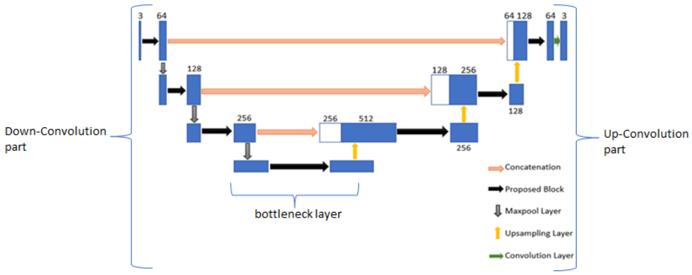

Fig. 3. PSU-Net architecture.

C. Loss Function

Knee image segmentation is done to divide the voxels of the cartilage of knee image into three classes: femoral, patella and tibia, using neural network. The pixel value of cartilages is approximately the same as different organs of the knee like meniscus etc. In order to make the neural network pay more attention to the cartilage, we give these pixels of cartilage greater weights to improve knee image segmentation. The weights can be expressed as in equation (6):

$$w_i = \frac{\left(\frac{1}{N_i}\right)^2}{\sum_{i=1}^{3}\left(\frac{1}{N_i}\right)^2} \tag{6}$$

Where w_i represents weight for each class, N_i is the total number of pixels in each class of the image. This paper uses a weighted multi-class loss function, which is a combination of Dice loss function and cross-entropy loss function to optimize the model. The formulas of the Dice loss function and the cross-entropy loss function are mathematically expressed in equation (7) and (8):

$$\text{loss}_{\text{Dice}} = 1 - \sum_{n=1}^{M} \sum_{i=1}^{C} w_i \frac{2 \cdot y_{ni} y'_{ni}}{y_{ni} + y'_{ni}} \tag{7}$$

$$\text{loss}_{\text{ce}} = - \sum_{n=1}^{M} \sum_{i=1}^{C} w_i y_{ni} \log \left(y'_{ni} \right) \tag{8}$$

Where M represents the total number of pixels in the image in a batch, C represents the class (femoral, patella, tibia), w_i Indicates the class weight obtained by using equation (6), and y_{ni} indicates the true probability value of the pixel belonging to class i, y'_{ni} represents the predicted probability value. Finally, the weighted loss function is as expressed in (9)

$$\text{Loss} = \lambda_1 \, \text{loss}_{\text{Dice}} + \lambda_2 \, \text{loss}_{\text{ce}} \tag{9}$$

IV. Experiment

A. Dataset

This study is carried out on 30 datasets from OAI [27] that can be found at http://oai.epi-ucsf.org/datarelease/About.asp, consisting of 160 slices each of Knee MR images. The datasets consist of various KL grades as listed in Table I. The KL grades are generally referred to in the medical images to reflect the damage of the cartilage in between joints. We labelled the cartilage of these 30 datasets using slicer [28] software. we divided these 30 datasets into 3 categories. 23 of training datsets, 5 of validation datasets and 2 of testing datasets.

TABLE I. Amount of Datasets for Various KL Grades

KL Grades	Dataset Numbers
0	8
1	4
2	5
3	6
4	7

B. Experimental Setup

The operating environment of this study is NVIDIA cuDNN7.5, CUDA10.0, Python 3.4, Anaconda, the hardware configuration is GTX 1060Ti GPU, 1 TB capacity hard disk, and the deep learning framework is built using Keras [29] with Tensorflow [30] as backend. Other libraries also used like SimpleITK [31], matplotlib [32], Scikit learn [33] and numpy [34] for reading, processing NRRD data and for other functions as well. The neural network learns the weights of each layer through training data and selects the optimal model through validation data to verify the performance of the model. Each epoch of learning randomly selects 80 percent of the training model from the training set, and the remaining 20 percent is used to verify the model to improve model learning ability. We have entered data in batches to reduce training time. In this study, the Adam optimization method is used to optimize the network, and the weighted joint loss function proposed in equation (9) is used to judge the training process of the network model. We have adjusted the parameters according to the training results, the parameter of loss function λ_1 and λ_2 Set to 0.3 and 0.7, respectively, set the training batch size to 2, and iterate the training data set for 50 epochs.

V. Evaluation Metrics

In order to quantitatively evaluate the segmentation performance of the algorithm in this paper, Dice coefficient (F1) and Intersection over union (IoU) are used as evaluation metrics, and these scores were measured by calculating the regional similarity between deep neural neural network predicted result and expert annotated result.

F1 score can be calculated by using following mathematical equation:

$$\text{F1} = \frac{2|A \cap B|}{|A| + |B|} \tag{10}$$

IoU score can be expressed mathematically as:

$$\text{IoU} = \frac{|A \cap B|}{|A \cup B|} \tag{11}$$

In above equation 10 and 11, A represents the ground truth of knee cartilage and B is the predicted segmentation result by segmentation models.

VI. Results and Discussion

Using the model of this paper to trained on 30 datasets of knee images to calculate the dice coefficient of our proposed model on training dataset and validation datasets during training of each epoch using dice coefficient and intersection over union. The box plot shown in Fig. 4 indicates the distribution of the dice coefficient of the femoral, tibia and patella cartilages during training. Usually, each of the datasets consists of 160 slices in which we have slices with cartilage and without cartilage. The average training dice coefficient of our proposed model during training on those slices which have femoral cartilage is up to 0.925, the average training dice coefficient on those segmented slice which has tibia cartilage is up to 0.945, and the average training dice coefficient on those slices which have patella cartilage is 0.978. The distribution of dice coefficient is also relatively concentrated, which shows that the network can effectively segment the cartilage under normal circumstances. Table II shows the average validation dice coefficient (F1) and intersection over union (IoU) of our model. The average validation dice coefficient of femoral cartilage is 0.79 and the average validation IoU is 0.74, the average validation dice coefficient of the tibia is 0.85 and the average validation IoU is 0.78 and for patella cartilage, the average validation dice coefficient is 0.82 and the average validation IoU is 0.73. The reason of low validation F1 score from training F1 scores is that in the evaluation process of validation datasets, some slices in datasets have no cartilage.

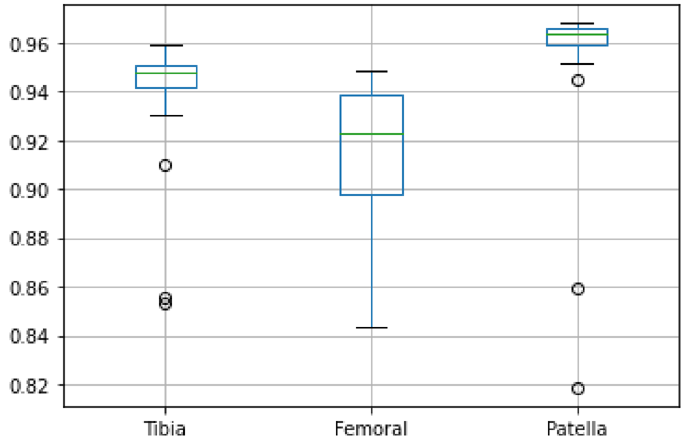

Fig. 4. Boxplot of dice-coefficient of those slices having cartilage from PSU-Net.

TABLE II. Average validation Dice-Coefficient(F1) and Intersection Over Union(IoU) Scores of Different Cartilages using PSU-Net

Performance Metrics	Femoral	Tibia	Patella
F1	0.79	0.85	0.82
IoU	0.74	0.78	0.73

This article also compares proposed model with the U-Net, Branch residual U-Net (BRUNet) based on dilated convolution [35] and FU-Net [36] with batch normalization and residual block. Table III describes the dice coefficients of the four networks, which automatically segment femoral, tibia and patella cartilages. Compared with other segmentation models, the dice coefficients of knee cartilages have improved to a certain extent in PSU-Net, which shows that the model can segment knee cartilages more effectively. This is mainly because the proposed Squeeze and Excitation block with residual connection reduces the loss of feature information during propagation to a certain extent. At the same time, the proposed block increases the weights of useful features of the image and improves the segmentation performance in consequence.

Fig. 5 shows the segmentation results on some image slices from the test dataset. The first column is the slices of knee image from the test datasets, the second column is the label mask manually annotated, which provides the ground-truth, and the third column is the prediction result of the cartilage area by the PSU-Net. The green area represents femoral cartilage, the yellow area represents tibia cartilage, and the pink area shows patella cartilage. The first to fourth rows show a simple situation. When the knee image slices show different cartilages, our model outperforms contemporary models in segmenting different type of cartilage in input image slice. However, in some slices when the cartilage boundary is closely in contact with other organs like meniscus and tissue, then the segmentation performance of our model becomes weak as shown in the first column, the reason is that assigning weights in such condition becomes difficult. Fig. 6 shows the predicted axial 3D view of cartilage using Slicer software for two test datasets.

TABLE III. Comparison of Dice-Coefficient Score using Different Models for Two Test Datasets after Training

Models	Femoral	Tibia	Patella
U-Net	0.80	0.76	0.84
FU-Net	0.82	0.80	0.87
BRUNET	0.77	0.73	0.78
PSU-Net	**0.86**	**0.89**	**0.85**

VII. Conclusion

In this paper, the improved network PSU-Net is proposed to automatically segment the femoral, tibia and patella cartilage in the knee MR image. The proposed model has employed Squeeze and Excitation block with residual connection instead of only convolution layer in U-Net to learn the feature information of the image more effectively. In order to reduce the problem of imbalance between the background and the bone area in the image, the image is clipped before training. In the training, a weighted loss function is used to optimize the model, and the weight of femoral, tibia and patella is increased to improve the cartilage segmentation. Our proposed model has achieved good segmentation results of each cartilage on the test datasets compared to other variants of U-Net models. The authors have noticed that proposed model clearly outperforms U-Net and other variants of U-Nets in segmenting the cartilages of femoral, tibia and Patella of the knee with Dice-Coefficient of 0.86, 0.89 and 0.85, respectively. PSU-Net can quickly and accurately segment femoral, tibia and patella, which help physicians to adjust treatment plans according to the condition. Detection and segmentation of cartilages in knee Image based on deep learning requires a large amount of training data. However, due to the limitation of segmentation targets, the number of annotated datasets in the Knee image group is small, which limits the effect of model training. As the number of publicly available annotated Knee images increases in the future, the segmentation performance of the proposed network will also be further improved. The segmentation of those cartilages whose boundary are in contact with meniscus or other tissues, are hard to be segmented by our model, is suggested in the future part of this work. Additionally, augmentation of data using generative model will also finish the problem of less data in medical images that will affect the segmentation results of the potential models.

Acknowledgment

The authors would like to express their sincere gratitude to University Kuala Lumpur (UniKL) for its generous support in funding this research project under the UniKL Excellent Research Grant Scheme (UniKL/CoRI/UER21013).

An Integrated Framework for Relevance Classification of Trending Topics in Arabic Tweets

Abdullah M. Alkadri*, Abeer ElKorany, Cherry A. Ezzat
Faculty of Computers and Artificial Intelligence, Cairo University, Giza, Egypt

***Abstract*—Social media platforms such as Twitter are a valuable source of information about current events and trends. Trending topics aim to promote public events such as political events, market changes, and other types of breaking news. However, with so much data being generated, it would be difficult to identify relevant tweets that are related to a particular trending topic. Therefore, in this paper, an integrated framework is proposed for the detection of the degree of relevance between Arabic tweets and trending topics. This framework integrates natural language processing, data augmentation, and machine learning techniques to identify text that is likely to be relevant to a given trending topic. The proposed framework was evaluated using a real-life dataset of Arabic tweets that was collected and labeled. The results of the evaluation showed that the proposed framework achieved the highest macro F1 score of 82% in binary classification (relevant/irrelevant) and 77% in categorical classification (degree of relevance), which outperforms the current state of the art.**

***Keywords*—Trending topics; social media platforms; machine learning; Arabic relevance classification; data augmentation**

I. Introduction

In recent years, social media platforms have become a significant source of information for real-time events and trending topics [1]. The vast amount of user-generated content on these platforms, especially Twitter, provides a wealth of information for various applications, including sentiment analysis, event detection, and trend analysis [2].Twitter is now a real-time information distribution channel that is utilized for news, politics, and advertising [3]. Users can use the trending topics feature or popular hashtags to discover current popular news. However, trending topics are often irrelevant to the content being discussed. Therefore, trending topics relevance classification is considered as an important text analysis task for Twitter data. Trending topics relevance aims to identify relevant tweets that are related to a particular trending topic. However, this task is challenging due to the noisy and unstructured nature of social media text, misspellings, slang, and various other factors that can affect the relevance of a tweet to a trending topic [4], [5].

Currently, the hashtag trending topic feature is used by users to find out what topics are currently popular on Twitter [6], [7]. Some users employ trending topics, to get more attention to their tweets. However, the trending topic is irrelevant to the topic being discussed by the tweet itself. For example, some people include political trending topics that are popular during the election period in their tweets, but the tweet content does not include any political topics.

Irrelevant content for trending topics reduces the level of communication offered by social media networks. They pollute social networks and affect how people perceive the contents of the internet. The user experience will significantly decrease if someone is excessively exposed to irrelevant information, which would result in user losses for the social service provider [8]. Therefore, social platforms must develop algorithms to filter unwanted information and determine the relevance of content to trending topics.

Several approaches have been proposed for automatic learning and detection including trending topics detection on social media [9]. Previous research has extracted and utilized a wide range of features, from simple to complex, as well as a wide range of learning and classification algorithms, from traditional machine learning techniques to deep learning [9], [10].

However, these approaches face several challenges specific to Arabic language processing, such as the absence of diacritics, the presence of multiple dialects, and the use of Arabic script, which can affect the accuracy of the model. Additionally, the availability of labeled datasets for Arabic text relevance classification in trending topics is limited, making it difficult to train and evaluate models on this task.

This paper focuses on the problem of detecting the relevance level of Arabic texts related to trending topics on Twitter. Specifically, we aim to identify tweets that are relevant to a given trending topic in order to be able to filter out irrelevant content. A novel framework that integrates several techniques, including text preprocessing, feature extraction, and machine learning algorithms is proposed to classify tweets associated to trending topics into relevant/irrelevant. Furthermore, this framework is able to categorize the relevant content into low, medium, and high based on its degree of relevancy. This work is based on the trending topics and tweets related to Yemeni politics written in Arabic.

The main contributions of this paper are the following:

- Build a public and available dataset of Arabic tweets related to trending topics in both binary and categorical classes.
- Develop a trending topics relevance text classification framework using machine learning algorithms with two scenarios: binary and categorical classes.
- Apply data augmentation to enhance the performance of the framework.

[*] Corresponding Authors

As will be explained later, to overcome the challenge of limited labeled datasets, data augmentation techniques [11] were applied to improve the performance of the model. Several techniques will be applied including word embedding-based techniques, to generate additional training data, which helps the model better generalize to unseen data and handle noisy, misspelled tweets and improve the overall performance of the model.

The proposed framework is beneficial for researchers, journalists, and businesses who require analysis of trending topics on social media platforms. It can also be used to extract insights about public opinions, monitor the impact of events, and discover emerging trends. The rest of the paper is organized as follows: Section II discusses the background and related work; Section III explains the methodology used in our approach; Section IV presents the experimental results; Discussion are in section V; Finally, section VI concludes the paper and outlines possible directions for future work.

II. Background and Related Work

A. Trending Topics

Trending topics refer to popular and widely discussed topics on social media platforms such as Twitter, Facebook, and Instagram. These topics are characterized by a large volume of posts or tweets that use a specific hashtag or keyword, and they often reflect current events, news, and opinions that are of interest to the public [6].Trending topics are important because they provide valuable insights into public opinion and social trends. They allow individuals and organizations to track and monitor the conversation around a particular topic, and they can be used to identify emerging trends and issues in real-time [12]. In recent years, the analysis of trending topics has become an important field of research. Researchers have explored various approaches and techniques to identify and analyze these topics based on different domains and languages. For example, some studies have focused on identifying trending topics related to politics, sports, entertainment, or health, while others have looked at trending topics in different languages such as English, or Arabic. Some of these approaches include [13], [14]:

- Keyword-based approach: This approach involves using a set of pre-defined keywords to identify the trending topics.
- Text classification approach: This approach involves training a classifier on a labeled dataset to identify the trending topics.
- Topic modeling approach: This approach involves using topic modeling techniques such as Latent Dirichlet Allocation (LDA) to identify the trending topics.
- Hybrid approach: This approach combines multiple methods to improve trending topic detection accuracy. For example, a hybrid approach may use both keyword-based and text classification methods to identify trending topics.

Overall, the choice of the approach depends on the specific requirements of the task, such as the available resources, the amount of labeled data, and the desired level of accuracy.

Trending topics analysis has many applications, including social media monitoring, reputation management, crisis management, and market research. It can be used by businesses, governments, and other organizations to gain insights into public opinion, track the effectiveness of their social media campaigns, and respond to emerging trends and issues in real time.

B. Related Work

1) Topic detection: There is limited research on trending topics relevance text classification in social media. However, significant research has focused on related areas such as topic detection and sentiment analysis [15]. Here, we only provide a brief overview of a few of the most pertinent studies for topic detection. There is a wide range of techniques employed for topic analysis on Twitter. Studies that utilize machine learning techniques generally rely on supervised learning [16], [17], [7], while others adopt a hybrid approach that incorporates latent Dirichlet allocation (LDA) [18]. The combination of sentiment analysis and topic detection has been employed to analyze content related to COVID-19 in Brazil and the USA [3]. Lee et al. [7] categorized Twitter Trending Topics into 18 broad categories, including sports, politics, and technology, using a text-based classification approach with a Bag-of-Words and a network-based classification.

There have been several significant works related to topic detection on social media for the Arabic language. An assimilated model was introduced to identify events from Arabic Twitter data by Alsaedi et al. [19]. Their main objective was to distinguish disruptive events from other events in social media data streams. The model they developed relies on the frequency of terms occurring together over time. In a different study [20], a comprehensive framework for event detection was introduced. The authors emphasized the importance of temporal, spatial, and textual characteristics of each cluster in event detection. They compared the effectiveness of their proposed framework with LDA and demonstrated that LDA was not suitable for analyzing short messages like tweets. In [21], a feature-pivot method was employed to identify bursty features of terms from Arabic Tweets. The approach employed TFIDF, entropy, and stream chunking to capture bursty terms that were highly relevant to a particular event during a given time interval. The document-pivot method was introduced in [22] to extract trending topics for Arabic Twitter users. These works serve as examples of the diverse range of approaches that can be utilized to detect topics on Twitter.

2) Relevance text classification of trending topics: Despite the abundance of research on topic detection on Twitter, comparatively less work has focused on classifying relevant text within trending topics, which is the primary focus of our proposed approach. A framework model known as TORHID (Topic Relevant Hashtag Identification) was introduced in a research paper [23] to identify and retrieve hashtags relevant to a particular topic on Twitter. The model utilized small tweets of a hashtag as seeds and employed a Support Vector Machine to classify new tweets as relevant or irrelevant. According to the reported results, the TORHID model achieved an accuracy of 67.25%. Cahyaniet et al. [4] conducted research on the relevance classification of tweet content and trending topics on social media. The study focused on political tweet data related to Indonesian trending topics and employed Support Vector Machine (SVM) for classifying tweets as either relevant or irrelevant. The study reported an F1 measure of 70% for the applied model. However, the absence of research on trending topics relevance text classification in Arabic represents a noteworthy gap in the existing literature, which we aim to address.

III. Proposed Framework for Relevance Classification of Trending Topics in Arabic Tweets

As shown in Fig. 1, an integrated framework for Relevance Classification of Trending Topics in Arabic Tweets (RCTAT) is proposed. This framework consists of two main components: data preparation and augmentation and trending topics relevance text classification. In the following subsections, each component will be described in details.

A. Data Preparation and Augmentation

Data preparation involves collecting and cleaning the data, while data augmentation involves generating more data from the existing data to improve the model's generalization and reduce overfitting [24]. The following steps were taken in data preparation and augmentation for Relevance Classification of Trending Topics in Arabic Tweets:

1) Data collection: The first step was to collect Arabic tweets from Twitter. The tweets were collected using the Twitter Streaming API starting December 2019 to April 2020, using the query "lang: ar" (language is Arabic) and the trending hashtag (#YEMEN).

2) Data cleaning: To obtain distinct tweets, several cleaning steps were applied. These steps involved removing diacritics, repeated characters, and punctuations from the tweets. Additionally, both Arabic and non-Arabic alphabets were normalized to ensure consistency. Furthermore, the Python NLTK library[*] was utilized to perform Arabic light stemming (ARLSTem) and remove Arabic stop words. These cleaning techniques enhanced the quality and readability of the tweets, making them more suitable for further analysis.

3) Relevant terms extraction: To build a list of commonly used terms related to the situation in Yemen, the 313k distinct tweets are analyzed. The frequency analysis technique [25] is used to identify the most frequently used and important terms by counting the occurrence of words in the tweets. As shown in Fig. 2, a list of terms was extracted and used to construct our dataset. These terms cover a variety of topics associated with the situation in Yemen.

4) Manual data labeling: From the 313 k unique tweets, a random sample of 5,000 was chosen for manual labeling. To construct our relevant/irrelevant dataset, the extracted tweets have been manually annotated into six categories: irrelevant (1), 30% relevant (2), 50% relevant (3), 65% relevant (4), 85% relevant (5), and fully Relevant (6) to the situation in Yemen. To assist in the labeling process, a website[†] was developed and 15 Arabic annotators helped in this process. The annotators had diverse educational qualifications, including advanced educational degrees such as B.C, M.S., or Ph.D. with an age range spanning from 25 to 40 years old. This combination of advanced education and diverse age range allowed the annotators to bring a wealth of knowledge and perspectives to the annotation task. Each annotator was provided with our definition of relevant, relevant ranges, and irrelevant content, along with relevant examples, before commencing the labeling process. The criteria for definition are as follows:

- If one or more relevant terms are discussed, a tweet is typically considered fully relevant.
- If no relevant term is included, a tweet is considered fully irrelevant.
- If a tweet contains a mixture of relevant and irrelevant terms, it is considered partially relevant.

The 5,000 tweets were divided into five groups of 1,000 tweets each. Three different annotators were assigned to work independently on each set of 1,000 tweets. This means that each tweet was annotated by three different annotators, resulting in three values for each tweet based on the six categories, with each category from a different expert. This expedited the process and enabled multiple experts to label the same tweet. After the annotations were completed, a tweet-relevant ratio (r) was calculated for each tweet by adding the three annotation results and dividing the total by the highest summation result (N).

$$r = (\sum_{i=1}^{3} annotatorResult_i)/N \qquad (1)$$

Where :

$$annotatorResult_i \text{ is value from 1 to 6}$$

$$N \text{ is the highest summation result = 18}$$

After calculating the tweet-relevant ratio (r) for each tweet, the tweets were further categorized into binary (relevant or irrelevant) and categorical (low, medium, high) datasets. This categorization was likely based on a threshold value determined by the tweet-relevant ratio (r). In order to determine the optimal threshold for tweet categorization, we adopted an experimentation approach. A series of experiments were conducted by systematically varying the threshold values and assessing their impact on the performance of our classification model. A representative dataset of tweets was collected, and their tweet-relevant ratios (r) were computed. Through iterative adjustments of the threshold values and comprehensive analysis of evaluation metrics including accuracy, precision, recall, and F1-score, we successfully identified the threshold that yielded the best performance. This meticulous experimentation and analysis process allowed us to select the threshold value that maximized our chosen evaluation metric, ensuring the accurate differentiation of relevant and irrelevant tweets within our tweet categorization framework. Furthermore, these tweets were appropriately assigned to their respective relevance categories.

For example, if the threshold value was set at 0.34, tweets with a tweet-relevant ratio (r) higher 0.34 would be considered relevant, and those with a ratio of 0.34 or below 0.34 would be considered irrelevant. The binary dataset would then consist of two categories: relevant and irrelevant. Similarly, the

24516	إيران	Iran	19887	الحرب	The war

Fig. 2. List of terms used to label the dataset.

categorical dataset would be created by dividing the relevant tweets into three categories based on their tweet-relevant ratio (r), such as low (0 to 0.17), medium (0.17 to 0.34), and high (0.34 and above). This categorization was used to evaluate the performance of the framework in identifying relevant tweets and to compare it against human annotations. Tables I and II shows the number of tweets in both manual binary (relevant or irrelevant) and categorical (low, medium, high) datasets.

TABLE I. BINARY MANUAL ANNOTATED DATASET

Binary Class	Ratio	Number of tweets
Irrelevant	r<=34 %	1589
Relevant	r>34 %	3411

TABLE II. CATEGORICAL MANUAL ANNOTATED DATASET

Categorical Class	Ratio	Number of tweets
Low	r<=17 %	791
Medium	r<=34 %	798
High	r>34 %	3411

5) Expanding the annotated dataset: In order to increase the size of the manually labeled dataset, which can be expensive and time-consuming to create manually, we utilized text data augmentation techniques to automatically generate a labeled dataset from the existing one. Data augmentation is employed to improve the classification of relevant tweets in trending topics.

Data augmentation aims to tackle overfitting at the data level, address class imbalance, and enhance the model's generalization [24]. Increasing the diversity of training samples through data augmentation can help the model learn more fundamental features of the data, leading to a higher quality classifier. Tables III and IV show how the size of the binary (irrelevant) and categorical (low, medium) samples changed after the data augmentation technique was employed. In our previous work [26], data augmentation techniques were applied to increase the size of our datasets. This approach aimed to address the class imbalance, avoid overfitting, and enhance the generalization of the model. The authors utilized word embedding techniques [27], specifically the AraVec word vectors trained on Arabic content from Wikipedia and Twitter. They replaced words in the dataset with synonyms based on similarity scores obtained from the word vectors. By applying a random ratio of 50% to 70% for token replacement, they effectively increased the diversity and quantity of training samples. This data augmentation process resulted in a substantial increase in the size of our datasets, which can potentially improve the accuracy and performance of our model by providing a more comprehensive representation of the data.

Table III shows that the size of the irrelevant binary class increased from 1589 to 3236 tweets after data augmentation. Similarly, the low categorical class increased from 791 to 2439 tweets, and the mid categorical class increased from 798 to 2388 tweets as shown in Table IV. This suggests that the data augmentation technique was successful in increasing the size of the datasets, which can help improve the performance of the model by increasing the diversity of the training samples.

TABLE III. BINARY AUGMENTED DATASET

Binary Class	Ratio	Number of tweets
Irrelevant	r<=34 %	3236
Relevant	r>34 %	3411

TABLE IV. CATEGORICAL AUGMENTED DATASET

Categorical Class	Ratio	Number of tweets
Low	r<=17 %	2439
Medium	r<=34 %	2388
High	r>34 %	3411

B. Trending Topics Relevance Text Classification

This section describes the Trending topics relevance text classification process by applying different machine learning techniques. This process includes the following steps: Data pre-processing, feature extraction, and finally, applying various machine learning classifiers.

1) Data pre-processing: In order to ensure data cleansing and eliminate noise that could impact the accuracy of the system, various techniques were employed on the dataset. These techniques include tokenization, normalization, removal of diacritics, removal of repeated characters, removal of punctuations, removal of stop words, removal of non-Arabic alphabets, and light stemming.

2) Content features extraction: Once the data is prepared and augmented, features need to be extracted from the text to represent it into a numerical representation that can be used by the machine learning models. The features listed in Table V were employed for this purpose.

TABLE V. RELEVANCE DETECTION FEATURES

Feature	Description
Word-Level	Each word in the dataset is represented using the TF-IDF matrix.
N-gram-Level	Unigram, bigram, and trigram models are used and represented using the TF-IDF matrix.
Character-Level	TF-IDF character scores for each tweet are represented in the dataset.
Count Vector	The text in the dataset is represented as a vector of term counts.

3) Machine learning classification: Several machine learning classifiers have been utilized to classify relevance text in Trending topics. Three classifiers were trained based on the extracted features to assess their effectiveness in classifying relevant content. The classifiers used were Naive Bayes, Logistic Regression, and LinearSVC, which were selected because they have been widely used as a baseline in previous works on Arabic classification. The experiments' outcomes are discussed in Section IV.

IV. EXPERIMENTS

Experiments were conducted to evaluate the quality of manually labeled and augmented datasets using the features extracted in Section III-B2. Two types of Arabic relevance classification were explored: binary classification (relevant/irrelevant) and categorical classification (low, medium, high). The dataset comprised 5000 tweets in the non-augmented labeled dataset and up to 8000 tweets in the augmented dataset, as shown in Sections III-A4 and III-A5. The Arabic relevance classification was performed using LinearSVC (SVC), Naive Bayes (NB), and Logistic Regression (LR) classifiers with 10-fold cross-validation on both datasets.

The results of binary classification and categorical classification for the Arabic relevance classification are presented in the following subsections:

A. Binary Classification

In this section, we present the results of our experiments for Arabic trending topic relevance text classification using binary classification, as shown in Table VI and Fig. 3.

The results showed that the Logistic Regression classifier with the n-gram TF-IDF feature achieved superior classification performance. Specifically, the classifier attained a macro F1 (M-F1) score of 72% for the non-augmented dataset. On the other hand, applying the same feature with the SVC classifier resulted in the best classification performance for the augmented dataset. The classifier obtained a macro F1-score of 82%.

Likewise, the n-gram TF-IDF feature with the LR classifier and the word TF-IDF feature with the SVC classifier produced the highest precision (P) values of 71% on the non-augmented dataset. On the other hand, the n-gram TF-IDF feature with the SVC classifier achieved the highest precision value of 82% on the augmented dataset.

In terms of recall (R), the SVC classifier with the n-gram TF-IDF and character TF-IDF features yielded the highest recall of 74% on the non-augmented dataset, while the SVC classifier with the n-gram TF-IDF feature achieved the highest recall of 82% on the augmented dataset. Finally, the n-gram TF-IDF feature with the Logistic Regression classifier yielded the highest accuracy (A) of 76% on the non-augmented dataset, while the n-gram TF-IDF feature with the SVC classifier produced the highest accuracy of 82% on the augmented dataset .

B. Categorical Classification

In this section, we present the results of our experiments for Arabic trending topic relevance text classification using categorical classification, as shown in Table VII and Fig. 4.

The results showed that, using the Logistic Regression classifier with n-gram TF-IDF and word count features, as well as the SVC classifier with word TF-IDF, led to significantly better classification performance. These classifiers achieved a macro F1-score of 51% with the non-augmented dataset. On the other hand, the SVC classifier that utilized word, n-gram, and character TF-IDF features obtained the best classification performance on the augmented dataset. This classifier achieved a macro F1-score of 77%.

Likewise, the highest precision value of 51% was achieved with the SVC classifier using the word TF-IDF feature, and the

N-gram TF-IDF and word count features. On the other hand, the SVC classifier with word, n-gram, and character TF-IDF features obtained the highest precision value of 77% on the augmented dataset.

Likewise, the highest recall value of 61% was achieved using the character TF-IDF feature with the SVC classifier on non-augmented datasets, whereas, on augmented datasets, the highest recall value of 78% was obtained by the same classifier with word, n-gram, and character TF-IDF features. Additionally, the highest accuracy was attained using the SVC classifier with n-gram and character TF-IDF features of 71% on the non-augmented dataset, and the same classifier with word, n-gram, and character TF-IDF features of 78% on the augmented dataset.

V. Discussion

The main goal of this study was to create a benchmark dataset of tweets related to popular topics in Arabic social media. The dataset includes Relevance tweets in Arabic for both binary and categorical classifications. Based on the experimental outcomes, the manually annotated dataset can be utilized as a baseline for future research on Relevance Classification of Trending Topics in Arabic Tweets. As no benchmark dataset exists for classifying Arabic trending topic Relevance tweets, this dataset will prove beneficial to the research community once it becomes publicly accessible.

According to the statistical analysis, the non-augmented dataset had lower values for macro F1, accuracy, recall, and precision in its classification compared to the augmented dataset, which exhibited better results. Based on the findings of the previous section, it can be concluded that the use of data augmentation techniques has improved the classification results, leading to the highest macro F1 score of 82% in binary classification and 77% in categorical classification. The results achieved in the binary classification outperform the work in [6], This work is closest to our work as it also aimed to classify relevant tweets on Indonesian trending topics, and they achieved an F1 measure of 70%.

Machine learning techniques that employ N-gram features provide better results in classifying Relevance tweets within trending topic datasets than other features. Moreover, binary classification achieved superior results compared to categorical classification. Learning in categorical classification is comparatively less accurate than binary classification, as it is a more complex process.

VI. Conclusion and Future Work

This paper presents a novel Arabic dataset consisting of Relevance tweets for binary and categorical classifications, which will be available for public research. The process of tweet collection, manual labeling, and data augmentation for the dataset is described in details. We employed three classifiers, namely Naive Bayes, Logistic Regression, and Support Vector Machine, for Relevance Classification of Trending Topics in Arabic Tweets. The classifiers were trained using four types of features: count vector and TF-IDF (word-level, n-gram-level, and character-level). The study found that the performance varied depending on the classifiers and features used and that higher performance could be achieved with more annotated data. The Support Vector Machine approach was found to perform well for Relevance classification of Twitter content, with average macro F1 scores of 82% and 77% obtained in the binary and categorical datasets, respectively.

In future work, it would be valuable to explore the effectiveness of advanced deep learning techniques like convolutional neural networks, recurrent neural networks, and BERT for Relevance Classification of Trending Topics in Arabic Tweets. Moreover, extending the dataset to include a wider range of topics and domains and evaluating the generalizability of the proposed classification models across diverse datasets would be of interest.

Generative Adversarial Network-based Approach for Automated Generation of Adversarial Attacks Against a Deep-Learning based XSS Attack Detection Model

Rokia Lamrani Alaoui, El Habib Nfaoui
LISAC Laboratory, Department of Computer Science
University Sidi Mohamed Ben Abdallah, Faculty of Science Dhar El Mahraz, Fez, Morrocco

***Abstract*—Cross Site Scripting attack (XSS) is one of the most famous and dangerous web attacks. In XSS attacks, illegitimate technical methods are used by attackers to disclose sensitive data from web site users, which result in an important finance and reputation loss to the web site's owner. There exist numerous XSS attack countermeasures. Deep Learning has been shown to be effective when used to detect XSS attacks in HTTP web requests. Yet, Deep Learning models are inherently vulnerable to adversarial attacks, which aim to deceive the detection model into mis-classifying malicious HTTP web requests. Thus, it is important to evaluate the robustness of the detection model against adversarial attacks before its deployment to production in real web applications. In this work, we developed a Generative Adversarial Network (GAN) model for automated generation of adversarial XSS attacks against an LSTM-based XSS attack detection model. We showed that the detection model performance drops drastically when evaluated on the XSS instances, originally used in the model development, but modified by the GAN model. We also provided some guidelines to the development of detection models that can defend against adversarial attacks in the particular context of web attacks detection.**

***Keywords*—Deep learning; generative adversarial network; LSTM; web attacks; adversarial attacks; Cross Site Scripting attack**

I. Introduction

Organizations and enterprises are more concerned now than never before about the mitigation of cyber-attacks. Indeed, a successful cyber-attack can cause the enterprise an important financial loss and a reputation damage. Cross Site Scripting Attack is one of the most serious cyber-attacks that target web sites to compromise the confidentiality of the user's data. We distinguish three types of XSS attacks: Stored XSS attacks, Reflected XSS attacks and DOM(Document Object Model) XSS attacks, which consist of executing a malicious code that was injected into the database server, the web server response, or the DOM, respectively. Different methods are used to protect web applications from XSS attacks. However, XSS attacks are still ranked in the top 10 web vulnerabilities since 2017 [13]. Recently, more research works have been devoted to the use of Deep Learning to build Web Applications Firewalls. The results of these works are overall promising (e.g. [2], [4], [5], [6], [7], [8], [9]). Yet, few works have analyzed whether the proposed model is vulnerable to adversarial attacks. Indeed, Deep Learning models can be victim to adversarial attacks which may result in a significant drop in their classification performance. In the case of XSS attacks detection, adversarial attacks attempt to deceive the model into mis-classifying HTTP web requests, by generating HTTP web requests that resemble to normal HTTP web requests, but are in reality malicious HTTP web requests. In this paper, we proposed a Generative Adversarial Network (GAN) model for an automated generation of adversarial attacks against an LSTM-based XSS attacks detection model. The main contributions of our work is two fold:

- We conducted experiments to demonstrate the negative impact of adversarial attacks on the classification performance of an XSS attacks detection model that returned good results upon its evaluation on a public dataset.
- We proposed some guidelines to how to optimize the detection model to defend against adversarial attacks in the particular context of web attacks detection.

To this end, we followed the steps below:

1) We developed an LSTM model to detect XSS attacks. For that, we used a dataset A, and we recorded the classification results of the model on XSS instances.
2) We developed a Feed Forward Neural Network (FFNN)-based GAN model to generate adversarial XSS examples. For that, we used the dataset A and a dataset B.
3) We passed the XSS instances of the dataset A to the trained GAN model, and we obtained a set of XSS samples that we call carftedXSS.
4) We passed craftedXSS to the trained detection model, and we recorded the difference in the results obtained in this step and in the first step.

The remainder of the paper is divided into seven sections: Section II presents research works related to both XSS attack detection based on Deep Learning and, adversarial attacks against DL-based XSS attack detection models. Section III explains the basic concepts behind the present work. Section IV describes the development process of the XSS detection model and the adversarial attack model. Section V reports and discusses the experimental settings and results. Section VI provide some guidelines to the development of XSS attack detection models that have a good defense against adversarial attacks. Section VII review the contributions and the limitations of the present work and discusses potential future works.

II. Related Work

In this section, we will review research works related to DL-based XSS attack detection models as well as adversarial attacks models on DL-based XSS attack detection models.

A. XSS Attacks Detection Models

We find few research works about the detection of XSS attacks using Deep Learning models [1]. We cite the following papers [2], [3], [4], [5], [6], [7], [8], [9], and [10], which all use common Deep Learning models like GRU or LSTM based encoder-decoder, CNN, LSTM, DFFN, stacked generalization ensemble model, along with classical vectorization techniques, like word2vec, glove, fasttext, and n-gram, for the conversion of HTTP web requests to numerical vectors. According to the experimental results reported in the cited papers, the models achieve excellent classification results. Yet, the detection of XSS attacks is still challenging, which rises the question of what are the reasons behind the fine or zero utilization of the models proposed by the scientific community in real web sites and applications.

B. Adversarial Attacks Models

Independently of their application domain, Deep Learning models are known to be vulnerable to adversarial attacks. In the following, we present the research papers that have studied adversarial attacks on DL-based XSS attack detection models. [11] used greedy search to find the minimum number of transformations needed for the detection model to misclassify URLs. They showed that adversarial training can improve the model robustness by 7% while adversarial attacks undermine the model classification performance by 56%. [12] used reinforcement learning to build HTTP web requests that evade an XSS attacks detection model based on a pre-defined set of escaping rules. They also leveraged the adversarial attack model to improve the detection model defense capability. Indeed, after adversarial training, the detection model was able to detect 91.75% of XSS examples and miss out only 8%. [14] used a technique called Soft Actor-Critic (SAC) reinforcement learning algorithm to select the most appropriate strategies to build HTTP web requests that escape the XSS attack detection model. They showed that the adversarial model achieves an escape rate of more than 92%. [15] proposed an adversarial attack model based on a reinforcement learning algorithm (Soft Q-learning) to evade different XSS attack detection models. They experimentally showed that the proposed adversarial model bypassed the detection model in 85% of cases. While all existing research works propose a manual approach for creating adversarial attacks against XSS detection models, the present work use GANs model to automate this process. However, the semantic of generated XSS attacks is guaranteed in the manual approach more than in the automatic approach.

III. Background

A. Problem Definition

Deep Learning based XSS attack detection models can be used as part of Web applications Firewalls to protect web sites and applications from XSS attacks. Yet, because Deep Learning models are victim to adversarial attacks, the XSS attack detection model can yield a high false negative rate as it classifies malicious HTTP requests as normal requests. Before we dive into the approach we propose to demonstrate how adversarial attacks can deceive an efficient XSS attack detection model into mis-classifying XSS attacks as normal HTTP web requests, we will hover, in this section, the basic notions underlying our proposed approach.

B. XSS Attacks

In XSS attacks, the attacker injects malicious scripts in a way that allows him to steal sensitive information from users when they visit a web page or click on a link that includes the malicious code. There are three types of XSS attacks:

- Stored XSS attack: is triggered when the user visits a web page that includes a malicious code that was previously stored in the server database because of the lack of user input validation.
- Reflected XSS attack: occurs when the user clicks on a web link that contains malicious code, and the server sends back this code to the client in an HTTP response.
- DOM XSS attack: it does not involve the server, and it is completely handled by the Document Object Model to attack users.

C. Adversarial Attacks

An adversarial attack is an attack on data with the aim to deceive an already trained model or in training model. It introduces a subtle modification to the data so that a human eye could not notice the difference between the original and the noisy data, but causes the attacked model to output a wrong classification of the input data. Adversarial attacks can be classified into three main categories:

- Evasion: try to evade trained models by altering samples (e.g. HTTP web requests) so that the target model returns the wrong classification.
- Data Poisoning: attempt to contaminate training dataset such that the learning process of the model is undesirably impacted. For instance, after the training phase, the model would learn the wrong features that characterize for example malicious HTTP web requests. As a result, it would classify as normal HTTP web requests what it should be classified as malicious.
- Model extraction: aim at extracting the maximum of information about the model properties in order to rebuild the model and use it for personal use or as part of an adversarial attacks model.

Attackers usually target white-box or black-box threat model when they run an adversarial attack. In white-box model, the adversary knows the model's parameters and can get the classification of input data. In black-box model, the attacker can also acquire labels for input data but he does not know the model's parameters and structures.

D. Generative Adversarial Networks

Generative Adversarial Networks (GANs) are Deep Learning based generative models. Unlike discriminative models, which assign a class label to each input data, generative models objective is to create data that maintains the statistical input data distribution.
GAN was first described by [16] and formalized by [17] in a standardized approach called Deep Convolutional Generative Adversarial Networks (DCGAN). Most GANs that are proposed nowadays are based on DCGANs.
GANs are basically composed of two sub-models (Fig. 1):

- Generator model: generates new samples from the problem domain.
- Discriminator model: classifies the generated samples as fake or real.

The generator and discriminator models are, in general, trained separately. The discriminator is trained until it reaches a high classification performance, and then the generator is trained until the discriminator classifies as real a high percentage of fake samples. After the training process, the discriminator model is discarded and the generator model is kept. In the context of adversarial attacks, the GAN model is usually composed of:

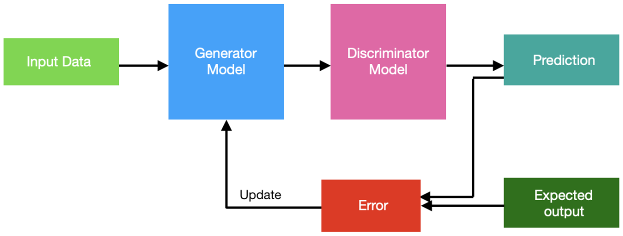

Fig. 1. GAN architecture.

- The generator model that can be any Deep Learning based model.
- The discriminator model that is the attacked model.

In this case, the generator model is trained with the purpose of generating adversarial samples that can evade the discriminator model (or the attacked model), which results in a misclassification of potential XSS attacks.

E. Deep Learning and LSTM Neural Network

Deep Learning is a subfield of machine learning that makes predictions on data based on deep features extraction. Long Short Term Memory or LSTM is a well known neural network especially used in sequence prediction problems. It is a variety of recurrent neural networks (RNNs) that are capable of learning long-term dependencies. It was proposed by [18] to resolve the vanishing and exploding gradients problem inherent to the use of RNNs. Fig. 2 describes the basic functioning of LSTMs. They consist of a four types of gates: the forget gate (f_t), the input gate (i_t), the cell gate (g_t) and the output gate (o_t). LSTM uses these cell gates and associated activation functions, to decide what to retain and what to forget. The following equations describe the calculations performed at each gate, where W_f,W_i,W_g,W_o are the weight matrices for the forget gate, the input gate, the cell gate, and the output gate, respectively while b_f,b_i,b_g,b_o are the corresponding bias:

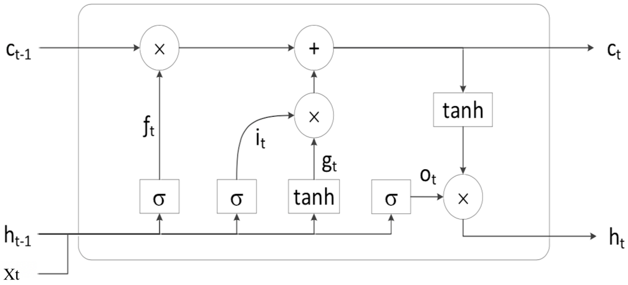

Fig. 2. LSTM architecture.

$$f_t = \sigma(W_f \cdot [h_{t-1}, x_t] + b_f) \quad (1)$$

$$i_t = \sigma(W_i \cdot [h_{t-1}, x_t] + b_i) \quad (2)$$

$$g_t = tanh(W_g \cdot [h_{t-1}, x_t] + b_g) \quad (3)$$

$$o_t = \sigma(W_o \cdot [h_{t-1}, x_t] + b_o) \quad (4)$$

$$c_t = f_t \cdot c_{t-1} + i_t \cdot g_t \quad (5)$$

$$h_t = o_t \cdot tanh(c_t) \quad (6)$$

F. Word Embedding: Word2vec

Word embedding is the technique that allows for the application of deep learning models to textual classification problems, as it transforms words to fixed-size numerical vectors. Word2vec is one of the most commonly used word embeddings techniques. CBOW and skip-gram are the main implementations of word2vec. They consist of a Feed Forward Neural Network composed of an input layer, a hidden layer, and an output layer. The CBOW model predicts the contextual words given the main word, while the skip-gram model predicts the target word given the surrounding words.

IV. Proposed Method

A. Overview

Fig. 3 presents an overview of the proposed model architecture. Overall, The GAN model takes as input XSS attacks instances - that the XSS detection model would classify as such if they were not altered by the GAN model-, and then creates a corresponding XSS attack instances, that the detection model could not recognize as such, resulting in a mis-classification of XSS attacks as normal HTTP web requests. In Section V-E, we provide some concrete examples of XSS attacks generated by the GAN model.

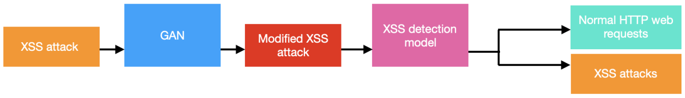

Fig. 3. Overview of the proposed model architecture.

B. XSS Attacks Detection Model

We developed an LSTM neural network to classify HTTP web requests into normal and XSS attacks. It was trained using a dataset A that contains XSS attacks and normal HTTP web requests. We used Word2vec to transform the HTTP web requests into numerical vectors. The choice of LSTM is justified by the fact that the majority of research works about adversarial attacks against Deep Learning based XSS attack detection model, have also selected the LSTM model, which leave a possible space for comparison. Fig. 4 describes the proposed XSS attack detection model.

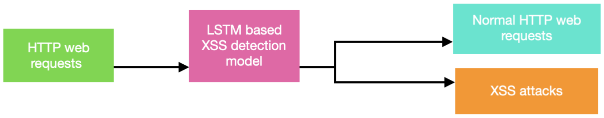

Fig. 4. XSS attacks detection model.

C. Adversarial Attacks Model

Fig. 5 show that the adversarial attacks model is a Feed Forward Neural Network that takes as input HTTP web requests, and then creates a modified version of the same HTTP web requests, which are then passed to the detection model. The adversarial attacks model is constantly updated until the detection model can barely recognize XSS attacks. The adversarial attacks model is developed based on a dataset B that contains XSS attacks from the dataset A and another dataset C that contains XSS instances only.

V. Experiments and Discussions

In this section, we present and discuss the settings and results of the experiments conducted in the present work.

TABLE I. XSS Attacks Detection Model Results

Classification results of the LSTM+W2V model	
F1-score	0.98
Accuracy	0.98
Precision	0.98
Recall	0.98
AUC	0.98
FNR	0.002
FPR	0.02

A. Dataset

For the development of the LSTM-based XSS detection model, we used xssed, a public dataset available on GitHub [12], built specifically for XSS attacks. It contains 33428 XSS attacks and 31428 normal HTTP web requests. We splitted the dataset into three balanced sets; the training set, the validation set and the test set, which we used to train the model, tune the model hyper-parameters, and test the model, respectively. As for the adversarial attack model, we collected XSS attacks from the xssed [12] dataset and we added the XSS attacks listed in the online XSS cheat sheet available at [19]. We obtained a dataset of 41542 XSS attacks examples. We splitted the dataset into two sets; the training and the validation sets which are used at the training phase. As for the testing set, it is composed of the XSS attacks contained in the xssed dataset (33427 example), and we used it to evaluate the detection model capability to identify XSS attacks before and after the modification introduced by the GAN model.

B. Performance Indicators

We used traditional performance metrics, namely accuracy, recall, precision, F1-score, AUC, False Positive Rate (FPR), and False Negative Rate (TNR), to evaluate the classification performance of the XSS attack detection model. As regards the adversarial attacks model, we referred to the following indicators to assess its performance:

- DR (detection rate): DR is the ratio of the number of XSS instances that are still classified as XSS examples by the XSS attack detection model to the total examples of XSS attacks.
- ER (escape rate): ER is the ratio of the number of XSS instances classified as normal by the XSS attack detection model after being modified by the adversarial attack model to the total examples of XSS attacks.

C. XSS Attacks Detection Model Results

Table I reports the performance results of the XSS attack detection model. The results indicate that the LSTM-based XSS attacks detection model achieves a high detection accuracy with a low false negative rate (0.002).

D. Adversarial Attacks Model Results

Table II shows that the GAN-based adversarial attack model escape the detection model in 100% of cases (or the detection rate of the detection model is 0%). Because the adversarial attack model uses a large vocabulary, the generated XSS attacks contain a vocabulary that is unknown to the

TABLE II. ADVERSARIAL ATTACK RESULTS

DL Model	Detection rate	Escape rate
LSTM based XSS detection	0	1

detection model as well as the vocabulary that appeared in normal HTTP web requests. Also, the detection model does not account for the semantic of the HTTP web requests. These two factors maximize the escape rate because generated XSS attacks are judged normal HTTP web requests by the detection model. However, this does not mean that the generated XSS attacks if executed will be successful, it will depend on whether they are semantically correct.

E. Examples of Generated XSS Attacks

In this section, we show some examples of XSS attacks generated by the GAN model. Listing 1 shows the original XSS instances, while Listing 2 shows the modified XSS instances. We can clearly see that the generated XSS example widely differ from the original one although it is composed of a vocabulary that is recognized by the detection model. Also, the generated XSS example is not semantically correct as it includes invalid HTML tags. Moreover, the generated XSS example contains some suspicious keywords such as "alert", or "fromcharcode" that appear only in malicious HTTP web requests. Although the human-eye can easily classify the generated instance as malicious, the detection model failed to output the correct classification label.

Listing 1: original XSS instances

```

VI. GUIDELINES

Adversarial attacks constitute a real danger to the reliability of Deep Learning models. In particular, if the Deep Learning model is used to secure a web application, adversarial attacks can increase the false negative rate which results in a low detection rate of XSS attacks. Based on the outcome of this work, we advise the following guidelines to the development of a detection model that has a good defense against adversarial attacks:

- The HTTP web request should be decoded into its original form. Indeed, web attackers obfuscate HTTP web requests by using different encoding techniques.
- The detection model should be trained on a large dataset that include the maximum number of HTML and JavaScript tags.
- The detection model should not restrict its classification decision to the lexical words that compose the HTTP web request, but also include the semantic validity of HTTP web requests.
- The detection model should discard any HTTP web request that exceeds a certain threshold of unknown words.
- It is important to include adversarial learning in the development process of the detection model in order to optimize its defense against adversarial attacks.

VII. CONCLUSION, LIMITATIONS AND FUTURE WORK

In this work, we developed a GAN-based adversarial attacks model to generate adversarial examples that can bypass an LSTM-based XSS attack detection model. The results of our experiments show that the detection model performance drops drastically when comes to the classification of adversarial XSS examples. Indeed, while the detection model classified correctly 32904 out of 33427 XSS attacks, it could not classify correctly any of the corresponding adversarial examples. Moreover, we provided some guidelines to optimize the defense of XSS attack detection models against adversarial attacks. The present work presents the following limitations:

- The adversarial model can not guarantee the semantic validity of the generated adversarial XSS examples.
- Although the proposed adversarial attacks model is applicable to other Deep Learning models, it was applied to only LSTM models.

As future work, we are going to improve the adversarial attacks model in order to generate XSS attacks that are semantically correct.

A Review on Machine-Learning and Nature-Inspired Algorithms for Genome Assembly

Asmae Yassine, Mohammed Essaid Riffi
LAROSERI Lab-Department of Computer Science, Chouaib Doukkali University, Morocco

Abstract—**Genome assembly plays a crucial role in the field of bioinformatics, as current sequencing technologies are unable to sequence an entire genome at once where the need for fragmenting into short sequences and reassembling them. The genomes often contain repetitive sequences and duplicated regions, which can lead to ambiguities during assembly. Thus, the process of reconstructing a complete genome from a set of reads necessitates the use of efficient assembly programs. Over time, as genome sequencing technology has advanced, the methods for genome assembly have also evolved, resulting in the utilization of various genome assemblers. Many artificial intelligence techniques such as machine learning and nature-inspired algorithms have been applied in genome assembly in recent years. These technologies have the potential to significantly enhance the accuracy of genome assembly, leading to functionally correct genome reconstructions. This review paper aims to provide an overview of the genome assembly, highlighting the significance of different methods used in machine learning techniques and nature-inspiring algorithms in achieving accurate and efficient genome assembly. By examining the advancements and possibilities brought about by different machine learning and metaheuristics approaches, this review paper offers insights into the future directions of genome assembly.**

Keywords*—*Artificial intelligence; genome assembly; machine learning; bioinformatics; bio-inspired algorithms

I. Introduction

DNA, short for Deoxyribonucleic acid, is a macromolecule that contains the genetic instructions for the development, functioning, and reproduction of all living organisms. It consists of two strands that form a double helix structure [1]. The four nucleotides—adenine (A), cytosine (C), guanine (G), and thymine (T)— make up the building blocks of DNA. The sequence of these nucleotides determines the genetic code. DNA carries the hereditary information passed from parents to offspring, containing genes that encode proteins and regulate various biological processes. DNA replication ensures that each new cell receives a complete copy of the genetic material during cell division.

Advances in DNA sequencing technologies have revolutionized biological research, enabling the analysis of DNA sequences on a large scale. DNA sequencing helps unravel the genetic code, identify mutations, study genetic variations, trace evolutionary relationships, and diagnose genetic diseases. DNA plays a central role in fields such as genomics, evolutionary biology, genetic engineering, forensic science, and medicine. It serves as a foundation for understanding the complexities of life, exploring the diversity of species, and developing innovative approaches [2] for disease treatment and prevention.

To determine the DNA material code within specific living organisms, the DNA sequencing is utilized for the identification and characterization of genes within an organism's genome. By determining the sequence of genes, researchers can analyze their functions, regulatory elements, and evolutionary history. Genome assembly is the computational process that comes after sequencing and aims to align reads of a DNA sequence into the correct order to reconstruct the original structure of the genome [3].

The novelty of this review stands out for its in-depth analysis of the most important advancements and challenges involved in genome assembly. By achieving a synthesis of findings from multiple research studies, the review presents a comprehensive survey of the current state of the machine-learning and nature-inspired genome assemblers, while also evaluating the recent bio-inspired techniques and providing recommendations for future research. This gives researchers insightful information and direction about the latest techniques and approaches used in this rapidly growing field. Thus, this study remains as an exceptional and valuable contribution to the existing literature.

The work in this paper is organized as follows: Section II presents an overview about the genome assembly. Section III describe machine-learning techniques used in DNA sequence assembly. Section IV introduce de novo assemblers. Section V review nature-inspired algorithms and metaheuristics solving the genome assembly problem and their best computational results. Section VI provide a discussion and analysis of the findings, proceeded by a conclusion in the last section.

II. Genome Assembly Overview

The DNA genome assembly is one of many bioinformatics problems that uses machine learning technologies and nature-inspired approaches and metaheuristics in aim to be solved. When sequencing the genomes of bacteria, viruses, or humans, this problem is extremely important; it occurs during the final stage of DNA reading, particularly for long strands of DNA. Large strands are repeatedly broken into several little fragments. After that a computer program will assemble together the fragments into a string that matches the original DNA sequence. Finding an organism's DNA sequence is helpful for both applied and fundamental study into how and why they live. Given the significance of DNA to living organisms, understanding a DNA sequence could be helpful in almost any biological study. For instance, it can be applied in medicine to locate, identify, and potentially develop cures for and genetic diseases. Similar to how pathogen research may result in medicines for infectious diseases and virus transmissions. Due to the rapid advancements in sequencing technologies and the increasing demand for sequencing services, various sequencing platforms have become extensively utilized in recent years. As a consequence, sequence assembly has emerged as a critical process with diverse applications in the field of bioinformatics [4]. Consequently, the significance of efficient DNA assemblers has escalated, as they play a pivotal role in reconstructing complete genomes from fragmented sequencing data

III. Machine Learning Techniques

McCarthy et al. suggested in the summer of 1956 in a conference at Dartmouth College, that computers could be programmed to think and reason. They referred to this idea as artificial intelligence (AI) [5] a field used to the simulation of human intelligence processes by computer systems. Machine learning (ML) is a specific method to achieve this goal which include deep learning (DL) and artificial neural networks (ANN) methods [6].

Machine learning is used in DNA sequence assembly for pre-grouping reads into similar groups before the assembly process is carried out and it was proven that is an alternate method for lowering the overall computational complexity of the genome assembly process. In [7] the authors suggested building a recurrent neural network (RNN), where the goal is to train the network to track the sequence of bases that constitute a given fragment and assign all of the sequences that are properly tracked by this network to the same cluster [7]. This machine learning method applies a three-layer RMLP (Recurrent Multi Layer Perceptron) neural network with five input nodes dedicated to the five possible incoming symbols (A, C, G, T, and N) in the first layer, a hidden layer of 27 nodes, and four output nodes for the output layer in the forecast of the next base of the sequence created by the network [7]. The experimental results obtained after comparing the proposed neural network method with another conventional algorithm have shown that if performed on multiprocessor machines, the proposed procedure may prove to be less expensive than ones that are currently used. Any assembly method may be employed in place of the CAP approach, which greatly improves its efficiency and yields superior outcomes. While employing various definitions of distance, the two approaches produce collections of fragments with more or less comparable properties. The authors also indicated [7] that their proposition is richer due to the fact that is based on the internal structure of the strings rather than just topological similarities.

The author [8] also proposed the construction of an artificial neural network based binning of reads to assist assembly process. After producing the required reads for assembly using a simulated shotgun sequencing technique. Four assembly techniques were then simulated : The greedy assembler, the de Bruijn assembler, the greedy neural network assembler, and the de Bruijn neural network assembler. In order to determine which of these assembly procedures provided the maximum coverage accuracy and with what level of computational complexity, simulations were performed. The research also looks into the advantages of combining the greedy and de Bruijn assembly algorithms with a "divide and conquer" strategy the greedy assembler's computational efficiency could be significantly improved. The author in [8] proposed in future work to investigate strategies of reducing the complexity associated with the training and grouping process and to take advantage of the parallelisable nature of the neural network grouping scheme.

The study in the paper [9] offers two techniques for separating sequencing method errors from natural variance. The first is an analytical technique for choosing appropriate error candidates. In order to identify the bases that are uncommon within fuzzy grouped clusters of closely related sequences, it applies similarity weights between pairs of sequences. The chosen candidates are then filtered using a classification model built using a suitable ML technique and rests on frequency vectors [9]. Both the usage of weights and the ML-based regrouping were proven to greatly reduce the set of potential errors, without missing simulated faults along the way for artificial neural networks and the Hoeffding tree classifier. The performance of the RIPPER rule learner and random forest classifier, however, drastically declined. On hexaploid wheat, the ML-based models showed raw accuracy high enough to imply that they might be utilized independently of the analytical approach for error discovery. According to the authors it was demonstrated that applying the ML model as an additional filter while calling variants significantly changes the results. Further validation were needed to validate the results achieved on hexaploid wheat.

IV. De-Novo Assemblers

Three major strategies are widely used for the novo assemblers in Bioinformatics to solve the DNA Assembly Problem: greedy graph-based algorithms, de Bruijn graphs, and the overlap-layout-consensus (OLC) approach mainly adopted by the nature-inspired algorithms presented in Section V.

De novo gene assemblers have no reference genome for assembling DNA sequences and they are classified into two types: Greedy-based De-novo assemblers Graph-method assemblers: String and DeBruijn. Several graph based common algorithms were used for genome sequence assembly CAP3 [10], PHRAP [11] , TIGR [12].

Authors in [13] suggested a novel DNA sequence assembly approach that combines the advantages of shotgun and sequencing by hybridization (SBH). The technique makes use of the high coverage and low error rates in sequencing made available by the development of efficient DNA sequencing machines. The authors were proceeding in the development of full software with all the characteristics stated in [13] .They created a prototype that incorporates some of the algorithm's fundamental components, and utilized this prototype to put together synthetic sequencing data. They presented results of such an experiment, mostly as a demonstration of concept for their methodology and based on their preliminary investigations [13], the algorithm promises to be very fast and practical for DNA sequence assembly.

A novel EULER algorithm have been designed in [14] and for the first time fixes the repeat problem in fragment assembly. The primaly goal of the authors was the fragment assembly's reduction to a variant of the standard Eulerian path problem, which makes it possible to produce precise answers to complex sequencing issues. In contrast to the CELERA assembler [15], EULER utilizes such repeats as a strong fragment assembly tool rather than masking them. Based on the de Bruijn graph concept. In order to explain their method, they adopted the DNA sequence as a thread with repeated sections attached together by glue. Every repeat in the resulting de Brujin graph having five edges [14], corresponds to one edge rather than a group of vertices in the layout graph.

In [16] the authors presented the ARACHNE computer system, which uses paired-end whole-genome shotgun reads to assemble genome sequences. The key characteristics of ARACHNE include an effective and sensitive method for detecting read overlaps, a method for scoring overlaps that achieves high accuracy by fixing errors prior to assembly, read merger using forward-reverse links, and identifying repeat contigs by forward-reverse link inconsistency.

ARACHNE begins by identifying and aligning overlaps, or pairs of reads that appear to be overlapping. In later rounds, some of these false overlaps caused by repeated sequences in the genome will be removed [16]. An effective overlap detection is achieved. The program utilizes a sort and extend technique that scales about linearly rather than comparing every pair of reads. This method entails creating a sorted table of each k-letter (k-mer) and its source so that related k-mers appear successively. The algorithm next eliminates highly frequent k-mers, which often correlate to highcopy, high-fidelity repetitive sequences in the genome, in order to improve the effectiveness of the overlap detection procedure. After identifying all read pairs that share one or more overlapping k-mer, the algorithm applies a three-step procedure to effectively align the reads. First, overlapping shared k-mers are combined. Next, shared k-mers are extended to alignments. Finally, dynamic programming is used to enhance the alignments. In a similar manner, ARACHNE corrects random insertions and deletions caused by apparent sequencing errors [16]. The alignments are modified in accordance with how the reads are adjusted.

Simulated reads that covered many genomes order have been generated to evaluate ARACHNE. These simulated reads' assemblies produced virtually full coverage of the corresponding genomes, with a few contigs combined into even fewer supercontigs (or scaffolds) [16]. Contig coverage after genome assembly ranged between 97 and 98 percent, with at least 92 percent of the reads being used in every case. For full coverage, the N50 contig length is 350 kb, whereas for half coverage, it is 17 kb. The length of the N50 supercontigs varies significantly within the genomes.

The authors precised that assembly accuracy was good, but it wasn't perfect due the fact that there were a very small number of additional misassemblies and little errors happened about once every 1 Mb. Assembling the Drosophila genome was quick, requiring only 21 hours on 8.4 Gb of RAM in a single 667 MHz processor.

In this work [17], the authors developed Velvet a novel collection of de Bruijn graph-based sequence assembly methods for very small reads. The main objective of the approach is both remove errors and resolve large number of repeats repeats in the presence of pair read information. The error correction technique initially merges sequences that belong together, and the repetition solver then separates path that share local overlaps. Authors have evaluated Velvet using both simulated and real data [17]. The algorithm has the potential of assembling bacterial genomes with N50 contig lengths of up to 50 kb and simulations on 5-Mb portions of large mammalian genomes with contigs of 3 kb using only relatively small paired simulated reads. The two other short read assemblers, SSAKE [18] and VCAKE [19], were compared to Velvet. The algorithms are different from one another mostly in how they handle errors. By looking for reads in a hash table, SSAKE and VCAKE automatically explore a de Bruijn graph in a step-by-step manner. Velvet is considerably faster and generates larger contigs without misassembly, but it takes a little bit more memory. Furthermore, it has great precision and covers a significant part of the genome. The authors attempted to use EULER [14] and SHARCGS [20], but the tools were unable to handle their data sets. According to authors, this was most likely because the differed expected input, notably in terms of covering depth and read lenght.

Building on earlier works [21] [14] the authors in [22] developed MULTIBRIDGING a de Brujin graph based assembly algorithm for shotgun sequencing under the criterion of complete reconstruction, which can achieve very close to the lower bound for repeat statistics of a variety of sequenced genomes, including the GAGE datasets. As results assembling the repeat statistics of hc19, have shown successful reassembling desired with probability 99%.

The La Jolla Assembler (LJA) [23] a fast algorithm with three modules that address the three challenges in assembling HiFi reads: jumboDBG (constructing large de Bruijn graphs), multiplexDBG (using the entire read-length for resolving repeats), and mowerDBG (error-correcting reads), was designed to enable automated assemblies of long, HiFi reads. The Bloom filter [24], sparse de Bruijn graphs [25], disjoint generation [26] and rolling hash [27] were all used in the jumboDBG approach. LJA builds the de Bruijn graph for huge genomes and large k-mer sizes and turns it into a multiplex de Bruijn graph with changing k-mer sizes, reducing the error rate in HiFi reads by three orders of magnitude. The suggested approach not only produces five times fewer misassemblies than state-of-the-art assemblers, but also generates more contiguous assemblies. In the publication, the automated assembly of a human genome which successfully assembled all six chromosomes was used to illustrate the usefulness of LJA.

V. Nature-inspired Algorithms for Genome Assembly

Nature-inspired optimization algorithms is defined as a group of algorithms that are inspired by the behavior natural systems, including bio-inspired algorithms , swarm intelligence and evolutionary algorithms. Inspired by animal, insects behaviors, biology and chemical reactions, those algorithms have provided many engineering, medical and bioinformatics solutions such as solving the DNA Fragment Assembly Problem. The genetic assembly is a critical step in any genomic project, it attempts in reconstructing a DNA sequence from a set of a large number of fragments taken obtained by biologists in the laboratory. DNA Fragment Assembly Problem is known to be an NP-hard combinatorial optimization problem, therefore efficient approximate metaheuristics are required to solve such kinds of problems. The purpose of the study presented in this section is to analyze and synthesize the existing nature-inspired optimization algorithms in for genome assembly. Since the genome assembly is a particularly difficult problem in computational biology due to the problem's NP-hardness, the ideal solution cannot be found. So, it necessitates the use of metaheuristics and other computational techniques of intermediate complexity. Which their goal is to compare all possible solutions to an optimization problem in order to choose the best (feasible) one. They evaluate prospective solutions and perform a number of operations on them in an effort to find better alternatives in order to accomplish this.

As genome assembly is a combinatorial optimization problem, different nature inspired algorithms and metaheuristics have been proposed in past few decades to solve this problem. The process of these metaheuristics involves the reconstruction of the original genome sequence from a set of fragments (reads) aligned in a correct order by exploring a large solution space. Numbers from 1 to N are assigned to the set of fragments, where N represents the total number of fragments. By reordering this list of numbers using the fitness function, the algorithm aims to find the optimal order that reconstructs the complete genome sequence through a process of iterative optimization.

Generally an incremental solution of a metaheuristic algorithm for DNA fragment assembly is described as follows: The algorithm starts by setting up parameters and creating an initial assembly of DNA fragments. To assess the quality of the assembly, a fitness function is established. In the case of genome assembly the fitness function involves maximizing the fragment's scores obtained through semi-global alignment of the DNA fragments. The metaheuristic algorithm proceeds with iterations, each aimed at optimizing the assembly step by step. In each iteration, the current assembly is perturbed to explore neighboring solutions in the search space. The algorithm decides whether to accept the newly generated solution or keep the previous one based on a specific acceptance criterion for each iteration. As the algorithm progresses through iterations, the incremental assembly continues to integrate improvements made in previous steps. The process is considered final when the algorithm reaches a near-optimal solution or fulfills the desired quality standards, the stopping criterion is based on predefined conditions, such as a fixed number of iterations or convergence of the fitness function.

Many Swarm Optimization algorithms have evolved the fragment assembly problem: [28], [29], [30], [31] Cuckoo Search algorithm [33] Harmony Search algorithm [34] hybrid crow search algorithm [35], Cat Swarm Optimization [36], etc. A total of 30 publications on nature-inspired optimization algorithms dealing with DNA genome assembly have been reviewed as shown in Table I.

A. Swarm Intelligence Algorithms

Verma et al. have proposed the DSAPSO method [28] to resolve the DNA sequence assembly problem using Particle Swarm Optimization (PSO) with Shortest Position Value (SPV) rule. To convert the continuous version of PSO to discrete version SPV rule is used in solving the DNA sequence assembly problem wich is a discret problem. The proposed methodology outperforms the genetic algorithm (GA) for every DNA data set, according to the results of a comparison of the DSAPSO results with those of the GA.

By maximizing the overlapping-score measurement, a hybrid particle swarm optimization VNS-based local search approach for solving the DNA fragment assembly (DFA) problem is proposed in [31]. To make PSO appropriate for DFA, the particles are encoded using the lowest position value (SPV) rule. During the PSO search process, VNS local search is used to enhance the quality of the globally best solution generated from the PSO algorithm. The results demonstrated that the algorithm can significantly outperform other PSO-based algorithms with different-sized benchmarks in terms of overlap score.

In other research [32], the same authors suggests a novel memetic GSA method called MGSA in order to solve DNA FAP problem. The overlap-layout-consensus model known as MGSA is based on tabu search for population initialization. This algorithm uses an SPV rule to convert continuous position values into job sequences, initializes the population with a tabu search, and then uses simulated annealing with VNS as the local search method to improve the quality of the best global solution produced by the GSA algorithm.These modifications create a balance between exploitation and exploration. The simulation results show that the algorithm MGSA maximizes the overlap score of 19 benchmark instances, however its disadvantage is requiring more processing time than the current techniques. In order to resolve this issue, the authors want to take into account DNA sequence compression, fuzzy entropy and adapting the MGSA strategy to the de-Bruijn-graph (DBG) model in future works in order to decrease the computation time.

Adaptive Particle Swarm Optimization was proposed in [30] and the experimental results of study on the impact of inertia weight and the cognitive and social components for enhancing the PSO efficiency to obtain the optimal fitness score, were presented with the simulation of three methods: The PSO with constant inertia weight (CIW), PSO with dynamically varying inertia weight (DVIW) and APSO.

The paper [37] presents a new particle swarm optimization and differential evolution approach using the SPV rule to convert the continuous variables used in PSO and DE to the permutation required to solve the FAP. The authors have conducted four different experiments The purpose of Experiment 1 was to evaluate the PPSO+DE algorithm with those that performed the best on the sixteen typical benchmarks. The Lin-Kernighan method was used in Experiment 2 to tackle each of the sixteen benchmark issues utilizing the TSP approach. The results of the Lin-Kernighan algorithm were used to determine the best solutions in Experiment 3. In Experiment 4, the Staphylococcus aureus COL Main Chromosome test data was used to test the TSP technique.

In this study [38], the authors suggested a new approach to solve the sequence assembly problem using Particle Swarm optimization (PSO) with Naive crossover and shortest position value (SPV) rule. There are two phases in PSO with Naive Crossover with SPV: The initialization phase, where individuals are initialized, and the update phase, where new solutions are generated and updated. The real coded values are converted to discrete values using SPV rules. According to the authors, the DNA sequence assembly utilizing PSO algorithm with naïve crossover (DSAPSONC) has demonstrated the effectiveness in solving the sequence assembly problem.

In order to effectively solve the fragment assembly problem, a new DPSO method that operates directly in the search space of permutations has been proposed [39]. The Probabilistic Edge Recombination (PER) operator is the main element of the suggested approach. Through the probabilistic recombination of edges connecting adges from current position, the personal best, and the group best, this operator creates an alternate position. In this probabilistic construction, the utilization of overlap lengths between fragments has also been taken into consideration. With this purpose, memetic algorithms with a new fast variant local search of PALS known as quick-PALS were developed to improve the intensification potential. To show the efficiency and potency of the employed algorithms, two sets of validation experiments have been performed. The authors claim that when compared to present in litterature assembly techniques, the algorithms performed better.

A new PSO variation was suggested in [40] that uses chaos, levy flight, and adaptive parameters to solve the genome sequencing problem which is transformed into a discrete optimization problem while using the SPV rule. The proposed algorithm incorporates chaos in two distinct ways: applying chaotic inertia weight and chaotic initialization. To ensure the balance between exploitation, which is encouraged by a lower inertia weight, and exploration, which is encouraged by a bigger inertia weight, a chaotic inertia weight was applied. The production of particles through using Levy, chaos and refinement Flight ensure that the particles are initialized with a high fitness score. The chaotic initialization provides favorable circumstances for discovering better values [40]. For the four datasets studied in the paper, the Chaotic Particle Swarm Optimization with Levy Flight performs better than other PSO variations by 7% to 24%. When compared to other algorithms on the basis of Standard Deviation, the proposed approach does not, however, demonstrate a significant improvement. It has a higher ranking but inconsistent performance. To solve this issue the authors suggests to used alternative PSO algorithm versions in future.

This study [33] presents the Cuckoo Search Algorithm (CS) as a novel optimization approach for genome sequence assembly, inspired by the behavior of cuckoos. CS incorporates levy flight and brood parasitic behavior, mimicking the process of cuckoos laying eggs in host nests. The algorithm is a population-based search procedure widely applicable to complex optimization problems. These birds lay their eggs in the nests of other birds and use various strategies to increase the chances of their eggs hatching. The algorithm models this behavior by representing each solution as an egg and using Levy flight to generate new solutions. The algorithm follows three main rules: -Each cuckoo lays one egg at a time in a random nest -Only the nests with high-quality eggs are preserved, - Hosts have a probability of discovering alien eggs and can either remove them or abandon their nests. Various algorithm settings are analyzed to determine the most effective configuration, and CS's efficiency is evaluated against PSO and its variants.

In this study [41], a hybrid cuckoo-search genetic algorithm (CSGA) was suggested as a nature-inspired swarm optimization algorithm. The total assembly time and the number of reorientations during the assembly process are taken into account by the cost criterion for optimization. An example assembly with 19 components has been shown to demonstrate how the CSGA is applied, and the results have been compared with those of the Genetic Algorithm (GA). According to the findings, the CSGA algorithm not only generates optimal assembly sequences for the given problem at costs equivalent to those of GA, but it has also been discovered to have a faster convergence rate than GA.

The study [42] introduces subsequence-based matching techniques using the CS and PSO algorithms. These methods were implemented in Java and utilized MapReduce for Hadoop. The experimental results validate the effectiveness of the proposed techniques, showcasing their ability to achieve extensive DNA fragment coverage and high matching accuracy. Furthermore, the performance analysis reveals that the CS algorithm outperforms the PSO algorithm in terms of overall performance.

B. Simulated Annealing based Algorithms

Simulated annealing is a computing technique that seeks for the optimal solution by using randomness. It's inspired from a related technique called Annealing in Metallurgy which mimics the physical solid annealing process where a glass material or metal is heated to a high temperature and then allowed to cool. The authors in [43], [44] have introduced and applied methods solving the DNA fragment assembly problem with the addition of the inversion and transposition operators to a simulated annealer by [45] the performance have successfully been increased. These studies generally raise a variety of other important issues, particularly those relating to the significance of solution space redundancy and the synergistic interactions between the various operators [46].

In this paper [47], a parallel models of Simulated Annealing (SA) was proposed combined with Genetic Algorithm (GA) for solving the DNA fragment assembly problem. They employed SA as a local search method within the GA framework. The experimental results demonstrate that the parallel approach improves the quality of solutions while reducing the overall runtime. Comparing the execution times, SA outperforms GA by being faster. However, SA tends to produce worse fitness values compared to GA In this paper [48], Simulated Annealing-based local search have been utilized to improve the final solution obtained by the Chemical Reaction Optimisation (CRO) algorithm in solving the DNA fragment assembly problem. The CRO approach is used in seeking for the best layout where the objective function is minimized. The main process of the algorithm starts with setting valued to the control parameters after the determination of the initial population. Then one of the four collisions of the CRO algorithm is performed in each iteration. After any new minimum fitness value is checked and saved. After that, to retain the diversity of the population the worst 20 percent of the population is replaced with new solutions. When no amelioration has occured, the simulated annealing method is used in order to enhance the best solution found.

SA maintains at the same temperature for a period of time while a predetermined number of iterations are set. Then, the heat becomes colder. One of the following three operators is chosen for each iteration [48]:

1) Inversion: Two points are chosen at random for this operator [48]. Then, between them, the order of the fragments is reversed.

2) Specific inversion: One contig's orientation is reversed. To do this, a permutation point is randomly chosen, and the contig containing this fragment is identified. The fragments in the chosen contig are then rearranged in reverse order [48].

3) Transposition: This operator [48] shifts a contig to a new position between two points in different distinct nearby contigs that are selected for the contig movement.

The experimental results in the paper [48] have shown that combining CRO and SA have lead to the highest overlap scores.

C. Local Search based Algorithms

In this paper [49], the authors have presented PALS (Problem Aware Local Search) a fast and accurate local search algorithm that, after comparing its results with commercially available assemblers Phrap and CAP3, pattern matching algorithms (PMA) and genetic algorithms (GA), it have shown to be competitive against those present specialized assemblers. They also explored the effect of many alternative approaches on the efficacy of the suggested algorithm. The main objective of PALS algorithm is to obtain one single contig by finding a fragment's order that minimizes the number of contigs, which is different from the other assembling algorithms that aim to search for solutions having in the layout maximum overlap between adjacent fragments . The three main methods of the PALS algorithm are [49]:

- GenerateInitialSolution method: Generates a single solution (successive overlapping fragments) and is continually updated by the application of ordered movements.
- ApplyMovement method: Makes a movement perturbation and alters the subpermutation between to positions i and j.
- CalculateDelta method: Calculates the variation in the overlap and in the number of contigs this method is considered the main step of the PALS algorithm.

In another paper [50] two changes were proposed to the principal PALS: The first goal is to avoid the local optima and premature convergence. In this case, the method for choosing the enhancing perturbation to be applied to the existing solution at each algorithmic step is changed in a way that leads to a significant improvement. The second one is to minimize the computational demands of the algorithm, this change involves applying multiple independent perturbations rather than a single perturbation to enhance the present solution at each algorithmic step.

The authors in [50] have noticed that the optimization of the fitness is not the same as the optimization of the number of contigs which is the present objective although the two goals are complementary. As a result, the search mechanism in PALS includes an estimation of the number of contigs. It selects the movement with the lowest variation of contigs to orient the search towards solutions that improve the number of contigs which is the movement that reduces or maintains the number of contigs.

Authors in [50] have suggested changing the movement selection technique to prevent the premature convergence. With the modified PALS known as PALS2, the movement with the lowest contigs variation have always been selected, but in contrast to the main PALS, in the situation that there are several movements with the same contig variation, the movement with the lowest fitness variation is chosen.

To avoid the significant amount of recalculations required in each step in the process of PALS where only one single movement in every step is applied, the authors have proposed the algorithm PALS2-many [50] where many movements are used in each step by developing a second variant in PALS2 in order to improve the solution

The paper [51] have presented a discrete whale optimization algorithm (DWOA) modeling the approach taken by humpback whales when looking for victim or prey by employing conventional operators adapted from evolutionary algorithms. The whales assault their victim or prey using a remarkable feeding technique known as the bubble-net approach. They swim up to the surface after constricting loop after spiraling around the victim [52]. In order to avoid reducing the variation in the population, the whale positions used to look for the prey were produced randomly from the fragment numbers rather than utilizing a random whale. To show how effective DWOA is in converting continuous whale behaviors to discrete ones, it was compared to various WOA, DE, and SCA methods. The paper have also demonstrated the performance of the DWOA over those algorithms. To enhance the performance of the proposed Discrete Whale Optimization Algorithm (DWOA) in terms of fragment order, a local search technique called PALS2-many was incorporated [51]. This approach, known as DWOA-LS, combines the benefits of both DWOA and local search to optimize the fragment order. By integrating the local search, DWOA-LS not only maximizes the overlap score among the fragments but also minimizes the number of contigs, resulting in improved overall performance.

D. Genetic Algorithms

Genetic algorithm have also been applied in the DNA fragment assembly problem by [46]. The authors investigated various evolutionary algorithm operators for the issue and discovered that using "macro-operators" considerably boosts performance by exploiting fragment construction at gradually higher levels.

Individuals are the population of potential solutions that genetic algorithms operate on [53] [54] [55]. Usually, random people are used to initialize the population. Depending on their relative fitness, individuals are then either removed from the population or reproduced within it. Different operators are applied to the existing population of individuals to create new individuals ones. A generation is a group of people in any consecutive population. Typically, the genetic algorithm [46] [56] processes in the following order:

1) The algorithm creates a pool of solutions at random where random individuals are used to initialize the population.

2) It uses a fitness function for superior solutions selection. The fitness of each individual is evaluated during the selection process. Based on fitness, individuals are reproduced (copied) in different ways. Various genetic algorithms implement the concept of differential reproduction using various techniques [46]. However Parsons et al. have used generational genetic algorithm where a A new population is formed at each generation, totally replacing the prior population. Low fitness individuals have a low likelihood of being copied into the next generation, whereas high fitness individuals have a high likelihood of having several copies in the following generation.

3) To produce next-generation solutions, crossover and mutation processes are applied to successful solutions [56]. The authors have discussed in [46] all the crossover operators where the crossover rate indicates the average percentage of new people created by crossover per generation and defined the crossover as the selection of two individuals from the population, and the swapping of substrings from corresponding regions within the individuals. At the next generation, one or both of the new individuals are incorporated into the population. The operator's goal is to let incomplete solutions develop on various individuals before combining them to create a better solution.

By modifying a basic component of an individual, a mutation modifies that individual is the definitions of mutation in [46]. The chances that any element in an individual will change depends on the mutation rate. The resultant individual takes the place of the mutation's parent. It is thought by authors that mutation is successful because it both explores the search space close to existing individuals and saves solution components that have been totally excluded from the population by selection for the following generations [46]. Noting that in genetic algorithm the individuals are the fragment orders representing the DNA sequence solutions.

A new Hybrid genetic algorithm (GA+PALS) have been presented in the paper [57], the genetic algorithm have been used with PALS that was utilized as a mutation operator.The authors have compared the hybrid method with the original GA and PALS methods.A very effective assembler that enables the search of optimal solutions for numerous instances of this problem was obtained as a result. Authors have used the conventional recombination and mutation operators,then some solutions with a low probability, are randomly chosen from the existing offspring and enhanced utilizing the local search algorithm in the method's main loop. This type of hybridization is justified by the fact that, while the GA identifies good positions of the search space , PALS facilitates exploitation in the best regions discovered by its collaborator. Obviously, the goal in this situation is to determine whether we can develop another heuristic from the best of the two (the GA and PALS algorithm) that would outperform either of the two methods from which it was derived.

The authors have introduced two novel algorithms in recent publications: the Recentering-Restarting Genetic Algorithm (RRGA) and the Recentering-Restarting Hybrid Genetic Algorithm (RRHGA), as mentioned in the papers [58] and [59]respectively. The primary advantage emphasized in the paper [58] for RRGA is its ability to avoid local optima by exploring the search space and leveraging specific dynamic representations. Before initiating the algorithm, a center or reference point, representing a potential solution, is selected either through seeding or random selection. Uzma and Halim [59] suggest that starting with a solid solution is preferable, while RRGA refines the potential solutions. Once the center is determined, the population is generated.

In the direct representation approach, each individual in the population is created by applying a sequence of n transpositions to the center of the population. The ordered lists of fragments are modified through evolution, as explained in the work by [59]. The RRGA algorithm incorporates the Power Aware Local Search (PALS) operator as an evolutionary operator. The performance of the proposed algorithm is evaluated based on overlap scores and the quantity of contigs.

According to the authors, the initial arrangement of fragment orders in RRGA is known as the center, which represents the default arrangement of the dataset's fragments. The center is then optimized using a 2-opt heuristic. This process generates a set of chromosomes, from which the best chromosome is selected based on its fitness value. A comparison is made between the fitness value of the best chromosome and the center. If the fitness value of the best chromosome surpasses that of the center, the number of transpositions is reduced by five percent, and the center is replaced with the best chromosome.

To evaluate their work, the authors conducted three types of experiments. In the first set of experiments, the PALS operator was used as a genetic operator. In the second set, PALS was applied after running the Genetic Algorithm (GA). Finally, in the third set, PALS served as a genetic operator and was also used after the execution of the GA. The experiments were performed with and without force recentre methodologies, and the results were compared with the Recentering-Restarting Genetic Algorithm, PALS, Genetic Algorithm, and Hybrid Genetic Algorithm. The RRHGA approach demonstrated superior performance across all of these methods.

The paper [60] discusses the importance of studying genetic algorithms to address the DNA fragment assembly problem. The efficient GA operators that have proven successful in the TSP and QAP contexts served as the inspiration for the construction of a GA platform to tackle the DNA FAP problem. By identifying commonalities between the three DNA FAP, TSP, and QAP problems these efficient GA operators successfully been identified and integrated in the platform.

By carefully combining various GAs operators of the platform, an effective GA variant was created in this research [61] . In order to do that, various GAs operators have been studied in solving the DNA FAP problem [60]. The performance of these operators in the contexts of the TSP and QAP issues is already established, and this study has the advantage of comparing the GA results with the results of other previous GA studies in the context of the overlap score. The SCX crossover, a smart crossover that has never been utilized with DNA FAP, provided better results than the other crossover types under consideration, which is the study's most evident and important discovery. The best-designed GA variant outperformed the current GA algorithms at solving the DNA FAP problem and showed a notable improvement in accuracy with good and competitive results. This paper [61] is the first study to solve the DNA FAP problem form this perspective.

TABLE I. Nature-inspired Algorithms in Literature

Inspiration	Stand alone algorithm	Hybridization algorithm	Total

E. Ant Colony Algorithms

This paper [62] introduces the application of an ant colony system algorithm for DNA fragment assembly. The proposed approach utilizes an asymmetric ordering representation, where the collective path generated by the ant colony represents the search solution. The study investigates two types of assembly problems: single-contig and multiple-contig problems. The simulation results demonstrate that, for single-contig problems, the ant colony system algorithm performs comparably to a nearest neighbor heuristic algorithm. However, in the case of multiple-contig problems, the ant colony system algorithm surpasses the nearest neighbor heuristic algorithm.

In [63] and [64] the ant colony system (ACS) algorithm was combined with the nearest neighbor heuristic (NNH) algorithm for solving the DNA fragment assembly. The ACS algorithm is utilized to create an optimized ordering sequence for the fragments, while the resulting contigs are assembled using the NNH rule. To evaluate its effectiveness, the ACS+NNH procedure is compared to the standard sequence assembly program CAP3. The results indicate that the overall performance of the combined ACS/NNH technique surpasses that of CAP3. Specifically, when dealing with large problem sizes, the ACS/NNH solutions exhibit higher quality than the CAP3 solutions. It is observed that CAP3 tends to generate a greater number of contigs compared to the ACS+NNH procedure. Thus, the combined ACS/NNH approach demonstrates superior performance and improved contig quality, particularly for larger-scale problems, as opposed to the CAP3 program.

F. Bee Algorithms

The nature-inspired Bee Colony metaheuristic algorithms are population-based search algorithms based on various biological and natural processes observed in the food foraging behaviour of honey bee colonies. In [65] the authors have designed two different Bee algorithms: Artificial Bee Colony (ABC) Algorithm and Queen-bee Evaluation Based On Genetic Algorithm (QEGA).

Artificial bee colony (ABC) algorithm was developed using the notion of the honey bee swarm's intelligent behavior. To create new effective search algorithms, honey bees use strategies like the waggle dance [65]. Three types of bees that compose the artificial bee colony in the ABC algorithm are workers or employed, onlookers, and scouts. A bee that waits at the dance area to decide which food source to choose, representing one possible solution of a permutation of DNA sequence fragments based on the waggle dance of the employed bee, is referred to as an onlooker. And a bee that moves to the food source that had previously visited is referred to as a worker bee. A scout bee is one that hunts for food at random.The nectar content of a food source represents the DNA assembly problem's fitness solution.

In the ABC algorithm [65], the employed artificial bees make up the first half of the colony, while the observers make up the second half. When both the employed and onlookers bees have consumed the employed bee's food supply, it turns into a scout. A worker or onlooker bee modifies the solution with PALS method for the locating a new food source and evaluates its nectar by calculating the fitness value of the new solution.

In the other category of Bee Colony algorithms, authors [65] designed Queen-bee evolution based on genetic algorithm (QEGA), which was inspired by the queen bee evolution process and has been utilized to improve the optimization capabilities of genetic algorithms in solving the DNA FAP. Genetic algorithms are capable of reaching the global optimum quickly due to the queen-bee evolution, which also reduces the risk of premature convergence. The authors have utilized problem aware local search (PALS) for an effective mutation.

G. Firefly Algorithm

The Firefly Algorithm (FA), a population-based algorithm inspired by the behavior and lighting patterns of fireflies created by Yang [66], is a recent nature-inspired algorithm that has excelled in many number of fields.The firefly have the following attributes according to Yang's theory:

1) As all fireflies are not gender-specific, they are attracted to each other regardless of their gender orientation.

2) Their brightness is inversely correlated with attractiveness. The less brilliant firefly will therefore travel toward the brighter one for any pair of flashing fireflies. When their distance grows, their attractiveness decrease. Hence, when there is no distance between two fireflies, the attractiveness is equal to the brightness. If none can see a better firefly it will move at random.

3) The environment of the objective function influences or determines a firefly's radiance.

Authors in the paper [67] have designed Discrete Firefly Algorithm design for Graphics Processing Units (GPU-DFA) and analyzed it behaviour to solve the DNA assembly problem. The main objective of the authors of the paper while designing the algorithm GPU-DFA is to establish an efficient model that runs the main processes of DFA entirely on GPU so the algorithm can support large numbers of fireflies due to optimized data-structures. The initialization and evaluation of each solution are completed one at a time in the paper's GPU-DFA method. DNA pieces are randomly permuted to produce each firefly i. The firefly I is then assessed, and its brightness (fitness) is determined. In order to compute them, GPU-DFA uses parallel threads. Several consecutive threads can make use of different memory space.

TABLE II. Comparison of the Fitness Value of the Studied Algorithms from [48], [67], [35], [51],[59], [37], [65], [39] on Different Instances

Dataset	CRO+SA [48]	GPU-DFA+LS [67]	CSA-P2M*Fit [35]	DWOA-LS [51]	RRHGA [59]	PPSO+DE [37]	QEGA [65]	PER-PSO-(hi)-ls [39]

H. Crow Search Algorithms

A novel crow search inspired algorithm (CSA) was proposed [35] to solve the DNA fragment assembly problem following the OLC model. Crows represent individuals in the population. Each crow maintains a unique hiding place, analogous to a solution candidate in the DNA fragment assembly problem. To protect their hiding places, crows employ specific defensive measures against potential followers, This behavior is presented through the following descriptions: -Crows live in social groups known as flocks. -Each crow maintains a memory of the location of its own hiding place. -Crows engage in a follow-the-leader strategy to identify the hiding places of other crows. -A crow defends its hiding place from potential attackers by employing a probabilistic defense mechanism. Since the FAP is a discrete problem, and the original algorithm was designed for continuous optimization problems, Allaoui et al. proposed using a modified version of the ordered crossover operator (OX). CSA was also combined with a local search method and utilized standard operators from evolutionary algorithms. The resulting approach, CSA-P2M *Fit Algorithm, outperformed other algorithms designed for the same purpose. It demonstrated accelerated search and yielded high-quality solutions in the context of DNA fragment assembly.

I. Cat Swarm Optimization

Recently, Yassine et al. presented in [36] the application of the Cat Swarm Optimization algorithm (CSO) in the DNA fragment assembly problem. This metaheuristic is a swarm intelligence algorithm that incorporates the natural behavior of cats and takes inspiration from the characteristics of cats, which are typically lazy creatures that spend a significant amount of time resting in a seeking mode. However, even during their resting periods, they remain aware of their surroundings. When cats sense a target, they switch to a tracing mode and start moving towards it.

In CSO, each cat within the swarm is represented by its position, velocity, and a flag indicating whether it is in seeking mode or tracing mode. The position of a cat corresponds to a potential solution to the problem being optimized. The velocity of the cat influences its movement within the search space. The flag determines the current mode of the cat, indicating whether it is in seeking mode (resting) or tracing mode (actively moving towards a target). The mixing ratio (MR) is a parameter in CSO that determines in which mode the cat will go into.

By simulating the natural behavior of cats and incorporating it into an optimization algorithm, CSO aims to find accurate solutions to the DNA fragment assembly problem by efficiently exploring the search space. The balancing of seeking and tracing modes through the mixing ratio enables the algorithm to adapt its exploration and exploitation strategies based on the problem characteristics and the current state of the swarm.

The Table II synthesize eight main algorithms hybridized with local search and other methods for solving the DNA fragment assembly problem. The first column of the table presents the dataset instances names provided from [68]: M15421(5), M15421(6) and M15421(7) from the human apolipoprotein B gene. j02459(7) instance from Complete nucleotide sequence of the cohesive ends of bacteriophage lambda DNA. The two instances bx842596(4) and bx842596(7) from Neurospora crassa DNA linkage group II BAC clone B10K17. In the other columns the fitness results obtained by the algorithms are presented: CRO+SA (Chemical Reaction Optimisation) [48], GPU-DFA+LS (Discrete Firefly Algorithm design for Graphics Processing Units) [67], CSA-P2M*Fit (Crow Search Algorithm and ALS2-many) [35], DWOA-LS (Discrete Whale Optimization Algorithm PALS2-many) [51], RRHGA (Recentering–Restarting Hybrid Genetic Algorithm) [59], PPSO+DE (Parallel Particle Swarm Optimization and Differential Evolution) [37], QEGA (Queen-bee Evaluation Based On Genetic Algorithm)[65], PER-PSO-(hi)-ls (Probabilistic Edge Recombination Particle Swarm Optimization and quick-PALS) [39].

It's clear seen from the Table II that the hybrid methods CSA-P2M*Fit, DWOA-LS and PER-PSO-(hi)-ls outperfomed in all the instances. CRO+SA give better results in M15421(5), M15421(6), M15421(7) and j02459(7). GPU-DFA+LS showed high fitness values too in M15421(5) and j02459(7).

However, it is important to consider that every metaheuristic algorithm possesses certain parameters that contribute to enhancing the algorithm's results. In most of the algorithms, the different parameters settings were applied in different test experiments and were varying for each instance of the dataset.

VI. Discussion

The field of genome assembly algorithms has experienced rapid and exponential growth. Over time, there has been a significant increase in the development and advancement of these algorithms. This growth can be attributed to several factors, including the availability of high-throughput sequencing technologies, the decreasing cost of sequencing, and the increasing demand for accurate and complete genome assemblies. Genome assembly algorithms play a crucial role in reconstructing the fragmented DNA sequences obtained from sequencing machines into complete genomes. As the complexity and size of genomes vary across different organisms, the development of efficient and accurate assembly algorithms has become essential. Advancements in assembly algorithms have been driven by a combination of algorithmic innovations, computational resources, and improved understanding of the characteristics of DNA sequences. Researchers have developed various algorithmic approaches, including machine learning methods, nature inspired metaheuristics based on overlap-layout-consensus and de Bruijn graph-based approaches, and hybrid methods that combine multiple strategies.

As a result of these combined factors, the field of genome assembly algorithms has experienced remarkable growth, with continuous improvements in scalability, computational efficiency and in assembly quality [69]. This ongoing progress in algorithm development is crucial for advancing genomics research, enabling discoveries, and understanding the complexities of genomes across different species. This review paper provide collaboration and knowledge exchange among researchers, enabling them to overcome the genome assembly challenges through the application of machine learning and nature-inspired optimization algorithms. Machine learning methods and metaheuristic methods are known to be two distinct approaches used in problem-solving domains including genome assembly. Each approach has its strengths and limitations, and a comparison between the two can provide insights into their applicability and effectiveness in different scenarios. Methods provided by machine learning, such as supervised learning, unsupervised learning, and reinforcement learning, utilize algorithms that learn patterns and relationships from data. These methods excel in tasks where large amounts of labeled or unlabeled data are available. In genome assembly, machine learning methods can be employed for various purposes, such as error correction, read alignment, and sequence classification. They can leverage the inherent structure and patterns within the genomic data to make predictions and improve assembly accuracy. However, machine learning methods often require extensive training data and may be computationally intensive, especially for complex problems with high-dimensional data. Metaheuristics in the other side, explore the search space systematically, looking for optimal solutions without relying on explicit problem-specific knowledge. Metaheuristics are well-suited for combinatorial optimization problems, including genome assembly as shown in the results (Table II). They can effectively handle large-scale datasets and non-linear optimization objectives. Metaheuristic algorithms offer a balance between exploration and exploitation, enabling them to escape local optima and find near-optimal solutions. However, they do not provide guarantees of finding the global optimum, and the convergence speed can vary depending on the problem and parameter settings. Researchers can combine these approaches to laverage the strengths of both and to improve genome assembly outcomes. Machine learning models can be used to guide hybrid metaheuristic algorithms combined with parallelism technologies like mapreduce in the search process like in [42] or to extract meaningful features from genomic data, enhancing the effectiveness of the optimization process of genome assembly.

VII. Conclusion

In this paper, a comprehensive review of existing literature in the field of genome assembly was established with a particular emphasis on practical algorithms. The reviewed algorithms include OLC (overlap-layout-consensus) based algorithms, de Bruijn graph-based algorithms, swarm algorithms, and machine learning methods. For each algorithm, detailed insights and highlights were provided, outlining their characteristics, strengths, and potential applications. Recent advancements in the literature also were examined, considering how these algorithms have evolved to address the challenges of genome assembly problem.In the future, the suggested DNA fragment assembler could be further developed by leveraging both machine learning techniques and nature-inspired algorithms, having the potential to be adapted into a parallel version using parallel programming frameworks like MapReduce. These enhancements are expected to lead to significantly improved performance, allowing for more efficient results and reduced execution times.

Predicting Customer Segment Changes to Enhance Customer Retention: A Case Study for Online Retail using Machine Learning

Lahcen ABIDAR, Dounia ZAIDOUNI, Ikram EL ASRI and Abdeslam ENNOUAARY
Department of Mathematics, Networks and Computer Science
National Institute of Posts and Telecommunications, Rabat, Morocco

***Abstract*—In today's highly competitive marketplace, advertisers strive to tailor their messages to specific individuals or groups, often overlooking their most significant clients. The Pareto principle, asserting that 80% of sales come from 20% of customers, offers valuable insights, imagine if companies could accurately forecast this vital 20% and recognize its historical significance. Predicting customer lifetime value (CLV) at this juncture becomes crucial in aiding firms to effectively prioritize their efforts. To achieve this, organizations can leverage predictive models and analytical tools to target specific customers with tailored campaigns, enabling well-informed decisions about advertising investments. By being aware of these segment transitions, advertisers can efficiently deploy resources and increase their return on investment. By implementing the strategies outlined in this study, businesses can gain a competitive edge by identifying and retaining their most valuable clients. The potential for growth and client retention is immense when anticipating changes in customer segments and adjusting advertising strategies accordingly. This paper provides a comprehensive methodology, tools, and insights to assist marketers in optimizing their advertising campaigns by anticipating customer lifetime value and actively predicting changes in client segmentation.**

***Keywords*—Customer segment changes; customer retention; marketing actions; informed decisions; advertising strategies**

I. Introduction

In today's highly competitive marketplace, advertisers face the ongoing challenge of delivering targeted and personalized advertisements to capture the attention of potential customers. However, amidst the quest for broad reach and mass appeal, businesses often overlook a crucial aspect – focusing on their most valuable customers. The Pareto principle [1], a well-known economic principle, sheds light on this phenomenon by revealing that a small portion of customers typically contributes a significant proportion of sales. While the Pareto principle has long been cited in reference to sales patterns, its implications for advertising strategies have been underexplored. What if businesses could not only identify this 20% historically but also predict it for the future? The concept of predicting customer lifetime value (CLV) arises as a powerful tool in this context. By leveraging predictive modeling and analytical techniques, businesses can forecast future customer behavior and identify those individuals who will likely make up the high-value customer segment. The primary objective of this paper is to propose an approach for predicting customer segment changes based on CLV predictions. By accurately predicting shifts in customer segments, businesses can strategically prioritize their marketing actions and allocate resources more efficiently. This includes determining the optimal investment in advertising, identifying the specific customers to target with tailored campaigns, and devising strategies to transition customers from one segment to another. Understanding and leveraging customer segment changes present several strategic advantages for businesses. Firstly, it allows for the efficient allocation of advertising resources [2], ensuring that marketing efforts are focused on the most valuable customers who are likely to drive significant sales [3]. Secondly, by tailoring advertising messages and offers to this high-value segment, businesses can improve customer engagement and conversion rates[4]. Lastly, actively managing customer transitions between segments enables businesses to nurture relationships, increase customer loyalty [5], and maximize long-term customer value. This paper serves as a comprehensive guide for businesses seeking to optimize their advertising strategies by harnessing the power of CLV predictions and proactively targeting customer segments. Through an exploration of predictive modeling techniques and actionable insights derived from customer segment changes, businesses can gain a competitive edge in today's dynamic marketplace. By aligning their advertising efforts with anticipated shifts in customer segments, businesses can enhance customer retention, maximize profitability, and foster sustainable growth. This paper is organized as follows: In Section II, we provide an overview of the existing literature. Next, in Section III, we present a comprehensive framework that outlines the step-by-step process of predicting customer segment changes based on customer lifetime value. Moving on to Section IV, we present the empirical study conducted to evaluate the effectiveness of our approach. We describe the dataset used, the experimental setup, and the evaluation metrics employed. We then present and analyze the results obtained from applying the proposed approach, discussing the performance of the predictive models and any significant findings or insights gained. In Section V, we interpret and discuss the empirical results in the context of our research objectives and identify potential areas for future research and improvement. Finally, in Section VI, we summarize the key findings of our study and draw meaningful conclusions based on the empirical analysis and discussions. By structuring the paper in this manner, we aim to provide a comprehensive overview of our research, methodology, and findings, offering valuable insights and practical guidance for advertisers seeking to optimize their advertising strategies using customer lifetime value prediction and proactive customer segment targeting.

II. Literature Review

In the realm of personalized advertising and maximizing return on investment, the understanding of customer segments and their dynamic changes over time has emerged as a crucial area of research. This literature review explores key studies related to customer segment changes, customer lifetime value (CLV) prediction, and proactive customer segment targeting.

Customer segmentation, a vital concept in marketing, allows businesses to categorize their customer base into distinct groups based on common characteristics [6], behaviors, or preferences. Various factors influencing customer segment changes and transitions have been examined by researchers. Christy et al highlighted the significance of RFM analysis for identifying valuable customer segments and guiding marketing initiatives [7]. Yuliari et al introduced a customer segmentation method using fuzzy C-means and fuzzy RFM, accounting for uncertainties in customer data [8]. Sembiring Brahmana et al investigated customer segmentation using the RFM model and clustering techniques such as K-means, K-medoids, and DBSCAN [9]. Dullaghan and Rozaki explored machine learning techniques for dynamic customer segmentation analysis in the mobile industry [10]. Ahani et al conducted market segmentation and travel choice prediction in spa hotels using online reviews [11]. Albuquerque et al applied support vector clustering for customer segmentation in the context of mobile TV service [12].

The prediction of customer lifetime value (CLV) has gained significant attention as it enables businesses to identify their most valuable customers historically and forecast their future value. Several predictive modeling and analytical techniques have been explored in this context. De Marco et al utilized cognitive analytics and artificial neural networks to manage CLV, facilitating customer value prediction and optimization. They found that the self-organizing map better classifies the customer base of the retailer [13]. Marisa et al explored the relationship between CLV and core drives, using clustering and the octalysis gamification framework. Their study analyzed the relationship between CLV and eight core drives of customer motivation [14]. Yuan et al focused on a data-driven customer segmentation strategy based on the contribution to system peak demand [15]. Mosaddegh et al studied the dynamics of bank customers through value segments using big data analytics, identifying six major categories, including the pattern of Local Leaders whose transitions are repeated by some follower groups within the next two periods [16]. Khalili-Damghani et al proposed a hybrid approach combining clustering, rule mining, and decision tree analysis for personalized marketing [17].

To optimize advertising strategies, businesses need to proactively target specific customer segments that are likely to yield higher returns. Researchers have developed approaches to identify and prioritize these segments. Heldt et al introduced a predictive model called RFM/P, extending RFM analysis to enhance customer segmentation and targeting strategies [18]. Abidar et al proposed a new strategy for customer segmentation using machine learning techniques, highlighting the importance of targeted actions in marketing. Their approach demonstrates the effectiveness of machine learning in identifying customer segments and enabling businesses to tailor their marketing efforts for improved customer satisfaction and profitability [19]. Yuan et al focused on a data-driven customer segmentation strategy based on the contribution to system peak demand [15].

The ability to predict customer segment changes and align advertising efforts accordingly present substantial opportunities for growth and customer retention. By effectively identifying and engaging their most valuable customers, businesses can gain a competitive edge in the marketplace. The findings from studies in this field highlight the importance of leveraging CLV prediction and proactive customer segment targeting to optimize advertising strategies, allocate resources efficiently, and maximize return on investment.

In summary, the literature review emphasizes the significance of understanding customer segment changes, predicting CLV, and leveraging proactive targeting strategies in the realm of personalized advertising. The studies reviewed provide valuable insights and methodologies for businesses seeking to optimize their advertising strategies and enhance customer retention.

III. Workflow Model

In order to reach a final outcome, various techniques and methods will be utilized in this research. The resulting framework workflow, depicted in Fig. 1, incorporates customer segmentation, RFM parameters, clustering, data analytics, CLV Prediction, and targeted actions.

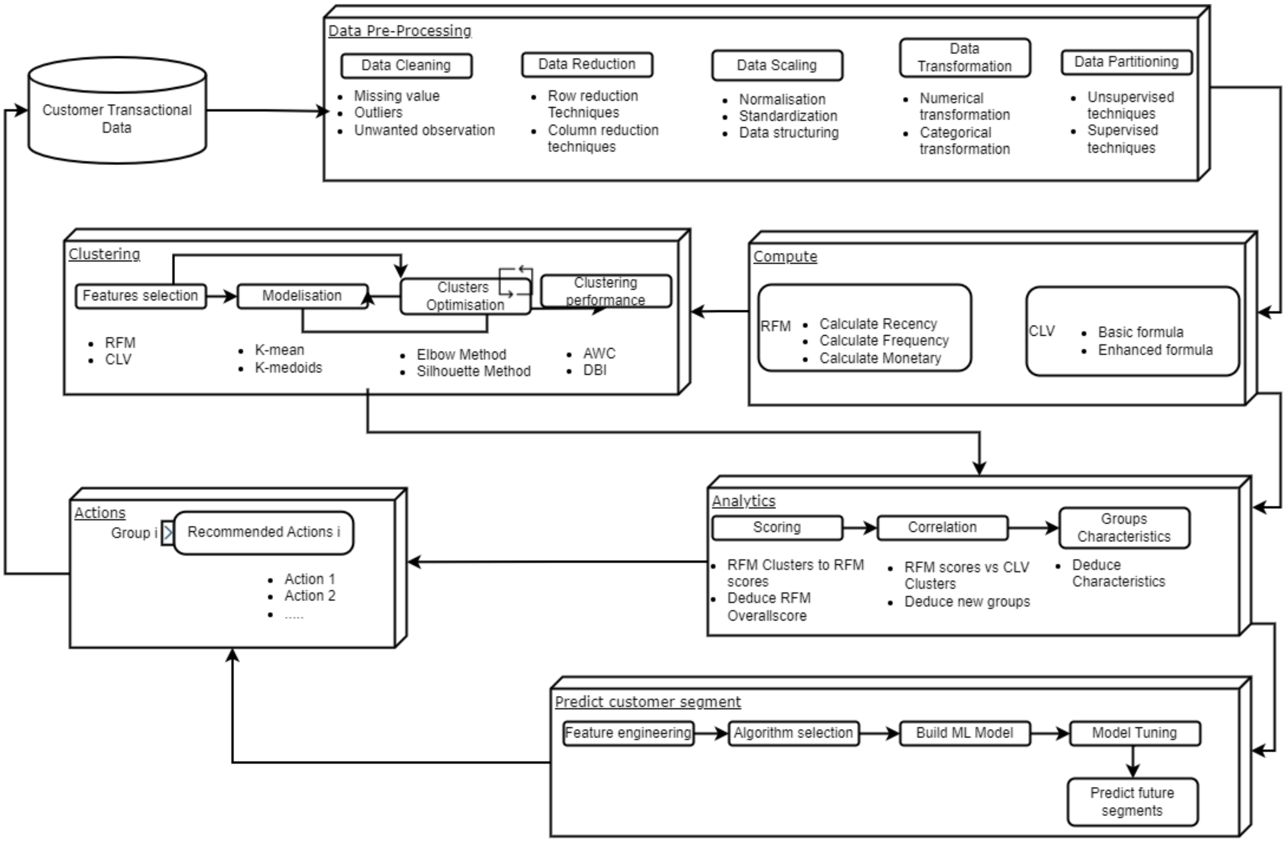
A. Data Pre-processing

1) Data cleaning: When creating operational data, there are two standard approaches to handling missing numbers. As most data mining algorithms cannot handle data with missing values, the initial step is to simply remove data samples with missing values. This approach is only appropriate when the percentage of missing values is negligible. The second is to use missing value imputation techniques to substitute inferred values for missing data. There are two techniques for detecting outliers: statistical and clustering-based techniques [20].

2) Data reduction: Row-wise for data sample reduction and column-wise for data variable reduction are the two usual directions in which data reduction is carried out. Row-wise data reduction is possible using a variety of data sampling methods, including random and stratified sampling. The goal of feature extraction is to create new features based on linear or nonlinear combinations of existing variables, as opposed to feature selection, which only chooses usable features from already-existing variables [20].

3) Data scaling: Predictive modeling frequently requires data scaling, particularly when the input variables have multiple scales. The max-min normalization (i.e., $x' = x - x_{min}/x_{max} - x_{min}$) and z-score standardization (i.e., $x' = x - \mu/\sigma$) are two of the most widely used methods in the building field, where x_{min} and x_{max} refer to the minimum and maximum of variable x, values of the variable, μ is the mean and σ is the standard deviation [20].

4) Data transformation: Data transformation is mostly used in the construction industry to convert numerical data into categorical data in order to assure interoperability with data mining methods. Due to their simplicity, the equal-width and equal-frequency approaches are frequently utilized [20].



(a)

Fig. 1. Framework workflow.

5) Data partitioning: The goal of data partitioning is to separate the entire set of data into various categories for in-depth study. For this goal, decision tree approaches and clustering analysis have been frequently applied in the building industry. For data partitioning, a variety of clustering methods have been used, including fuzzy c-means clustering, hierarchical clustering, entropy weighting k-means (EWKM), and k-means [20].

B. Clustering

1) Features selection: In practice, it is uncommon for all of a dataset's variables to be helpful in creating a machine learning model. Repetitive variables decrease a model's capacity to generalize and may also lower a classifier's overall accuracy. A model's overall complexity is also increased by including more variables. The objective of feature selection in machine learning is to identify the best set of features that make it possible to create effective models of the phenomena being examined. In machine learning, there are two different kinds of feature selection methods: supervised and unsupervised methods.

2) Modelization: A file that has been trained to detect various patterns is referred to as a machine learning model. By giving a model a method it can use to analyze and learn from a set of data, we may train it on that data. After the model has been trained, we can use it to analyze new data and forecast what will happen to it.

3) Cluster optimisation: Every clustering algorithm has its own strengths and weaknesses, In order to overcome these flaws in clustering algorithms, it is necessary to estimate the number of clusters based on assumptions and rely significantly on the initial centroids choice. It is vital to optimize, and the Elbow approach is one of the most used cluster optimization techniques.

4) Clustering performance: Any typical clustering system must answer the fundamental question of how accurate or reliable the clustering is. The separation between clusters is calculated using the Silhouette Score and Silhouette Plot. It shows the distance between each point in a cluster and points in other clusters. This metric, which has a range of [-1, 1], is excellent for visually examining similarities and differences between clusters.

C. Compute

1) RFM compute: RFM is a technique for providing significant value to each consumer. It is mostly utilized in marketing and has drawn the attention of the retail and business services industries. Based on the following criteria, RFM:

- Recent: When was the client's most recent order?

- Frequency: How frequently do they purchase?
- Monetary: How much do they spend?

The Fig. 2 displays a series of prior sales for a group of four clients.

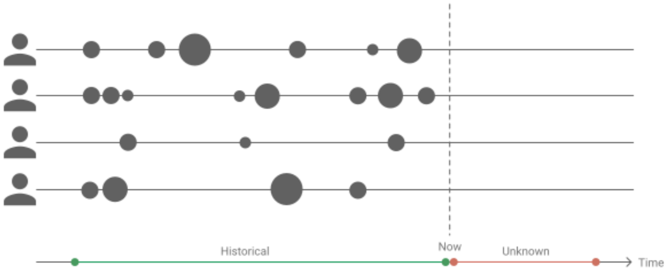


Fig. 2. Past sales for a set of four customers.

The diagram depicts the RFM values for the clients, with the following information for each client:

- Recency: The amount of time that has passed since the last purchase, as indicated by the separation between the rightmost circle and the vertical dotted line that reads ‘Now”.
- Frequency: The space between the circles on a single line, which represents the interval between purchases.
- Monetary: The size of the circle represents the amount of money spent on each purchase. This sum could represent either the typical order value or the number of products the buyer ordered.

2) CLV compute: CLV is calculated as the total of net cash flows from consumers over their anticipated lifetime, taking the time value of money into account. The following formula can be used to represent this model. The research in [21] and Table I is showing it’s parameters:

$$CLV = \sum_{i=1}^{n} \frac{R_i - C_i}{(1+d)^{i-0.5}} \tag{1}$$

TABLE I. CLV FORMULA PARAMETERS

Var	Explanation	Operationalization
n	Expected life of a customer	n = the total number of periods of projected life of the customer under consideration
C_i	The total cost of customer in period i	Total cost of generating the revenue R_i in period i
R_i	Total revenue of customer in period i	The revenues of customers were assigned as their monetary values.
d	Discount rate (annual)	Discount.

D. Analytics

The analysis phase includes several key components. One of these components is the RFM cluster analysis, which is used to assign RFM scores to different customer segments. The RFM scores represent the recency, frequency, and monetary value of customer transactions, providing insights into their purchasing behavior. the overall score is calculated based on the RFM scores, this overall score serves as a valuable metric for evaluating customer segments. To enhance understanding, the analysis also includes a detailed examination of the characteristics and attributes of each customer group within the RFM and CLV clusters.

E. Predict Customer Segment

In this part, we focus on the process of predicting future customer segments based on the developed workflow model. We delve into the various steps involved, including feature engineering, algorithm selection, building the machine learning model, model tuning, and ultimately predicting the future segments of customers. Feature engineering plays a crucial role in creating meaningful predictors for the machine learning model. We explore the different techniques and strategies employed to transform raw data into informative features that capture the relevant characteristics of customer behavior. Choosing the appropriate machine learning algorithm is a critical decision that impacts the accuracy and effectiveness of segment prediction. We explore a range of algorithms commonly used in customer segmentation tasks, such as decision trees, random forests, logistic regression, and gradient-boosting algorithms. In building the ML Model section, we detail the process of building the machine learning model for predicting customer segments. We discuss the steps involved in model training, validation, and evaluation. We split the dataset into training and test sets, and we discuss model performance metrics and interpretability, ensuring that the chosen model aligns with the objectives and requirements of segment prediction. In the Model Tuning section, we did some tuning to optimize the performance of the machine learning model. The final step in this part of our workflow is to use the trained and tuned model to predict future customer segments.

F. Actions

Based on the results obtained, businesses can implement effective actions to help to develop customer retention strategies and allocate their advertising and marketing investments more strategically. They can also tailor their advertising campaigns to target specific customer groups and help to draw roadmap for segment transition planning.

IV. EMPIRICAL RESULTS AND ANALYSIS

A. Data

The data used in this study was gathered from an online retailer [22]. The dataset covers the time period from the end of 2009 to November 2011. The collection includes 16759 invoices for 3881 items produced by 889 clients (Table II).

B. Data Pre-processing

1) Data cleaning: Following the completion of the data cleaning process, certain incorrect and missing values were removed from the data set. Table III summarises The attributes that were employed in this study. Table IV demonstrates a few modifications that we make to the data to make it cleaner.

TABLE II. TRANSACTIONAL DATA

Id	Invoice	StockCode	Description	Quantity	InvoiceDate	UnitPrice	CustomerID	Country
931932	574387	22726	ALARM CLOCK BAKELIKE GREEN	8	11/4/2011 11:04	3.75	12944.0	United Kingdom
404468	528600	22028	PENNY FARTHING BIRTHDAY CARD	12	10/22/2010 14:57	0.42	12787.0	Netherlands
764721	560569	22423	REGENCY CAKESTAND 3 TIER	1	7/19/2011 14:04	12.75	12480.0	Germany
442525	532056	21530	DAIRY MAID TOASTRACK	6	11/10/2010 14:27	2.95	12739.0	United Arab Emirates
272695	516189	85049D	BRIGHT BLUES RIBBONS	12	7/18/2010 15:56	1.25	12625.0	Germany
164614	505168	16053	POPART COL BALLPOINT PEN ASST	50	4/20/2010 12:48	0.21	14156.0	EIRE
88489	497879	21931	JUMBO STORAGE BAG SUKI	10	2/14/2010 11:15	1.95	12422.0	Australia

TABLE III. ATTRIBUTES

Attributes	Description
InvoiceNo	Unique ID to identify each Invoice
StockCode	Unique ID for each item in stock
Description	A short description for each item
Quantity	Number of items bought
UnitPrice	The price of each item
CustomerID	Unique ID for each Customer
Country	The country where the Customer lives

TABLE IV. DATA CLEANING

Problem	Solution
Null Invoices	Subtract from the dataset (not pertinent to this study)
Negative UnitPrice	Delete from this data (the organization included this in order to adjust bad credit)
Invoice with no customerID	Since we will be doing customer segmentation, remove any rows where customerID is NA.

We use whole prepared population in the analysis. Thus, we did not use any sampling method.

2) Data selection: We chose the following elements for this study: CustomerID, InvoiceDate, Quantity, UnitPrice. These attributes will make it easier for us to apply RFM models to this company's customers and determine customer lifetime value.

3) Data transformation: No data transformations have been made in the database.

C. Time Frame for CLTV Calculation

In this study, we will assess the Customer Lifetime Value (CLTV) over a 6-month period and use it in parameter correlation analysis with other variables for the purpose of feature engineering.

D. LTV Clusters

The Table V represents the three LTVCluster derived from the Elbow method, along with various statistical measures such as count, mean, standard deviation, minimum, 25^{th} percentile, median (50^{th} percentile), 75^{th} percentile, and maximum. Here's what each column represents: **LTVCluster** represents different clusters or segments based on the Lifetime Value (LTV) of customers and the **Count** column indicates the number of data points or observations within each LTVCluster. The **Mean** column represents the average value of the Lifetime Value within each LTVCluster. It provides insight into the average LTV for customers within each cluster. The **Std** column represents the standard deviation of the Lifetime Value within each LTVCluster. It provides a measure of the variability or dispersion of LTV values within each cluster and the **Min** column indicates the minimum value of the Lifetime Value within each LTVCluster. It represents the lowest observed LTV for customers within each cluster. The 25^{th} percentile column represents the value below which 25% of the Lifetime Values fall within each LTVCluster. It provides an insight into the lower quartile or first quartile value for LTV within each cluster and The 50^{th} percentile column represents the median value of the Lifetime Value within each LTVCluster. It indicates the midpoint of the LTV distribution within each cluster. The 75^{th} percentile column represents the value below which 75% of the Lifetime Values fall within each LTVCluster. It provides an insight into the upper quartile or third quartile value for LTV within each cluster. Finally, the **Max** column indicates the maximum value of the Lifetime Value within each LTVCluster. It represents the highest observed LTV for customers within each cluster.

These statistics provide an overview of the distribution and characteristics of the Lifetime Value within each LTVCluster. They can be used to compare and understand the differences in LTV between different customer clusters or segments.

E. Feature Engineering

In the feature engineering phase, we utilize RFM (Recency, Frequency, Monetary) scores calculated using the model introduced in our previous paper. These scores are merged with the calculated Customer Lifetime Value (CLV) for the 6-month period. To prepare the data for modeling, we perform various feature engineering techniques. First, we convert categorical columns, such as segment categories (low, mid, high), into numerical columns by assigning them values of 0 or 1. This enables us to incorporate these categorical variables into our machine-learning model effectively. Next, we examine the correlation between the features and our target variable, LTVCluster (Table VI). The correlation coefficients are as follows:

- LTVCluster: 1.000000
- DataF2_Monetary: 0.861441
- Monetary: 0.578009
- MonetaryCluster: 0.505388
- Segment_High-Value: 0.450551
- Frequency: 0.406573
- FrequencyCluster: 0.406352
- OverallScore: 0.392761
- RecencyCluster: 0.231834

TABLE V. LTV CLUSTER

LTVCluster	Count	Mean	Std	Min	25%	50%	75%	Max
0	2014.0	332.786480	390.273105	-609.40	0.0000	191.805	569.8225	1369.27
1	400.0	2408.376375	917.844417	1375.75	1695.0325	2075.775	2905.2150	4969.83
2	50.0	7633.641200	2225.110687	5074.93	6088.2675	6708.085	8838.1825	13636.42

- Segment_Mid-Value: 0.105407
- CustomerID: -0.055825
- Recency: -0.241712
- Segment_Low-Value: -0.263938

These correlation values provide insights into the relationships between the LTVCluster and other parameters. A positive correlation indicates a direct relationship, where an increase in one parameter is associated with an increase in LTVCluster. For example, DataF2_Monetary, Monetary, and MonetaryCluster show strong positive correlations, suggesting that higher monetary value and overall customer spending are indicative of a higher LTVCluster. Conversely, negative correlation coefficients suggest an inverse relationship, where an increase in one parameter is associated with a decrease in LTVCluster. In this case, Recency and Segment_Low-Value exhibit negative correlations, indicating that longer periods of inactivity and lower segment values are linked to a lower LTVCluster.

To build the machine-learning model, we split the dataset into training and test sets. The training set is utilized for training the model, while the test set is used to evaluate the model's performance on unseen data.

F. Algorithms Comparison

In this section, we compare the performance of different machine learning algorithms based on their mean and standard deviation scores in Table VII.

Among the algorithms evaluated in our study, LogisticRegressionCV (LR) demonstrated a mean score of 0.839304 and a low standard deviation of 0.019146, indicating consistently good performance. The XGBClassifier (XGB) followed closely with a mean score of 0.831148 and a standard deviation of 0.012742, showcasing reliable and consistent results. The KNeighborsClassifier (KNN) achieved a mean score of 0.838491, similar to LR, but with a slightly higher standard deviation of 0.023427, implying a slightly higher variability in its performance. On the other hand, the DecisionTreeClassifier (DT) algorithm outperformed the others with the highest mean score of 0.845802 and a low standard deviation of 0.012548, demonstrating both high accuracy and consistency. The RandomForestClassifier (RF) achieved a mean score of 0.831974, similar to XGB and LR, with a moderate standard deviation of 0.015155. The AdaBoostClassifier (ADA) also performed well with a mean score of 0.834416 and a low standard deviation of 0.014393, comparable to XGB and LR. Lastly, the SVC algorithm obtained a mean score of 0.825506, slightly lower than other algorithms, but with a low standard deviation of 0.012568, indicating consistent results. These findings provide valuable insights into the performance and stability of each algorithm, guiding the selection of the most suitable model for predicting customer segment changes.

Based on this analysis, the DecisionTreeClassifier (DT) and XGBClassifier (XGB) show the highest mean score and lowest standard deviation, suggesting it performs the best among the listed algorithms. However, it's also important to consider other factors such as computational complexity, interpretability, and specific requirements of your task when choosing the most suitable algorithm.

The choice between XGBClassifier and DecisionTreeClassifier depends on various factors and considerations. Our preference for XGBClassifier stems from its utilization of the powerful XGBoost algorithm, renowned for its exceptional performance in machine learning tasks. Unlike a single Decision Tree, XGBClassifier excels in handling complex datasets and often achieves higher accuracy. This is achieved by combining multiple weak decision trees through boosting techniques, resulting in improved overall performance. While Decision trees can be prone to overfitting, XGBClassifier incorporates regularization techniques such as shrinkage to mitigate this issue. Moreover, it performs automatic feature selection, ensuring the inclusion of relevant features and reducing the risk of using irrelevant or noisy ones. Although decision trees are generally regarded as more interpretable, XGBClassifier provides valuable insights through variable importances, indicating the relative significance of features. Additionally, XGBClassifier offers greater flexibility in handling missing values, enhancing the robustness of the model. With its ability to capture complex nonlinear relationships and interactions through gradient boosting, XGBClassifier surpasses DecisionTreeClassifier in scenarios where features exhibit nonlinear relationships with the target variable. Furthermore, XGBClassifier's optimization for performance and efficiency, including parallel processing and tree pruning techniques, makes it more adept at handling large datasets with numerous features. While DecisionTreeClassifier can be faster for training and prediction, XGBClassifier provides superior scalability and efficiency in such cases.

TABLE VII. ALGORITHMS COMPARISON

Algorithme Name	Mean	Std
LogisticRegressionCV(LR)	0.839304	019146
XGBClassifier(XGB)	0.831148	012742
KNeighborsClassifier(KNN)	0.838491	023427
DecisionTreeClassifier(DT)	0.845802	012548
RandomForestClassifier(RF)	0.831974	015155
AdaBoostClassifier(ADA)	0.834416	014393
SVC	0.825506	012568

TABLE VI. Parameter Correlation

	Customer ID	Recency	Recency Cluster	Frequency	Frequency Cluster	Monetary	Monetary Cluster	Overall Score	DataF2_ Monetary	LTV Cluster	Segment_ High-Value	Segment_ Low-Value	Segment_ Mid-Value
Customer ID	1.00	-0.02	0.02	-0.03	-0.02	-0.09	-0.07	-0.00	-0.06	-0.06	-0.02	0.01	-0.00

G. Build and Run the ML XGB Model

The “clvcluster” represents the predicted customer clusters based on the features in our dataset. The precision, recall, and f1-score metrics provide insights into how well the XGBClassifier is performing in predicting customer clusters. Based on the provided metrics for each class, we can evaluate the model’s performance for customer segmentation. Higher precision, recall, and f1-scores for a particular cluster indicate that the model is more accurate in predicting customers belonging to that cluster.

The XGB classifier achieved an accuracy of 96% on the training set and an accuracy of 84% on the test set. This suggests that the model has learned the patterns in the training data well and is performing reasonably well on unseen data.

In terms of class-wise metrics:
Class 0:

Precision: 0.89 Recall: 0.94 F1-score: 0.91 Support: 1017
Class 1:

Precision: 0.45 Recall: 0.33 F1-score: 0.38 Support: 184
Class 2:

Precision: 0.56 Recall: 0.32 F1-score: 0.41 Support: 31

These metrics provide insights into the performance of the XGB classifier for each customer cluster. Class 0 has relatively high precision, recall, and F1-score, indicating good predictive performance for this cluster. Class 1 has a lower precision, recall, and F1-score, suggesting that the model struggles more to accurately predict instances in this cluster. Class 2 also has relatively lower precision, recall, and F1-score, indicating room for improvement in predicting instances for this cluster (Table VIII).

TABLE VIII. Precision

Class	Precision	Recall	F1-score	Support
0	0.89	0.94	0.91	1017
1	0.45	0.33	0.38	184
2	0.56	0.32	0.41	31

To further analyze and improve the customer segmentation using the XGBClassifier, we should consider techniques such as hyperparameter tuning and do more feature engineering.

H. Improve the Model

The XGB classifier achieved an accuracy of 93% on the training set and maintained the same accuracy of 84% on the test set. This indicates that the model is still performing well on the test data and is not overfitting, as the training and test accuracies are relatively close.
Let’s look at the class-wise metrics:
Class 0:

Precision: 0.89 Recall: 0.95 F1-score: 0.92 Support: 1017
Class 1:

Precision: 0.49 Recall: 0.36 F1-score: 0.42 Support: 184
Class 2:

Precision: 0.73 Recall: 0.35 F1-score: 0.48 Support: 31

Comparing these metrics (Table VII) with the previous results (Table IX), we can observe some changes. The precision, recall, and F1-scores for class 0 remain relatively similar, indicating that the model’s performance for this cluster is consistent.

For class 1, there is a slight improvement in precision, recall, and F1-score, suggesting that the adjustment to max_depth=4 might have helped the model better capture patterns for this cluster.

Class 2 shows a significant improvement in precision, recall, and F1-score. The model’s ability to predict instances in this cluster has notably improved.

The adjustment in max_depth seems to have improved the model’s performance for some classes while maintaining a similar level of accuracy. However, it’s important to note that further evaluation and analysis are needed to fully assess the effectiveness of the model, such as considering other evaluation metrics and potentially exploring additional model adjustments or techniques without forgetting the specific goals and requirements for customer segmentation.

TABLE IX. ENHANCE MODEL

Class	Precision	Recall	F1-score	Support
0	0.89	0.95	0.92	1017
1	0.49	0.36	0.42	184
2	0.73	0.35	0.48	31

I. *False Positive Rate*

The receiver operating characteristic (ROC) curve is a graphical representation of the performance of a classification model. It illustrates the relationship between the true positive rate (sensitivity) and the false positive rate (specificity) for different threshold values.

In our case (Fig. 3), we have three classes: segment_low_value, segment_mid_value, and segment_high_value. Each class has its own ROC curve with its corresponding area under the curve (AUC) value.

- ROC of segment_low_value: The AUC value for this class is 0.84. This indicates that the model performs well in distinguishing between the low-value segment and the other classes. The higher the AUC value, the better the model's ability to correctly classify instances of the low-value segment.
- ROC of segment_mid_value: The AUC value for this class is 0.80. This suggests that the model's performance in distinguishing between the mid-value segment and the other classes is slightly lower compared to the low-value segment. However, an AUC of 0.80 still indicates a reasonably good classification performance.
- ROC of segment_high_value: The AUC value for this class is 0.97. This suggests that the model excels in distinguishing between the high-value segment and the other classes. An AUC of 0.97 indicates a high level of accuracy in correctly classifying instances of the high-value segment.

Additionally, we have two overall performance measures:

- Micro-average ROC curve: The AUC value for the micro-average ROC curve is 0.96. This measure takes into account the performance across all classes and provides an aggregated evaluation of the model's overall classification performance. An AUC of 0.96 suggests a high level of accuracy in predicting the correct class across all segments.
- Macro-average ROC curve: The AUC value for the macro-average ROC curve is 0.87. This measure calculates the average AUC value across all classes, giving equal weight to each class. An AUC of 0.87 indicates a good overall performance of the model in distinguishing between the different segments.

Our model demonstrates strong performance in classifying the low-value, mid-value, and high-value segments individually, as indicated by the respective AUC values. The micro-average ROC curve also indicates high accuracy across all segments, while the macro-average ROC curve provides a balanced evaluation of the model's overall performance.

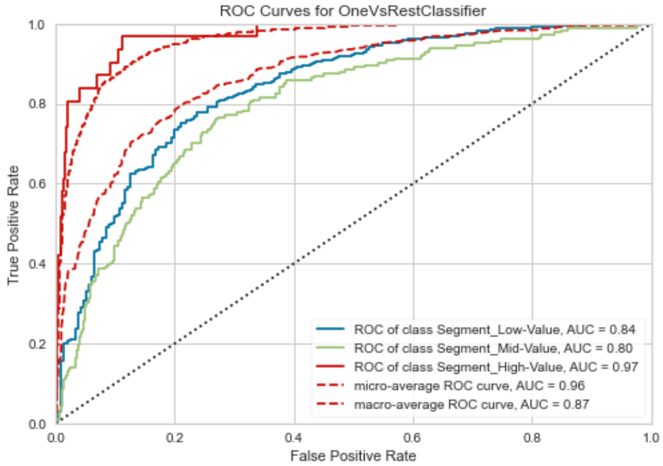

Fig. 3. ROC curve.

J. *Precision Recall Curve*

The PrecisionRecallCurve shows the tradeoff between a classifier's precision, a measure of result relevancy, and recall, a measure of completeness. For each class, precision is defined as the ratio of true positives to the sum of true and false positives, and recall is the ratio of true positives to the sum of true positives and false negatives.

$$Precision = \frac{TP}{TP + FP} \tag{2}$$

$$Recall = \frac{TP}{TP + FN} \tag{3}$$

where TP denotes true positive, TN stands for true negative, FP means false positive, FN denotes false negative.
A classifier's precision can be thought of as a gauge of its accuracy. It is described for each class as the proportion of true positives to the total of true and false positives. Another way to phrase this question is, "For all instances classified positive, what percent was correct?" The capacity of a classifier to accurately detect all positive cases is measured by recall, which is also known as the completeness of the classifier. It is described as the ratio of true positives to the total of true positives and false negatives for each class. Another way to phrase this question is, for all instances that were actually positive, what percentage was classified correctly? Average precision expresses the precision-recall curve in a single number, which represents the area under the curve. It is determined by computing the weighted average of the precision attained at each threshold, where the weights correspond to the variations in recall between thresholds. When there are class imbalances, the Precision-Recall (PR) curve sheds important light on how well a classification model performs. The average precision value of 0.9 and the Micro-average PR curve for all clusters are both included in our PR curve. The aggregated accuracy and recall for all clusters are shown by the Micro-average PR curve. It offers a comprehensive assessment of the model's capacity to locate favorable occurrences across all classes while taking into account the imbalances in a class distribution (Fig. 4).

The fact that the Micro-average PR curve intersects with the average precision curve at a recall value of 0.7 indicates a crucial point of trade-off in the classification performance. At this threshold, the precision achieved by the model is equal to the average precision of 0.9. It suggests that, on average, the model can correctly identify 90% of positive instances when the recall is 0.7. This threshold represents a balance between precision and recall for the overall classification performance.

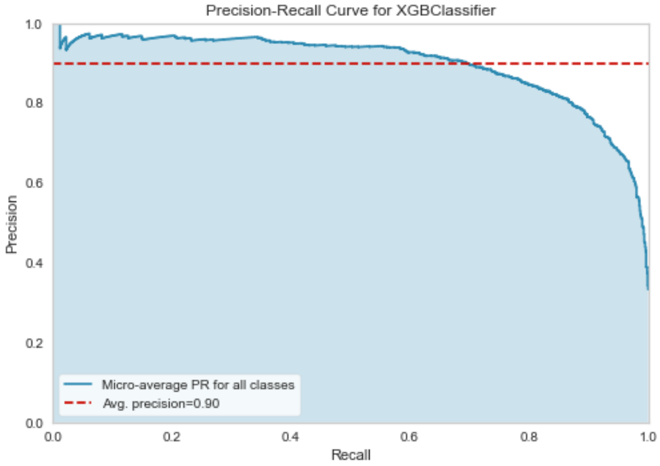

Fig. 4. Precision recall curve.

K. Class Prediction Error

The Yellowbrick ClassPredictionError plot is a twist on other and sometimes more familiar classification model diagnostic tools like the Confusion Matrix and Classification Report [23], [24]. Similar to the classification report, this plot displays a stacked bar chart of the support (number of training samples) for each class in the fitted classification model. As in a Confusion Matrix, each segmented bar displays the percentage of predictions (including false negatives and false positives) for each class. We can utilize a ClassPredictionError to see which classes our classifier is struggling with and, more critically, what false positives it is producing for each class. This frequently enables us to better comprehend the advantages and disadvantages of various models as well as specific difficulties pertaining to your dataset. The class prediction error chart is a fast way to gauge how well the classifier predicts the appropriate classes.

The XGBClassifier demonstrates accurate predictions for the Segment_High_Value class. However, there are instances where it mislabels Segment_Low_Value as Segment_Mid_Value and misclassifies Segment_Mid_Value as Low_Value_Value. In a few cases, it also misclassifies Segment_Mid_Value as Segment_High_Value (Fig. 5).

V. Discussion

The work conducted in this study provides valuable insights and tools that can significantly contribute to enhancing customer retention. This work can help improve customer retention by accurately predicting customer segment changes, businesses can identify customers who are at risk of churn or transitioning to lower-value segments. This enables proactive intervention through targeted retention strategies. By offering personalized incentives, tailored communication, and exclusive offers to these customers, businesses can increase their likelihood of staying engaged and loyal. Understanding which customers make up the high-value segment (Segment_High_Value) allows businesses to allocate their resources more effectively. By focusing efforts on retaining these high-value customers, businesses can maximize their return on investment. This can include allocating more advertising budget towards targeted campaigns for high-value customers, providing exceptional customer service, and offering exclusive benefits to strengthen their loyalty. The insights gained from predicting customer segment changes can be used to personalize marketing efforts. By tailoring advertisements, promotions, and communication to specific customer segments, businesses can increase engagement and relevance. This personalized approach enhances the customer experience and strengthens the bond between the customer and the business, leading to improved retention rates. By leveraging predictive models and analytics, businesses can estimate the customer lifetime value (CLV) for different segments. This information helps prioritize efforts and resources towards segments with higher CLV potential By focusing on increasing CLV through customer retention, businesses can optimize their revenue streams and profitability. Anticipating customer segment changes allows businesses to take a proactive approach to customer relationship management. By identifying customers who are likely to transition to higher-value segments, businesses can develop strategies to nurture and guide their journey. This can involve providing personalized recommendations, cross-selling and upselling opportunities, and proactive customer support to enhance their overall experience and increase loyalty.

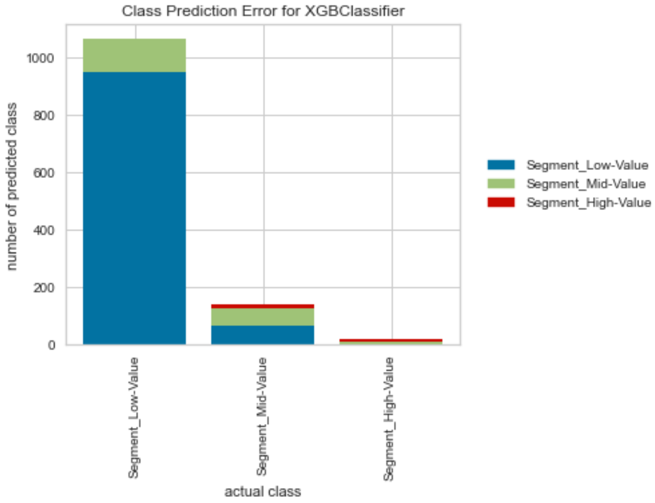

Fig. 5. Class prediction error.

The work conducted in this study equips businesses with the knowledge and tools to better understand and predict customer segment changes. By leveraging this information, businesses can implement targeted retention strategies, optimize resource allocation, personalize marketing efforts, and proactively manage customer relationships. These efforts collectively contribute to improving customer retention rates and fostering long-term customer loyalty.

Like every research study, our work also faces certain constraints and shortcomings. One limitation is the size of the dataset used for analysis, which may affect the representativeness of the findings. Additionally, the research focused on a specific industry, and the results may not be directly applicable to other sectors.

VI. Conclusions

This paper highlights the effectiveness of predicting customer segment changes to enhance customer retention strategies in the online retail industry. By leveraging machine learning techniques and analytical approaches, businesses can gain valuable insights into customer behavior and forecast future segment transitions. This enables proactive decision-making and targeted actions to retain high-value customers, optimize marketing efforts, and allocate resources efficiently. Future research directions include refining predictive models and algorithms, incorporating external factors, and utilizing real-time data for dynamic segmentation. Advanced customer analytics techniques, like customer journey analysis and sentiment analysis, can provide deeper insights into customer preferences and needs, further enhancing retention strategies. Moreover, predictive analytics can extend beyond customer retention to areas like personalized pricing, inventory management, and supply chain optimization, enabling businesses to deliver a superior customer experience. The study's findings underscore the potential of predicting customer segment changes for enhancing customer retention in the online retail industry. Continued research and innovation in this field will drive the ongoing evolution of customer retention strategies and foster long-term customer loyalty in the competitive online retail landscape.

***Abstract*—The Software Effort Estimation (SEE) tool calculates an estimate of the amount of work that will be necessary to effectively finish the project. Managers usually want to know how hard a new project will be ahead of time so they can divide their limited resources in a fair way. In fact, it is common to use effort datasets to train a prediction model that can predict how much work a project will take. To train a good estimator, you need enough data, but most data owners don't want to share their closed source project effort data because they are worried about privacy. This means that we can only get a small amount of effort data. The purpose of this research was to evaluate the quality of 15 datasets that have been widely utilized in studies of software project estimation. The analysis shows that most of the chosen studies use artificial neural networks (ANN) as ML models, NASA as datasets, and the mean magnitude of relative error (MMRE) as a measure of accuracy. In more cases, ANN and support vector machine (SVM) have done better than other ML techniques.**

***Keywords*—Software effort estimation; software effort prediction; software effort estimation datasets**

I. Introduction

Estimating how much work has to be put into creating software is a hot topic of study because of its significance in any software development process. If the amount of work involved is underestimated, not enough money or manpower will be put into the project, leaving no room for error in terms of the final product's quality. On the other side, if you overestimate the amount of work that has to be done, you'll likely end up with a large budget, which will drive up the cost of the program and reduce its competitive edge. Therefore, it is crucial to have a reliable estimate of the time and effort required to complete a project. Bosu et al. [1] emphasized the significance of data, defining software metrics as the gathering of quantitative measures as an intrinsic element of software quality control and assurance operations (particularly, the monitoring and recording of errors during development and testing). This way of thinking has won out. SEE research has expanded to cover a wide variety of problems since its inception, although the largest collections of work in the discipline have either suggested or evaluated models designed largely for effort/cost estimation. It has been argued that the use of metrics in SEE is invaluable because it allows for more informed decision-making during software development and maintenance, which in turn improves development productivity, decreases deployment cycle time, and boosts software quality [2]. Although there is no debate about the benefits of metrics in theory for software engineering, in recent years there have been growing concerns about the quality of the data being gathered and used in the creation of models to predict factors like software size and development effort.

Several recent publications [3] [4] [5] [6] detail the difficulties in assembling and analyzing empirical software engineering datasets. While the SEE research community has acknowledged and prioritized the detection and resolution of issues like noise, outliers, and missingness (or incompleteness), they have largely ignored issues like poor provenance, inconsistency, and commercial sensitivity [1]. Several "classic" SEE datasets have been used extensively in previous research on software effort estimation, and we detail such datasets here. These datasets may be found mostly in the PROMISE repository. These datasets were chosen because of their convenience and widespread application in SEE modeling. Our goal is to perform a comparative analysis of the content of these datasets by using them as a baseline. This will serve to draw attention to any problems related to SEE data collection in general. As a bonus, we'll see how well it works as a comparative tool. By analyzing these established datasets, a standard model could be formulated by academics and practitioners would benefit greatly. Decisions on whether or not to employ a specific dataset in SEE modeling will be improved as a result of this.

Numerous estimation strategies are described in the SEE literature and are grouped into the three primary categories of algorithmic, non-algorithmic, and machine learning (see Fig. 1). For software work estimation, algorithmic strategies use statistical and mathematical formulation. Non-algorithmic models are based on evaluative and interpretive analyses. These models analyze historical data from previously completed projects. Techniques based on machine learning offer an alternative to algorithmic modeling [7]. There is no clear "front-runner" technique for any of the data quality issues in the considered dataset, despite the fact that several methods have been presented to identify or analyze the various quality aspects of SEE datasets. Therefore, we apply the best-in-class method(s) for evaluating the quality of these widely-referenced datasets in Table I. The ultimate goal of this benchmarking exercise is to promote a comprehensive evaluation of data quality before modeling by showing how appropriate techniques, such as algorithmic, non-algorithmic, and machine learning (Fig. 1) can be used by researchers and practitioners to evaluate the quality of their own datasets and inspire them to create or adopt new and improved methods of data collection. The following are the article's main contributions:

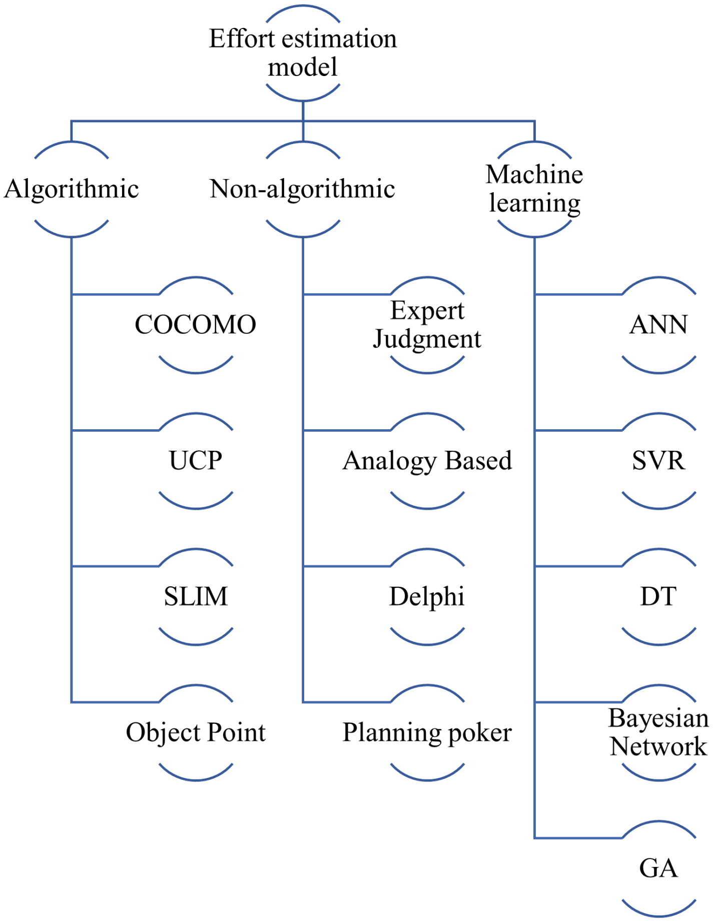

Fig. 1. SEE model description.

- We provide insights into some of the most popular datasets used for estimating software development efforts.
- We find out which is the most used technique for the SEE datasets.
- Which is the most used performance matrix, we also find out this for future researchers.

The rest of the article is divided into the following sections. Section II contains research findings related to the SEE dataset. Section III explains the methodology of our study. The details of the dataset are described in Section IV. The discussion of our work is covered in Section V. Section VI concludes the paper.

II. Related Work

It is impossible to exaggerate the significance of data to the study of SEE because they are at the center of the field's practical application. It is crucial that personnel in charge of gathering data be well-trained and aware of the various issues that could exist in datasets. It is seen that the majority of researchers use secondary data in SEE modeling [24]. Secondary data is research information that has already been obtained and is available to researchers. Secondary users are individuals who only infrequently make use of the product or those who do so via a third party. This is vital to make sure that the best procedures are used to produce and make use of the accessible data that is most trustworthy. In order to provide secondary users with an understanding of how the data were gathered, the processes that were used should, at the very least, be documented. In recent years, there has been a growing awareness of the difficulties associated with the collection and utilization of empirical software engineering datasets [25] [26], despite the fact that the overall body of literature on SEE data quality remains quite limited [27]. In this part, we examine previous assessment studies and provide a cursory mention of a few of the steps that others have done to enhance the quality of SEE datasets and repositories. First, We present a sample of studies that have assessed the state of SEE datasets from a particular angle or aspect of data quality. The SEE community mostly employs this approach to address problems that have an impact on software engineering datasets. The studies we present assess the state of SEE datasets from several dimensions of data quality. Additionally, we provide examples of studies in this chapter that built SEE prediction models using metrics from open-source projects. These metrics were gathered from the projects themselves. After this, a discussion of the few research works that have analyzed the current state of SEE datasets from numerous perspectives that have considered multiple data quality dimensions is discussed later. Table I shows the summary of the datasets used in this paper.

TABLE I. SUMMARY OF THE DATASET USED IN THIS STUDY

SL NO	Dataset name	Source	No of records	No of attributes	Output attribute-effort	Size(Unit measurement)	Ref

We conducted a metareview of the study and survey papers, and using that information, we were able to determine the SEE methodologies, datasets, and accuracy measurements that are most commonly employed. Table II provides an overview of the SEE methods, datasets, and accuracy measurements that are most frequently utilized.

We discuss the strengths and disadvantages of the most commonly used SEE approaches after doing a review of the relevant research and gaining an understanding of SEE techniques. Following are the SEE approaches which are most used by the researchers.

Linear regression: Linear regression is a statistical modeling technique used to examine the relationship between one or more independent variables and a dependent variable. It assumes that the variables are linearly related, meaning that changes in the dependent variable are proportional to changes in the independent variable. The benefits include being simple to grasp, apply, interpret, and clarify. Additionally, it is computationally cheap and works well with tiny datasets. Here are some of the flaws: it presupposes a linear connection and is therefore inappropriate for data with a nonlinear connection [45].

Artificial neural network: The following are its strengths: Feature engineering is not necessary, and it can learn complex correlations in the data. The shortcomings are as follows: training requires a lot of data, therefore it is computationally expensive. Additionally, it is challenging to evaluate the results since it is difficult to comprehend the assumptions that underlie them. It might have an overfitting issue, can’t handle missing values, and needs to convert categorical values to numeric values [45].

Analogy-based approaches: An analogy-based strategy is a way of thinking or addressing a problem that depends on discovering connections or analogies between various circumstances, things, or ideas. Analogies, which are similarities or correspondences between two or more items, are used to gather knowledge, draw conclusions, or resolve issues [34]. The following are its advantages: It can handle outliers and the justification for the result is simple to understand. The following are the flaws: computationally demanding, susceptible to the similarity function, requiring the conversion of categorical variables to numeric types, unable to handle missing values, and challenging to find a solution if similar work has not been done previously.

Fuzzy logic: Fuzzy logic is a mathematical foundation for reasoning and making decisions in ambiguous, imprecise, and uncertain situations. The following are the virtues: It is based on the theory of classes with flexible boundaries so that it can accommodate data uncertainty caused by measurement errors in data collection. It can also cope with model uncertainty. It enhances the performance of ML and non-ML models and resembles human reasoning. Its only limitation is that when combined with ML or non-ML models, it becomes computationally intensive.

Machine Learning (ML) techniques: The most popular ML methods for SEE are tree-based models and Support vector Machine(SVM) [46]. Each ML method has advantages and disadvantages of its own. The following are the strengths of the tree-based ML models that use the decision tree (DT) [47], CART, and random forest(RF) techniques: intuitive, making it simple to comprehend and analyze the model's findings. It is appropriate when there are nonlinear relationships in the data and can handle both category and numerical data. It can be said that it is capable of handling the outliers or that it is robust with them. The following are its flaws: If the dataset is small, DT is prone to overfitting. It is unable to handle missing values. A huge dataset has a high time complexity, and even a minor change in the data can significantly alter the model [48]. The following are some of SVM's advantages: It learns nonlinear relationships in the data and is appropriate for large dimensional data [48]. the following are the flaws: memory-intensive and possibly not scalable for large datasets.

Optimization techniques: Optimization techniques are mathematical methods and algorithms that are used to discover the optimal solution to a given problem given a set of constraints. The purpose is to maximize or reduce an objective function, which represents the quantity to be optimized, while adhering to specified conditions or constraints. The following are its advantages: it may be used to pick and weight features, and when combined with ML or non-ML techniques, it can increase estimation accuracy. the following are the flaws: Due to its nondeterministic nature and high processing cost, outcomes may differ from one attempt to the next [28].

III. Review Methodology

we downloaded all relevant papers and analyzed the number of SEE papers published in recent years (2020-2023(June)), categorizing them by the journals in which they appeared. Our searches began by retrieving all SEE files, which were then sorted by the publisher. For the search, we used reputable online resources such as Google, Springer, Elsevier, and similar databases. We compiled a research database of abstracts, keywords, and titles and carefully analyzed both the content and algorithms of each publication. Based on the inclusion/exclusion criteria we have selected the related paper. In this way, we were able to classify the publications on the topic of SEE.

A. Research Questions

We answer the following study questions:

- What are the most commonly utilized datasets in SEE research?
- What accuracy metrics are utilized most frequently in SEE studies?

B. Inclusion/Exclusion Criteria

Inclusion Criteria.

- Studies that used both ML and non-ML techniques for software effort estimation.
- Papers that are written in English.
- Papers that are published in a conference or journal.
- Paper that used publicly available datasets.

Exclusion Criteria.

- The title, abstract, or even their content was not closely related to our search string, however without any semantic interplay.
- No similarity with the research theme, or even the focal aim was completely contrary to the purpose of the issues addressed in the RQs.
- Not based on publicly available datasets.

When searching for information in the literature, we utilized the following search strings: “software effort estimation” OR “software cost estimation.” The aims of the study as well as its research questions were taken into consideration when developing the search string.

C. Dataset Description

For accurate effort forecasts, the dataset's quality that supports an estimating model's central premise is crucial. According to this theory, a characteristic is only considered a trustworthy predictor of the outcome if it has a strong correlation with the effort; else, it is unimportant. Datasets considered for this review paper were Desharnais, Cocomo81, China, Maxwell, Miyazaki94, Tukutuku, ISBSG, Albrecht, Kemerer, Kitchenham, Nasa93, and Edusoft dataset. The mean, also known as the average, is a measure of central tendency that is calculated by dividing the sum of all values in a dataset by the total number of data points. The standard deviation measures the spread or dispersion of data points around the mean. It expresses how far the data deviates from the average. Min is the dataset's minimum value, and Max is the dataset's maximum value.

CHINA dataset: The CHINA dataset for predicting software effort consists of 19 attributes. There are 499 different project instances in total. Table III provides the CHINA dataset's descriptive statistics.

1) Maxwell dataset: The Maxwell dataset, which was compiled from one of the largest commercial banks in Finland, has 62 projects that are each described by 23 attributes. Table IV provides a comprehensive summary of the Maxwell dataset. Project Size in Function Points serves as the only numerical attribute.

2) COCOMO81 dataset: The COCOMO81 dataset was often used to verify various effort estimation techniques. It consists of 63 software projects, each of which is described by 18 qualities along with a concrete effort. The COCOMO81 dataset measures real effort in terms of person-months, which are the number of months required for one person to develop a certain project. Table V provides the full description of the COCOMO81 dataset.

3) Albrecht dataset: The Albrecht dataset includes 24 software programs created with third-generation languages like COBOL, PL1, etc. Six independent number attributes and one dependent numeric attribute, "work hours," which indicates the appropriate effort in 1000 hours, are used to define the dataset. Projects were developed in COBOL, PL1, and database management languages for the remainder. Table VI gives a detailed explanation of the Albrecht dataset.

4) Desharnais dataset: The Desharnais dataset began with 81 software projects gathered from Canadian software businesses. This dataset is described by ten attributes: two dependent factors (time and effort in 'person-hours') and eight independent attributes. Unfortunately, four projects out of 81 had missing values, therefore we eliminated them because they could have influenced the estimation procedure. This data preprocessing stage yielded 77 finished software projects. Table VII provides the full description of the Desharnais dataset.

5) Kemerer dataset: In the Kemerer dataset, which consists of 15 software projects, six qualities and one predictable attribute with a "man-month" unit of measurement are used to define the projects. Two categories and four numerical qualities each represent one of the six attributes. Table VIII provides the full description of the Kemerer dataset.

6) Miyazaki94 dataset: Miyazaki provided the Miyazaki94 dataset. 48 software projects are represented in this collection. In total, there are nine qualities. Seven of the nine attributes are conditional attributes, one is a decision attribute, and one is an identifier. Table IX provides the full description of the Miyazaki94 dataset.

7) Tukutuku dataset: In the Tukutuku dataset, 53 online projects are present. Nine numerical attributes are used to describe each online application, including the quantity of media assets, HTML or SHTML files used, and team experience. Table X provides the full description of the Tukutuku dataset.

8) UCP dataset: The UCP dataset consists of 70 instances with 17 attributes for software effort estimation. Table XI provides the full description of this dataset.

9) NASA dataset: NASA datasets have been used to assess how well evolutionary algorithms function. Bailey and Basili provided this dataset in 1981. Shin and Goel utilized it for the first time in 2000, followed by Oliveira in 2006. There are 18 project instances in the dataset. M (methodology utilized) and DL (number of developed lines of source code with comments) are two independent qualities. The dependent characteristic of effort is the number of man-months needed to complete the project. Table XII provides the full description of the NASA dataset.

10) ISBSG dataset: ISBSG21 dataset version 2021 includes 10,531 cross-company projects from various nations, organizations kinds, and development kinds. We chose the dataset instances in accordance with ISBSG rules and the procedure described in [49]. As a result, 1179 novel project category IFPUG version 4+ projects with quality A and B have been created. The feature selection was carried out in accordance with the technique proposed by Dejaeger et al. [50]. The features include project sequencing-related features, features that are not expected to be accessible at the time of first estimation highly correlated features, and features with only one value. Table XIII provides the full description of the ISBSG dataset.

11) Telecom dataset: The Telecom dataset contains information on 18 software development initiatives for a UK telecommunication product. The dataset version utilized in this investigation has four attributes. However, since the other three variables are not available at the time of the work estimation, just the number of files attribute is employed. Table XIV provides the full description of the Telecom dataset.

12) Finnish dataset: The TIEKE organization obtained the Finnish dataset from nine Finnish businesses. Initially, 40 records were obtained, however, because of missing values in some of the attributes of two projects (Kitchenham and Kansala 1993), their data were eliminated, leaving 38 records for analysis. This dataset has nine attributes, each of which has a size measured in function points. Table XV provides the full description of the Finish Dataset.

13) Edusoft dataset: For estimating the time and effort needed for software development using a real-world dataset compiled by Edusoft Consultant Ltd. Noteworthy features of this dataset include task history ID, project ID, client id, task types, task priority, task overall state, total working time in hours, etc. 2000 samples of real-time data make up our dataset.

IV. Discussion

A. What ML Approaches are Employed in SEE Studies?

The process of estimating the time, resources, and cost needed to accomplish a software development project is known as software effort estimation. A particular kind of regression issue is software effort estimation. Regression attempts to forecast a continuous numerical number, in this case, the amount of work needed, using information from the input (such as project size, complexity measures, and historical data). Various project parameters and variables that affect the amount of work necessary for development could be included in the input features.

To estimate the SEE, the following ML techniques were utilized either alone or in combination with other (ML and nonML) estimation techniques. Artificial neural network

B. Which Datasets are most Commonly Utilized in SEE Research? (Research Question 1)

The selected studies made use of around 15 different datasets. We look for datasets that have been used in at least one study. we showed a literature review in Table II. The NASA dataset is one of the most extensively used datasets in the SEE literature, and it has been utilized in several research. Most of the datasets related to SEE are provided by different software companies. A few datasets come from different sources. The sources of these datasets are listed below.

China dataset basically focuses on function points. The Maxwell dataset was obtained from a Finnish commercial bank so anyone can work with bank data if it needs for his/her research. The multinational American company Computer Sciences Corporation provided the Kitchenham dataset. Ten Canadian organizations provided data for the Desharnais dataset. The NASA93 dataset represents 14 distinct application types and was gathered by NASA from five of its development centers. The Albrecht dataset was created using third-generation programming languages such as COBOL, PL1, and database management languages. The ISBSG Repository now houses software projects acquired from various global software development firms. The Telecom dataset was created by software development initiatives on a telecommunication product used in the United Kingdom. The Tukutuku dataset contains audio, video, animation, and webpages, so it might be useful for candidates who work with graphical data. The TIEKE group gathered the Finnish dataset from nine enterprises in Finland. Edusoft dataset can be used to estimate the time and effort required for software development using a real-world dataset provided by Edusoft Consultant Ltd.

C. Performance Evaluation Matrix (Research Question 2)

In a regression problem, the effectiveness of a predictive model that seeks to estimate a continuous target variable is evaluated using evaluation metrics. Several measures have been established and used for assessing the accuracy of a prediction model in the literature on software work estimation. Prediction error (or absolute error), which is the difference between the anticipated value and the actual value, serves as the foundation for these metrics in most cases [45]. Before it was discovered that they are biased towards underestimates and behave differently when comparing different prediction models, the Mean of

Magnitude of Relative Error (MMRE), Mean of Magnitude of Relative Error Relative to Estimate (MEMRE), and Prediction at Level l (Pred(l)) were the three most widely used metrics. As a result, their use is discouraged, and future studies should rely on standardized measurements such as the Sum of Absolute Errors (SAE), Mean Absolute Error (MAE), and Standard Accuracy (SA) that are not skewed towards underestimates or overestimates. A technique is regarded as better ML if it has more accuracy, for example, a lower mean magnitude of relative error (MMRE) number. For example, if model A is compared to model B, and A has a lower MMRE value in the majority of investigations, we can argue that model A outperforms model B. We may conclude that MSE, MRE, and MMRE are the most often used performance evaluation matrices based on the literature review Table II mentioned in Section 2.

V. CONCLUSION

In this study, we examined the datasets used for software effort assessment and discovered 15 widely used SEE datasets. We've talked in depth about these datasets. Based on our study of the most recent article, we discover that the NASA dataset is the most often used dataset for software effect estimation. The majority of these datasets also lacked timing details. Since software engineering is an ever-evolving field, it is crucial that SEE records include dates for important events like project launches and wrap-ups. This would allow researchers and practitioners to build models over time, allowing them to examine the impact of new development strategies. It was unclear in numerous cases whether datasets were obtained from a single company or from several. Given the continuous discussion over which datasets produce the best prediction accuracy results, it seems only right that this information be disclosed alongside datasets made available for modeling purposes. We also discover that the most popular machine learning techniques are Decision trees (DT), K-nearest neighbors (kNNs), Bayesian networks (BN), Support vector machines (SVM), and Artificial neural networks (ANN). On the other hand, Mean Absolute Error (MAE), Mean Squared Error (MSE), and Root Mean Squared Error (RMSE) are the most commonly utilized performance evaluation matrices for software effort estimation.

One limitation of our paper is that we did not build those datasets using alternative machine learning algorithms, which would have allowed us to provide a more detailed description of the dataset. In the future, we will experiment with these datasets using machine learning methods in order to better visualize the results of the evaluation matrix and other pertinent information.

ACKNOWLEDGMENT

The work reported in this paper is funded by the Institute for Advanced Research (IAR), United International University (UIU), Bangladesh titled: Implementation of 3D model to

assess the performance improvement of a software company UIU/IAR/02/2019-20/SE/06.

Employee Attrition Prediction using Nested Ensemble Learning Techniques

Muneera Saad Alshiddy, Bader Nasser Aljaber
Information Systems Department, College of Computer and Information Sciences
Imam Mohammad Ibn Saud Islamic University (IMSIU), Riyadh, Kingdom of Saudi Arabia

Abstract—**In many industries, including the IT industry, rising employee attrition is a major concern. Hiring a candidate for an unsuitable job because of issues with the employment process can lead to employee attrition. Thus, enhancing the employment process would reduce the attrition rate. This paper aims to investigate the effect of ensemble learning techniques on enhancing the employment process by predicting employee attrition. This paper applied a two-layer nested ensemble model to the *IBM HR Analytics Employee Attrition & Performance* dataset. The performance of this model was compared to that of the random forest (RF) algorithm as a baseline for comparison. The results showed that the proposed model outperformed the baseline algorithm. The RF model achieved an accuracy of 94.2417%, an F1-score of 94.2%, and an AUC of 98.4%. However, the proposed model had the highest performance. It outperformed with an accuracy of 94.5255%, an F1-score of 94.5%, and an AUC of 98.5%. The performance of the proposed model was compared with that of the baseline comparison algorithm by using a paired t-test. According to the paired t-test, the performance of the proposed model was statistically better than that of the baseline comparison algorithm at the significance level of 0.05. Thus, the two-layer nested ensemble model improved the employee attrition prediction.**

Keywords*—*Nested ensemble learning; employee attrition; machine learning; employment process

I. Introduction

The workforce is a crucial asset of an organization due to the strong positive correlation between the success of the organization and its employees' performance. The performance of employees can be affected by human resource management practices, such as the selection process [1], which aims to choose suitable candidates for specific job vacancies based on job-related criteria [2]. The wrong selection of candidates can lead to something called employee attrition, which is described as a large decrease in the labor force. Employee attrition occurs for several reasons [3], such as professional reasons, personal reasons, workplace challenges, and poor employee-job fit [4]. The last reason has a significant relationship with the employment process. It is about hiring a candidate for an inappropriate job because of issues in the employment process [5], or, in other words, the wrong selection of candidates. While a poor employment process can increase the chance of employee attrition, taking steps to reduce the rate of attrition can improve the employment process. Thus, employee attrition can be considered an indicator of the effectiveness of the employment process.

Some literature has studied employee attrition using machine learning (ML) techniques including but not limited to the works [6]–[15]. They conducted their experiments on the same dataset, the *IBM HR Analytics Employee Attrition & Performance* dataset. Three of them [6], [10], [13] used ensemble techniques in their experiments. To the best of the authors' knowledge, this study is the first to apply a nested ensemble technique to the *IBM HR Analytics Employee Attrition & Performance* dataset.

The problem addressed in this paper is the increasing rate of employee attrition [16], which is a major concern in several sectors, such as the IT industry. Employee attrition impacts an organization's performance. It drains many budgets and affects employee satisfaction [3]. Thus, it is necessary to control the rate of attrition [16]. This paper seeks to find the answer of the following question: What is the effect of using nested ensemble learning techniques to improve employee attrition prediction when applied to an employee dataset that has been optimized by a feature selection technique? Additionally, this study aims to investigate the effect of using nested ensemble learning techniques to improve employee attrition prediction when applied to an employee dataset that has been optimized by a feature selection technique.

The rest of this paper is organized as follows: Section II gives a background on the subject and an overview of the related work. Section III explains the methodology. Section IV presents the results and discussion. Section V summarizes the findings of the research and recommends future research directions.

II. Related Work

This paper used the *IBM HR Analytics Employee Attrition & Performance* dataset. It was developed by IBM's data scientists and made publicly available on the Kaggle website [17]. It was chosen because its attributes can be obtained easily from HR departments and its characteristics can simulate real-world HR issues [18]. Several studies conducted their research on this dataset using ML techniques. The current research adopts some of them as related work and reviews them in this section. Table I shows some information about the related work.

Each study was summarized in a single paragraph by reviewing the methods adopted for balancing data, selecting features, applying algorithms, and evaluating performance. Then, each paragraph was concluded by evaluating the performance of the research model using performance evaluation metrics.

The work [6], data balancing was not applied and was considered for future work. As well, feature selection techniques

were not used. The research built models using several algorithms, such as logistic regression (LR), decision tree (DT), random forest (RF), naive bayes (NB), and artificial neural networks (ANN). It used these algorithms to build a voting ensemble based on the majority vote strategy (hard vote). The performance of the models was measured by accuracy, F1-score, and AUC metrics. The best performance in terms of accuracy and AUC went to LR, which scored 87.96% and 85.01%, respectively. The highest F1-score reached 33.78%, which was accomplished by NB.

The work [7] did not apply data balancing, feature selection methods, or ensemble learning techniques. It applied light-GBM and TabNet algorithms. It evaluated the performance of the models using an accuracy metric. LightGBM had the best performance, with an accuracy of 85.3%.

In [8], neither data balancing nor feature selection methods were mentioned. It did not use ensemble learning techniques. Six ML algorithms were applied, which were LR, DT, SVM, NB, k-nearest neighbors (KNN), and RF. The accuracy metric was used to evaluate the performance of the models. SVM achieved the highest accuracy, with a value of 86.77%.

The work [9] used SMOTE to balance the dataset. It did not use feature selection methods to select appropriate features. Likewise, it did not apply ensemble learning techniques. However, it applied four algorithms named the extra tree classifier (ETC), SVM, LR, and DT. The performance of the models was estimated using four measures: accuracy, precision, recall, and F1-score. The performance of ETC was the highest, scoring 93% in all four measures.

The work [10] did not mention handling the imbalanced dataset. However, it applied a filter feature selection technique called information gain. As well, it applied bagging ensemble learning. Eight algorithms were used: RF, NB, LR, SVM, KNN, AdaBoost, DT, and logistic model tree (LMT). The performance was evaluated using four metrics: accuracy, precision, recall, and F1-measure. The performance of LMT was the best in terms of accuracy and recall. It achieved 86.94% and 86.90%, respectively. The performance of RF was the best in terms of precision, which was 85.50%. The performance of SVM was the best in terms of the F1-measure, which was 85.10%.

In [11], data balancing techniques were not mentioned. It used a wrapper feature selection technique named max-out, which was a proposed method. The ensemble learning technique was not applied. This work applied just one algorithm, LR. Accuracy, precision, recall, and F1-score measures were used to evaluate the performance of the models. It had an accuracy of 81%, a precision of 43%, a recall of 82%, and an F1-score of 56%.

In [12], both data balancing techniques and feature selection techniques were not mentioned. The ensemble learning technique was not implemented. Six algorithms were applied to the dataset: classification and regression tree, RF, LR, SVM, KNN, and NB. The performance of the models was assessed using accuracy and AUC. The best performance in terms of accuracy went to RF with 85.12%, while the best performance in terms of AUC went to LR with 80.85%.

Data balancing in [13] was not applied, and it was considered for future work. Two feature selection techniques were used: recursive feature elimination, a wrapper method, and selectKBest, a filter method. It used two ensemble learning techniques: the stacking ensemble learning technique and the voting ensemble technique based on the majority vote strategy (hard vote). Furthermore, eight algorithms were implemented, which were DT, LR, SVM, RF, XGBoost, DNN, long short-term memory (LSTM), and convolutional neural networks (CNN). Accuracy and F1-score were used to evaluate the performance of the models. The voting ensemble technique achieved the highest accuracy with 96%, while RF achieved the highest F1-score with 82.8%.

In [14], data balancing, feature selection methods, and ensemble learning techniques were not applied. It applied eight algorithms, which were Gaussian NB, Bernoulli NB, LR, KNN, DT, RF, SVM, and linearSVM. The performance of the models was evaluated using five metrics: accuracy, precision, specificity, recall, and F1-score. The performance of SVM was the best in terms of accuracy, precision, and specificity. It achieved 87.9%, 87.9%, and 99.4%, respectively. In addition, the performance of Gaussian NB was the best in terms of recall and F1-score. It obtained 54.1% and 44.6%, respectively.

The final work, [15], did not mention handling imbalanced data. Moreover, it did not use feature selection techniques to choose the relevant features. Besides, it did not apply ensemble learning techniques. However, it built CLARA, a system designed to enhance employee retention. It compared

CLARA's performance to six algorithms: RF, XGBoost, SVM, spectral clustering, standalone k-means clustering, and standalone frequent pattern mining. It used precision to evaluate the performance. The performance of the proposed system achieved a precision of approximately 70%.

III. Methodology

The idea of the proposed solution is to apply a nested ensemble model to predict employee attrition. To this end, the research prepared the dataset and used the nested ensemble model. All experiments in this paper were done using Waikato Environment for Knowledge Analysis (WEKA) platform version 3.8.6.

A. The Preprocessing Phase

This section shows the steps that were done to prepare the dataset. The preprocessing phase aims to prepare the dataset to be ready for applying ML algorithms in order to obtain the best results. In this research, different steps were applied to deal with several issues that may affect the ML performance, such as having values that are missing, duplicated, or irrelevant, or having features with various scales.

1) Dataset: The dataset used is the *IBM HR Analytics Employee Attrition & Performance* dataset, a public dataset generated by IBM data scientists and available on Kaggle [17]. It consists of 1470 instances and 35 features. Table II shows a brief description of the dataset. The table outlines the data type of each feature, data measurement scales, and descriptions of the feature's values (the number between brackets indicates the number of employees who share the same value).

The feature *Attrition* is a binary categorical variable that has two values: *No* and *Yes*. The value *No* indicates employees who did not leave the company. The value *Yes* indicates employees who left the company. The dataset contains 1233 on-the-job employees, representing 83.88% of the total employees. As for the rest of the employees, representing 16.12%, they left the company. Thus, the dataset is imbalanced because the minority class represents 16.12% of the entire dataset. For data balancing, the SMOTE technique was used. It was adopted because it has been widely used in similar studies; as well, it was applied in the related work [9].

In this dataset, *Attrition* was the second attribute. It was set as a class attribute by choosing *Attribute as class* command after clicking on the *Edit* button under the *Preprocess* tab. Therefore, it was moved to the end of the dataset as the last attribute.

2) Checking for missing and duplicate values: After checking the information shown in the *Selected attribute* panel, the dataset had no missing values. Moreover, it had no duplicate values after checking the values using the *RemoveDuplicates* filter.

3) Checking for unnecessary attributes: Referring to [19], constant attributes or unique attributes are considered unnecessary attributes that should be dropped. Three features were constant, and one had unique values. The features *EmployeeCount*, *Over18*, and *StandardHours* are constant for all instances. Their respective values were 1, Y, and 80. The feature *EmployeeNumber* has employees' identification codes (IDs), which are unique for all instances. Therefore, these four features were dropped because they did not further the research purpose; in other words, they were unnecessary data [19].

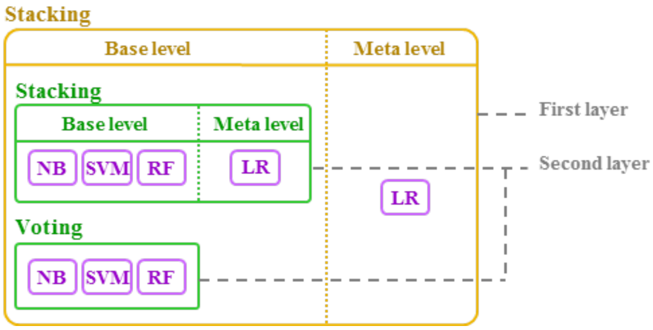

Fig. 1. The proposed model's architecture.

4) Data transformation: The purpose of this step is convert data from one format to another without changing the dataset's content. It helps to improve the ML algorithms' performance and enhance the data's understanding [20]. This research used the *OrdinalToNumeric* filter to unify the data type to be numeric, except *Attrition*, which is the class attribute.

5) Data scaling: Having features with several scales, for instance, the attribute *MonthlyRate* that ranges in thousands and *Age* that ranges in tens, can lead to the *numerical overflow* problem, which is computing numbers that are very small or very big. Thus, it is recommended to put all features on the same scale in order to give them equal weights [21]. This research used the *Normalize* filter to unify all the feature scales to start with 0 and end with 1.

6) The dataset optimization: For optimizing the dataset, the feature selection technique was used, and the information gain-based feature selection method was chosen as it was in the related work [10].

B. The Proposed Model

The proposed model is a nested ensemble learning technique. It is a special type of ensemble learning technique that combines several ensemble methods within one model in order to improve performance [22]. It contains multiple ensemble learning models; each one is inside of another one at different layers. The idea of this model is to use ensemble techniques in the classifier part instead of simple algorithms. In this research, a two-layer nested ensemble model was applied. It used a stacking model in the first layer and both stacking and voting models in the second layer. Moreover, it used traditional algorithms such as NB, SVM, RF, and LR as base-level algorithms of the model's ensemble models. Fig. 1 shows the architecture of the proposed model.

The following ML algorithms were used to build the proposed model:

1) Naive Bayes (NB): It is a probabilistic algorithm that uses probability rules to make predictions [23]. It can deal with different types of data; therefore, it has different models, such as Gaussian, Multinomial, and Bernoulli [24].

TABLE II. THE DATASET DESCRIPTION

No	Attribute	Data Type	Scale	Values Description
1	Age	Numeric	Ratio	Min = 18, Max = 60, Mean = 36.924, StdDev = 9.135
2	Attrition	Textual	Nominal	Yes (237), No (1233)
3	BusinessTravel	Textual	Nominal	Non-Travel (150), Travel_Rarely (1043), Travel_Frequently (277)
4	DailyRate	Numeric	Ratio	Min = 102, Max = 1499, Mean = 802.486, StdDev = 403.509
5	Department	Textual	Nominal	Sales (446), Research & Development (961), Human Resources (63)
6	DistanceFromHome	Numeric	Ratio	Min = 1, Max = 29, Mean = 9.193, StdDev = 8.107
7	Education	Numeric	Ordinal	1 'Below College' (170), 2 'College' (282), 3 'Bachelor' (572), 4 'Master' (398), 5 'Doctor' (48)
8	EducationField	Textual	Nominal	Life Sciences (606), Medical (464), Marketing (159), Technical Degree (132), Human Resources (27), Other (82)
9	EmployeeCount	Numeric	Ratio	1 (1470)
10	EmployeeNumber	Numeric	Nominal	1470 unique identification codes (IDs), start with 1 and end with 2068. They can be classified as the following: IDs <= 500 (377), IDs range between 501 and 1000 (340), IDs range between 1001 and 1500 (348), IDs range between 1501 and 2000 (357), IDs > 2000 (48)
11	EnvironmentSatisfaction	Numeric	Ordinal	1 'Low' (284), 2 'Medium' (287), 3 'High' (453), 4 'Very High' (446)
12	Gender	Textual	Nominal	Female (588), Male (882)
13	HourlyRate	Numeric	Ratio	Min = 30, Max = 100, Mean = 65.891, StdDev = 20.329
14	JobInvolvement	Numeric	Ordinal	1 'Low' (83), 2 'Medium' (375), 3 'High' (868), 4 'Very High' (144)
15	JobLevel	Numeric	Ordinal	1 (543), 2 (534), 3 (218), 4 (106), 5 (69)
16	JobRole	Textual	Nominal	Sales Executive (326), Research Scientist (292), Laboratory Technician (259), Manufacturing Director (145), Healthcare Representative (131), Manager (102), Sales Representative (83), Research Director (80), Human Resources (52)
17	JobSatisfaction	Numeric	Ordinal	1 'Low' (289), 2 'Medium' (280), 3 'High' (442), 4 'Very High' (459)

2) Support Vector Machines (SVM): It is a very powerful and popular algorithm in machine learning. In addition, it works well with complex datasets of small or medium size [25].

3) Random Forests (RF): It is a widely used algorithm consisting of numerous decision trees that learn from subsets of a training dataset [26]. It is a special type of bagging ensemble technique that uses bagging to combine tree models' predictions [27].

4) Stacking ensemble learning technique: Stacking, short for stacked generalization, is an approach that uses different types of algorithms to make their predictions, which they called base-level algorithms. Then, it uses an algorithm to predict the outcome. This algorithm is called a meta-level algorithm [25]. Recently, several studies that applied the stacking ensemble technique have used logistic regression (LR) as a meta-level algorithm [28]. They prefer using LR because of its speed of training and the small number of parameters that it requires [29]. In this research, the algorithms NB, SVM, and RF were used as base-level algorithms, while the algorithm LR was used as a meta-level algorithm.

5) Voting ensemble learning technique: Voting is an approach that uses different types of algorithms to make its prediction. It is similar to the stacking technique except it predicts the final outcome by using the majority voting approach or the averaging approach [25]. In this research, the algorithms NB, SVM, and RF were used as its algorithms. Furthermore, it predicts the final outcome by using the majority voting approach.

C. Performance Evaluation

1) Accuracy: It is a metric that calculates the percentage of correct predictions out of the total number of predictions. It is appropriate to know to what extent the model can predict correctly. Mathematically, accuracy = (TP + TN) / (TP + TN + FP + FN) [30], as shown in Fig. 2.

2) Precision: It is a metric that calculates the percentage of correct predictions of positive instances out of the total number of predictions of positive instances. It is appropriate to know to what extent the model can exclude any instance that actually does not belong to the positive class. Mathematically, precision = TP / (TP + FP) [30], as shown in Fig. 2.

3) Recall: It is a metric that calculates the percentage of correct predictions of positive instances out of the total of actual positive instances. It is appropriate to know to what extent the model can include any instance that actually belongs to the positive class. Mathematically, recall = TP / (TP + FN) [30], as shown in Fig. 2.

4) F1-score: F1-score, or F1-measure, is a metric that measures the harmonic mean of recall and precision [30]. The harmonic mean gives much weight to small values. Hence, a model can get a high F1-score when both recall and precision are high, or it can get a low score when both recall and precision are low [25]. Mathematically, F1-score = 2 * (recall * precision) / (recall + precision) [30], or F1-score = (2 * TP) / (2 * TP + FN + FP) [25], or simply F1-score = (TP + TP) / (TP + FN + TP + FP), as shown in Fig. 2.

5) The Area Under the Curve (AUC): It is a metric that compares the performance of several models for the same dataset. A model with an AUC above 80% is recommended [31]. The higher the AUC, the better the performance [30].

D. Cross-Validation Technique

The cross-validation method is a statistical method that is used to evaluate and compare ML algorithms. Its mechanism is based on dividing datasets into several sets: one is for validating an ML model, and the rest is for learning the ML model. It is called cross-validation because the training set and validation set cross over in sequential rounds to validate every data point [32].

The two most popular cross-validation approaches are *K-fold cross-validation* and *Hold-out validation*. Both of them are effective as long as the dataset is balanced. However, when the dataset is imbalanced, some modifications are applied in order to stratify the folds by the class label. So, the *stratified* keyword would precede the methods' names. The **stratification** process splits the data into folds, and each fold has instances with class labels that are similar to the entire dataset. In this case, every fold represents the class in approximately the correct proportions. Hence, the stratification technique is appropriate for imbalanced datasets [32].

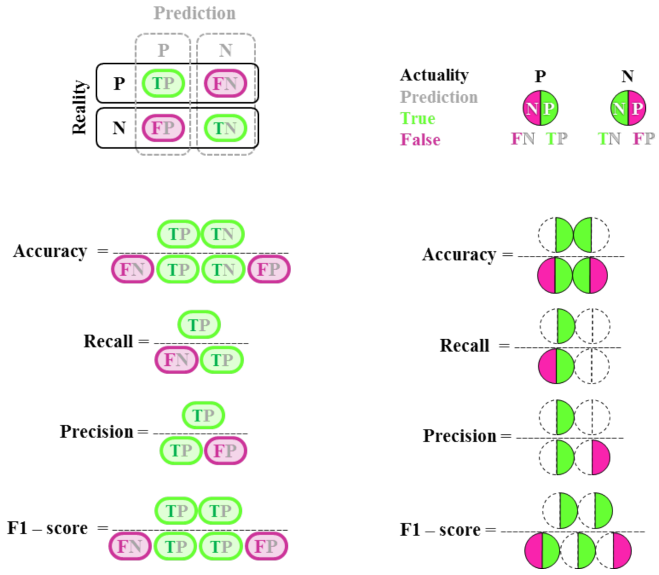

Fig. 2. Illustration of four evaluation metrics derived from the confusion matrix.

Note: The left-hand side clarifies the equations of these metrics, while the right-hand side represents them pictorially.

In this thesis, stratified 10-fold cross-validation was applied because it is recommended for imbalanced datasets [32], [33]. Additionally, the related works [7] and [10] were applied the same technique.

IV. Results and Discussion

This research is part of master's thesis, thus it is limited in time and computer resources. It used the WEKA platform to conduct the research experiments. The scope of this study is limited to the following:

- The research used *IBM HR Analytics Employee Attrition & Performance* dataset because it is a benchmark dataset created by data scientists from IBM, a well-known and reputable company [17]. Further, its features are usually found in real-world employee databases [18]. Besides, it has been widely studied in several research works.
- The research selected its related works on the basis that they used the *IBM HR Analytics Employee Attrition& Performance* dataset, provided they were published in ranked journals or conferences.
- The research studied employee attrition as a criterion to evaluate the effectiveness of the employment process. However, the study did not expand to cover any further criteria.
- The research limited its baseline comparison algorithms to NB, SVM, and RF since they are among the most popular ML techniques [34], especially for binary classification problems [35].
- The research studied nested ensemble techniques by using ensemble models as base-level algorithms. However, the study did not expand to cover any further details of this technique.
- The thesis optimized the dataset by using a feature selection technique.

The proposed model was built as shown in Fig. 1. Its performance was compared with that of NB, SVM, and RF as baseline comparisons, as well as that of other models in related work. The algorithms' hyperparameters were tuned as displayed in Table III. The findings are shown in Table IV.

TABLE III. The Tuning of the Algorithms' Hyperparameters

Algorithm	Hyperparameters' Tuning
NB	useKernelEstimator = True
SVM	C = 2, Kernel = PUK
RF	numIterations = 680

TABLE IV. The Performance of the Baseline Comparison Algorithms and the Proposed Ensemble Model

Algorithm	Accuracy	Precision	Recall	F1-Measure	AUC
NB	90.957%	91.9%	91%	90.9%	95.5%
SVM	92.7818%	92.8%	92.8%	92.8%	92.8%
RF	94.2417%	94.3%	94.2%	94.2%	98.4%
The proposed model	94.5255%	94.5%	94.5%	94.5%	98.5%*

* In terms of the performance evaluated by AUC, the proposed model is statistically better than RF (the baseline) at the significance level of 0.05.

TABLE V. THE PERFORMANCE OF THE MODELS IN THE CURRENT WORK AND THE RELATED WORK

The Work	Algorithm	Accuracy	Precision	Recall	F1-Measure	AUC
[6]	Voting Classifier	79.25%	N/A	N/A	12.22%	83.83%
[7]	LightGBM	85.3%	N/A %	N/A %	N/A %	N/A %
[8]	SVM	86.77 %	N/A %	N/A %	N/A %	N/A %
[9]	Extra Trees	93%	93%	93%	93%	N/A%
[10]	Bagging	83.74%	83.70%	83.70%	77.50%	N/A
[11]	LR	81%	43%	82%	56%	N/A
[12]	RF	85.12%	N/A%	N/A%	N/A%	80.84%
[13]	Voting Classifier	93%	N/A	N/A	58%	N/A
[13]	Stacking	88%	N/A	N/A	50%	N/A
[14]	NB	82.5%	38.6%	54.1%	44.6%	N/A%
[15]	CLARA[1]	65%	N/A%	N/A%	N/A%	N/A%
This Work	The proposed model	94.5255%	94.5%	94.5%	94.5%	98.5%

[1] A proposed end-to-end system.

The results demonstrated that the performance of RF as a baseline comparison algorithm was the best, with an accuracy of 94.2417%, a precision of 94.3%, a recall of 94.2%, an F1-score of 94.2%, and an AUC of 98.4%. However, the proposed model outperformed the other models, including RF. It exceeded the other models in terms of all metrics. It achieved 94.5255% in accuracy, 98.5% in AUC, and 94.5% in precision, recall, and F1-score.

As shown in Table IV, the best performance for each model, except SVM, was given by the AUC. The performance scores given by accuracy, precision, recall, and F1-measure to NB were within 91%, while AUC gave a performance score that was within 95%. Likewise, the performance scores of RF and the proposed model were within the range of 94%, which were given by accuracy, precision, recall, and F1-measure, whereas AUC gave them performance scores that were within 98%. However, SVM was given performance scores close to 93% by all the metrics.

In order to determine whether the proposed model provided a significant improvement in the employee attrition prediction, its performance was compared with that of the baseline comparison algorithms by using a paired t-test, a common statistical test that is used to compare two sets of values [36]. The performance evaluated by AUC was chosen because the AUC metric compares models for the same dataset in terms of their performance; the higher the AUC, the better the performance [30]. Furthermore, it is strongly recommended to use AUC when the dataset is imbalanced. In determining the test base for the paired t-test, RF was chosen because it is a baseline comparison algorithm and has the best performance among the baseline algorithms. The level of significance was set at 0.05. As shown in Table IV, the RF model and the proposed model had an AUC of 98.4% and 98.5%, respectively. According to the paired t-test, the performance of the proposed model was statistically better than that of RF at the significance level of 0.05. Thus, the two-layer nested ensemble model improved the employee attrition prediction.

Table V shows the comparison between the performance of the proposed model in this work and the models in the related work. It is noted that the proposed model achieved great performance. Its performance exceeded the performance of almost all models.

V. CONCLUSION AND FUTURE WORK

Rising employee attrition rates are a major concern that has an influence on an organization's performance [3]. It is affected by the success of the employment process, since the improvement of this process reduces the rate of employee attrition [4]. This paper investigated the effect of using nested ensemble learning technique to improve employee attrition prediction when applied to the *IBM HR Analytics Employee Attrition & Performance* dataset that has been optimized by the information gain-based feature selection method. To the best of the authors' knowledge, no previous research has applied nested ensemble techniques to the *IBM HR Analytics Employee Attrition & Performance* dataset.

The experimental results showed that the performance of RF was better than that of NB and SVM. Despite this, the proposed model outperformed RF. The RF model had an accuracy of 94.2417%, an AUC of 98.4%, a precision of 94.3%, and a recall and an F1-score of 94.2%. However, the proposed two-layer nested ensemble model achieved 94.5255% in accuracy, 98.5% in AUC, and 94.5% in precision, recall, and F1-score. In addition, the proposed model was statistically better than that of RF at the significance level of 0.05. To compare the performance of the proposed model in this work with the models in the related work mentioned in Section II, the proposed model showed excellent performance. Its performance exceeded that of all the models. Accordingly, the findings showed the capability of the proposed model to predict employee attrition. Thus, the nested ensemble learning technique assists the employment process and improve employee attrition prediction.

This paper suggests conducting more studies on the nested ensemble technique as future work. The reviewed studies, such as [37] [22], and [38], which applied nested ensemble techniques, focused on applying an ensemble technique as a meta-level algorithm, whereas in this work, the proposed model is a two-layer nested ensemble model that applied ensemble techniques as base-level algorithms and LR as a meta-level algorithm. However, the proposed model approved its capability in prediction as it scored more than 98% in AUC.

Bird Detection and Species Classification: Using YOLOv5 and Deep Transfer Learning Models

Hoang-Tu Vo, Nhon Nguyen Thien, Kheo Chau Mui
Software Engineering Department, FPT University, Cantho city, Vietnam

Abstract—**Bird detection and species classification are important tasks in ecological research and bird conservation efforts. The study aims to address the challenges of accurately identifying bird species in images, which plays a crucial role in various fields such as environmental monitoring, and wildlife conservation. This article presents a comprehensive study on bird detection and species classification using the YOLOv5 object detection algorithm and deep transfer learning models. The objective is to develop an efficient and accurate system for identifying bird species in images. The YOLOv5 model is utilized for robust bird detection, enabling the localization of birds within images. Deep transfer learning (TL) models, including VGG19, Inception V3, and EfficientNetB3, are employed for species classification, leveraging their pre-trained weights and learned features. The experimental findings show that the proposed approach is effective, with excellent accuracy in both bird detection and tasks for species classification. The study showcases the potential of combining YOLOv5 with deep transfer learning models for comprehensive bird analysis, opening avenues for automated bird monitoring, ecological research, and conservation efforts. Furthermore, the study investigated the effects of optimization algorithms, including SGD, Adam, and Adamax, on the performance of the models. The findings contribute to the advancement of bird recognition systems and provide insights into the performance and suitability of various deep transfer learning architectures for avian image analysis.**

Keywords—Bird detection; species classification; YOLOv5; deep transfer learning models; automated bird monitoring

I. Introduction

Birds play a crucial role in maintaining ecological balance. Conducting research on bird species enables us to enhance our understanding of the surrounding world, and the Earth's ecosystem, and acquire valuable insights into nature. Birds exhibit diverse characteristics, including varying sizes, shapes, and colors, and can be found in different locations. Identifying birds holds immense significance for ornithologists. Environmental scientists frequently rely on birds to gain insights into ecosystems due to their sensitivity to environmental fluctuations. Accurate identification of bird species provides crucial data on environmental conditions.

However, the process of manually collecting and data processing for bird species identification poses a significant challenge for researchers. To mitigate this challenge, the development of automated bird identification systems that collect, process, and classify bird species based on relevant information has emerged as a potential solution. The classification of bird species holds importance in diverse practical applications, including environmental pollution monitoring [1]. The presence of different bird species within an ecosystem serves various environmental purposes. Presently, image classification has emerged as a prominent domain of study in machine learning (ML) and deep learning (DL) [2]. However, accurately identifying bird species from images presents a complex undertaking due to challenges such as distinguishing between different bird species based on their unique shapes and appearances, accounting for background variations, managing varying lighting conditions in images, and accounting for the birds' dynamic postures.

The study employed yolov5, an object detection algorithm, to identify bird regions within images. Furthermore, three distinct models, namely VGG19, EfficientNetB3, and InceptionV3, were trained to classify a total of 525 bird species. By leveraging yolov5's capabilities, the researchers successfully detected the presence of birds in the images. Additionally, the classification task was accomplished using the trained models, which enabled accurate identification of the specific bird species among the 525 possibilities. This comprehensive approach allowed for both detection and classification of birds in the study.

The purpose of this article is to explore the application of YOLOv5 [3] (You Only Look Once) in detecting specific image areas that contain birds. Additionally, the article aims to compare the results achieved by various deep learning models such as VGG19, InceptionV3, and EfficientNetB3 in classifying different types of birds. To create a comprehensive model, the article proposes combining both bird detection and classification techniques. By leveraging the strengths of YOLO and deep learning models, this research aims to contribute to the development of robust systems for bird detection and classification in images. Moreover, the study examined how the performance of the models was influenced by optimization algorithms such as SGD, Adam, and Adamax.

The paper's structure is organized as follows: In Section II, a thorough literature review is presented, covering the relevant background. Section III elaborates on the method employed for bird detection in image, as well as the implementation of three proposed transfer learning models for the task of bird classification. This section discusses various aspects, including Data Set and Data Preparation, Optimizers, and Model Evaluation Metrics. The experimental system and results are then detailed in Section IV. Section V offers conclusive remarks to wrap up the paper.

II. Related Works

In today's era, CNN (Convolutional Neural Network) models have emerged as powerful tools for addressing classification problems across various fields. With their ability to automatically learn hierarchical representations from raw data, CNN models have revolutionized the field of computer vision and beyond. These models excel in extracting meaningful features and patterns from images, making them particularly well-suited for tasks like object recognition, image classification, and segmentation. By leveraging deep learning techniques, CNN models have achieved remarkable success in domains such as healthcare, autonomous vehicles, natural language processing, and more. Their versatility, scalability, and robustness make them widely adopted in academia and industry alike, as they continue to push the boundaries of what is possible in the realm of classification problems. Several studies have been conducted focusing on TL techniques for the purpose of classification; in the medical field [4], [5], [6], [7], [8]; in the field of agriculture [9], [10], [11] and many other fields. In the problem of bird classification, Shazzadul Islam et al. [12] propose a ML approach for identifying the species of Bangladeshi birds. To extract image features from bird pictures, the researchers utilized the VGG-16 network. Among the various classification methods employed, Support Vector Machine (SVM) attained the highest accuracy, reaching an impressive 89%. Samparthi V S Kumar et al. [13] compares the performance of MobileNet, AlexNet, InceptionResNet V2, Inception V3, and EfficientNet for bird species recognition using a dataset of 11,488 images (increased to 40,000 through data augmentation). The results indicate that MobileNet and EfficientNet are the fastest to train, and EfficientNet achieves the highest test accuracy of 87.13%. The study [14] utilized traditional ML algorithms, DL algorithms, and transfer learning-based deep learning algorithms to classify the Kaggle-180-birds dataset, with the transfer learning-based classifier achieving the highest classification accuracy of 98%. The paper [15] compares and evaluates DL models (SSD, YOLOv4, and YOLOv5) for the classification and identification of bird species using the CUB-200-2011 dataset, with the YOLOv4 model achieving superior performance, including 95.43% accuracy, 93.94% precision, 94.34% recall, 94.27% F-1 score for 20 classes, and 96.99% mAP score. Ichsan Budiman et al. [16] utilized the K-Nearest Neighbor (KNN) algorithm to classify bird species based on a dataset of 58,388 images belonging to 400 species, achieving an accuracy of 95.5%. This paper [17] introduces a dual TL method for enhanced seabird image classification with spatial pyramid pooling, concatenating outputs from InceptionV3 and DenseNet201 backbones, and applying global average-pooling and global max-pooling. The proposed method achieved high accuracy, precision, recall, and F1-score of 95.11%, 95.33%, 95.11%, and 95.13%, respectively, on a 10-class seabird image dataset. Apart from the image-based classification of birds, extensive research has also been conducted on classifying birds using sound signals. This research [18] focuses on utilizing convolutional neural networks (CNNs) to develop an automated system for bird species identification based on spectrogram images. By analyzing the challenges of bird species detection, segmentation, and classification using a publicly available dataset of 8000 audio examples, the study concludes that a CNN-based approach with fully convolutional learning achieves efficient and accurate results. Through a 9-step implementation, the system demonstrates high accuracy (0.9895), precision (0.9), and a minimal loss (less than 0.0063) after training and validation with 50 epochs. Kumar et al. [19] explores the use of deep neural networks (DNN) and TL for automatic voice recognition and species identification of 22 bird species using various feature extraction techniques. The results indicate that models like ResNet50, DenseNet201, InceptionV3, Xception, and EfficientNet achieve high prediction accuracy, with DenseNet201 and ResNet50 attaining the best classification accuracy of 97.43% on the validation set. The study [20] focuses on identifying the most suitable cepstral features for the accurate classification of 15 endemic Bornean bird sounds. By comparing different feature types, the model utilizing gamma tone frequency cepstral coefficients (GTCC) achieves superior performance with 93.3% accuracy. The most advanced CNN models currently utilize pre-trained networks and can classify bird species from various angles and positions. These methods have the potential to significantly enhance the accuracy. This article investigates YOLOv5 (You Only Look Once) for detecting bird-specific image areas and compares the classification performance of DL models like VGG19, Inception V3, and EfficientNetB3. By leveraging YOLO and deep learning, the research aims to enhance the development of robust systems for accurately detecting and classifying birds in images. Furthermore, the study delved into the influence of optimization algorithms, namely SGD, Adam, and Adamax, on the performance of the models.

III. Methodology

A. Dataset and Data Preparation

The dataset utilized in the article consists of a vast collection of 89,885 images. It encompasses a diverse range of 525 bird species, with 84,635 images allocated for training purposes. Additionally, the dataset includes 2,625 images each for testing and validation. All the images possess a resolution of 224x224 pixels and are in JPG format with RGB channels. The dataset was sourced from https://www.kaggle.com/datasets/gpiosenka/100-bird-species [21]. Significantly, a meticulously chosen set of five images per species was incorporated for testing and validation purposes. Fig. 1 provides additional information regarding the dataset.

B. Transfer Deep Learning Models, Proposed Model

The objective of this study is to employ the yolov5 algorithm for bird region detection in images, followed by utilizing a transfer learning model for bird classification. To assess the effectiveness of this approach, we compare the efficiency of bird classification using multiple proposed models based on transfer learning techniques, namely VGG19 [22], InceptionV3 [23], and EfficientNetB3 [24]. The architecture of the classification models proposed in this study is depicted in Fig. 2. Through this comparative analysis, we aim to evaluate the performance and efficacy of our solution in accurately classifying birds. In Fig. 3, the study conducted training on 03 bird classification models based on the EfficientNetB3, InceptionV3, and VGG19 network architectures, and selected the model with the highest accuracy. Fig. 4 presents the architecture and layers of the proposed models for bird classification based on the EfficientNetB3, InceptionV3, and VGG19 network architectures. The architecture and layers of the proposed model with the best results for the bird classification problem are built based on the EfficientNetB3 network architecture shown in Fig. 5.

C. Optimizers

An optimizer is a key element in machine learning and deep learning that facilitates the training of models. Its primary purpose is to iteratively adjust the parameters of a model with the objective of minimizing a specific loss function. By finding optimal parameter values, the optimizer helps enhance the model's performance on various tasks like classification, regression, or generative modeling. Different optimizers employ distinct algorithms and techniques to update the model's parameters based on gradients computed from the training data.

The choice of optimizer greatly influences convergence speed, generalization ability, and overall model performance. Overall, an optimizer is a vital tool that guides the optimization process in machine learning by iteratively refining model parameters to achieve better results. In this paper, we assess the performance of transfer learning models by employing three highly effective algorithms: Stochastic Gradient Descent (SGD) [25], Adam [26], and Adamax [27]. These optimizers have demonstrated remarkable capabilities in various machine learning tasks and are widely recognized for their ability to optimize model parameters efficiently. By leveraging SGD, Adam, and Adamax, we aim to evaluate the accuracy and effectiveness of transfer learning models and explore their potential for enhancing performance in diverse domains.

D. Evaluation Metrics

In this investigation, the efficacy of DL models was evaluated using a diverse set of metrics, including Precision, Recall, F1-score, and Accuracy. The overall performance of the models in predicting the target variable was assessed using Accuracy. Precision was utilized to measure the ratio of correctly predicted positive outcomes to all positive predictions, while recall quantified the proportion of accurately predicted instances of positive outcomes to all instances of positivity in the dataset. To provide a balanced perspective on the model's effectiveness, particularly in cases of imbalanced classes, the F1-score, which combines precision and recall, was employed. By employing multiple evaluation metrics, we obtained a comprehensive understanding of the model's effectiveness and were able to make informed judgments regarding its effectiveness.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{1}$$

$$Precision = \frac{TP}{TP + FP} \tag{2}$$

$$Recall = \frac{TP}{TP + FN} \tag{3}$$

$$F_1 - Score = \frac{Precision * Recall}{Precision + Recall} \tag{4}$$

In which, TP: True Positive, TN: True Negative, FP: False Positive, FN: False Negative.

IV. Results

In this section, we present the training and test results obtained for three models based on: EfficientNetB3, VGG19, and Inception V3. These models are based on their respective architectures and were trained using different optimizers, namely Adam, Adamax, and SGD. The purpose of these experiments was to evaluate the performance of the models under varying optimization algorithms. By utilizing different optimizers, we aimed to explore the impact on training and test outcomes, thereby gaining insights into the models' effectiveness.

EfficientNetB3: Among the three models, EfficientNetB3 consistently demonstrates the highest test accuracy of 98% across all optimizers (SGD, Adam, and Adamax). This indicates that EfficientNetB3 performs exceptionally well in correctly classifying unseen data. In addition to test accuracy, EfficientNetB3 also achieves high train accuracy, with values ranging from 0.967 to 0.9915 across all optimizers (SGD, Adam, and Adamax), indicating its ability to effectively learn from the training data. Furthermore, EfficientNetB3 exhibits low loss values during training, with the lowest recorded value of 0.0288 using the Adam optimizer. This suggests that the model effectively minimizes the discrepancy between predicted and actual values, resulting in improved performance. Detailed results are presented in Fig. 6.

VGG19: VGG19 performs slightly lower than EfficientNetB3 but still delivers respectable results. Among the optimizers used, VGG19 achieves the highest test accuracy of 95% when trained with the Adam optimizer. This indicates its ability to classify unseen data with a relatively high level of accuracy. VGG19 also demonstrates reasonably good train accuracy, ranging from 0.9088 to 0.9264. However, compared to EfficientNetB3, VGG19 exhibits higher loss values during training, indicating a relatively higher error rate in the predicted outputs. Detailed results are presented in Fig. 7.

Inception V3: Inception V3 achieves test accuracies of 92% to 93% across all optimizers. While it performs slightly lower than EfficientNetB3 and VGG19, Inception V3 still demonstrates a reasonable ability to classify unseen data

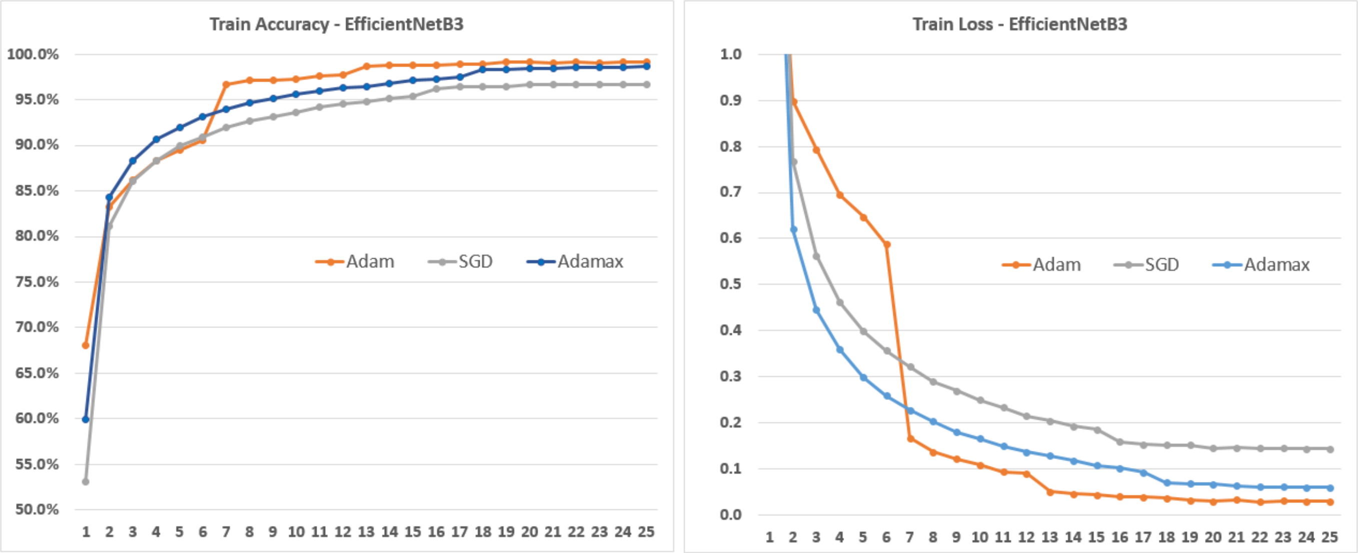

Fig. 6. Comparing the training accuracy and loss values of the EfficientNetB3 model using Adam, Adamax, and SGD.

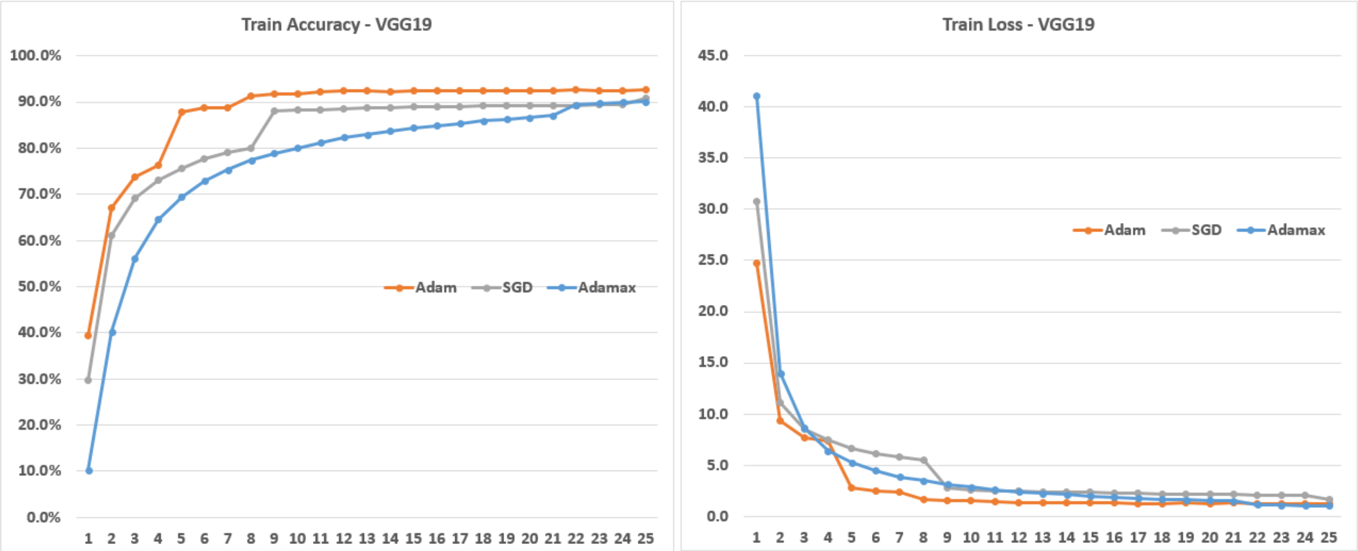

Fig. 7. Comparing the training accuracy and loss values of the VGG19 model using Adam, Adamax, and SGD.

accurately. In terms of train accuracy, Inception V3 achieves values ranging from 0.8624 to 0.913, which are slightly lower than the other two models. However, it shows relatively lower loss values during training compared to VGG19, indicating better convergence toward the desired outputs. Detailed results are presented in Fig. 8.

In summary, EfficientNetB3 consistently achieves the highest test accuracy across all optimizers, indicating its superior performance in classifying unseen data. VGG19 performs slightly lower but still achieves respectable results, with the best test accuracy attained using the Adam optimizer. Inception V3 also demonstrates good performance, although slightly lower than the other two models, with the best test accuracy achieved using the Adam optimizer. Detailed results comparing the testing accuracy and loss values of the EfficientNetB3, VGG19, and InceptionV3 models using Adam Optimizer are presented in Fig. 9.

Based on the information given in Table I, it appears that EfficientNetB3 consistently achieves high precision, recall, and F1 scores across all optimizers. It consistently achieves a score of 0.98 for precision, recall, and F1 score, indicating its effectiveness in correctly identifying positive instances and achieving a balance between precision and recall. While VGG19 and Inception V3 also show relatively strong performance, EfficientNetB3 consistently demonstrates higher scores in all metrics.

Fig. 10 shows comparisons of test accuracy value between EfficientNetB3, VGG19 and Inception V3. Fig. 11 shows the results obtained by using YOLOv5 to detect birds in the image (https://ebird.org/species/abbbab1) will be further classified into bird species using an EfficientNetB3-based model.

TABLE I. MODEL COMPARISON - PRECISION, RECALL, F1 SCORE

Models	Optimizer	Precision	Recall	F1 Score
EfficientNetB3	SGD	0.98	0.98	0.98
EfficientNetB3	Adam	0.98	0.98	0.98
EfficientNetB3	Adamax	0.98	0.98	0.98
VGG19	SGD	0.95	0.94	0.94
VGG19	Adam	0.96	0.95	0.95
VGG19	Adamax	0.94	0.92	0.92
Inception V3	SGD	0.93	0.92	0.91
Inception V3	Adam	0.94	0.93	0.93
Inception V3	Adamax	0.94	0.93	0.93

V. CONCLUSION

In conclusion, this study has successfully addressed the challenges associated with accurately identifying bird species in images, a task of great significance in ecological research and bird conservation efforts. By employing the YOLOv5 object detection algorithm for bird localization and leveraging deep transfer learning models like VGG19, Inception V3, and EfficientNetB3 for species classification, the researchers have developed an efficient and accurate system for bird detection and classification. The experimental results demonstrate the effectiveness of this approach, achieving high levels of accuracy in both bird detection and species classification tasks. The combination of YOLOv5 with deep transfer learning models has shown great potential for comprehensive bird analysis, paving the way for automated bird monitoring, ecological research, and conservation efforts. Moreover, the study also investigated the impact of optimization algorithms, including SGD, Adam, and Adamax, on the model's performance, providing valuable insights into the suitability of different deep transfer learning architectures for avian image analysis. Overall, these findings contribute to the advancement of bird recognition systems and offer valuable knowledge for improving the field of avian image analysis.

Abstract*—For the ecosystem to maintain a balance between the social and environmental spheres, forests play a crucial role. The greatest threat to forests for this significance, is fires and natural disasters caused by several factors. It is crucial to assess the genesis and behavioral characteristics of fires in forest areas. The discovery of the forest fire areas and the intensity of the fire affected are greatly facilitated by the satellite image obtained by different sensors and data sets. We are suggesting a novel approach to compute changes using spectral indices, using landsat-9 and sentinel-2 satellite datasets for measuring the change in forest areas affected by fire accidents over Kochi areas on March 2023. Kochi is a city in Kerala, South India, and is located at 9° 50' 20.7348" N and 77° 10' 13.8828" E. coordinates. Computation is performed by calculating forest area before the fire incident (pre-fire) and after the fire incident (post-fire) and total loss is calculated by the difference between pre-fire and post-fire incident. The proposed work uses Sentinel-2 and Landsat-9 satellite images to recover burn scars using several vegetation indicators. We have identified the fire locations using the object-based classification approach. For verification of results computed by vegetation indices, we have also performed land use land cover classification and calculated the changes in forest areas. Accuracy is computed by the confusion matrix with an accuracy of 89.45% and the kappa coefficient with an accuracy of 87.68%. In particular, there was a strong correlation between forest loss and the burned area in the subtropical evergreen broadleaf forest zone (6.9%) and the deciduous coniferous forest zone (18.9% of the lands). These findings serve as a foundation for future forecasts of fire-induced forest loss in regions with similar climatic and environmental conditions.

***Keywords*—GEE; remote sensing; classification; landsat; sentinel; forest fire**

I. Introduction

The forest is a foundation for all living things and is crucial in influencing global climate change. The forest is divided into basically three types: Reserved Forest (RF), Protected Forest (PF), and Unclassified Forest (UF). Under federal or state forest legislation, a place is known as a Reserved Forest (RF), which is completely protected. Unless otherwise permitted, no activity is allowed in the reserved forest. The State Forest Act or the Federal Forest Act may designate a territory as a Protected Forest (PF). An unclassified Forest (UF) is a place that has been given a forest designation but is not a restricted or protected forest. Depending on the state, these woodlands may be owned differently. Being the primary categories of natural landscapes, forests are the most priceless natural resources on earth. Unlike other natural resources like minerals, mineral oils, and natural gas, which are finite and cannot be replenished, forests have the amazing advantage of being renewable. However, the productivity of forests depends heavily on human activity. More than four billion acres of forest cover the entire earth, according to a survey by the Global Forest Resource Assessment (GFRA) in 2020 [1] the size of these forests cover varies, and it covers the entire surface of the earth. With around 45% of the world's total forest cover, Europe has the largest forest cover, according to another report from 2011. Considering percentages, South America is the top continent in terms of the area that is covered by forests, with almost half of its land mass falling under forests. If we consider per capita forest area, Oceania is placed first. But a percentage of these forest areas are degraded year to year due to several natural factors or man-made activity. According to the Forest Survey of India in the Year 2023 between the dates 1 March 2023 to 15 March 2023, a total of 772 large fire accidents happened. Mizoram has been affected by a maximum total of 110 fire incidents, and Meghalaya, Manipur, and Assam forest areas have been affected a total of 59, 52, and 43 fire incidents respectively. The reasons behind these fire incidents in forest areas are less precipitation level in February 2023. The country recorded only a 7.2 mm rain level in February which is the sixth lowest from the year 1901, central India recorded 77% rain deficiency while the northwest, southern, and northeast area recorded 76%, 54%, and 43% rain deficiency respectively. Total 38 forest fire incidents were reported in Kerala between January and April of 2018. Kerala had numerous fire events, from January to March 2017; 2,100 hectares were destroyed in 440 fire incidents. The reason behind this incident is climate change; also because one of the factors that contribute to fires is the increase of dryness in the environment. Forest Fires can be identified and characterized by several indicators. The spectral reflectance characteristics of healthy vegetation and burnt scar vegetation can be used to identify forest fires. For fire detection, thermal variations between burning and background pixels are also frequently used. The thermal infrared bands on satellite sensors like ASTER, MODIS, and VIIRS also can be used to detect forest fires. Since the majority of these sensors are categorized as having coarser spatial resolutions, it is challenging to monitor

*Corresponding authors

fires on a regional scale. For instance, burn area products from the Moderate Resolution Imaging Spectroradiometer (MODIS) are available globally in 500 m (MCD64A1) since 2001 [2]. There are a number of researchers who performed change detection due to fire incidents over different land cover areas like [3] performed forest fire area computation over Mugla, Turkey using different vegetation indices. The authors in [4] performed their analysis over the Pacific Northwest, USA for finding the effects of climate change on fire regimes. The rest of the paper is structured as follows. Related work is presented in Section II. Section III illustrates the study area, Section IV presents a methodology and materials like data sets, vegetation indices, and classification algorithms used in the computation. The result is discussed in Section V and in the last Section VI presents the concluding remarks.

II. Related Work

Forests fire occurred in recent years in a very large manner. Remote sensing techniques are mainly used for the finding reason and computing loss for these fire incidents, there are a number of platforms available in geographic information systems (GIS) which are used to calculate these changes like QGIS, ArcGIS, and ELWIS using satellite images. But these GIS softwares required large processing of data before computation, [5] have used such geographic information, system-based software and produced a framework for computing change analysis. In this analysis data sampling was put into place in two primary stages: maintaining a binary map for the burned area and unburned areas and mapping the burned areas of various land cover classes. The primary stage focuses on mainly five steps: removal of cloud cover and other noise (prepossessing), spatial and spectral feature extraction for pre-fire and post-fire, analysis of change in forest area in pre-fire and post-fire computation, extraction of features, mapping of burned areas based on the selection of feature from VIIRS hotspots, but extraction of burned area and unburned area takes a very large amount of time and computation so some researchers used Google Earth Engine for computation and pre-analysis. The authors in [6] have performed their analysis using Google Earth Engine (GEE) [7], over two satellites Landsat 8 and Sentinel 2. The researchers performed their computation by partitioning into four-level, performed the supervised burned area over the cartography tool for stratified random sampling, after the selection of data change in the area over a given time period. In [8] researcher performed his study by use of 14 different sets of fire variables that are taken from spectral vegetation indices, environmental variables, climate factors, and other spatial features. The training and testing validation is performed using a classification algorithm later use bootstrap, and optimistic bootstrap approaches to evaluate the models' accuracy and estimate the variance and bias of the estimate. But these researchers are focusing on the sample and collected data set only not on real-time data sets. Later Andrea Tassi and Marco Vizzari [9] proposed point-based (PB) and object-based (OB) classification and categorization techniques, that may be implemented on the spatial cloud platform, Google Earth Engine (GEE). Ramita Manandhar [10] also studied the framework-based technique of classification to enhance the accuracy of the classification algorithm by combining other data, such as different land cover classes, spatial features, spectral indices, and digital elevation models. The study [11] discusses the other category of classification, he performed categories based on the study of light detection and ranging (LIDAR) was used as part of an innovative strategy for mapping the danger of forest fires. The hierarchy process was used to calculate the criteria weights that affect fire risk and was applied to two different data sets over the different locations of Spain. The findings indicate that about 50 % - 65% of the study area is classified as 3-moderate fire risk zones. The researcher will be able to choose the best vegetation management strategies based on the danger of forest fires according to the technique given in the [11] study. The forest fires problem does not occur only in the global region but also causes in many places in small areas like the valley of the Himalayas. Over the course of the whole research region, the forest fire burn area dramatically fluctuates with time and space. Research [12] concluded that fire problems arose in the west-to-south Himalayan region multiple times between years 2000 -2010. Higher burn area fraction patches (0.7sq-km to 1 sq-km) were discovered over the southeast regions of the eastern Himalayas, the central Himalayas, and the western Himalayas. Over the past two decades (2001–2020), the average yearly burn area was 5557.35 sq-km, with a large amount of variability (standard deviation 2661.71 sq-km). The yearly burn area increased significantly by 755.7 sq-km per year between 2001 and 2010 but declined in the following decade. Further [13] provides three models for anticipated forest fire susceptibility maps (FFSM) using the Google earth engine (GEE) platform and then maps it over geographic information system software. The researcher [14] uses a range of probability mechanisms for finding change due to fire incidents; value lie between 1 to 0 if it surrounds near 1 then occurrence and loss is high and in other case occurrence and loss is very less. Deforestation is the long-term loss of trees as a result of anthropogenic or natural activity. It happens everywhere as a result of intricate socioeconomic processes like population and housing increase, agricultural expansion, and wood exploitation in underdeveloped nations. Deforestation is also made worse by economic, political, technological, and cultural causes. Deforestation contributes to a number of serious issues, such as soil erosion, disruptions to the water cycle, and possibly global repercussions. Deforestation has caused the land to change too quickly, resulting in the loss of vegetation, and wildlife, which hinders the functioning of ecosystems [15], [16] computed the growth in urbanization and loss of forests between the years 2009 and 2019, and found the current trend of urban growth is continuing at a pace of 0.16% each year. Environmentalists and land planners comprehend the effects of land use and land cover to provide recommendations for effective policy strategies to manage growth in Cameron Highlands. The study [17] discussed the forest management systems in Finland and Scandinavia. Satellite images are used in Finland and Sweden's national forest inventories. Researchers [18] witnessed fast changes in land use and cover, with the area covered by vegetation dropping from roughly 46% in 2009 to 28% in 2019. Area of about 27.54 percent of the area covered by vegetation is converted to urban/built-up areas, 4.60 percent to agriculture, and 6 percent to arid terrain. The amount of agriculture and urban/built-up area has greatly expanded. The research [19] analyzed the change in different classes of land cover using a number of sample points and training and testing points for each class. Points are split into subgroups for training

(70%) and evaluation (30%). Metrics obtained from an error matrix were used to measure accuracy. The research [20] describes that global service on SUHI monitoring is available to provide helpful cues for our cities' increasingly sustainable urban design. In [21] the author discusses different spatial resolution and wavelength of satellite Sentinel-2 and Landsat-8 and describe that both satellites are useful and provide good accuracy in measuring changes that occur in a fire-prone area. Sentinel-2 satellites have a spatial resolution of 10 meters while landsat data sets have a spatial resolution of 30 meters. The researcher in [22] states that planning for conservation and management, as well as ecological study, is made more difficult in tropical rainforests due to a dearth of spatially and thematically precise vegetation maps. Such maps have a great deal of potential to be produced by remote sensing, but the categorization accuracy within primary rain forests has typically fallen short of practical uses.

III. Study Area

The study area Fig. 1 is located at 9.50°N and 77.10°E. covering about 2407 square kilometers (1,171sq mi) and bordered on the north by the district of Thrissur, on the south by the districts Kottayam and Alappuzha, on the east by the district Idukki, and on the west by the Arabian Sea. Three separate sections make up the district: Hills and woods, plains, and the seashore, respectively, make up the highland, midland, and lowland regions. The highlands are located at a height of around 300 m. (980 ft). Except for Muvattupuzha, the Periyar River, Kerala's longest, traverses every taluk. The district is traversed by the Chalakkudy River and the Muvattupuzha River.

It consists of several land cover classes like urban, water, and forest (high vegetation), agriculture (low vegetation) but forest alone consists of 45.20% of total land. In the year 2022-23, a total of nearly 430.75 hectares was affected by 391 fire incidents. According to data from the state pollution control board, the mean air quality index remained above 300 $PM_{2.5}$ (particulate matter) concentrations in the air for five days before the fire occurrence.

It was 441 $PM_{2.5}$ concentrations on March 5; 445 $PM_{2.5}$ concentrations on March 6; 465 $PM_{2.5}$ concentrations on March 7; 324 $PM_{2.5}$ concentrations on March 8; and 380 $PM_{2.5}$ concentrations on March 9. Good breathable air quality has an index value of less than 50 $PM_{2.5}$ concentrations, while before the dump yard fire, the city's average air quality index was below 100 $PM_{2.5}$ concentrations. The study area is computed as 3,432 mm of rain falls on average in the district this year. The district has a mild temperature average temperature between May 2022 to March 2023 as shown in Fig. 2.

The temperature rapidly increases during fire time and is largely located in the Malabar Coast moist forests ecoregion, while the highlands are a part of the South-Western Ghats moist deciduous forests ecoregion. On the border of the districts of Ernakulam and Idukki, the Anamudi is the tallest mountain in South India. Sholas can be found in some areas of the Mankulam Forest Division and Idamalayar Reserve Forest, however, these areas cannot be reached by road. Edamalakkudy and the Idamalayar Protected Forest, have different kinds of rocks, silt, and sand. The majority of the district's eastern forests are secluded and are a portion of the Anamalais. Temperature is also a very significant factor after the forest fire incident it changed moderately.

IV. Materials and Methods

Since the 1970s, surface soil moisture (SSM) and change in the surface area has been determined by remote sensing. The primary benefit of remote sensing is that it offers geographically diverse data, as surface variables with spatial information are necessary for many applications, including evapotranspiration evaluation, soil erosion mitigation, irrigation scheduling, drought monitoring, and forest management.

The study is performed by using the satellite data set from Sentinel and Landsat over the cloud platform Google Earth Engine (GEE). GEE is a planetary platform that has access to different satellite data like Sentinel, Landsat, MODIS, etc. Each satellite has the unique characteristic as wavelength, band combination, and resolution. Here we are accessing sentinel-2 and Landsat-9 to observe forest area changes. A detailed description of the analysis is shown in the Fig. 3 and used bands used for analysis by both data sets are detailed in Table I.

Research is subdivided into two parts. We calculate the change in forest area from pre-fire and post-fire accidents. Later we perform observation over the burn area and calculate the different changes in the forest area. These changes are calculated by computing the change in a land cover class by the gradient tree boost classification model and also by computing the change in mean and standard deviation value of different indices like Green Normalized Difference Vegetation, Adjusted Transformed Soil Adjusted Vegetation Index (ATSAVI), Normalize difference water index (NDWI) and Enhance vegetation index (EVI). The methodology used in the research is illustrated in Fig. 3. GNDVI (Green Normalized Difference Vegetation) measures the "greenness" or photosynthetic activity of plants. While it saturates later than NDVI, it is a chlorophyll index that is utilized during later phases of development. It is one of the most popular vegetation indices for calculating crop canopy water and nitrogen uptake. The values for Normalize difference water index (NDWI), like other indices, range from -1 to 1, with high values denoting high plant water content and coverage of a significant portion of the plant and low values denoting low vegetation water content and sparse cover. Pre-fire and post-fire results are calculated by using the normalized burn ratio mechanism and calculated by equation 1.

$$NBR = \frac{(NIR - SWIR)}{(NIR + SWIR)} \tag{1}$$

Where: NIR (Near Infra-Red) as a Band 5
SWIR (Short Wave Infra-Red) as a Band 7

GNDVI has a greater saturation point than NDVI and is more sensitive to changes in the crop's chlorophyll content. While NDVI is useful for predicting crop vigor in the early stages, it can be used in crops with dense canopies or in more mature phases of growth.

$$GNDVI = \frac{NIR - GREEN}{NIR + GREEN} \tag{2}$$

the visible green wavelengths. The near-infrared wavelengths maximize the high reflectance of terrestrial vegetation and soil components while minimizing the low reflection of aquatic features. The NDWI equation yields positive values for water features and negative ones (or zero) for soil and terrestrial vegetation.

$$EVI = \frac{2.5 * (Band5 - Band4)}{(Band5 + 6 * Band4 - 7.5 * Band2 + 1)} \tag{4}$$

In dense vegetation, EVI is more sensitive and can compensate for some atmospheric conditions and canopy background noise. While ATSAVI is used where vegetation cover is very low.

$$ATSAVI = a\frac{(NIR - a * RED - b)}{((a * NIR) + (RED - a * b) + (X * (1 + a^2))} \tag{5}$$

Classification is performed using the Gradient tree boost machine learning classifier algorithm [23]. It provides a hypothetical model in the form of an ensemble of decision trees. Mainly it is a collection of nodes of weak prediction models. The resulting technique, called gradient-boosted trees, typically it beats random forest when a decision tree is a weak learner. The construction of a gradient-boost trees model follows the same stage-wise process as previous boosting techniques, but it generalizes other techniques by optimizing any differentiable loss function, later we computed accuracy by using the confusion matrix by equation 6 and kappa coefficient by equation 7. Cohen recommended the following interpretation of the Kappa result: values 0 as showing no agreement and 0.01-0.20 as none to the partial agreement, 0.21-0.40 as fair agreement, 0.41- 0.60 as moderate agreement, 0.61-0.80 as significant agreement, and 0.81-1.00 as almost perfect agreement.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{6}$$

Where T̄P= True Positive,
F̄P = False Positive

TABLE I. Band Uses for Calculating Changes in Forest Cover

COLOR	LANDSAT		SENTINEL	
	BAND	WAVE LENGTH	BAND	WAVE LENGTH
BLUE	BAND - 2	0.45 - 0.51	BAND - 2	0.492 - 0.496
GREEN	BAND - 3	0.53 - 0.59	BAND - 3	0.559 - 0.560
RED	BAND - 4	0.63 - 0.67	BAND - 4	0.664 - 0.665

SWIR	BAND - 7	2.1 - 2.2	BAND - 12	2.18 - 2.20

T̄N = True Negative,
F̄N = False Negative

$$\kappa \& = \frac{P_o - P_e}{1 - P_e}. \tag{7}$$

Where P$_o$ = Observed proportional agreement,

P$_e$ = Hypothetical probability of chance agreement.

V. Result

Deforestation is taking place day to day in a very large manner, sometimes it is being done by human activity, and sometimes it is by natural activity, like flood, and fire. We are calculating a change in the forest area of Kochi district from all the above mention activity. The primary reason for the change in forest area over the study area is some fire accidents that occurred between January 2023 and March 2023. But we are not only rigid for these fire issues we also calculate all other possible reasons also for deforestation. So here we calculated vegetation indices like NDVI (Normalize Difference Vegetation Index), GNDVI (Green Normalize Difference Vegetation Index), ATSAVI (Adjusted Transformed Soil Vegetation Index), and EVI (Enhanced Vegetation Index). These vegetation indices are used for the calculation of Change of Vegetation indices and also for evaluating the effect on soil moisture and water due to these changes. For the calculation of forest change in the study area we first calculate the change as shown in Fig. 4 and Fig. 5 using a supervised classification technique Gradient Tree Boosting. For this, we calculated about 1200 data points of different land cover classes and took 70% data as training points and 30% data as testing points. Results of this classification are shown in Fig. 4 and Fig. 5 and these changes are described that a large amount of forest loss occurred by these fire incidents. So for calculating these losses here, we computed the percentage of the forest before the fire incident (pre-fire) and after the fire incident (post-fire). After classification, we computed the accuracy of the classification result by confusion matrix and kappa coefficient, total accuracy computed by confusion matrix is 89.45% and by kappa coefficient is 87.68%. On focusing output generated by the gradient tree boost in Fig. 4 and Fig. 5, there is a lot of change happening in the east-south region of the study area. The reason behind these changes is fire accidents in these areas. So we calculate fire accidents in this area, mainly two major fire accidents found at two places, and many vegetation changes occur due to this fire accident. Fig. 6 and Fig. 7 shows the change in vegetation due to these fire accidents in the study area.

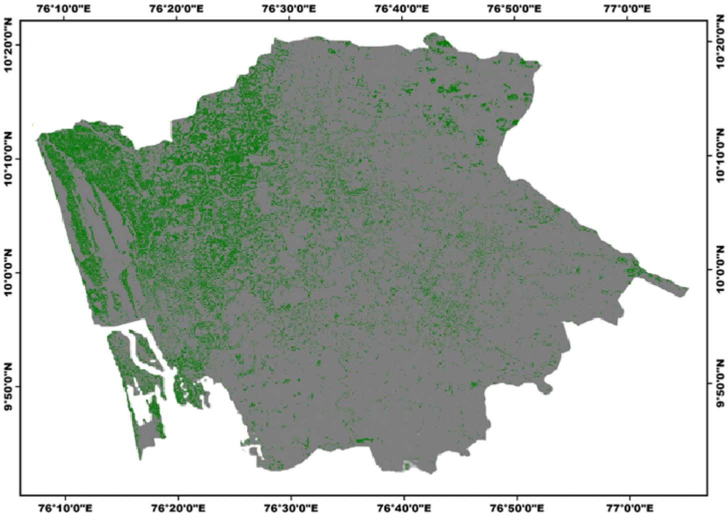

Fig. 4. Output generated over landsat-9 data sets before fire incident.

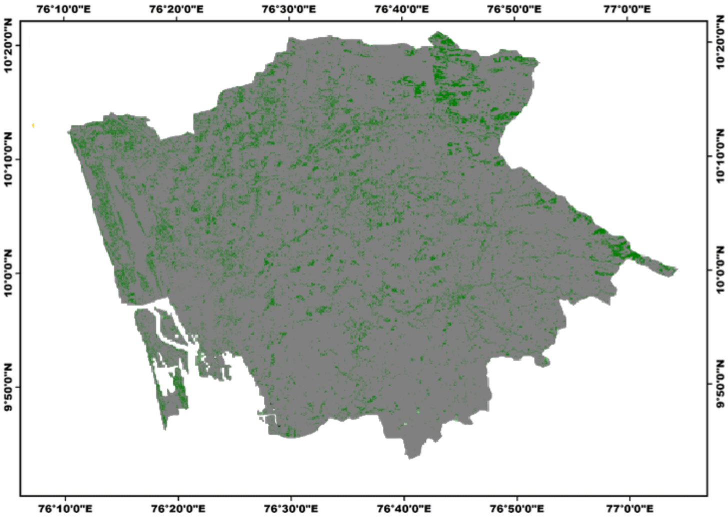

Fig. 5. Output generated over landsat-9 data sets after fire incident.

Fig. 8 shows the loss of land cover areas during a fire incident. The fire affected approximately 24.67% of land cover

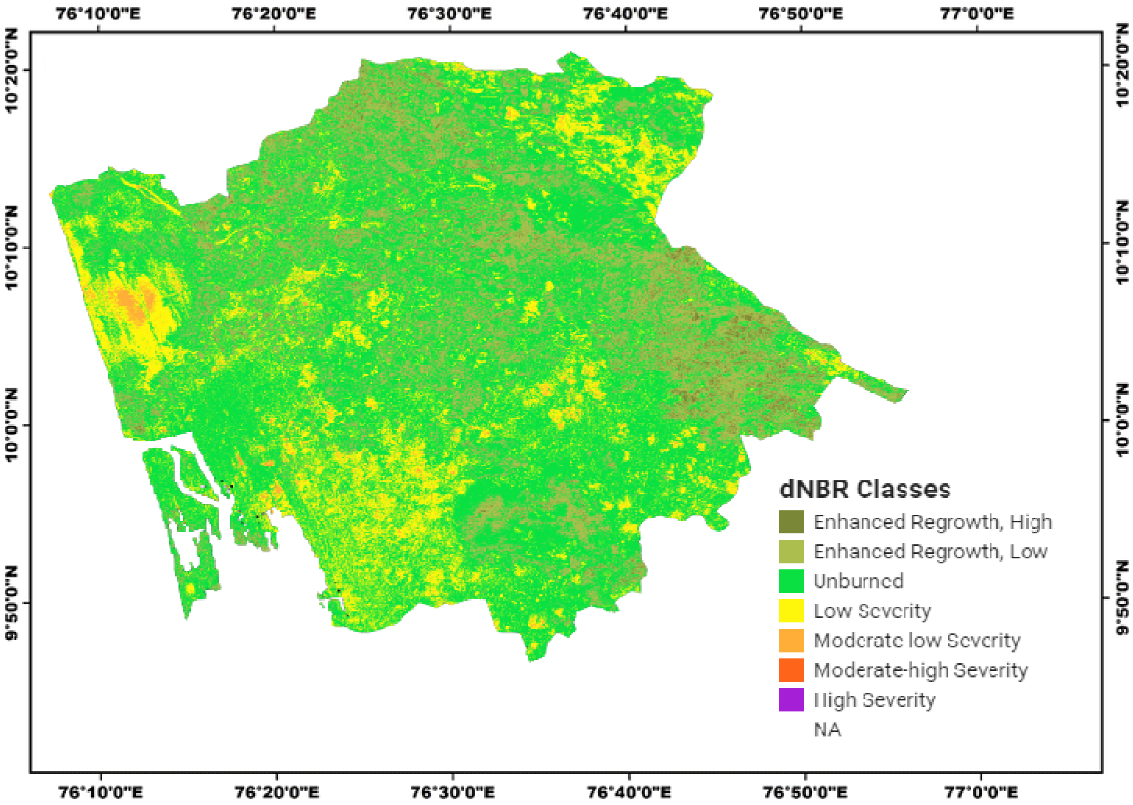

Fig. 7. Fire incidents happened between February and March months.

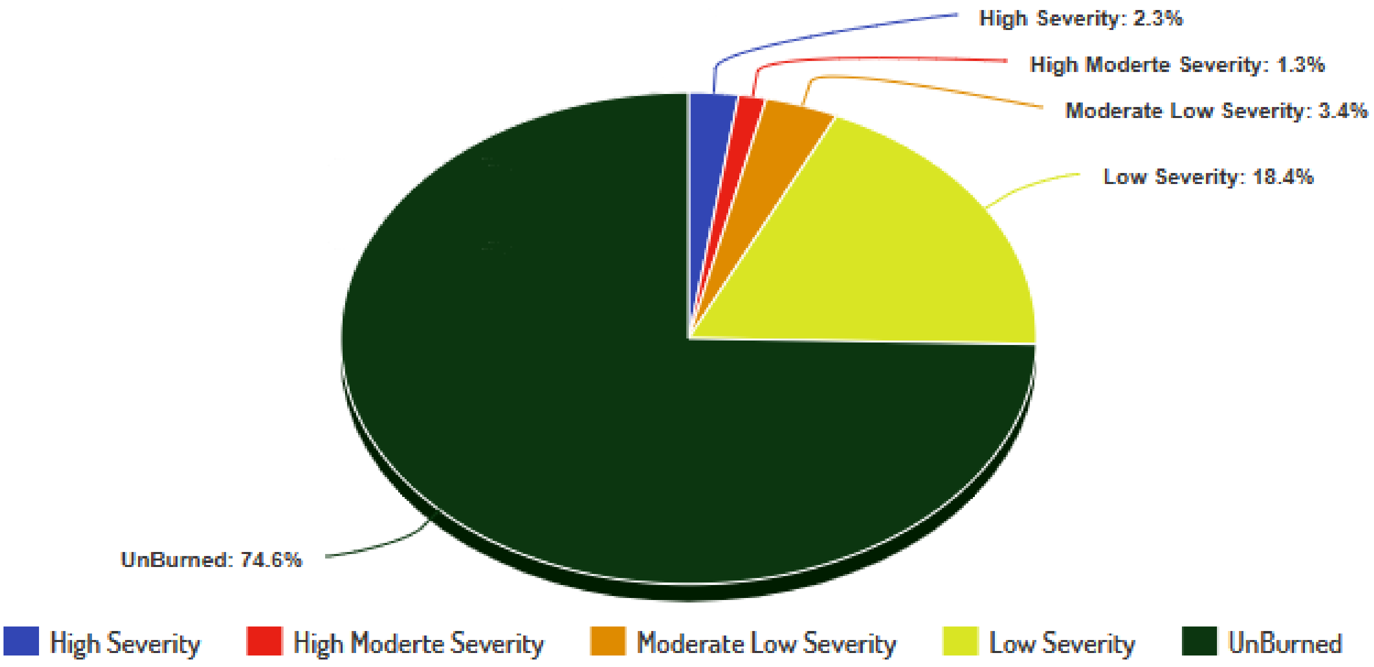

Fig. 8. Changes in the study area.

areas. These areas come under dense forest, moderate dense forest, open forest, and scrubland as we computed here forest loss. So non-forest areas about 74% are detected as having no loss.

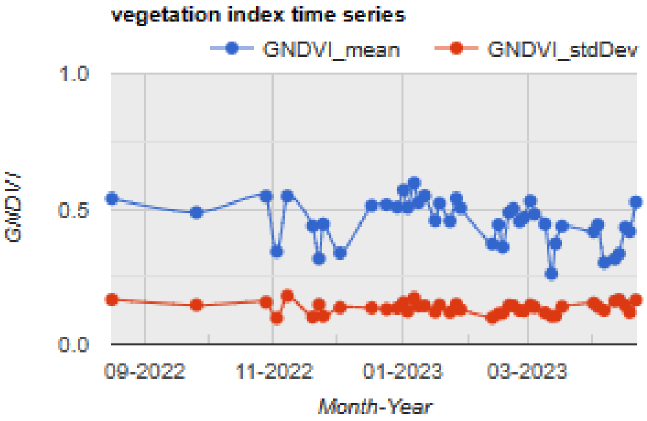

Fig. 9. Green normalize difference vegetation index calculated over study area during forest fire using sentinel 2 data set.

Green Normalize Difference Vegetation index, Normalize Difference Water Index, Adjusted Transformed Soil Adjusted Vegetation Index. Enhanced Vegetation Index is calculated over Ernakulum during the forest fire time from September 2022 to March 2023. We found that time when rapid fire arises, its mean and standard deviation value change. For verification purposes, we have computed the mean GNDVI over two data sets Landsat-9 and Sentinel-2.

These two data sets are easily available in the Google Earth Engine directory; basic difference between both data sets in terms of resolution is Landsat-9 data sets having a resolution of 30 meters and Sentinel data sets having a resolution of 10 meters, these data sets also have a collection of nine different bands each band having unique attributes and the ratio of these bands providing a different signature for each vegetation indices. Fig. 9 and Fig. 10 show the change in green normalize difference vegetation index over sentinel-2 and landsat -9 data sets respectively and both data sets have nearly the same result over the study area. Later we calculate mean and standard deviation values over normalized difference water index (NDWI), adjusted transformed soil adjusted vegetation index (ATSAVI), and enhanced vegetation index (EVI). For observing the effects of fire incidents over water, soil, and natural vegetation indices. Fig. 11, and Fig. 12 shows results

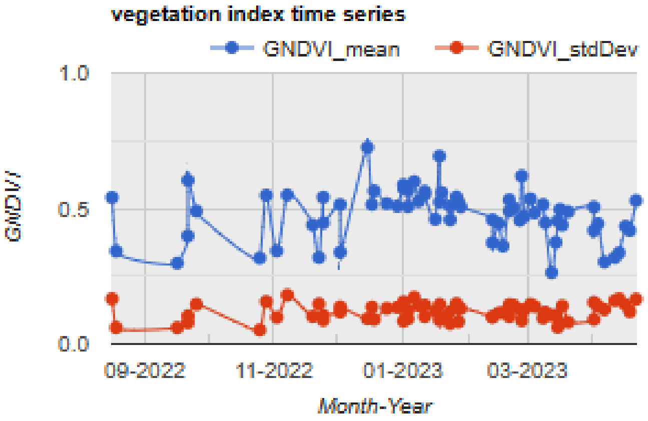

Fig. 10. Green normalize difference vegetation index calculated over study area during forest fire using landsat 9 data set.

Fig. 18. Snip of user interface available at https://paper1.users.earthengine.app/view/forest-cover-change.

enhanced vegetation index over Sentinel-2 and Landsat -9 data sets respectively; this result shows that change in these indices occurred at the time of fire incident over the study area and also after the fire incident also. From the above observations, we find that fire forest reduces greenery as well as affects water and soil also. Equations (1 to 5) are used for the calculation of these indices and finding change during fire incidents. Equation 1 is used for calculating a change in the study area due to fire incidents and providing details results which are shown in Fig. 6 and Fig. 7. Areas affected by these fire incidents are described in Fig. 8. From the result, it is shown that a large area of forest loss nearly happened over the study area due to fire incidents. These fire incidents not only disrupted climate conditions and global warming but also had a huge effect on soil and other vegetation indices. We have calculated total forest loss from the year 2000 to the year 2021 using Hansen forest loss cover analysis data sets, and find loss increased from the year 2017 due to multiple reasons over the study area. Detailed analysis of loss cover is shown in Fig. 17

Later at the end, we develop an application user interface that collects data in the form of geometry or if the user has their shape or CSV file of the study area can provide a path in user access link. Users can select desired geometry in the form of a point, polygon, or in rectangle form. A snip of the User interface is located in Fig. 18.

VI. Conclusion

The proposed analysis model is used to compute forest loss in Ernakulum (Kochi) using Landsat-9 OLI, and Sentinels 2 satellite data due to the occurrence of the fire incident. Through our analysis, we found deciduous forests are more vulnerable to fires. About 18.2% of vegetation area was affected by fires in 2023. Among all types of vegetation classes, vegetation that has higher density is affected most by the fire incident. Fire not only destroys vegetation cover but also has an impact on soil and water as well as on climate conditions also. We are also focused on finding factors behind these multiple fire occurrences over study and find an increase in temperature always increases the probability of fire occurrence. We have computed our analysis with more than 85% accuracy. Later our objective is to develop a model that can be used for analyzing change due to fire or another natural disaster by a number of vegetation indices using our defined model.

Abstract—**Computer-Assisted Bone Fractures Diagnosis in musculoskeletal radiographs plays a crucial role in aiding medical professionals in accurate and timely fracture detection. In this work, we explore a Generative Adversarial Network based approach for this task, which is a powerful deep learning model capable of generating realistic images and detecting anomalies. Our proposed approach leverages the potential of GANs to generate synthetic radiographs with fractures and identify anomalous patterns, thereby enhancing fracture diagnosis. Through extensive experimentation and evaluation on musculoskeletal radiograph datasets (MURA), we demonstrate the effectiveness of GAN-based models in improving fracture detection performance by adopting several evaluation metrics notably accuracy, precision, F1-score and detection speed. These findings highlight the potential of integrating GANs into computer-assisted diagnosis, contributing to the advancement of fracture diagnosis methodologies in orthopedics. It is important to note that GANs operate by training a generator network to produce synthetic images and a discriminator network to distinguish between real and generated images. This adversarial process fosters the generation of realistic radiographs with fractures, enabling accurate and automated detection. Our findings contribute to the advancement of fracture diagnosis methodologies and pave the way for more efficient and precise diagnostic tools in the field of orthopedics.**

Keywords*—*Deep learning; generative adversarial network; diagnosis; orthopedics; fracture detection; x-ray image

I. Introduction

Accurate and timely diagnosis of bone fractures is crucial in musculoskeletal radiology for effective patient care and treatment planning[1], [2], [3]. Conventional methods heavily rely on the expertise of radiologists [4], which can be subjective and time-consuming. However, recent advancements in artificial intelligence and deep learning techniques have paved the way for computer-assisted diagnosis systems that can aid radiologists in detecting and classifying fractures with improved accuracy [5].

In this article, we explore the application of generative adversarial networks (GANs) for computer-assisted bone fracture diagnosis in musculoskeletal radiographs. GANs are a class of deep learning models comprising two neural networks: a generator and a discriminator[6]. Its architecture give a promising future for anomaly detection in several fields[7], [8], [9]. The integration of GANs in fracture diagnosis presents several advantages. Firstly, it offers the potential to reduce radiologists' workload by automating the initial screening process. This allows radiologists to allocate more time and attention to complex cases, ultimately improving patient care. Secondly, GANs have shown promise in enhancing diagnostic accuracy by providing a reliable second opinion. By learning from a large dataset of medical images, GANs can capture subtle fracture features and aid radiologists in making more informed decisions. Moreover, GAN-based systems have the potential to contribute to the standardization of fracture diagnosis. By learning from diverse cases and incorporating a wide range of fracture patterns, these systems can help minimize inter-observer variability and increase diagnostic consistency across different healthcare settings. Furthermore, the continuous learning capabilities of GANs enable the system to adapt to new data and improve its diagnostic performance over time. Despite these promising advancements, several challenges must be addressed. Ensuring the robustness and generalizability of GAN-based fracture diagnosis systems across various patient populations, imaging modalities, and fracture types is essential. Furthermore, ethical considerations, data privacy, and regulatory frameworks need to be carefully considered to ensure the responsible and safe implementation of these technologies in clinical practice.

In this work, we will investigate how the integration of GANs in computer-assisted bone fracture diagnosis can hold a great potential in revolutionizing musculoskeletal radiology. By combining the expertise of radiologists with the power of deep learning, these systems can enhance diagnostic accuracy, streamline workflow, and contribute to standardized fracture diagnosis. As ongoing research and development in this field continue to unfold, it is expected that GAN-based computer-assisted diagnosis systems will play a pivotal role in improving fracture detection and patient care in the near future. To this end, we will explore MURA dataset [10], the largest public radiographic image datasets, to see what GANs may be drawn on orthopedic anomaly detection on X-ray images.

The contribution through this work can be summarized as follows:

- Efficient and accurate anomaly detection techniques based on deep learning to detect bone fractures.
- Applying several GANs models in one work to have a rich comparative study.
- Review the examined deep learning models, approaches and architectures.
- Identification of the most suitable data pre-processing techniques for our study, especially for the dataset em-

ployed. This analysis provides valuable insights into the optimal preprocessing steps required to improve the overall effectiveness of the models.

- Optimize the performance of the examined models to overcome the performance of recent and relevant works.
- Evaluates the effectiveness of the examined models using different evaluation metrics to have a comparison and analysis study based on their results.

The rest of the paper is designed as follows: In Section I we provide the essential background to understand the rest of the paper. Section II lays out a brief summary of the related work in the same field. Section III presents our paper's methodology. Section IV presents the experiment, materials used, dataset description and evaluation metrics for a promising comparative analysis study. Section V presents models' results and discusses the outcomes based on several evaluation metrics. Finally, the conclusion and the findings of this work are in Section VI.

II. Related Work

Fractures are highly accurate indicators of orthopedic pathology in most hospitals. However, analyzing medical images to identify bone fractures can be time-consuming and requires the expertise of qualified professionals. To address these challenges, scientists have been investigating ways to reduce diagnosis time and improve decision precision, aiming to assist doctors in their diagnostic processes [11], [12], [5], [13]. Several studies have demonstrated the potential of AI/DL in supporting medical professionals and decision-makers by developing automated tools that enhance the accuracy of physician interpretation [14], [5], [15], [16], [17], [18], [19], [20] and facilitate the creation of effective and cost-efficient treatment plans [15]. While many studies have focused on accurately detecting musculoskeletal abnormalities using CNN models, our research specifically explores the application of generative adversarial networks (GANs) [21] as a novel approach as shown in Table I. In this article [22], we propose the Res-UnetGAN network, an unsupervised anomaly detection approach based on GANs. The architecture combines the ResNet50 and UNet models within the generative network to calculate the normal distribution of samples. The discriminator employs a deep separable convolution-based convolutional neural network model to facilitate the adversarial training process. Anomaly identification is achieved by evaluating the reconstruction error score, which measures the quality of reconstruction and detects the presence of defects. Extensive testing on the Mura dataset demonstrates that our proposed method outperforms several other models in terms of defect detection accuracy.

In addition, [23] Davletshina et al. highlighted the value of unsupervised techniques trained on radiographic images without anomalies. Their approach aims to improve diagnostic accuracy and reduce the possibility of overlooking critical areas. By leveraging cutting-edge unsupervised learning techniques, they successfully identify anomalies and demonstrate the justifiability of the results.

Through our research, we aim to contribute to the advancement of fracture diagnosis by integrating the capabilities of GANs in framework will be used by radiographs. Hopefully this approach will have the potential to enhance the efficiency and accuracy of fracture diagnosis, enabling timely interventions and improved patient care.

III. Methods

In this section we will present our proposed framework and we will review GAN models investigated in this study.

A. Proposed Framework

In the proposed framework for fracture diagnosis as shown in Fig. 1, the process begins with the acquisition of the images using medical imaging devices; then will be integrated into computers. These medical images are then passed through a deep learning system that performs preprocessing tasks such as image enhancement, augmentation, rotation, and normalization. The preprocessed images are then fed into the fracture detection algorithm, which utilizes GAN models and CAM technique to identify and visualize fractures within the medical image. Once the detection process is complete, the system evaluates the results using various evaluation metrics such as accuracy, precision, F1-score, and detection speed. These metrics provide quantitative measures of the system's performance in correctly identifying fractures. Based on these metrics, a final decision is generated, indicating the presence or absence of fractures in the input image. This decision is crucial in assisting radiologists in making accurate diagnoses and treatment decisions. The framework aims to enhance the efficiency and time to diagnosis fracture detection, ultimately improving patient care in the field of musculoskeletal radiology.

B. Overview of GANs

Generative Adversarial Network (GAN) is a powerful deep learning framework that has gained considerable attention in recent years [6]. As in Fig. 2 GANs are composed of two main components: a generator and a discriminator. The concept behind GANs is to train the generator and discriminator in a competitive manner. Initially, the generator produces random samples, and the discriminator tries to correctly identify them as fake. As training progresses, both the generator and discriminator learn and improve their capabilities. The generator aims to generate samples that are increasingly difficult for the discriminator to differentiate from real data, while the discriminator continuously adapts to distinguish the real and generated samples accurately.

One of the significant advantages of GANs is their ability to generate new and realistic data that captures the underlying distribution of the training data. GANs have been widely used for various applications, including image synthesis, text generation, anomaly detection, medical diagnosis, and data augmentation [5], [8], [7], [24], [26], [27]. The generated samples can be used to enhance training datasets, generate novel and diverse content, or assist in data analysis tasks. Despite their remarkable capabilities, GANs come with their own challenges. Training GANs can be complex and prone to instability, often requiring careful hyperparameter tuning and architectural considerations. Issues like mode collapse, where the generator fails to explore the entire distribution of

real data, can also arise. However, ongoing research aims to address these challenges and further improve the performance and stability of GANs.

To sum up, the ability of GANs to generate realistic and novel data has opened up new possibilities in various domains, including computer vision and data analysis. With continued advancements and research, GANs hold great promise for generating high-quality synthetic data and pushing the boundaries of generative modeling even further.

In the following Table II, we describe the different GAN models implemented in this work.

IV. Experiment

A. Experimentation Setup

The following subsection provide an overview of the dataset utilized in this study, including a description of its characteristics. The training settings and evaluation metrics employed.

1) Dataset description: The MURA dataset is a widely recognized and utilized dataset in the field of musculoskeletal imaging[10]. It comprises a large collection of radiographic images across different anatomical regions, including upper extremities, lower extremities, and the torso. The dataset focuses on various musculoskeletal conditions, especially fractures. The MURA dataset serves as a valuable resource for developing and evaluating algorithms and models in the domain of musculoskeletal radiography. Researchers and practitioners leverage this dataset to advance the field and improve diagnostic accuracy, automated diagnosis systems, and computer-assisted fracture detection techniques. The dataset is provide by the Stanford Program for Artificial Intelligence in Medicine: https://stanfordmlgroup.github.io/competitions/mura/.

2) Evaluation metrics: **Accuracy:** Accuracy is a widely used evaluation metric that measures the overall correctness of a fracture detection model [30]. It calculates the percentage

TABLE II. DESCRIPTION OF IMPLEMENTED MODELS

Model	Type	Description
[24] GANomaly	GAN-based anomaly detection model	Ganomaly combines GAN architecture with anomaly detection techniques to identify fractures in radiographs. It learns to generate normal images and detects anomalies based on reconstruction error.
[24] SkipGANomaly	GAN-based anomaly detection model	SkipGanomaly extends the GAN architecture by incorporating skip connections to improve the quality of reconstructed images.
[26] AnoGAN	GAN-based anomaly detection model	AnoGAN combines GAN architecture with unsupervised learning to detect anomalies in images.
[27] MadGAN	GAN-based anomaly detection model	MadGAN is a GAN architecture that utilizes multiple discriminators to enhance the detection of anomalies.
[28] AttentionGAN	GAN model image-to-image translation	AttentionGAN is a type of GAN that incorporates an attention mechanism to improve the quality of generated images. It selectively focuses on important regions, capturing fine details and producing realistic outputs.
[5] DCGAN	GAN model with deep convolutional layers	DCGAN is a foundational GAN model that employs deep convolutional layers for image generation. It can be utilized to generate synthetic radiographs with fractures for training or augmenting the dataset.
[5] CycleGAN	GAN model for image-to-image translation	CycleGAN is primarily used for domain adaptation and image translation tasks. Although not directly designed for fracture detection, it can potentially be employed to translate normal radiographs to fractured ones, facilitating the identification of fractures based on the translated images.
[29] SAGAN	GAN model with self-attention mechanism	SAGAN incorporates self-attention mechanisms to improve the quality and coherence of generated images.

of correctly identified fractures out of all the samples in the dataset.

$$Accuracy = \frac{TruePositives + TrueNegatives}{TotalSamples}$$

Precision: Precision is a metric that focuses on the positive predictions made by the fracture detection model[30]. It measures the proportion of correctly identified fractures out of all the predicted fractures. Precision helps assess the model's ability to minimize false positives, indicating how reliable the model is when it identifies a sample as a fracture.

$$Precision = \frac{TruePositives}{TruePositives + FalsePositives}$$

F1-Score: The F1-Score is a combined metric that takes into account both precision and recall, providing a balanced measure of the fracture detection model's performance[30]. It considers the trade-off between false positives and false negatives. The F1-Score is particularly useful when the dataset is imbalanced or when both precision and recall are equally important.

$$F1_{Score} = 2 * \frac{Precision * Recall}{Precision + Recall}$$

Detection Speed: Detection speed is an essential evaluation aspect that measures the efficiency of a fracture detection model in processing and analyzing musculoskeletal radiographs[30]. It quantifies the time taken by the model to detect fractures in a given dataset or per image. Faster detection speeds are desirable, particularly in clinical settings where time is of the essence.

By considering these evaluation metrics - accuracy, precision, F1-Score, and detection speed - we can thoroughly assess the performance and efficiency of fracture detection models. These metrics provide valuable insights into the model's ability to correctly identify fractures, minimize false positives, achieve a balance between precision and recall, and process radiographic images efficiently.

B. Preprocessing

The MURA dataset, presents a challenge due to its diverse range of images of bone abnormalities with different formats and sizes. To address this issue and make the data more uniform, we employed image pre-processing techniques to enhance the image quality. Initially, we applied binary thresholding to identify the Region of Interest (RoI) within the image and extract its contours. This process enabled us to isolate the relevant region for classification and crop it accordingly.

Data augmentation played a vital role in our research, helping to expand the dataset and improve the learning algorithm. Several augmentation approaches were employed, including horizontal image flipping, random rotation within a range of 30 degrees, scaling within the range of 95-130 percent, and randomly adjusting brightness within the range of 80-120 percent.

Prior to initiating the learning process, radiographs were normalized to have the same mean and standard deviation as the images in the ImageNet training set. This normalization step ensured consistency and facilitated subsequent stages of the project.

Following data augmentation and normalization contributed to enhancing the quality, consistency, and effectiveness of the dataset for our research purposes.

V. Results and Discussion

In this section, we discuss the performance of GAN models for bone fracture detection in radiographs, focusing on key evaluation metrics such as accuracy, precision, F1-score, and detection speed. These metrics provide valuable insights into the effectiveness and efficiency of the models in identifying fractures and aiding in clinical decision-making. Various factors influence the performance of the models, including architectural approach, layer design, padding, shape, normalization, activation, loss function, optimizer, batch size, learning rate, pooling, and output layer. Consequently, achieving an effective result required multiple tuning iterations. Many of our models comprised computationally expensive layers and modules, necessitating long training durations that were often impractical on basic hardware or laptop configurations. Preprocessing played a crucial role in obtaining good results in our deep learning tasks. After selecting the appropriate GAN models for the study based on a benchmark between the different GAN model, extensive data preparation was necessary. The image size proved to be a significant parameter impacting the accuracy of detecting fractures. To this end, several treatments were involved on our dataset as mentioned in preprocessing section. Also, to overcome the limitations of the available data, we employed data augmentation techniques, which augmented the amount of data during the training phase. However, we had to be cautious regarding the rotation methods, excessive compression, and shear, as they could negatively affect the performance of bone fracture diagnosis. By considering these factors and conducting thorough experimentation, we aimed to optimize our models and enhance the accuracy of our results. It is evident that preprocessing, data augmentation, data normalization and careful parameter selection are vital considerations when striving for accurate and reliable outcomes in deep learning tasks related to bone fracture detection. Overall, as shown in Fig. 3 and 4 after selecting the input image we configure our framework by choosing body part treated, image modality and evaluation metrics that the user want to display. We see the visualized results by Grad-CAM and obtained from our implemented GAN models for bone fracture detection in radiographs were promising. The models demonstrated a high level of accuracy, achieving performance within the range of 0.7% to 0.954%. These results indicate that the GAN-based approach holds considerable potential for improving fracture diagnosis in the field of orthopedics.

Comparing our GAN models with previous works, it is evident that they compare favorably in terms of performance. The accuracy achieved by our models aligns with some results reported in works with the same task with different techniques and surpasses others results reported in relevant literature. This suggests that the utilization of GANs for bone fracture diagnosis can yield significant improvements in diagnostic accuracy and support medical professionals in their decision-making processes.

Detailly, Table III shows that MadGAN, CycleGAN, SAGAN and SkipGANomaly on average achieves the best accuracy (0.954%; 0.922%; 0.9%;0.901%). These accuracy scores indicate that the models were successful in correctly classifying fractures in radiographs, contributing to improved diagnostic capabilities. While with less processing time MadGAN and SAGAN have speed detection higher than other models. So we can consider MagGAN and SAGAN are the most powerful models. This is due to their architectures. MadGAN has the incorporation of multiple discriminators that can enhance the detection and identification of fractures in radiographs as anomalous patterns. SAGAN use self-attention mechanisms can improve the coherence and quality of generated images. Although not specifically tailored for fracture detection, its ability to produce visually consistent radiographs was the main cause to have an accurate fracture identification. Then we had GANomaly, AttentionGAN and AnoGAN achieved an accuracy of 0.861% and 0.842%. Those are reputable results even those models were not explicitly designed for fracture detection, but it could give a better performance in anomaly detection in other fields and with other parameters notably type of data, size of dataset, experiment setting, etc. For DCGAN, its performance in fracture detection be less compared to the models explicitly designed for anomaly detection or fracture identification. Because its architecture is not explicitly designed for fracture detection also due to the high number of convolutional layers that take more time to give the predictive result.

One notable advantage of GAN models is their ability to generate synthetic data, which can be beneficial in addressing

TABLE III. COMPARISON OF MODELS BASED ON PERFORMANCE METRICS

Models	**Accuracy**	**Precision**	**F1-Score**	**Detection Speed**
Ganomaly	0.861	0.873	2.863	2.987
SkipGanomaly	0.901	0.903	0.907	5.837
AttentionGAN	0.842	0.877	0.8418	2.291
MadGAN	0.954	0.958	0.953	1,418
SAGAN	0.9	0.905	0.907	0,2
AnoGAN	0.838	0.848	0.842	3.738
DCGAN	0.7	0.724	0.705	15.233
CycleGAN	0.932	0.917	0.928	8.412

the issue of limited labeled datasets. By leveraging the generative capabilities of GANs, it becomes possible to augment the available data and improve the robustness and generalization of the models. This can be particularly valuable in medical imaging, where acquiring large annotated datasets can be challenging. Despite the promising results, it is important to acknowledge the limitations and challenges associated with GAN models for fracture detection. One key consideration is the computational complexity and resource requirements of training and deploying GAN models. The training process of GANs can be computationally intensive and time-consuming, necessitating powerful hardware and substantial computational resources. This can pose practical limitations, especially in clinical settings where quick and efficient diagnosis is crucial.

To sum up, our study demonstrates the potential of GAN models in detecting bone fractures in radiographs. The achieved accuracy and performance indicate that GANs can serve as valuable tools for assisting medical professionals in fracture diagnosis. However, challenges related to computational complexity, data availability, and interpretability need to be addressed for broader adoption and real-world application. Future research should focus on optimizing GAN architectures, addressing dataset limitations to further enhance the performance and practicality of GAN models in fracture detection.

VI. CONCLUSION

In conclusion, this article has presented an exploration of Computer-assisted Bone Fractures Diagnosis in musculoskeletal radiographs using Generative Adversarial Networks (GANs). The use of GANs in medical image analysis has shown great potential in aiding clinicians and radiologists in the accurate and efficient detection of bone fractures. By leveraging the power of GANs, we have demonstrated the ability to generate realistic radiographs with fractures, detect anomalies, and improve the overall diagnostic process. Through our research, we have observed promising results in utilizing GAN-based models such as MadGAN, CycleGAN, SkipGanomaly, and SAGAN for fracture detection. These models have demonstrated their effectiveness in generating high-quality images, identifying anomalies, and translating normal radiographs to fractured ones. The performance of these models, although influenced by various factors such as dataset size, training configuration, and preprocessing techniques, has shown significant potential in enhancing fracture diagnosis accuracy and reducing the reliance on manual interpretation. However, it is important to acknowledge the challenges that lie ahead. Further research and development are required to address limitations such as data heterogeneity, model generalization, and interpretability. Additionally, the ethical implications, including patient privacy and the need for human oversight in the diagnostic process, should be carefully considered and addressed. In conclusion, the application of Generative Adversarial Networks for Computer-Assisted Bone Fractures Diagnosis in musculoskeletal radiographs holds great promise. By harnessing the power of GANs, we can improve the accuracy, efficiency, and overall quality of fracture detection, ultimately benefiting both clinicians and patients. Continued advancements in this field have the potential to revolutionize musculoskeletal radiography and pave the way for more effective and precise diagnostic tools in the future.

ACKNOWLEDGMENT

I would like to express my sincere gratitude to my supervisors and colleagues whose invaluable contributions and support have greatly enriched this article. Their guidance and insights have been instrumental in shaping its content and direction.

***Abstract*—Mask-wearing remains to be one of the primary protective measures against COVID-19. To address the difficulty of manual compliance monitoring, face mask detection models considerate of both frontal and angled faces were developed. This study aimed to test the performance of the said models in classifying multi-face images and upon running on a Raspberry Pi device. The accuracies and inference speeds were measured and compared when inferencing images with one, two, and three faces and on the desktop and the Raspberry Pi. With an increasing number of faces in an image, the models' accuracies were observed to decline, while their speeds were not significantly affected. Moreover, the YOLOv5 Small model was regarded to be potentially the best model for use on lower resource platforms, as it experienced a 3.33% increase in accuracy and recorded the least inference time of two seconds per image among the models.**

Keywords*—*Face mask detection; multi-face detection; Raspberry Pi; embedded platform

I. Introduction

Throughout history, infectious diseases have continuously emerged and evolved due to natural causes and human activities [1][2]. These diseases can affect a significant number of people and even become global health issues. A timely example would be the Coronavirus disease or COVID-19, a highly contagious disease caused by the Severe Acute Respiratory Syndrome Coronavirus 2 or SARS-CoV-2 [3]. It originated in Wuhan, China in December 2019 and was eventually declared by the World Health Organization (WHO) a pandemic from March 2020 to May 2023 [4][5]. In the first 50 days of its onset in China, there were more than 70,000 infected individuals and 1800 deaths recorded [6]. In the current Philippine context, the Department of Health (DOH) has reported a total of about 4.16 million cases of infection, 66,000 deaths, and 4.09 million recoveries in the Philippines as of June 2023 [7].

To combat the spread of COVID-19, several health protocols have been issued by authorities and institutions. Among the common ones are physical distancing, hand hygiene, surface disinfection, proper ventilation, and, especially, mask-wearing [8]. Regarding mask use, the WHO promotes the wearing of non-medical or medical masks in poorly ventilated or crowded indoor settings and public areas with insufficient physical distancing. Moreover, wearing strictly medical masks is recommended for vulnerable populations, potential or confirmed COVID-19 patients, and caretakers of COVID-19 patients [9]. The Centers for Disease Control and Prevention (CDC) recommends mask-wearing in public transportation vehicles and hubs. For people situated in COVID-19 hotspots, the CDC requires the use of face masks, especially for those who are highly susceptible to severe infection [10].

For guidelines against COVID-19 to take full effect, public compliance is essential. However, the extended pandemic duration has resulted in growing complacency and, consequently, disobedience to health protocols [11]. While stricter monitoring of compliance can be helpful, the need for physical distancing and a reduced workforce due to the pandemic makes it challenging. To address this issue, the Ateneo Laboratory for Intelligent Visual Environment (ALIVE) has developed face mask detection models that can classify medically-approved masks, non-medically-approved masks, and unmasked faces in consideration of both forward-looking and angled or side-view face images [12].

The said models were tested using only a desktop computer. In real-time monitoring of mask-wearing compliance, portable devices with relatively lower processing capabilities may be used for convenience. Moreover, only single-face images were considered in both model training and testing. In public settings, multiple faces may be captured by the mask detection models at a time.

With these, the study then aims to evaluate and compare the performance of the developed mask detection models on both desktop and the embedded platform Raspberry Pi. Multi-face mask detection will also be explored by testing the models on combined single-face images from the validation and test sets. It builds on [12] by making the following contributions:

- The real-time performance of robust mask detection models considerate of both frontal and angled faces are examined through deployment on a Raspberry Pi. This helps determine the viability of using the models for live monitoring on low-power systems.
- A comparative analysis of the models' mask detection capabilities in a desktop computer and a Raspberry Pi is performed. This results in insights into the strengths and limitations of the existing models based on the computational power of the hardware used.
- The models' performance in detecting multiple masked faces is observed. This helps identify the

suitability of using the models for simultaneous mask detection in crowded settings.

This paper contains the following sections: Section II provides a discussion on the object detection architectures used by the developed models, the robust detection models from [12] involved in this study, and related works on real-time and multi-face mask detection. Section III elaborates on the methods employed in this study, particularly multi-face inference and real-time implementation on a Raspberry Pi. Section IV presents a description of the results and their detailed analysis. Lastly, Section V summarizes the study's findings and offers recommendations on potential future developments.

II. Related Work

A. Object Detection Architectures

In developing the models involved in this study, the state-of-the-art object detection architectures CenterNet and YOLO, particularly YOLOv5, were used.

CenterNet [13] is characterized by anchorless object detection, which implements a more time- and resource-efficient algorithm in place of the standard Non-Maximum Suppression (NMS) technique. Under this approach, objects are modeled as a single point, corresponding to the center of the bounding box. Searching of center points is done through keypoint estimation, while determining other object properties including the size, location, and pose involves regression. In evaluating the relevance of bounding box predictions, the CenterNet architecture focuses on where their centers are located rather than how much they overlap with the object being detected. Compared to anchor-based detectors, fewer irrelevant detections are generated by CenterNet, resulting in faster inference and less power usage.

On the other hand, YOLO (You Only Look Once) is a state-of-the-art framework that generally operates by dividing an input image into grids, with object detection taking place in each grid. This approach boasts remarkable speed and efficient consumption of computational resources. YOLOv5 [14], one of the latest versions of YOLO, mostly differs from its predecessors in terms of the model backbone, neck, and head. In charge of image feature extraction, a combination of Cross Stage Partial Networks (CSPNet) [15] and Darknet termed CSPDarknet serves as the backbone of YOLOv5. With CSPNet, the issue of duplicate gradients common in large-scale backbones gets resolved, resulting in increased inference speed and reduced model size due to the decline in parameters and floating-point operations per second. Path Aggregation Network (PANet) [16] functions as the model neck, used to create feature pyramids for aggregating and passing features to the model head. It implements a novel feature pyramid structure with an improved bottom-up path that allows for better low-level feature propagation. Overall, PANet helps in locating objects more accurately. For generating predictions and bounding boxes, YOLOv5 retains the model head utilized by YOLOv4, which can perform multi-scale detection [17]. The activation and loss functions of YOLOv5 also set it apart from older YOLO models and contribute to its faster learning and enhanced performance. To deal with the vanishing gradient problem, it uses Leaky Rectified Linear Unit and Sigmoid activation functions. For the loss function, it employs the Binary Cross-Entropy with Logits Loss function.

B. Mask Detection Models and Dataset

As previously stated, this study makes use of the object detection models from [12] which include YOLOv5 Small, YOLOv5 Medium, CenterNet Resnet50 V1 FPN 512x512, and CenterNet HourGlass104 512x512. These models were trained for the image classification task on the relabeled Face Mask Label Dataset (FMLD) curated in [12]. The relabeled FMLD is made to train deep learning models in detecting three mask-wearing classifications, which are Medical Masks, Non-Medical Masks, and No Mask, in consideration of front and side view face images. With this, the six classes represented in the dataset are Front - Medical Mask, Front - Non-Medical Mask, Front - No Mask, Side - Medical Mask, Side - Non-Medical Mask, and Side - No Mask. In the relabeled FMLD, there are 50 images per class which sum up to a total of 300 images. In relation to this, the training of each object detection model involved 300 epochs. The classification accuracies of the models on the test set of the relabeled FMLD were then measured and compared. The models with the highest accuracy were found to be the CenterNet Resnet50 and CenterNet HourGlass104 models, both having an overall accuracy of 95%. The YOLOv5 Medium comes next with an overall accuracy of 93.33%, and the YOLOv5 Small model is the least accurate with 91.67%.

C. Similar Works

The study of ben Abdel Ouahab et al. [18] aimed to develop a mask detection model and evaluate its real-time performance on the Raspberry Pi. Fine-tuning was performed on the pre-trained MobileNetV2 model, constructing a new classification head with five layers: average pooling, flatten, dense with ReLU activation, dropout, and dense with softmax activation. The model was trained on a dataset with 1915 masked and 1918 unmasked face images. It achieved an accuracy of 99% upon testing on the validation set. For real-time implementation, two high-performing laptops, Raspberry Pi 3 and 4 devices, and Raspberry 4 devices with Intel Neural Compute Stick (NCS) 2 were used. The model obtained the highest average FPS value of 4.8 on the Raspberry Pi 4 (8 GB RAM) with NCS 2 among the different versions. It was observed that the performance of the model in terms of speed decreased significantly when deployed on low-power systems rather than on desktop devices.

Moreover, Mohandas et al. [19] focused on creating a real-time face mask detection system running on edge computing devices for access and egress control. For model training, transfer learning was employed on the SSD InceptionV2 model using a GPU-accelerated device. The dataset used for re-training consisted of images from the Real-World Masked Faces Dataset (RMFD), Labelled Faces in the Wild (LFW) dataset, and various web resources. Upon implementation on a Raspberry Pi 4 device, an average detection time of 1.13 ms per frame was obtained. The model also achieved perfect precision for both classes, 89% recall for masked faces, and 91% recall for unmasked faces on the Raspberry Pi 4, which is comparable to its performance on the GPU-enabled computer. While the system is meant to detect only one face at a time, restricting the face to a certain Region of Interest, it was found to be effective for detecting multiple masked or unmasked faces as well.

Lastly, the study of Reza et al. [20] investigated the face mask detection performance of selected Convolutional Neural Network (CNN) models on mobile IoT devices. New classifiers were added to the MobileNetV2, InceptionV3, VGG16, and ResNet50 models and trained on top of their frozen layers. Model training involved a public dataset containing both single- and multiple-face images of masked and unmasked people. The models were trained four times, using varying ratios of the training data, and tested accordingly on the NVIDIA Jetson TX2 and Jetson Nano. VGG16 had the highest average accuracy across all ratios and for both devices, reaching a peak of 96.07% for 20% training data, but obtained the slowest inference speed. On the other hand, MobileNetV2 performed the best in terms of speed, having the least inference time of 25.10 ms for 5% and 10% training data, but lagged behind in testing accuracy. InceptionV3 achieved promising accuracy results upon being trained and tested on the smallest dataset ratio.

III. Methodology

This study used two general sets of methods, which are Multi-Face Inference and Real-Time Implementation in Raspberry Pi. In the corresponding subsections, the procedures performed are discussed in greater detail.

A. Multi-Face Inference

To evaluate the multi-face mask detection performance of the models from [12], images with two or three faces must be included in the test set for this study. Since the mask detection models in [12] were trained and tested on the relabeled FMLD, the same dataset was used in building the test set. Single-face images from the validation and test sets in [12] were combined through the image editing tool Photopea to synthetically produce images that contain two or three faces. The images used per multi-face combination came from random classes, but the equal representation of all six classes among the test images with two or three faces was ensured as far as possible. Black pixels were used to fill the empty spaces left in the synthetic multi-face images which were caused by the varying dimensions of component images. Fig. 1 and 2 present sample test images with two and three faces, respectively.

Using the four mask detection models from [12], inferencing was done on the multi-face images created from the relabeled FMLD. The classification accuracy for each class and the overall classification accuracy were recorded. Moreover, the inference speed was examined to describe the relationship between the number of faces in an image and the speed at which the models classify the image, if any. First, baseline speeds for all four models were determined through the inferencing of single-face images from the validation and test sets used in [12] and the computation of average inference time per image. Then, similar steps were carried out to measure the speeds for inferencing two-face and three-face images using the four models. For the YOLOv5 models, the speeds were automatically printed out after the completion of inference. Conversely, calculating the inference speed for the CenterNet models was done using the timeit package for Python. The desktop computer utilized for testing was equipped with an NVIDIA GTX 1080 Ti GPU.

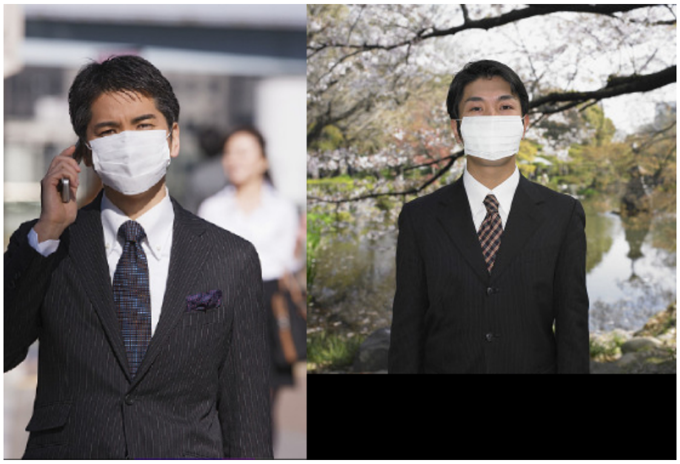

Fig. 1. Sample image containing two faces.

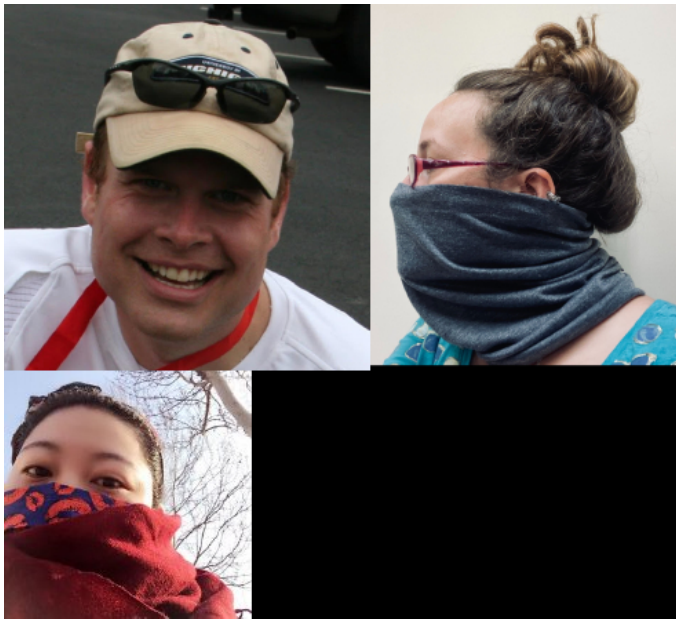

Fig. 2. Sample image containing three faces.

For further verification of the mask detection models' classification accuracies on the images with two or three faces, the single-face images that comprise the synthetic multi-face images went through individual inferencing. This process served as a way of confirming that any difference in classification accuracy between an image with a single face and one with multiple faces can be primarily attributed to the number of faces in an image instead of other possible factors. In individually inferencing the faces present in the test images containing two or three faces, the classification accuracy for each class and the overall classification accuracy were recorded.

B. Real-Time Implementation in Raspberry Pi

To test the capabilities of the mask detection models from [12] on lower resource machines, they were exported and run on an embedded system, and their performance in terms of accuracy and speed was measured. This process is aimed at assessing the feasibility of deploying the models on portable or mobile platforms for increased accessibility and convenience of use.

Initially, it was planned to export all four models from [12] to a Raspberry Pi 4 Model B with 4GB of RAM for testing procedures. Unfortunately, there were compatibility issues with the Tensorflow 2 Object Detection API, which facilitated the use of the CenterNet models. Transferring and running the said models on the Raspberry Pi turned out to be challenging due to the format in which they were exported by the Tensorflow 2 Object Detection API. While it is possible to run the CenterNet models on the Raspberry Pi, it was not done successfully for this study. In the end, only the YOLOv5 Small and Medium models were run and tested on the Raspberry Pi. The CenterNet models were excluded since it was taking a significant amount of time to resolve the problems.

In testing the YOLOv5 models on the Raspberry Pi, the classification accuracies were recorded, so that the performance in terms of accuracy when running on a desktop computer and an embedded system may be compared. This was performed using the same methods from the testing phase in [12] and Section III A as well. Inferencing with the YOLOv5 models running on the Raspberry Pi device was performed on the combined validation and test set images from [12]. The class with the highest predicted confidence score was determined to be the predicted class for each image. To compute the accuracy per class in percentage value, the number of correct predictions was divided by the total number of images per class, and the resulting quotient was then multiplied by 100. Python was used for inferencing and calculating the respective classification accuracies of each mask detection model. In particular, the PyTorch package was instrumental in inferencing with the YOLOv5 models.

Aside from their classification accuracies, the inference speeds of the YOLOv5 models upon testing on the Raspberry Pi were also recorded. This process served as a way of determining if the processing speeds of the YOLOv5 models on a low-end computing device fall within an acceptable range. This was performed using similar procedures from Section III A. Measuring of speeds took place while inferencing images with one, two, and three faces from the combination of the validation and test sets used in [12].

IV. Results and Discussion

A. Multi-Face Inference

A total of 20 synthetic multi-face images were produced from the dataset preparation stage of Section III-A, having ten images with two faces each and another ten images containing three faces each. Table I details the distribution of the six classes found in the relabeled FMLD from [12] among the two-face and three-face images.

Fig. 3, 4, 5, and 6 present the multi-face classification accuracies measured from the YOLOv5 Small, YOLOv5 Medium, CenterNet Resnet50, and CenterNet HourGlass104 models, respectively. Each figure consists of three bar graphs that show the corresponding mask detection model's accuracies in classifying images with one, two, and three faces. The accuracies for each class present in the relabeled FMLD are specified, as well as the overall accuracy per model. The labels for classification accuracies come in the form of percentages and fractions showing the number of correct predictions over the total of possible predictions. The dotted line found in each figure represents the overall accuracy per model, which is just another way of displaying the values from the bar for overall accuracy. It helps create a better visualization of the changes in accuracy while detecting images with varying numbers of faces. The values for the Single Face Accuracy section per model were taken from the results obtained in [12]. From the figures, it can be observed that the overall accuracy for all models tends to decrease as the number of faces present in an image increases. The YOLOv5 models perform with similar levels of accuracy when classifying two-face images, only suffering from reduced overall accuracies when classifying three-face images.

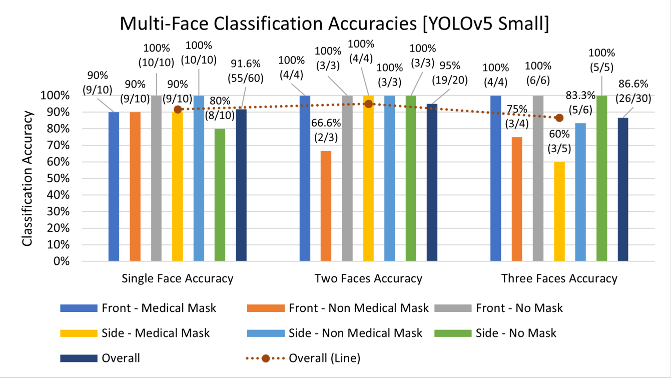

Fig. 3. Multi-face classification accuracies of the YOLOv5 small model.

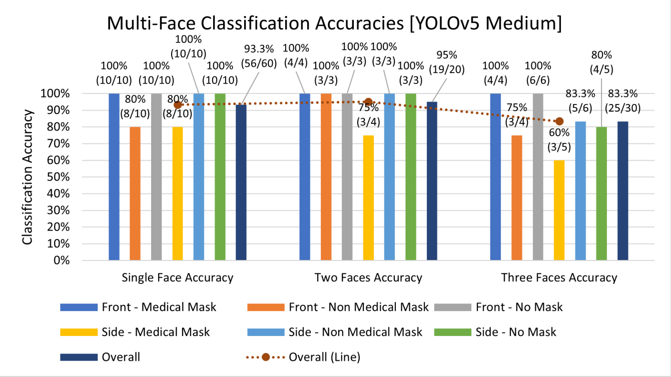

Fig. 4. Multi-face classification accuracies of the YOLOv5 medium model.

Going from detecting single-face images to detecting three-face images, the YOLOv5 Small and YOLOv5 Medium models incur an estimated 5% and 10% loss in overall accuracy, respectively. On the other hand, the CenterNet models are more prone to losses in overall accuracies upon classifying images with an increasing number of faces. Going from detecting single-face images to detecting two-face images, both

TABLE I. DISTRIBUTION OF THE SIX CLASSES OF THE RELABELED FMLD FOR THE IMAGES CONTAINING TWO OR THREE FACES

Class	Number of Faces	
	Images with Two Faces	Images with Three Faces
Front - Medical Mask	4	4
Front - Non-Medical Mask	3	4
Front - No Mask	3	6
Side - Medical Mask	4	5
Side - Non-Medical Mask	3	6
Side - No Mask	3	5
Total	20	30

Note: Ten images containing two faces each equals 20 faces in total. Similarly, ten images containing three faces each equals 30 faces in total.

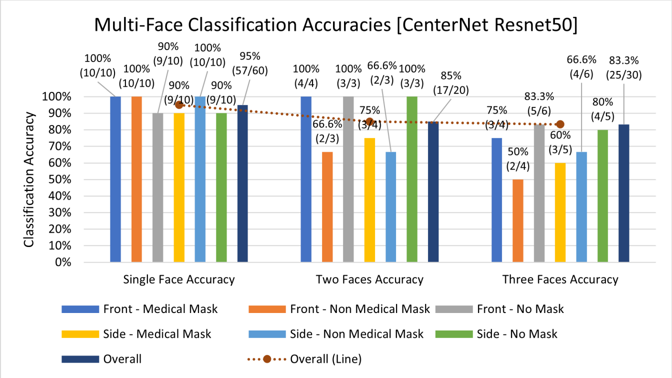

Fig. 5. Multi-face classification accuracies of the CenterNet Resnet50 model.

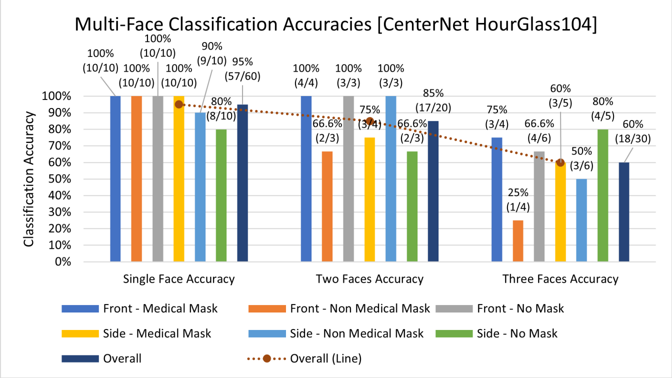

Fig. 6. Multi-face classification accuracies of the CenterNet HourGlass104.

CenterNet models suffer from an approximated 10% loss in overall accuracy. Moving further to detecting images with three faces, the CenterNet Resnet50 model somehow obtains the same level of accuracy compared to its performance on two-face image detection. Conversely, the CenterNet HourGlass104 model incurs an additional 25% decline in overall accuracy, accumulating an estimated total loss of 35% in overall accuracy when classifying three-face images compared to when classifying single-face images. Among all mask detection models, the CenterNet HourGlass104 model experiences the greatest decline in overall accuracy upon classifying images with multiple faces. This can be possibly attributed to the susceptibility of CenterNet models to overfitting as discussed in the model training procedure in [12]. Overfitting makes it difficult for the said models to perform well on inputs that differ from those that they were trained on, which are single-face images.

Fig. 7 presents the different inference speeds of the models on images with one, two, and three faces. From the graph, it can be observed that the fastest mask detection model, having the least inference time in milliseconds, is the YOLOv5 Small model, followed by the YOLOv5 Medium, then the CenterNet Resnet50, and finally the CenterNet HourGlass104. The arrangement of the models in increasing inference speed corresponds to their arrangement in increasing network size, making the former quite expected. Being the smallest of the four models, the YOLOv5 Small model is relatively computationally lightweight and thus faster to execute. Conversely, the CenterNet HourGlass104 model is computationally intensive and thus slower to run, since it has the largest network size among the models. In testing multi-face detection, the models' inference speeds incur an initial decrease upon detecting two-face images compared to when detecting single-face images. However, there is negligible change in the speeds of the models when going from detecting two-face images to detecting three-face images. Based on these results, classifying images with even more faces may not have significant effects on the models' inference speeds. It is also important to note that the speeds specified in Fig. 7 were recorded during the first round of inference on the test images. Upon repeated inferencing in several rounds, the speeds measured turned out to be faster, but such speeds were no longer considered.

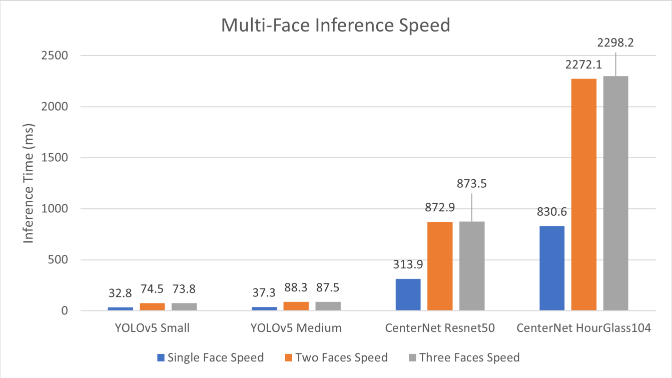

Fig. 7. Multi-face inference speeds of all of the four models of this study.

Furthermore, the multi-face inference speeds of the YOLOv5 models, which were also presented in Fig. 7, were shown in more detail in Fig. 8. From the graphs, it can be seen that the inference times were dominated by the inferencing process itself, while the pre-process and Non-Maximum Suppression (NMS) stages took up only small portions. The YOLOv5 models automatically generated the speed breakdown after the inferencing process. Since the CenterNet models have no similar capability, their inference speed breakdown did not get included anymore.

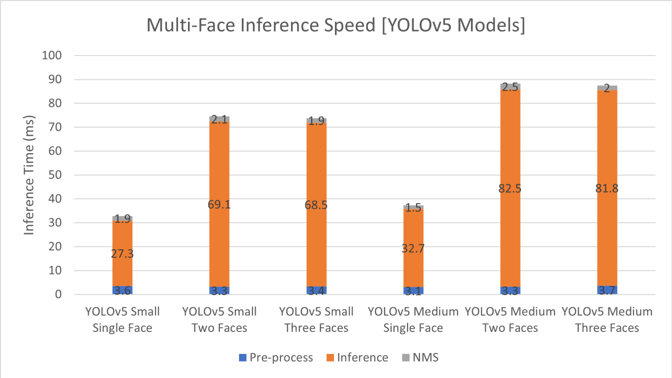

Fig. 8. Breakdown of the multi-face inference speeds of the YOLOv5 models.

Fig. 9, 10, 11, and 12 show the results for the validation of the multi-face classification accuracies of the YOLOv5 Small, YOLOv5 Medium, CenterNet Resnet50, and CenterNet HourGlass104 models, respectively. Each figure is divided into two cluster groups, the first group is for results on two-face images while the second one is for results on three-face images. The first cluster in each group presents the classification accuracies of the corresponding model when individually inferencing the faces that comprise the synthetic multi-face images. On the other hand, the second cluster in each group presents the model's accuracies upon inferencing the merged images with two or three faces themselves. The results verify that the differences in accuracy when classifying images with one face and those with multiple faces are caused by the changes in the number of faces contained in them. For most of the mask detection models, their classification accuracies were higher when single-face images were inferenced individually and not as components of a synthetic multi-face image. However, the results obtained from the YOLOv5 Small model deviate from the general observation, as its classification accuracies were found to be higher when inferencing images with multiple faces compared to those with only one face. These further support the earlier findings about YOLOv5 models being able to classify two-face images with similar levels of accuracy and only obtaining reduced overall accuracies upon classifying three-face images. The discussion on CenterNet models being more prone to declines in accuracy due to an increase in the number of detected faces also gets further confirmed.

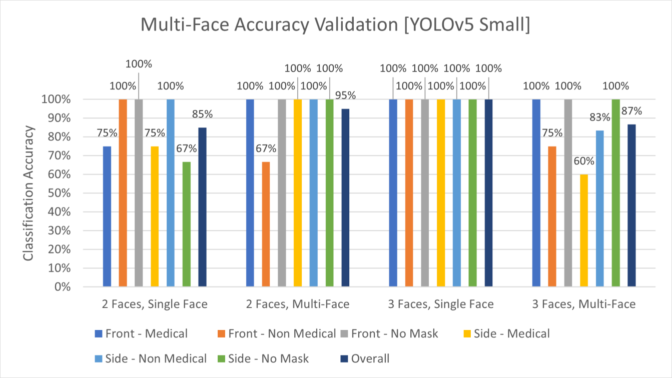

Fig. 9. Validation of the Multi-Face classification accuracies of the YOLOv5 small model.

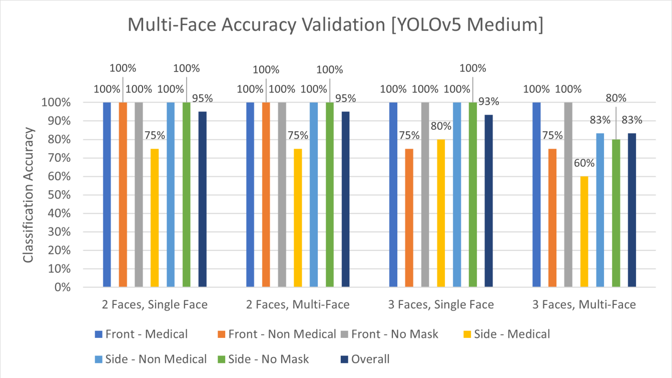

Fig. 10. Validation of the Multi-Face classification accuracies of the YOLOv5 medium model.

B. Real-Time Implementation in Raspberry Pi

Table II shows the classification accuracies of the YOLOv5 models when tested on the Raspberry Pi. These accuracies are for images with single faces only, as the combined validation and test set images from [12] are used without making modifications. The table presents a direct comparison between the model's classification accuracy on the desktop computer and its accuracy upon running on the Raspberry Pi. Each table cell corresponds to a particular mask detection model and image class, containing the ratio of the number of correctly predicted images from the class by the model to the total number of images in the class and the equivalent accuracy in percentage form.

From these results, the differences in classification accuracies of the YOLOv5 Small and Medium models when tested on

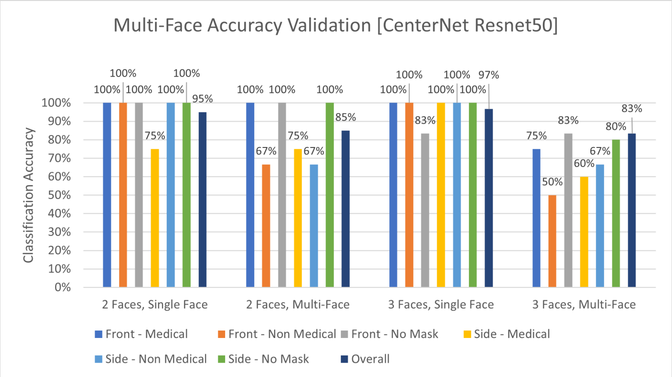

Fig. 11. Validation of the Multi-Face classification accuracies of the CenterNet Resnet50 model.

TABLE II. COMPARISON OF CLASSIFICATION ACCURACIES ON DESKTOP VERSUS ON RASPBERRY PI

Model	Front - Medical Mask	Front - Non Medical Mask	Front - No Mask	Side - Medical Mask	Side - Non Medical Mask	Side - No Mask	Overall
YOLOv5 Small (Desktop)	9/10 Accuracy = 90%	**9/10** **Accuracy = 90%**	**10/10** **Accuracy = 100%**	9/10 Accuracy = 90%	**10/10** **Accuracy = 100%**	8/10 Accuracy = 80%	55/60 Accuracy = 91.67%
YOLOv5 Small (Raspberry Pi)	9/10 Accuracy = 90%	**9/10** **Accuracy = 90%**	**10/10** **Accuracy = 100%**	**10/10** **Accuracy = 100%**	**10/10** **Accuracy = 100%**	9/10 Accuracy = 90%	**57/60** **Accuracy = 95%**
YOLOv5 Medium (Desktop)	**10/10** **Accuracy = 100%**	8/10 Accuracy = 80%	**10/10** **Accuracy = 100%**	8/10 Accuracy = 80%	**10/10** **Accuracy = 100%**	**10/10** **Accuracy = 100%**	56/60 Accuracy = 93.33%

Bold = Highest Value in Column

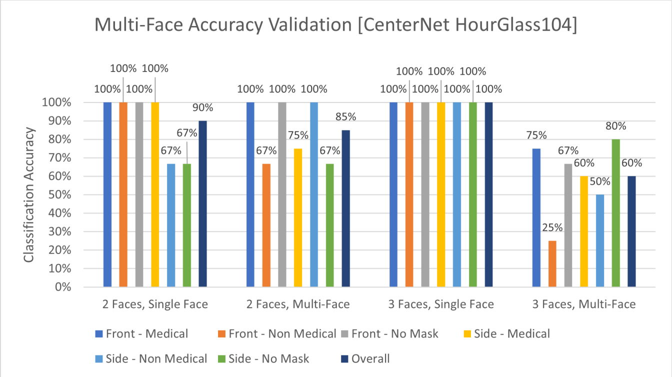

Fig. 12. Validation of the Multi-Face classification accuracies of the CenterNet HourGlass104 model.

the desktop computer and the Raspberry Pi can be examined. The YOLOv5 Small model obtained a greater classification accuracy on the Raspberry Pi than on the desktop computer, being able to correctly predict two additional images belonging to the Side - Medical Mask and Side - No Mask classes. The opposite was true for the YOLOv5 Medium model, as it achieved a lower classification accuracy when running on the Raspberry Pi than on the desktop computer. There were fewer correctly predicted images under the Front - Medical Mask, Front - Non-Medical Mask, Side - Non-Medical Mask, and Side - No Mask classes. Overall, there was a minimal difference of 3.33% for the classification accuracies of the YOLOv5 Small model and a larger discrepancy of 8.33% for the accuracies of the YOLOv5 Medium model.

Varying performance metric values for the same deep learning models when run on the Raspberry Pi and on other platforms have also been recorded in [21][22][23]. Unfortunately, the said studies could not offer an explanation behind the discrepancy in accuracies or confidence scores upon testing on different devices, including the Raspberry Pi. Similarly, this study failed to come up with reasons for the difference in the mask detection models' classification accuracies on the desktop computer and on the Raspberry Pi.

Moreover, Fig. 13 presents the inference speeds of the YOLOv5 models upon testing on the Raspberry Pi. In general, the inferencing of YOLOv5 models took a longer time on the Raspberry Pi than on the desktop computer. The inference times of the models on the Raspberry Pi were divided by their inference times on the desktop computer to obtain the speedup values. For the YOLOv5 Small model, it performed 68.75, 29.09, and 27.99 times faster on the desktop computer than on the Raspberry Pi in inferencing images containing one, two, and three faces, respectively. On the other hand, the YOLOv5 Medium model obtained speedup values of 137.28, 57.83, and 59.08 upon inferencing single-face, two-face, and three-face images, respectively. Both models experienced the highest speedups with single-face images, which aligns with how the YOLOv5 Small and Medium models had lower inference times on the desktop computer when inferencing images with one face than those with two or three faces. Meanwhile, the YOLOv5 Small and Medium models had inference times of similar levels for single-face, two-face, and three-face images on the Raspberry Pi.

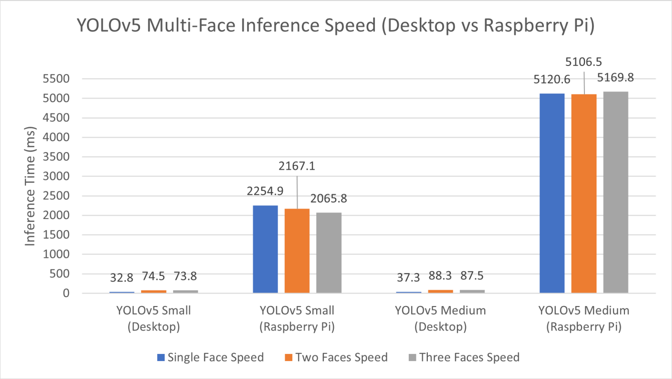

Fig. 13. Multi-face inference speeds of the YOLOv5 models when ran on the desktop machine versus when ran on the Raspberry Pi.

Overall, the YOLOv5 Small model turns out to be the most ideal for deployment on low-end computing devices. There was only a small difference in the classification accuracies of the YOLOv5 Small model when running it on the Raspberry Pi and on the desktop computer. As seen in Table II, the YOLOv5 Small model obtained the highest overall classification accuracy when tested on the Raspberry Pi. Furthermore, less discrepancy in the said model's inference speeds can be observed upon inferencing on the desktop computer then on the Raspberry Pi. The YOLOv5 Small model achieved an inference time of about two seconds per image on the Raspberry Pi, still falling within the acceptable range. Conversely, the YOLOv5 Medium model obtained an inference time of about five seconds per image, already considered to be somehow too slow. It also recorded a greater difference in inference speeds compared to the YOLOv5 Small model when inferencing on the desktop computer and on the Raspberry Pi.

V. Conclusion

Generally, the mask detection models were found to be capable of multi-face detection, although the accuracies were observed to decline in the presence of more faces in an image. In terms of inference speed, the YOLOv5 models performed faster than the CenterNet models due to their smaller network sizes. Moreover, it was observed that the number of faces in an image did not significantly affect the models' inference speeds.

For the implementation on the Raspberry Pi 4 Model B embedded platform, only the YOLOv5 Small and Medium models were used. Going from inferencing on the desktop computer to the Raspberry Pi, the YOLOv5 Small model experienced a 3.33% increase in classification accuracy, while the YOLOv5 Medium model suffered from an 8.33% decrease in accuracy. In terms of inference speed, the YOLOv5 models generally exhibited a slower mask detection performance on the Raspberry Pi than on the desktop computer, with the YOLOv5 Small model having an inference time of about two seconds per image and the YOLOv5 Medium model obtaining an inference time of about five seconds per image. Furthermore, both models recorded the highest speedup values when inferencing single-face images, just as they achieved lower inference times with single-face images on the desktop computer compared to multi-face images. Considering both the classification accuracy and inference speed, the YOLOv5 Small model was regarded to be potentially the best model for use on lower resource platforms.

Future work may involve the use and evaluation of other object detection models for the robust face mask detection task. Developed models can also be tested on several kinds of embedded systems, such as the Jetson Nano. It might also be worth looking into the addition of more mask-wearing categories, including incorrectly masked faces, among others.

***Abstract*—The classification of content on the deep and dark web has been a topic of interest for researchers. Researchers focus on adopting more efficient and effective classification methods as the data available on deep and dark web platforms continues to grow. Multi-label classification is the approach for simultaneously categorizing content into multiple classes. To address this, a hybrid approach combining Term Frequency-Inverse Document Frequency (TF-IDF) and Recurrent Neural Network (RNN) has been proposed. The approach involves preprocessing a dataset of Hypertext Markup Language (HTML) documents, selecting specific HTML tags to generate embeddings using TF-IDF, and using an RNN model for multi-label classification. The proposed model was evaluated against commonly used methods (Binary Relevance, Classifier Chains, and Label Powerset) using precision, recall, and F1-score as evaluation metrics, demonstrating promising results in accurately classifying data from the deep and dark web. This contribution represents a noteworthy advancement for researchers and analysts working in this field.**

***Keywords*—Deep web; dark web; multi-label classification; TF-IDF; FastText; RNN**

I. Introduction

A deep web is a portion of the internet not accessible by traditional search engines. A subsection of the deep web, the dark web, is known for its anonymity and association with illegal activities, while it requires specialized software to access [1]. An encrypted network called Tor, or "onion routing," is often used to access the dark web like the Tor browser. The Tor Network, a free, open-source software platform, enables anonymous communication. To provide anonymity to its users, Tor encrypts their internet traffic before it reaches its final destination and bounces it around multiple servers.

To comprehend cyber threat intelligence from the dark web, researchers collect deep and dark web data using web crawlers. Deep web crawler collects data from websites not listed in traditional search engines. Deep web data collection aims to find resources, often valuable, and provide insight into various domains, including science, medicine, and finance. Databases and APIs are examples of deep web content that may contain structured data suitable for data integration. In addition, researchers can use deep web data to study the behavior of users in online communities and analyze trends in e-commerce [2]. It is essential to use deep web data from vast and diverse corners of the internet that are difficult to access conventionally. Text classification is the primary method for inferring information from deep and dark web pages crawled to analyze content. Using text features, researchers propose a method to classify Deep Web data sources [3].

Since the dark web is anonymous, criminals can engage in these activities without fear of being caught, causing a proliferation of criminal enterprises. As a result, many illegal activities are happening on the dark web, including drug trafficking, arms trafficking, human trafficking, and selling stolen data. However, a challenge is associated with studying the dark web because of its unique characteristics [4]. First, due to the encrypted nature of the dark web, identifying users and tracking data origins is very difficult. Consequently, tracing the source of criminal activities and cyber threats is challenging for law enforcement agencies and researchers.

The dark web has been investigated for its content in recent years. Law enforcement agencies and cybersecurity experts can detect and prevent criminal activities using machine learning approaches on the dark web, where there is vast data. Researchers discuss how the dark web information they find can be assessed for its relevance, usefulness, and appropriateness [5]. Researchers have used Machine Learning (ML) approaches to investigate content on the dark web. Researchers can better understand how activities on the dark web are patterned by analyzing individual use cases and different forms of data. For example, text and image data can be automatically classified and analyzed using algorithms to detect potential illicit activities, such as illegally selling goods and services [6]–[8].

Using machine learning algorithms and external knowledge sources maximizes the efficiency and effectiveness of identifying and categorizing deep and dark web content. However, the lack of access to these deep and dark webs makes research into their nature and structure challenging. One standard method is to manually label crawled sites per a series of categories and then use this corpus as a training corpus for automated crawling in the future. While this approach has its benefits, it has limitations because it is time-consuming, expensive, and valuable only for specialized tasks. Also, related research mainly focuses on classifying content with a single label. As per the authors' knowledge, the presented work is the first attempt to label deep and dark web content with multi-label classification.

The contribution of this study lies in the methodology proposed, which provides a comprehensive and systematic approach for labeling hidden content on the deep and dark web with multi-label. This approach starts with a dataset of HTML documents scraped from the deep and dark web. Then, as part of the preprocessing, specific HTML tags are selected, irrelevant characters are removed, and embeddings are generated using TF-IDF. In the next step, FastText assigns labels to documents according to their similarity. Text classification and language modeling can be accomplished with FastText, a popular machine-learning algorithm.

Recurrent Neural Networks (RNNs) are trained on pre-processed datasets after the documents have been labeled. In particular, RNNs are well suited to dealing with sequential data, such as text. This study compared the proposed method to three existing methods: Binary Relevance (BR), Classifier Chains (CC), and Label Powerset (LP). Precision, recall, and F1-Score are used as evaluation metrics to measure the performance of the proposed approach. The proposed approach for multi-label classification of deep and dark web content has significant implications for enhancing security and combatting criminal activities on these platforms.

The following paper is organized into four sections: Related Work, Proposed Approach, Results and Discussion, and Conclusion. Section II, related work covers the need for deep and dark web content classification and existing multi-label classification approaches. Section III, proposed approach explains the methodology used, while Section IV, Results and Discussion, presents the findings. As a final section of the paper, Section V, the conclusion section summarizes and suggests future research directions.

II. Related Work

Information obtained from deep web sources often lacks structure, making it challenging to categorize and analyze. Instead, specialized algorithms must be used to extract text features to classify web pages in this vast and complex world of the deep web. As part of their extraction process, these algorithms use various techniques, including keyword encoding, topic modeling, sentiment analysis, and entity recognition, to identify meaningful features in the text. The algorithms can extract valuable insight from the text by categorizing it based on the extracted features. For example, in the context of mobile app stores, the paper highlights the importance of text feature classification algorithms for collecting and analyzing deep web data [9].

Deep web crawlers use their classification modules to understand the context of the data they collect. For example, through text classification algorithms, the classification module provides insight into the actual content of a web-page. The researchers proposed an Accurate crawler to harvest deep web content with accurate classification [10]. By ranking sites based on the similarity of their content, the framework attempted to reduce the number of pages that need to be visited. Consequently, deep web content can be extracted and classified more accurately. In addition, researchers proposed a smart crawler to search the deep web efficiently while avoiding irrelevant pages [11]. Dark web content classification is necessary because these parts of the internet are often used for illegal and criminal activities, like drug trafficking, drug sales, and cybercrime. Natural language processing techniques are used to classify texts on the dark web, and supervised machine learning algorithms are used to classify dark web content.

Researchers proposed an Automated Tool for Onion Labeling (ATOL) for mapping dark web content to thematic labels [12].In this approach, popularity scores for different categories were calculated using TF-IDF. Three components comprised the ATOL system: a module that finds keywords for different categories, a classification framework that maps onion content to categories when labeled data is available, and a clustering framework that categorizes onion content using external knowledge sources when labeled data is lacking.

The researchers proposed a crawler to search dark web links for markets [13]. A dataset was created and pre-processed using data-cleaning techniques. Linear Support Vector Machines outperformed Random Forests and Nave Bayes in classifying dark web pages. The proposed system effectively identified and classified dark web pages with high accuracy, precision, recall, and F1 score. In addition, researchers proposed a modified frequency-based term weighting scheme for identifying dark web content [14]. In a dataset selected from the dark web Portal Forum, the proposed term weighting scheme was compared to Term Frequency (TF), Term Frequency-Inverse Document Frequency (TF-IFD), and Term Frequency-Relative Frequency (TF.RF). Experimental results demonstrate that the proposed scheme outperforms other term weighting techniques based on classification accuracy and other evaluation measures.

Researchers analyzed using the Vector Space Model with two-term weighting schemas: TF and TF-IDF, to determine some of the most discussed topics within Arabic dark web forums [15]. In addition, researchers proposed a new method of tagging extracted data to provide a more balanced and effective method for detecting text features [16]. ELEMENT, a modified TF-IDF algorithm, considered several factors, including document length and term length. One study applied the TF-IDF to classify dark web marketplaces according to their offered products [17]. In addition, researchers identified language characteristics of dark web forums related to drug markets using TF-IDF [18]. Researchers confirmed the similarity between the subjects of dark web forums with affect analysis [19]. Focused topics identified in forums were piracy, hacking, drugs, politics, revolution, weapons, and guns.

Researchers evaluated some text embeddings and classifiers for classification tasks in the darknet domain [20]. In the study, researchers compared text classification to keyword searches by training the classifier using keyword search results. The study concluded that text classification performed better than a keyword-based search. Although dark web content is typically classified using a single label, multiple-label classifications can be helpful in cases where content belongs to multiple categories. However, dark web websites or contents are typically categorized into one of several categories, such as drugs, weapons, or hacking. Therefore, multi-label classification is helpful for dark web content that may be classified with multiple labels. For example, dark web data can be analyzed for multi-label classification tasks based on multiple labels such as ‘fraud,’ ‘drugs,’ and ‘weapon Researchers reviewed three significant areas of multi-label learning: paradigm formalization, learning algorithms, and learning environments [21]. Besides defining multi-label learning and evaluating its outcomes, the research examined traditional and deep learning-based algorithms for multi-label learning. The empirical results also discussed how different learning settings, such as feature selection and transfer learning, affect the learning process and algorithm performance.

Multi-label classification, in combination with other machine learning tasks, has led to the development of two main categories of methods: Problem Transformation (PT) and algorithm adaptation [22]. Several PT methods are independent of the algorithm and involve transforming a multi-label classification task into a single-label classification, regression, or ranking task. Methods such as BR, CC and LP fall into this category. The review provided valuable insights and techniques for multi-label learning, but it is necessary to adapt further and study these techniques for dark web data classification.

The presented work has been proposed to classify dark web data using techniques such as BR, CC, and LP. By including label interdependence and using probabilistic models to predict label combinations, these methods can improve the accuracy of multi-label classification.

BR is a decomposition method that assumes labels are independent and trains binary classifiers separately to determine the Relevance of each label [23], [24]. It has been proven that BR produces good machine learning classifiers both computationally and as a result of several metrics. An example of the application of BR is covered in the study, which developed a novel method for multi-label text classification for Arabic texts using binary relevance [25]. The study examined five multi-label classification approaches for enhancing Arabic multi-label text classification, including Support Vector Machines (SVMs), k-Nearest Neighbors (KNNs), Naive Bayes (NBs), and different classifiers.

Aside from BR, other multi-label classification models have also been developed to deal with label dependency. As one example, the CC method is becoming increasingly popular due to its simplicity and promising results [26]. As a method for solving multi-label learning problems, classifier chains consist of chaining together off-the-shelf binary classifiers in a directed structure [27]. Then, the label predictions are used to refine other classifiers. Various datasets and evaluation metrics have been used to evaluate the effectiveness and flexibility of this method.

There has been an alternative method developed to address label dependency in a multi-label classification called LP. The LP transformation aims to transform multi-label learning problems into single-label multi-class problems by transforming these into one-label multi-class problems [28]. By using LP transformations, all label combinations present in the original dataset are transformed into one label.

Multi-label classification has gained attention recently due to its application in solving complex real-world problems [29]. For example, multi-label classification is helpful in text classification, image annotation, and bio-informatics scenarios with multiple labels associated with each instance. In addition, using multi-label classification and feature selection techniques is an upcoming approach to identifying the most relevant features. Selecting features aims to reduce the number of irrelevant features while keeping only the most informative ones. Removing noisy or irrelevant features can enhance the performance of multi-label classification models by reducing the input space dimension.

Using multi-label classification for multitask learning is another example of combining multi-label classification with other machine learning tasks. A multitask learning model uses a single model to learn multiple related tasks simultaneously. However, as each document may contain multiple correlated labels, it is challenging to classify text using multiple labels. Therefore, the researchers introduced a new multi-label text classification technique, learning feature combinations from documents and labels while reinforcing label correlations [30]. As a result, researchers avoid label order dependency and ensure that label correlations are effectively learned. Applying the multi-label text classification technique for dark web content is feasible. The dark web contains a wide range of diverse and often hidden content, making its identification and classification particularly challenging. However, with the multi-label text classification approach, the model can learn to capture correlations between labels, even if they were not explicitly observed in the training data. This enables the possibility of improving dark web multi-label classification.

The proposed study presents a comprehensive and systematic approach to multi-label classification of dark web text. The method involves several steps: first, collecting HTML documents from the dark web, then preprocessing them by selecting relevant content, and generating embeddings using the TF-IDF method. Next, labels are assigned to the documents based on their similarities using FastText. Finally, an RNN is trained using these labels. The model's performance for multi-label classification problems is evaluated using Precision, Recall, and F1-Score. Section III provides a detailed description of the proposed approach.

III. Proposed Approach

The following discussion covers the proposed procedure for selectively picking and labeling the content of deep and dark web HTML tags based on their frequency and Relevance using the TF-IDF and FastText embeddings. To multi-label a text document, the authors propose combining TF-IDF and FastText. The TF-IDF statistic evaluates the importance of a term in a document by considering its frequency and inverse document frequency [31]. FastText, on the other hand, is a neural network-based approach that captures the semantic meaning of words through word embeddings [32].

The proposed method extracts TF-IDF features from textual data and trains a FastText model on top of these features. The trained model can then predict multiple labels for a single text instance. This method has yielded promising results in various multi-label classification tasks, including text categorization and sentiment analysis. The combination of TF-IDF and FastText yields a robust and efficient solution for multi-label textual data classification. The authors proposed neural network architecture for binary classification. The proposed architecture is a feed-forward neural network, a Multi-Layer Perceptron (MLP). The network is implemented using the Sequential API, which allows for the easy creation and addition of layers in a linear stack. Fig. 1 illustrates the model architecture along with crucial details regarding layer activations and layer names. The diagram provides a visual representation of the network's structure, showcasing the flow of information through the layers and the respective labels assigned to each layer.

The architecture consists of two dense layers. A dense layer, also known as a fully connected layer, is one in which every neuron in the layer is connected to every neuron in the previous layer. The first dense layer has 50 units, an

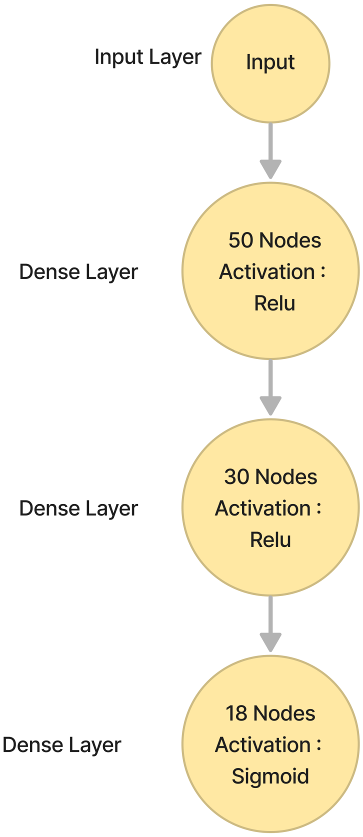

Fig. 1. Model architecture of neural network.

Algorithm 1: Multi-Label Text Classification Algorithm

```

input dimension of 300, and a Rectified Linear Unit (ReLU) activation function. The output of the sigmoid function, when applied to the input features, will be a value between 0 and 1, which can be interpreted as the probability of the input features belonging to the positive class. The network is then compiled using the Adam optimizer, a binary cross-entropy loss function, and accuracy as the evaluation metric. Adam is a stochastic gradient descent optimizer that adapts the learning rate for each parameter. It is computationally efficient and has been demonstrated to work well in various tasks. The binary cross-entropy loss function is a loss function that is often used for classifying things into two groups. It measures the dissimilarity between the predicted probability distribution and the true distribution.

A. *Proposed Algorithm*

The authors proposed an algorithm for multi-label text classification of dark web data. Algorithm 1 describes the proposed algorithm.

Multi-Label Text Classification Algorithm

Further authors describe each step in the algorithm in the following discussion.

1) Data cleaning: Three main steps are involved in cleaning and preprocessing HTML tags' content. The first step is the selection of relevant HTML tags. A second step involves removing accented and non-ASCII characters, stopwords, languages other than English, and punctuation, which add little value to the content and may cause errors. The final process standardizes and normalizes the data by converting all the remaining content to lowercase and separating it into individual tokens and words. As a result, these steps enable further analysis of the HTML tags' content.

2) Performing TF-IDF on the data: The next step of the algorithm is to perform the TF-IDF on the data. The TF-IDF is calculated as the product of the TF, which is the number of times a token appears in a document, and the IDF, which is the logarithm of the ratio of the number of documents in the corpus to the number of documents containing the token.

The TF-IDF assigns higher weights to the tokens that frequently occur in a document but infrequently in the corpus and lower weights to the tokens that frequently occur in the corpus but infrequently in a document. The TF-IDF can help filter out the common or irrelevant tokens and highlight the specific or distinctive ones.

3) Picking tokens having the highest TF-IDF weights in the document: predefined categories or domains to which the researcher wants to assign the picked tokens based on their meaning or context. The generalized tokens may be selected or created by the researcher based on the research question, the scope, or the analysis criteria. The similarity is measured using a distance or a similarity metric, such as Cosine similarity or Euclidean distance, between the embeddings of the picked token and the generalized token. The similarity reflects the degree or the probability of the picked token belonging to the generalized token.

The further step is to pick the tokens having the highest TF-IDF weights in the document based on the selection criteria. The selection criteria are designed to balance the tokens' importance or Relevance and the diversity of representativeness of the tokens. The selection criteria consist of three cases:

- If more than twenty tokens are in the document, pick the top 60% of the tokens, sorted by the TF-IDF weights in descending order.
- If in the document, tokens are between six and twenty, pick the top 70% of the tokens, sorted by the TF-IDF weights in descending order.
- If there are fewer than six tokens in the document, include all the tokens.

The authors use the selection criteria to identify the most relevant and significant tokens for the analysis while avoiding redundant data and over-representation. Also, the selection criteria aim to maintain the overall context and subtleties of the document while capturing its primary or specific aspects.

4) Using FastText to generate embeddings of the picked tokens from the document: The next step of the algorithm is to use FastText, a library for efficient text classification and representation learning, to generate the embeddings of the picked tokens from the document. The embeddings are dense, low-dimensional, continuous, and real-valued vectors representing the tokens' semantics or meaning in a multi-dimensional space. The embeddings are trained or learned from a large dataset using a supervised or unsupervised learning algorithm, such as skip-gram or CBOW. The embeddings capture the tokens' co-occurrence or context and the relationships or similarities between the tokens. The embeddings can be used to measure the similarity or the distance between the tokens or to classify or cluster the tokens.

5) Calculating the similarity of every picked token with every generalized token from the list: The next step of the algorithm is to calculate the similarity of every picked token with every generalized token from the list using the embeddings. The generalized tokens are the predefined categories or domains to which the researcher wants to assign the picked tokens based on their meaning or context. The generalized tokens may be selected or created by the researcher based on the research question, the scope, or the analysis criteria. The similarity is measured using a distance or a similarity metric, such as Cosine similarity or Euclidean distance, between the embeddings of the picked token and the generalized token. The similarity reflects the degree or the probability of the picked token belonging to the generalized token.

6) Assigning the generalized token with the highest similarity score to the token: The further step is to assign the generalized token with the highest similarity score to the token based on the assignment criteria. The assignment criteria are designed to ensure the assignment's reliability or confidence and to handle exceptions or special cases. The assignment criteria consist of two cases:

- Only assign the generalized token to the picked token, if the similarity is more than 60
- Manually assign certain labels, such as "onion" or "tor", to the generalized token "network" if the picked token belongs to those labels. The assignment criteria aim to assign the picked token to the most suitable or the most likely generalized token while avoiding the assignment's errors or ambiguities. The assignment criteria also aim to respect the dark web's particularities or conventions and avoid misusing or abusing the generalized tokens.

7) Creating a set of assigned generalized tokens per document: The next step is to create a set of assigned generalized tokens per document by collecting the generalized tokens assigned to the picked tokens in the document. The set of assigned generalized tokens per document represents the labels or the topics of the document. It can be used as the input or the output of a classification task, such as topic modeling or sentiment analysis, or as the input or the output of a recommendation or search system. The set of assigned generalized tokens per document reflects the document's main or specific aspects or themes and the context or nuance of the document.

8) Splitting the dataset into train and test sets: The dataset has split into training and testing sets using a predetermined ratio or a sampling method. The training set is used to fit or train the classifier neural network model, and the testing set is used to evaluate or test the performance of the classifier neural network model. The ratio of the split method should be chosen based on the dataset's size, quality, or representativeness and the purpose or objective of the analysis. In this paper, authors used a ratio of 25% testing set and 75% training set.

9) Fitting classifier neural network model: Next, a neural network model is trained using the training set using generalized tokens as labels. The classifier neural network model is an artificial neural network used to classify or predict the labels of the input data based on its patterns or features. The classifier neural network model consists of an input layer, two hidden layers, and an output layer.

To train the classifier neural network model, the following hyperparameters are used:

- Sequential Classifier: The neural network architecture is designed in a sequential manner, where each layer is added one after the other.
- Activation Functions:
  - ReLU (Rectified Linear Unit): Used as the activation function for the hidden layers to introduce non-linearity into the model.
  - Sigmoid: Used as the activation function for the output layer in multilabel classification to produce probabilities for each label independently.
- Optimizer: The Adam optimizer is employed to minimize the loss function during training. Adam is a popular optimization algorithm that combines the benefits of both AdaGrad and RMSProp.
- Loss Function: Binary Cross-entropy is utilized as the loss function for multilabel classification. This loss function is well-suited for problems where each input

sample can belong to multiple classes, as is the case in multilabel classification tasks.

- Hidden Layers: The classifier neural network model includes two hidden layers, which contribute to the network's ability to learn complex representations from the data.
- Learning Rate: The learning rate is set to 0.004. The learning rate is a hyperparameter that determines the step size at each iteration of the optimization algorithm. A higher learning rate can result in faster convergence but may risk overshooting the optimal solution, while a lower learning rate can provide more stability during training but might take longer to converge.

During the training process, the classifier neural network model learns the mapping or relationship between the input data and the output labels by adjusting the weights or biases of the connections between the layers. This allows the model to handle the complexity or variability of the data and generalize or adapt to new or unknown data.

10)Evaluating the model using the test set: The twelfth and final step of the procedure is to evaluate or test the performance of the classifier neural network model using the testing set and the generalized tokens assigned as the labels. The evaluation is performed by comparing the predicted labels of the model with the actual labels of the testing set, using evaluation metrics such as accuracy, precision, recall, or F1 score. The evaluation metrics measure the quality or the reliability of the model's predictions and provide insights or feedback for the improvement or optimization of the model.

The algorithm creates a clean HTML document by cleaning and preprocessing the HTML tags' content. On the data, TF-IDF is performed. TF-IDF weights are used to select tokens. The algorithm generates a FastText embedding. Based on a list of generalized tokens, it calculates the similarity between each token. This algorithm assigns the token to the generalized token with the highest similarity score. Per the document, it creates a set of generalized tokens. Train and test sets are separated in the dataset. Algorithms are designed to extract the main or specific elements of a document.

Further, Section IV presents the result and discussion of the proposed algorithm.

IV. Result and Discussion

A. Dataset Description

For a proposed work, data was gathered using a custom deep and dark web crawler. In order to explore Tor's hidden services, the crawler used seeds provided by the Hidden Wiki page. The crawler continued to collect data as it encountered new links. An extensive deep and dark web dataset was collected as a result. The dataset comprised fifty thousand web pages from the deep and dark web. Because the dataset included HTML code for every web page, the file size increased significantly. The crawled files were cleaned by removing HTML tags, JavaScript, and non-English web pages. After the keywords have been extracted from each website, the cosine similarity between these keywords and a set of custom keywords has been calculated. The predefined labels in the dataset are Business, Cybersecurity, Education, Entertainment, Finance, Food, Health, Literature, Nature, Network, Politics, Security, and Shopping.

The evaluation phase includes the examination of model accuracy and loss graphs, which are presented in Fig. 2 and Fig. 3, respectively. These graphs serve as important tools to assess the model's performance and identify potential areas for improvement.

Fig. 2 and Fig. 3 illustrate the model's performance over time, visually representing accuracy and loss metrics. By closely monitoring these metrics, adjustments can be made to address issues such as overfitting or underfitting, ensuring the model's optimal performance and generalization to unseen data.

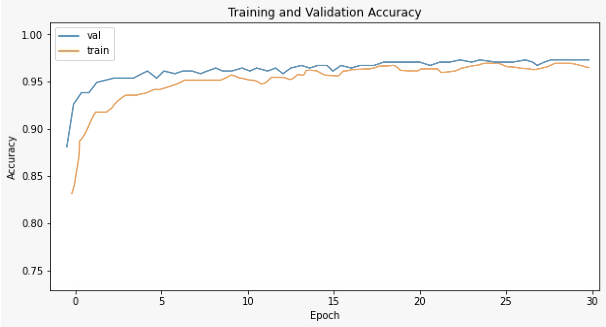

Fig. 2. Model accuracy graph for the proposed algorithm.

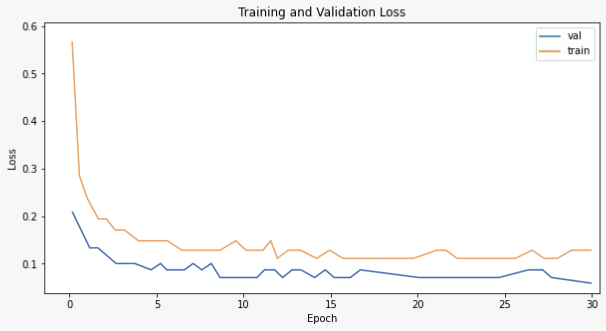

Fig. 3. Model loss graph for the proposed algorithm.

B. The Empirical Study of Multi-label Classification with BR, CC and LP Algorithms

Empirical studies collect and analyze data to gain insights and draw conclusions. The performance of different algorithms can be compared in the context of multi-label classification of dark web data, and the best algorithm can be determined through empirical research. In the context of multi-label classification of dark web data, an empirical study compares the performance of various algorithms such as BR, CC, and LP, and a proposed algorithm on the same dataset.

BR is a widely used baseline method for multi-label classification tasks. It treats each label as an independent binary classification problem and trains a separate binary classifier for each label. During the testing phase, each classifier predicts the presence or absence of its corresponding label. Then, the predictions are combined to generate the final set of labels for the input sample. Binary Relevance is a simple and efficient method, but it ignores the potential dependencies between labels and may not perform well when labels are highly correlated.

CC is a method that considers the label dependencies by creating a chain of binary classifiers. In this approach, the first classifier is trained on the input data, and each subsequent classifier is trained on the input data concatenated with the predictions of the previous classifiers. The order of the classifiers in the chain can be randomized or chosen based on some heuristic. Classifier Chains can capture the dependencies between labels and improve classification performance compared to Binary Relevance.

However, it requires more training time and is sensitive to the classifiers' order. Label Powerset is another method that considers the label dependencies by transforming the multi-label problem into a multiclass problem. In this approach, each unique combination of labels is treated as a separate class, and a classifier is trained to predict the class of each input sample. The Label Powerset method can handle many labels but can be computationally expensive due to the many possible label combinations. It may also suffer from the "curse of dimensionality" if the number of labels is too large.

The proposed algorithm is compared with BR, CC, and LP for multi-label classification, considering some potential factors for comparison:

1) **Performance** A proposed approach's performance will be compared with other algorithms as the most critical factor. The performance of different algorithms can be compared using evaluation metrics such as precision, recall, F1-score, accuracy, and others. The proposed approach may perform better or worse depending on the dataset and the characteristics of the problem.
2) **Scalability** The scalability of an algorithm is another factor to take into consideration. For example, there can be scalability issues with the LP algorithm, while the BR algorithm is generally more scalable when the number of labels is large.
3) **Interoperability** When the results need to be understood by humans, interpretability is an essential factor. Since CC model the dependency between labels, it may be easier to interpret than other algorithms.
4) **Complexity** In addition, complexity can be one of the factors to consider, affecting training times, memory requirements, and other aspects of the algorithm. As a result, there may be differences between the proposed approach and other algorithms in complexity.
5) **Data Distribution** Data attributes such as sparsity, imbalance, and noise can impact algorithm performance. Therefore, the proposed approach may have specific strengths or weaknesses based on the data distribution type.

Model performance for multi-label classification of dark web data with BR, CC, and LP algorithms:

Fig. 4, 5, and 6 illustrate the performance of the BR, CC, and LP algorithms in terms of accuracy and loss during both the training and testing phases. These figures provide valuable insights into the behavior of each algorithm over time, enabling a thorough analysis of their effectiveness and identifying potential areas for improvement in both training and testing scenarios.

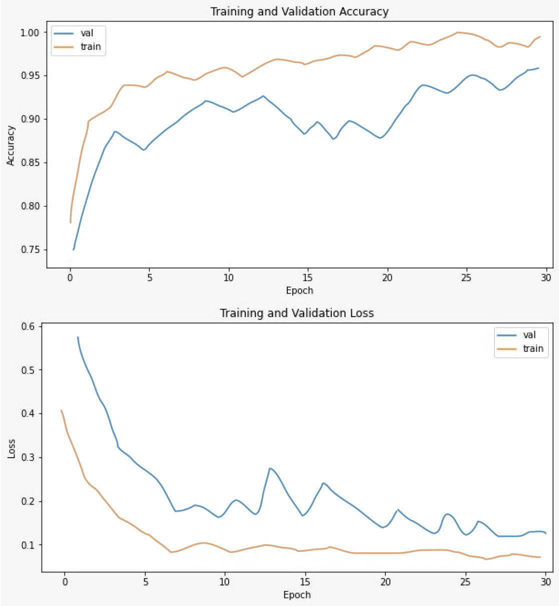

Fig. 4. Model accuracy and loss graphs for BR algorithm.

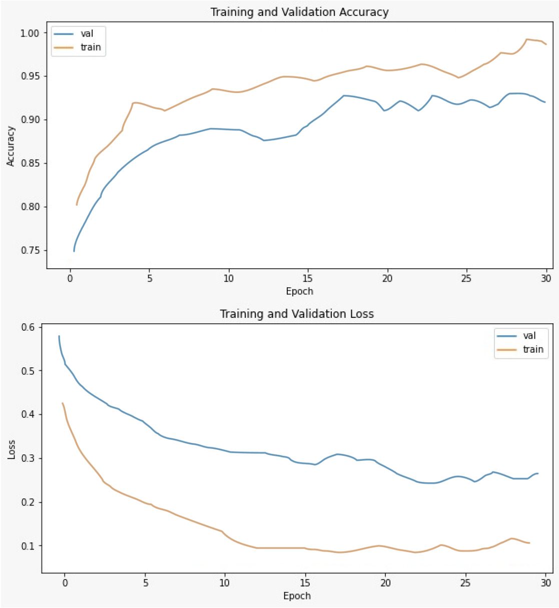

Fig. 5. Model accuracy and loss graphs for CC algorithm.

In the training and testing phases, accuracy and loss graphs are helpful indicators of the model's performance. High accuracy and low losses indicate that the model is learning and improving. Furthermore, when assessing the overall performance of a model, other metrics, such as precision, recall, and F1

TABLE I. Comparison of Precision (Prc), Recall (Rec), and F1 Score of Proposed Algorithm (Prp Alg), BR, CC, and LP

Algorithm	Prp Algo			BR			CC			LP		
Labels	Prc	Rec	F1	Prc	Rec	F1	Prc	Rec	F1	Prc	Rec	F1
Business	0.70	0.78	0.73	0.60	071	0.71	0.72	0.75	0.74	0.68	0.66	0.60

score, should also be considered.

C. Performance Evaluation of Algorithms

Comparison of precision, recall, and F1 scores provide insights into which algorithm performs better regarding identifying relevant labels. The F1 score is a harmonic mean of precision and recall. The accuracy of the predictions measures precision and recall by the ability to identify all relevant positive instances, while the precision of the forecasts measures recall.

Table I shows that comparing the proposed algorithm to the other three algorithms (BR, CC, and LP) for three labels (Business, Cybersecurity, and Education), the proposed algorithm has higher precision, recall, and F1 scores. Hence, the proposed algorithm outperforms the other algorithms for these labels. In addition, the proposed algorithm appears more accurate at identifying relevant instances within Entertainment than the other three algorithms.

In Finance, F1 scores for the baseline algorithm were the highest, while precision scores were the highest for the proposed algorithm. The proposed algorithm performs better than the other two algorithms in all but precision. Regarding Food, all algorithms performed well, with high precision, recall, and F1 scores. According to the proposed algorithm, the recall score was the highest, while the precision and F1 scores were the highest for the baseline and LP algorithms. BR algorithm had the highest recall and precision scores in Health, while the proposed algorithm had the highest precision and F1 scores.

For the Literature label, BR, LP, and the Proposed algorithm correctly identified labels for this category. For Nature, with F1 scores of 0.93 and 0.82, respectively, the Proposed Algorithm and LP perform well, while CC performs poorly with 0.80. In the Network category, the Proposed Algorithm, BR, and LP all achieve high F1 scores of 0.86, whereas CC achieves a slightly lower F1 score of 0.80. All algorithms perform reasonably well in this category.

In the politics category, the Proposed algorithm and BR scored 0.40, indicating they could not correctly identify the labels. On the other hand, there was a slight improvement in the F1 scores of LP and CC, respectively, with 0.43 and 0.41. In Security, a perfect score of 1.0 was achieved by all algorithms for precision, recall, and F1, indicating that all assigned labels were identified correctly. For the category of Shopping, BR, and LP have lower scores of 0.78 and 0.73, respectively, compared with the Proposed algorithm and CC.

Overall, the algorithms perform differently in different categories. However, most categories show that the Proposed algorithm and LP are better at identifying the labels for the given text data than BR and CC. The algorithm's poor performance in the Politics category demonstrates that category's characteristics affect the algorithm's effectiveness.

The number of labels per sample significantly affects multi-label classification using the proposed approach. Models may be unable to capture the complex relationships between features and labels when the number of labels is too low. This may cause the model to underperform on the test set and not generalize well. On the other hand, a model may suffer from the curse of dimensionality if there are too many labels per sample, which creates a very complex feature space. As a result, the model may struggle to learn effectively from the data, leading to poor performance. As a result, the optimal performance of the proposed approach depends on balancing the number of labels per sample.

V. Conclusion

The proposed work introduces a multi-label text classification approach to categorize deep and dark web content, aiming to predict multiple labels for a given text. Four machine learning algorithms were compared: the proposed algorithm, BR, CC, and LP. Evaluation metrics including precision, recall, and F1 score were used to assess their performance. The proposed algorithm exhibited significantly higher precision, recall, and F1 scores compared to the other three algorithms. Additionally, the study highlights the influence of the number of labels per sample on multi-label classification performance. Balancing the number of labels per sample is crucial to avoid poor results caused by either too few or too many labels per sample, which can lead to difficulties in capturing relationships between features and labels or the curse of dimensionality, respectively. In conclusion, this research proposes an efficient multi-label classification model for deep and dark web content analysis, demonstrating superior performance compared to existing methods, with potential applications in cybersecurity and law enforcement. Furthermore, the insights gained regarding the impact of the number of labels per sample can guide the development of future multi-label classification models. The multi-label text classification approach also enhances the model's capabilities to simultaneously learn entity recognition, relation extraction, and other related tasks, thus improving its overall performance.

***Abstract*—This paper presents intuitive directions for field research by introducing a ground-breaking IoT-ML-driven intelligent farm management platform. This study's main goal is to address agricultural difficulties by providing a thorough, integrated solution. This work makes a variety of important contributions. By utilizing cutting-edge technology like IoT and Machine Learning (ML), it first improves conventional farm management procedures. Farmers now have the capacity to remotely monitor and regulate irrigation management thanks to sensor-based real-time data. Second, based on data gathered from agricultural fields, our machine learning model offers improved water control management and fertilizer use recommendations, maximizing production while minimizing resource usage. The suggested solution also uses blockchain technology to create a safe, decentralized network that guarantees data integrity and defends against threats. We also introduce energy harvesting technology to address the issue of continuous energy supply for IoT devices, which lessens the load on farmers by removing the requirement for additional batteries. We achieved 89.5% accuracy in our proposed machine learning model. The suggested model would provide a variety of services to farmers, including pesticide recommendations and water motor control via mobile applications and a cloud database.**

***Keywords*—Smart agriculture; machine learning; internet of things; energy harvesting; blockchain technology**

I. Introduction

Without a doubt, agriculture is the most important source of livelihood in Bangladesh. As the world's population expands, increased agricultural output is essential. The amount of fresh water and appropriate fertilizer used in irrigation must be raised in order to maintain enhanced farm productivity. Unintentional water waste happens when water consumption is not planned. Choosing the right fertilizer for a particular farmland is likewise a difficult challenge for our farmers. This demonstrates the urgent need for alternatives to reduce water waste and appropriate fertilizer choices without placing farmers under stress. In the Electronic age, agriculture is rapidly becoming a data-intensive sector, with farmers collecting and analyzing massive amounts of data from various sources (e.g., sensors, farming machinery, etc.) to obtain vital information and become more efficient in production. Technology nowadays has advanced a lot. With the help of Machine Learning and IoT devices, a drastic change can be made possible in the agricultural industry [1].

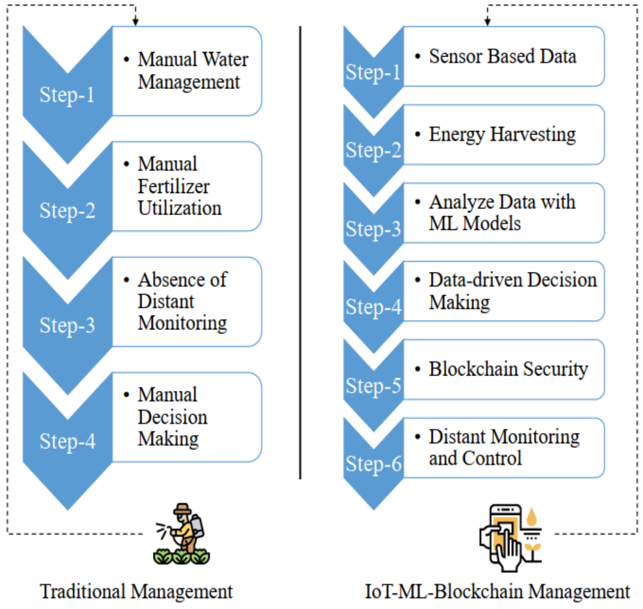
With the release of open-source Arduino devices and the availability of different sensors, it is now possible to build devices that can monitor soil moisture content and irrigate fields or landscapes as needed. Machine learning algorithms are used to assess various agricultural data and may readily forecast which decisions should be made to improve farmland productivity. In comparison to their previous farming ways, the farmer may easily combine ML and IoT into their farming and create an automated system that is more time effective and less risky. Here, Fig. 1 depicts the difference between the traditional system with the ML-based agricultural framework.

Wireless Sensor Networks(WSNs) technologies have a major challenge with limited energy. Many research in WSNs has also been focused on reliable energy supply to extend the survival time of limited power sources in a network [2]. Energy harvesting techniques are used to overcome the energy-scarcity problem of WSNs. Energy harvesting is a process in which energy is obtained from the environment as renewable energy sources like solar radiation, Radio Frequency (RF), wind, geothermal, electromagnetic (EM) waves, hydro, etc., and is stored effectively for driving various applications systems which may include wireless sensor networks (WSNs) [3] [4]. Therefore, it can be used to operate the devices of the embedded system for a reliable energy supply.

Security is one of the most critical aspects of IoT, as it deals with the protection of data and devices from unauthorized access, use, disclosure, disruption, modification, or destruction [5]. Encryption mechanisms are mostly used to ensure that data is securely transmitted. But, regularly used encryption algorithms such as DES, AES, and RSA will be heavy for small-scale embedded systems. Therefore, blockchain technology can be used as a lightweight calculation technique to reliably operate and secure an IoT system[6] [7].

This paper presents the latest IoT-ML-driven intelligent agricultural management and provides a substantial new research direction. The central insight of this work is to offer possible solutions to farming hazards while providing a combined framework. Some significant contributions of this paper are outlined as follows:

- **Smart Management:** Traditional agricultural management is strengthened with edge-cutting technologies (i.e., IoT and Machine Learning).
- **Distant Monitoring and Controlling:** Farmers can monitor and control irrigation management from a distance in terms of sensor-based real-time data.
- **Intelligent Decision Making:** Our machine learning model provides substantial water control management



Step-1
• Manual Water Management
Step-2
• Manual Fertilizer Utilization
Step-3
• Absence of Distant Monitoring
Step-4
• Manual Decision Making
Traditional Management
Step-1
• Sensor Based Data
Step-2
• Energy Harvesting
Step-3
• Analyze Data with ML Models
Step-4

and fertilizer utilization direction for a minimum resource with a maximum throughput based on the data collected from the farming field.

- **Block chain Based Security System:** Our proposed solution uses blockchain technology to create a secure and decentralized network that can ensure data integrity and protect data from denial of service (DDoS) attacks, and man-in-the-middle (MITM) attacks.
- **Energy Harvesting:** To ensure a continuous energy supply for the IoT system, we have introduced energy harvesting technology which reduces the hassle for the farmers of using extra batteries.

The rest of the paper is organized as follows: Section II provides an overview of existing works related to our proposed framework. Section III provides a detailed description of the hardware that have used in this research. Section IV discusses the proposed IoT-ML-based smart agricultural framework. Section V discusses the blockchain-based security of our system. Section VI presents the real-life implementation of our project. Next, Section VII illustrates and analyzes the experimental result from our machine learning models. Section VIII future research directions in this field of research. Finally, Section IX gives a brief conclusion.

II. Related Research

Several ML-IoT-based researches and project works on agriculture systems have been carried out till today.

In [8], For remote sensing and smart agriculture, Ullo et al. presented a review of research on the developments in smart sensors and IoT. They put forth some suggestions for IoT advancements that will support researchers and agriculturalists in their work.

In [9], Samuel et al. analyzed numerous techniques for crop selection, crop sowing, weed detection, and system monitoring. They have recommended different image processing methods for weed and leaf detection and evaluated the benefits and drawbacks of each. Drone implementation has been considered for real-time monitoring and seed planting. However, no actual implementation is shown in this research; they have only reviewed several smart agricultural strategies.

In [10], they analyze soil moisture levels and apply auto irrigation to the crops. In order to eliminate the need for human involvement, this system also senses temperature, humidity, and the presence of impediments in the targeted region. These data are accessible to the user via mobile from the cloud. By giving the motor driver the command YES/NO based on this data, the user can control the operation of the motor.

In [11], they use a cloud-based architecture and the Internet of Things to examine a smart irrigation system. This system is designed to measure soil moisture and humidity and then process this data in the cloud using a variety of machine-learning techniques. Farmers receive accurate information regarding water content regulations. If farmers apply smart irrigation, they can reduce their water usage.

In [12], they use IoT and machine learning to predict late blight disease in potatoes and tomatoes prior to the first occurrence. This will send farmers a warning message on the precise time to apply the protective pesticides.

In [13], for yield prediction, they present a hybrid ML model using IoT. They use a two-tier ML approach named aKNCN and ELM-mBOA.In the first tire, they estimate soil quality and in the second tier, they predict the crop yield.

In agriculture, supply, and demand have always been crucial issues for sustainable production management. To address and provide a possible solution to this problem, M. Lee et al. proposed an IoT-based controlled agricultural production management [14]. The authors developed a decision support system to predict specific criteria based on IoT-enabled sensor data.

A cloud-based real-time data analysis model is proposed in [15] instead of dew-point humidity. In this regard, they designed a CMM index measurement model to evaluate the crops' comfort level of relative humidity levels.

To increase the crop production rate, real-time data analysis based on an artificial model is proposed by Y. Zhou et al. in [16]. The current innovation trend expects farmers to use IoT and technology to identify the organization of those difficulties they face, such as water management deficiencies in agriculture and productivity concerns. This research has attempted to build dazzling agricultural cultivation patterns utilizing IoT technologies. IoT has significantly improved agriculture by analyzing various agricultural difficulties and issues.

An IOT-based intelligent technology for agriculture that can sense soils and environmental factors was proposed by Abhijith H. V. et al. in [17]. In order to identify the urgent needs for optimal crop growth, they applied data mining techniques to the sensed data.

Abraham et al. [18] create a proof-of-concept farm surveillance system that employs IoT and deep learning to identify farm encroachment.

The purpose of the study Wongpatikaseree et al. [19], is to propose a traceability system, summarizing and presenting observed data from the smart farm.

For smart farming, Deden Ardiansyah et al. [20] suggested a WSN Server that can handle and optimize agricultural data. They instantly store the data in the database, which is afterward represented as a website and accessible through the Internet network.

Automation in agriculture is a basic need for remote control-based agricultural management to ensure sustainable development in this field of research. In this regard, L. Vijayaraja et al. proposed an IoT-based monitoring system using wireless communication networks in [21]. The power supply management used in this framework is entirely from the renewable energy source that provides a cost-effective model for sensor-based decision management in intelligent farming.

In [22], Yaw-Wen Kuo, et al. presented a Long-range IoT system where they developed four types of IoT units based on Long-range technology. They employed pH, ORP, and EC in Type A and water, air, and humidity sensors in Type B. In type C, the pump can be operated remotely, and in type D, a water flow or water meter-controlling system is provided.

They presented a cloud service-based architecture in [23] that includes a variety of services for farmers, including agri-food-related services, financing, fostering, warehouse management, etc. They have suggested interactive video conferencing, voice-based services, text messaging, web portal services, and more under the heading of cloud services.

A key component of practicing smart agriculture is precision agriculture. In this context, Patil et al. [24] suggested a system that measures soil moisture using sensors for temperature, humidity, and soil moisture. Additionally, they offered various methods for highlighting the issue of data loss.

In [25], Quasim et al. use blockchain techniques in smart healthcare systems to ensure the security of healthcare data. It provides the security, privacy, and efficiency of the data in transmission between wearable sensors and Internet of Things (IoT) devices.

In [26], Makhdoom et al. made a blockchain-based framework for privacy-preserving and secure data sharing in smart cities. The system secures data sharing by segmenting the blockchain network into different channels, where each channel consists of a limited number of authorized organizations and handles a particular type of data, such as financial information, health data, smart car data, or data related to smart energy. Additionally, smart contracts contain access control rules that regulate who has access to the data of users within a channel.

Many different types of intelligent agricultural systems were developed in the earlier work. Some of these current systems are tabulated in Table I.

III. System Hardware

To set up the IoT environment for a smart agricultural system, we have selected a variety of hardware components, including the ESP8266 Node MCU (Fig. 2) processing unit and several sensors, including capacitive soil moisture (Fig. 3), PH sensor (Fig. 4), MH-RD Rain Sensor (Fig. 5), and LDR Sensor (Fig. 6). Our IoT system is powered by DC-DC power converter (Fig. 9), solar energy harvesting components (Fig. 10), single-channel relay modules (Fig. 7), DC motors (Fig. 8), etc.

A. Node MCU ESP8266

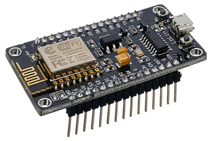

Fig. 2. Node MCU module.

Features[1]**:**

- Operating Voltage: 3.3V
- Input Voltage: 7-12V
- Digital I/O Pins (DIO): 16
- Clock Speed: 80 MHz
- Small size module

B. Capacitive Soil Moister Sensor v1.0

Fig. 3. Soil moisture sensor.

Features[2]**:**

- Operating Voltage: DC 3.3-5.5V
- Output Voltage: DC 0-3.0V
- Digital I/O Pins (DIO): 16
- Analog output
- Supports 3-Pin Sensor interface

C. PH Sensor(SEN-00239)

Features[3]**:**

- Supply voltage: 5V
- Current: 5-10 mA
- Consumption: $\leq$ 0.5 W
- Working temperature: 10-50°C

TABLE I. Previous Research Works in Terms of Objectives, used Tools, and Possible Research Gaps

Reference	Research Purpose	Used Technologies/Techniques	Focused Methods	Challenges/Research Gaps
[11]	IoT-Cloud based automated Irrigation	Raspberry Pi, central cloud storage, soil data set, machine learning techniques, and mobile applications	Focused to measure soil moisture and humidity and then process this data in the cloud using a variety of machine learning techniques	Farmers get information about water only, no other necessary information.
[12]	IoT-based agriculture monitoring system for predictive analysis	Air temperature sensor, air humidity sensor, and soil moisture sensor, Microcontroller Unit (NodeMCU), MQTT protocol, R-Pi 3 microcontroller, MYSQL	Focused to predict the late blight disease in potatoes and tomatoes before the first occurrence	Not fully automated, need human interference to apply the action
[14]	IoT-based agricultural production System	Dual CDMA protocol, pH sensor, water sensor, and temperature sensor	Focus on reliable agricultural production management	Absence of dynamic data analysis model
[15]	IoT-Cloud based agricultural monitoring system	Arduino UNO, temperature and humidity sensors, Arduino Ethernet shield and ThingSpeak cloud platform	Finding the index of thermal control functions to find the comfort levels of agricultural parameters	Sensor data processing time is slower in terms of CMM-MIST measurement algorithm.
[16]	Machine Learning based agricultural management	Threat Model (TM), Deep Crop Mapping Model (DCMM), Random Forest Regression Algorithm (RFRA)	An intelligent management to predict soil moisture content based on the ML architecture	The key challenge of this research is real-time data processing
[17]	Intelligent technology for IOT-based agriculture	PH sensor, temperature, rainfall, humidity sensor, Predictive classification algorithm, MatLab	Focused on the identification of urgent needs for optimal crop growth	Prediction of specific need isn't gained properly
[18]	Comprehensive farm monitoring system	Arduino Board, Node MCU, Sensors, mobile App, machine learning, deep learning	Centered on a surveillance system prototype and an app-based remote administration solution	Remotely monitoring but not fully automated controlling
[19]	IoT-based Smart farming	Sensors, mobile technology, Wi-Fi, cloud computing	Can measure soil temperature, soil moister, humidity, pH and EC values	Human interaction, water wastage
[20]	Water management based on IoT	Soil moisture, Wi-Fi segments	Real-time data monitoring for soil moisture and remote data access	Low or excessive irrigation, and water waste
[21]	IoT-based cost-effective agricultural management	Moisture and Water sensors, Node MCU, Solar panel and LCD display unit	Focused on the low-cost parameter while ensuring a sustainable energy efficient management	The key research gap of this work is that this model is applicable for small farming areas.
[22]	IoT platform has a long range for controlling pumps and monitoring agriculture	LP WAN, Base station, Ph sensor, Electrical Conductivity sensor, Water Temperature Sensor, GY39	Presented a complete IoT system including the design of a remote unit and server construction	It is required to conduct additional research on the pH sensor because the data that has been gathered is inaccurate and collected from other vendors.
[23]	Cloud service architecture for agriculture using IoT and Big Data	Different Sensor, Central Cloud Database	Proposed a cloud-based architecture for the agricultural industry that comprised a range of services, including farm monitoring, market-oriented service, agribusiness monitoring, etc.	Not implemented just proposed an architectural model.
[24]	AI in smart agriculture applications	Arduino UNO, Soil moisture sensor, Wi-Fi module	Aimed to use a single moisture sensor and make decisions, such as turning on or off the pump, based on the data collected.	Discussing the disease of crop using image analysis technique but no actual implementation is shown.
Proposed System	Smart agricultural system based on an IoT-ML-Blockchain Integrated Framework	IoT devices, Mobile Application, Machine Learning, and Blockchain-based security system	Focused on intelligent decision making, Distant Controlling, Energy Harvesting, and Security based smart agricultural management system	Future target to ensure Low latency network and high bandwidth transmission, easy deployment of Networks elements and Edge computing technology.

Fig. 4. PH Sensor with module.

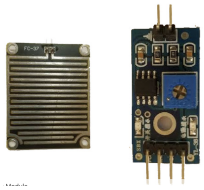

Fig. 5. MH RD rain sensor.

D. MH-RD Rain Sensor

Features[4]**:**

- Working voltage: 5V
- Output format: Digital switching output (0 and 1)
- With bolt holes for easy installation
- Uses a wide voltage LM393 comparator

E. LDR (Light Dependent Resistor)

Features[5]**:**

- Able to detect variable light resistance (50-100 K Ohms)

- Diameter: 3-20 mm

F. Single-Channel Relay Module

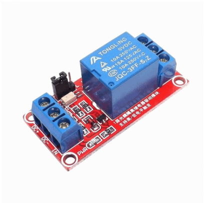

Fig. 7. Single-Channel relay module.

Features[6]**:**

- Ground Voltage: 0 V
- VCC: Provide input to the relay coil
- Supply Voltage: 3.75 to 6 V
- Current: 2 mA
- Relay Maximum Current: 10 A

G. DC Motor 6V

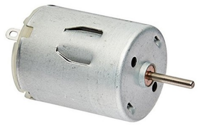

Fig. 8. DC motor.

Features[7]**:**

- Diameter of the motor: 23.5mm
- Height: 30mm
- Start voltage: 0.8V
- Rated voltage: 6V
- Non-charging current: 25mA
- Speed: 2980 RPM

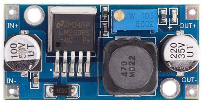

Fig. 9. Adjustable DC-DC power converter.

H. Adjustable DC-DC Power Converter (1.25V - 35V-3A)

Features[8]**:**

- Input Voltage: 3.2V - 40VDC
- Output Voltage: 1.25V - 35VDC
- Max. Output Current: 3A
- Max. Efficiency: 92
- Output Ripple: $\leq$ 100mV
- Switching Frequency: 65KHz
- Operating Temperature: -45°C to +85°C
- Dimensions: 43mm*21mm*14mm(l*w*h)

I. MSP430 Solar Energy Harvesting Tool

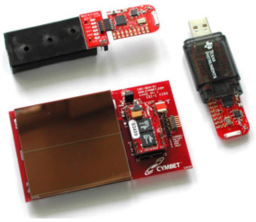

Fig. 10. MSP430 solar energy harvesting development tool texas instruments EZ430-RF2500-SEH.

Features[9]**:**

- Battery-less operation
- Functions in dim ambient light and 400+ transmissions
- Adaptable to any RF network or sensor input
- Inputs available for external harvesters (thermal, piezo, 2nd solar panel, etc.)
- USB debugging and programming interface with application backchannel to PC
- 18 available analog and communications input/output pins
- Highly integrated, ultra-low-power MSP430 MCU with 16-MHz performance

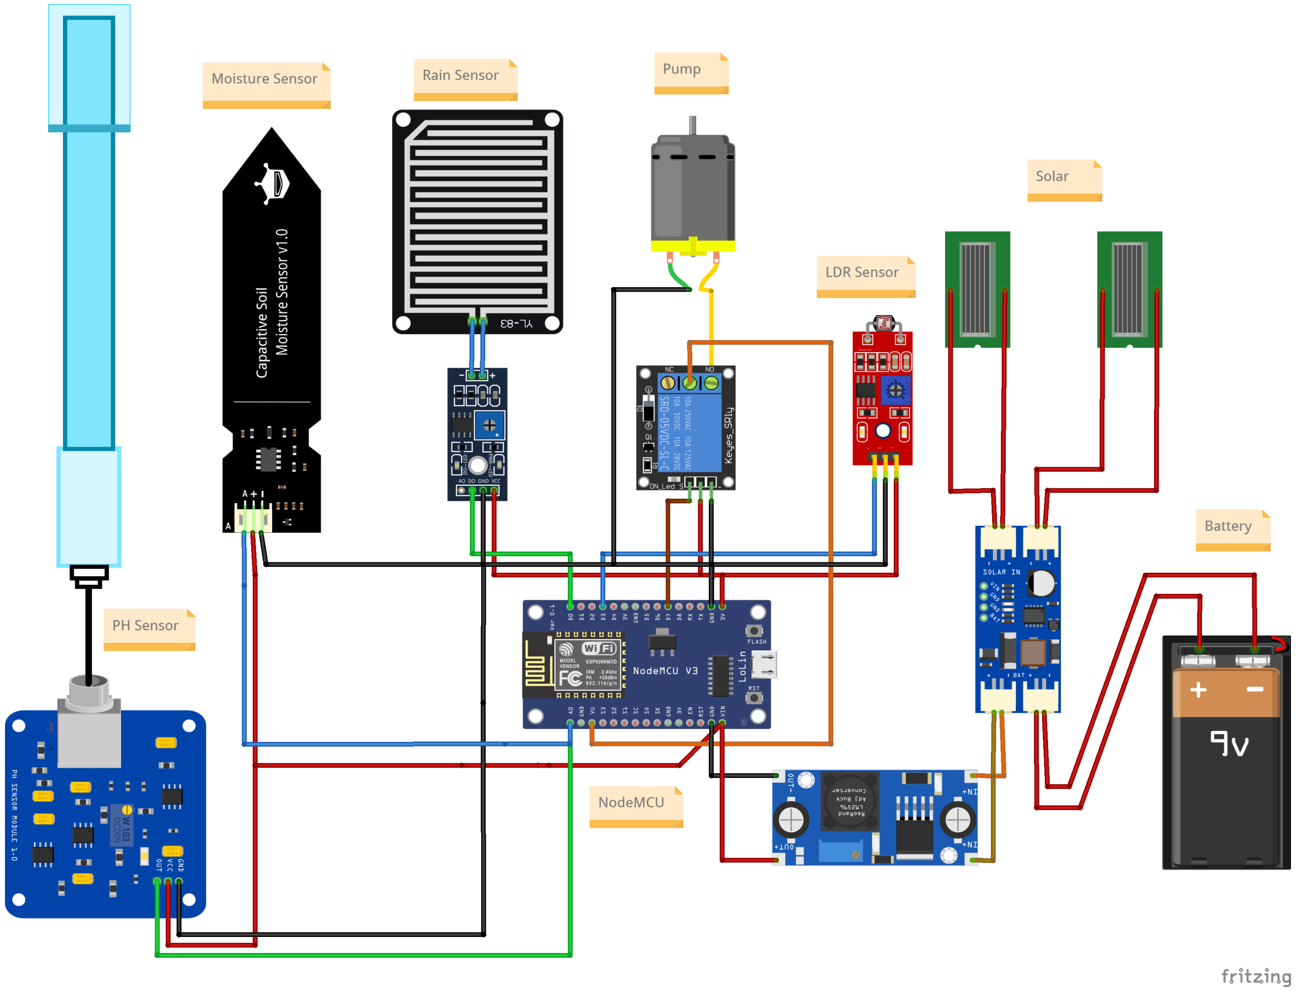

Fig. 11. Schematic pin configuration of our proposed framework.

IV. Proposed Framework

A. Circuit Diagram and Connections

We used Fritzing[10], an open-source hardware online application to make a schematic pin (Fig. 11) diagram of our smart agriculture system.

We used ESP8266 NodeMCU V3, with an integrated WIFI module as our processing hardware component. The system connects an analog capacitive soil moisture sensor and an analog pH sensor using multiplexing to the A0 analog input of NodeMCU, a photo-resistor known as Light Dependent Resistors (LDR) sensor to a D3 digital input, and a raindrop sensor with rain board and control module to D0 input Pin. In addition, the device is connected with a D3 output pin to a DC 5V micro submersible mini water pump with the relay. We used the NodeMCU's 5V VU pin to power the Motor and Relay. However the LDR Sensor and Rain Drop Sensor, only need a 3.3V supply, the Capacitive Soil Moisture Sensor and pH Sensor need 5V. The GND pin serves as the common ground for every sensor. A solar panel system that is coupled to a 9-volt battery backup powers the system.

B. Working Principle

We have divided our proposed framework into different subparts and each part's working procedure is given below. The overall working procedure is depicted in Fig. 12.

1) Collecting Data From Sensor: We used four different types of sensors, including capacitive soil moisture sensors, pH sensors, MH-RD rain sensors, and LDR sensors, to execute smart IoT agriculture. We can estimate how much water is in the soil with the aid of a soil moisture sensor. A pH sensor, which ranges from 0 to 14, allows us to determine the water's acidity or alkalinity. Water turns acidic if the value falls below 7, else it is alkanoic. Consider levels 5.5 to 7 to be ideal for growing crops. We can choose the best fertilizer for the soil with the aid of a pH sensor.

Basically, a rain sensor is used to detect rain. A rain board that can detect rain and a control module that can compare

analog and digital values are both included. The raindrop sensor aids in our selection of how to operate the motor. The LDR sensor, which is used to detect the presence of light, has also been employed.

Now, each of these sensors is linked to a node MCU board in our project, and data from the sensors is uploaded to the node MCU board and shown on the serial monitor of the Arduino UNO editor and

2) Sending Data to Cloud Server: The node MCU board receives all sensor data, which we would love to save in the cloud in order to control for remote distance. We have utilized Firebase as a cloud server. We linked the Firebase authentication and real-time database URL that we built for our project with the Arduino UNO script in order to integrate Firebase with Node MCU.

All data is sent as a parent-child combination to Firebase. All of the sensor data is sent from the node MCU as a child of Smart Irrigation, which we have constructed as Parent. The Firebase stores the child value as a key-value pair.

3) Data Collection: The Firebase's database contains all of the sensor data, which is compiled as a CSV file. Four columns make up our dataset: pH, LDR, Rain, and Moisture. Nearly 820 data are in our dataset. Only integer values are accepted in the Moisture column here, whereas string values are accepted in the Rain and LDR columns.

4) Data Pre-processing: Data can be often inconsistent. Missing values or values out of range is typical. So, the dataset needs some pre-processing before it can be used to train any model [27]. For this reason, we have considered three such cases.

- **Missing Value Handling:** While exploring our dataset, we observed humidity, raining status, daylight status, and pH level fields with missing values. Therefore, we have filled them with average values of the respective field.
- **One Hot Decoder:** Label encoding is simply the process of converting each value in a column to a number. By using label encoding, we have converted the categorical text data into model-understandable numerical data. We had to use the label encoding to get our dataset ready for our model.
- **Abnormal Data Handling:** Some data contain abnormal values. For example, the range of the temperature in our dataset falls between -20 to 30 degrees Celsius. However, we have even found some data above and below this range. Data tuples with these abnormalities have been dropped from the dataset.
- **Normalization:** Normalization is used to increase the accuracy of models [28]. It is simply the process of having all the data on the same scale. We have used

temperature, pressure, relative humidity, and pressure as features to train our model. The features used to teach a machine-learning algorithm have different ranges of values. This can badly affect the machine's learning ability. To solve this problem, we have standardized the feature values so that all the features stand equal in their representation. By normalization, all the feature values are mapped in the range between 0 and 1.

5) Machine Learning Model: The developed architecture is a Neural Network (NN) based because of its great accuracy. The fundamental advantage of NN over classical machine learning models is that it recognizes significant traits automatically and without human intervention. It's a feed-forward NN with parameters using the back-propagation algorithm and stochastic gradient descent. Distinct processing layers serve different purposes. The output of the feature map is produced by conventional layers, which conduct linear convolution between a series of input tensors and filters. The nonlinear transformation is performed using the $ReLU$, which is the most widely employed activation function. The activation function for the fully connected layer to the end must be careful on the tasks. Batch normalization and an activation layer are performed after each convolution.

$$ReLU = max(0, X) \tag{1}$$

$$d(x) = activation(w^x + b) \tag{2}$$

$$Dropout(x, p) = (x : prob., p)\ (x : prob., 1 - p) \tag{3}$$

$$S(x) = \frac{1}{1 + e^{-x}} \tag{4}$$

6) Mobile Application Development: A smart remote control application can ease our maximum task [29]. We have used the MIT app inventor to make the mobile application that will be connected to our system and by using this app we can do the following task

- **Fertilizer Suggestion:** By analyzing the pH value, the app may suggest which fertilizer is best for a given soil. The app will recommend some alkanoic fertilizer if the pH value rises to help reduce the rising pH value and vice versa. Algorithm 1 depicts how the fertilizer is suggested in our system.
- **Visualization of Predicted Results:** In order to predict whether the motor would turn off or not based on the moisture, LDR, and raindrop sensor values, we construct a neural network model and link it with our mobile app. Algorithm 2 depicts how the remote controlling is done to control the motor in our system.
- **Remote Motor Controlling:** The farmer can use the app to control the motor from any distant or remote location based on the prediction outcome. When the farmer presses the off button, it sends a value of 0 to the firebase, which then passes this signal on to the node MCU via the wifi module and sets the pin value to the LOW, so turning off the motor.

Algorithm 1: Decision Making for Fertilizer Suggestion

```
1. Initialize the pH sensor
2. Read data from pH sensor
3.if $pH >= 6.5\ \&\&\ pH <= 7.5$ then
    Soil is balanced.
    No fertilizer is recommended.
4.else if $pH < 6.5$ then
    Soil is acidic.
    Store the pH amount.
    Find the level_id corresponding pH amount.
    Search through the fertilizer data(in JSON format)
    if $level\_id == keyofJSONdata$ then
        Send the fertilizer name back to the user.
    else
        The result doesn't match our dataset.
else
    Soil is alkanoic
    Store the pH amount
    Find the level_id corresponding pH amount
    Search through the fertilizer data(in JSON format)
    if $level\_id == keyofJSONdata$ then
        Send the fertilizer name back to the user
    else
        The result doesn't match our dataset
```

Algorithm 2: Decision Making for Pump on/off

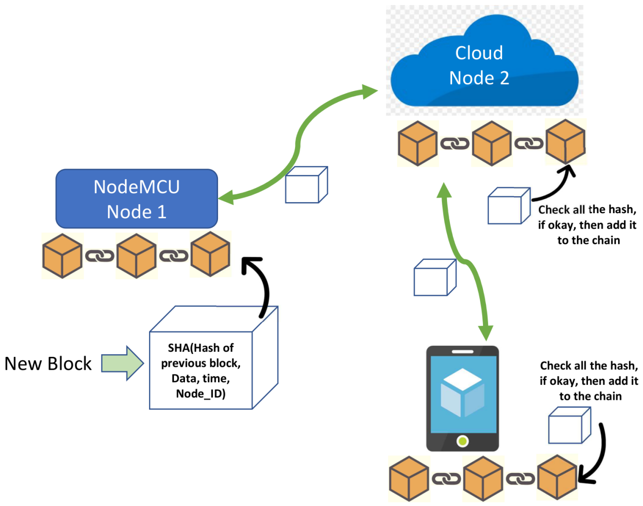
```
1. Initialize the Moisture, Rain, and LDR sensors.
2. Read data from each sensor.
3. Send the data to the server using an HTTP POST
   request.
4. Apply machine learning to the collected data.
5. Retrieve the predicted result(PUMP ON/OFF).
6. Send Predicted results to the mobile phone.
7. Wait for user input from the mobile phone.
8. if $user\_action = true$ then
    Send a signal to the node MCU board.
    Perform action according to signal.
else
    Wait for 300 seconds
    Take an automated action according to the
      predicted result (PUMP ON/OFF)
```

V. Blockchain-based Smart-Agri

Blockchain was described as a data structure using asymmetric encryption algorithms and hash functions to ensure that data tampering and forgery are impossible [30] [31] [32]. Every smart system needs to be taken under the shelter of a security system to avoid getting an external attack. Our smart agricultural system is public so any intruder can make attacks such as DoS attacks to crash the system, and spoofing to alter the control. In the IoT environment where high computational encryption, decryption, and high-level security are not possible.

Therefore, We are implanting blockchain technologies into our smart agricultural system through which we are capable to maintain high throughput, low latency, low communication cost, and tamper-proof and traceability. Blockchain refers to a distributed ledger system where data or transactions are stored in blocks that are connected to each other through making hash which can not only serve as unique IDs but also prove the integrity of the blocks. The hash of the previous block is used to make a hash for the next block along with its data. If any intruder wants to tamper or alter the block data, all the consecutive block hash will be changed. Therefore, any intruder attempts to alter the data or spoof the blockchain will not be possible.

In this system, we consider nodeMCU, Firebase cloud, and mobile app as nodes. In order to avoid altering data in the network, we are using blockchain technology. When any node wants to send data to other nodes, it encapsulates the data into a block along with its hash values (SHA256) and nodeID then adds it to the blockchain. All these nodes will contain the blockchain locally. After adding the block, the node sends it to the cloud through the network. We are not using any PoW, PoS, or accountant selection algorithms which is not possible because of a very small amount of nodes and our nodeMCU has very limited capabilities to run these algorithms (Algorithm 3). When the block is sent to the cloud, I validate the block by checking all the hashes of the previous block along with the nodeID. If it gets any error, the node will consider the block as from an attacker and reject the block from adding to the chain. Fig. 13 depicts the blockchain in our system.



Cloud
Node 2
NodeMCU
Node 1
Check all the hash, if okay, then add it to the chain
New Block
SHA(Hash of previous block, Data, time, Node_ID)
Check all the hash, if okay, then add it to the chain

Fig. 13. Blockchain in the system.

VI. Implementation

A. Hardware Implementation

Our Smart-agri system hardware demo showed in Fig. 14.

B. Mobile App Implementation

The interface of the mobile app that we developed in the MIT App Inventor resembles (Fig. 15). The “Fertilizer Suggestion" button can be found in the app. Depending on the pH sensor measurement, this button tells us whether the soil is alkanoic or acidic when we click it. We used the decision tree algorithm to determine the ideal fertilizer for a given soil based on its quality.

Algorithm 3: Blockchain-based data security in smart-agri

```
1. Initialization
2. Read data
3. $Block\_Hash \leftarrow SHA256$ (Previous_hash, data, nodeId, timestamp, nonce)
4. Make a block (Block_hash, data, nonce, nodeID, timestamp)
5. Add the block to the chain locally.
6. Send the block to the cloud.
7.if $Block\_hash = Previous\_Hash$ then
    Accept the block, then add it to the chain.
    Send acknowledgment.
```

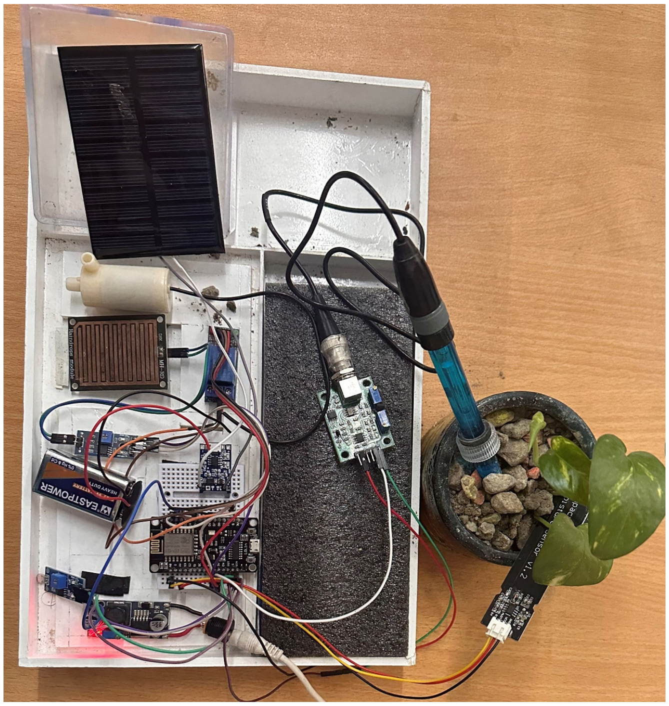


Fig. 14. Hardware set-up of our proposed framework.

The farmer can view the data from the moisture, raindrop, and daylight sensors in our app. Our program uses a neural network model that we built and implemented to forecast whether the motor would be on or off. We can operate our motor using the two buttons in our app labeled “ON" and “OFF". The motor status in the firebase changes to 1 when we press the “ON" button, and the firebase sends a signal to the nodeMCU board, which then turns the motor on automatically. And that is how we can use our mobile app to implement remote control.

VII. EXPERIMENTAL RESULT ANALYSIS

A. System Evaluation

In Table II, we have shown the difference between our system and the existing systems. The criterion based on which we have shown the differences are remote monitor control, data visualization, customized mobile application, machine learning integrated framework, creating own database, central cloud database, pH-based fertilizer suggestions, Machine learning model development, and full automation. The references from [11] to [24] there is no such system that has implemented all the criteria in their system. But we have successfully implemented all the criteria in our systems.

B. Machine Learning Model Evaluation

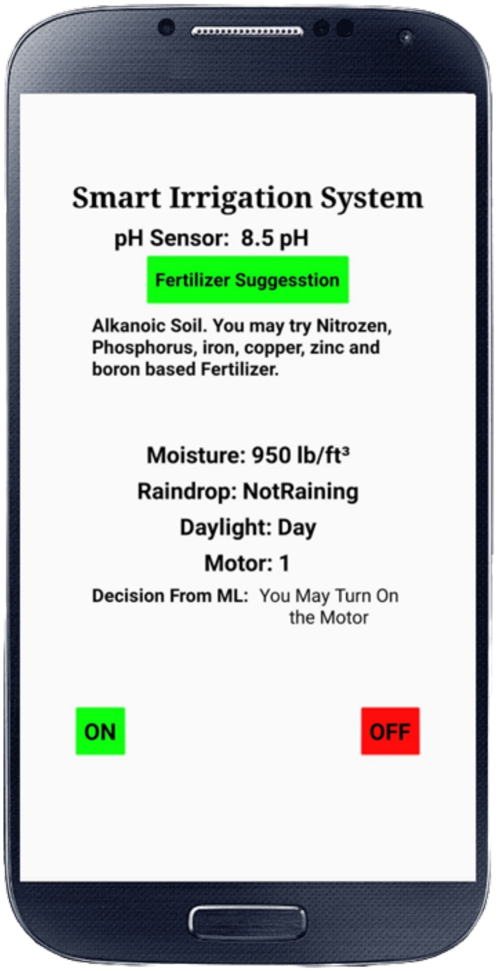
Our deep learning neural network is implemented with the help of our own dataset. We split the dataset into 80-20 ratios for training and validation purposes. The heat map of the features columns is illustrated in Fig. 16. We fit our gradient descent neural network within the data set. The input layer of the neural network receives 3 input lines from the features column, namely, rain status, moisture level, and daylight status respectively. Then we add one dense layer with 16 neurons and the activation function as $ReLu$. The next layer is a dropout layer with a 20% drop rate. Next, we add another dense layer with 8 neurons and apply the activation function as $ReLu$. Then we add another dropout layer with a 20% drop rate. Finally, for the output layer, we add another dense layer with a single neuron with is satiable for binary classification (i.e. motor on-off decision) with activation function as $Sigmoid$.

The experimental result of our model is represented in Table III while showing the validation loss rate as binary cross entropy and validation accuracy level in different epochs. Our model successfully outcomes a stable level of accuracy for the different epochs. We got almost 89.5% accuracy in our experimental set-up.

VIII. FUTURE RESEARCH DIRECTION

For future smart irrigation management, several issues must be addressed as follows:

- **Low-latency in Real-Time Application:** The monitoring and controlling mobile application must be able to transmit real-time data to the farmers or its entity while ensuring a low latency network.
- **High Bandwidth:** To facilitate a buffer-less transmission, we need to ensure maximum bandwidth level to the transmission process.
- **Connectivity:** To meet the high communication demands of future IoT-ML integrated irrigation systems, reliable synchronization between linked autos would be required.
- **Deployment of Network Elements:** When a network has a high enough number of nodes, its overall performance increases. Because network equipment deployment is costly, it is vital to have the required number of network components up and running as quickly as feasible.
- **Augmented Reality:** AR is a multimedia application that mixes real-world scenes into virtual scenes and superimposes virtual scenes over real-world scenes to supplement traditional real-image information. This technology has the potential to help farmers become more aware of the app's functionality.
- **Edge Computing:** This networking approach is built on a network control layer that is logically centralized.



Smart Irrigation System

pH Sensor: 8.5 pH

Fertilizer Suggesstion

Alkanoic Soil. You may try Nitrozen, Phosphorus, iron, copper, zinc and boron based Fertilizer.

Moisture: 950 lb/ft³

It contributes to the creation of a dependable resource management and traffic control system.

IX. Conclusion

We have put forth an integrated solution that enables farmers to solve the challenges that limit their production and profitability by utilizing cutting-edge technologies like machine learning (ML), the Internet of Things (IoT), and blockchain. Through user-friendly mobile applications and a secure cloud database, this model, implemented with a generated database, offers helpful insights and recommendations to farmers, including pesticide usage and water motor control. Real-time monitoring and data collecting is made possible by the integration of IoT devices, enabling accurate decision-making and assuring optimal resource allocation. Incorporating blockchain technology also improves data traceability, transparency, and integrity, fostering trust and accountability throughout the agricultural ecosystem. Farmers may gain from higher productivity, decreased expenses, and enhanced general agricultural management by implementing our Smart-Agri framework. They can obtain up-to-date, accurate information, make decisions that will increase productivity and reduce waste, and improve their agricultural techniques. We have applied the gradient descent neural network model for water control management and achieved up to 89.5% accuracy. In addition, the suggested structure creates chances for cooperation, information exchange, and market access, all of which help the agricultural industry thrive and flourish sustainably.

In the future, the framework's scalability, and its interoperability can all be explored through more research and development in this area, along with potential problems like connectivity problems and data privacy issues. We can build an ecosystem that really revolutionizes the agriculture sector by continually improving and building upon these technological achievements, making it more intelligent, efficient, and robust in the face of changing global issues.

Acknowledgment

We would like to acknowledge the support of the Bangladesh University of Business and Technology and the IoT lab for their suggestion and resource sharing.

***Abstract*—The expansion of data has prompted the creation of various NoSQL (Not only SQL) databases, including graph-oriented databases, which provide an understandable abstraction for modeling complex domains and managing highly connected data. However, to add graph data to existing decision support systems, new data warehouse systems that consider the special characteristics of graphs need to be developed. This work proposes a novel method for creating a data warehouse under a graph database and demonstrates how OLAP (Online Analytical Processing) structures created for reporting can be handled by graph databases. Additionally, the paper suggests using aggregation algorithms based association rules techniques to improve the efficiency of reporting and data analysis within a graph-based data warehouse. Finally, we provide a Cypher language implementation of the suggested approach to evaluate and validate our approach.**

***Keywords*—NoSQL; graph-oriented databases; data warehouse; OLAP; aggregation algorithms; association rules; cypher language**

I. INTRODUCTION

Modern databases have been considerably altered by the expansion of data. NoSQL databases have expanded as a result of these new demands and now come in a wide range of models [1], including key-value, document, column, and graph.

In particular, graph-oriented databases are one of the most-known various of NoSQL systems; they have attracted a lot of attention and popularity. Graph-oriented databases are a fundamental form that offer an understandable abstraction to model numerous complicated domains, manage highly connected data, and run sophisticated queries over them [2] [3].

Currently, many businesses and entrepreneurs are interested in developing business intelligence systems on graph databases to take advantage of its benefits. Enterprises are also interested in expanding their OLAP analysis to include the new forms of data because OLAP technology is currently widely used[4].However, despite the growing interest in graph-based data warehouses and their potential benefits, there is a lack of research addressing the challenge of creating an optimized OLAP model under graphs, specifically focusing on selecting the most relevant OLAP aggregations to effectively meet the diverse user's needs. This gap calls for further investigation and exploration to bridge the divide between the advantages of graph-based data warehousing and the need for efficient and user-centric aggregation selection techniques. The aim of this study is to create new data warehouse under graph database systems that consider the special characteristics of graphs, this work also aims to optimize the efficiency of reporting and data analysis within this graph-based data warehouse by employing user-centric aggregation techniques that select the most relevant OLAP aggregations to meet the diverse needs of users effectively. To address this issue, it is possible to use aggregation algorithms that automatically select the most relevant aggregations for the cube. These aggregation algorithms are often based on machine learning and data mining techniques to identify the best possible aggregations based on raw data. The use of these algorithms can help reduce cube build time and improve the accuracy of analysis results. In this context, we demonstrate how OLAP structures created for reporting can be handled by graph databases, additionally, We provide new approach to optimize OLAP cube using the association rules algorithm.

The remainder of this paper is organized as follows. In Section II, we present some works of the literature reviews related on graph data warehouse. In Section III, we give a background overview of our approach. In Section IV, we describe the implementation of our approach as well as a case study to assess it. Section V concludes this paper and suggest future research directions.

II. RELATED WORK

Many approaches were proposed in the literature as a result of the growing interest in combining graph databases and business intelligence technology in recent years. In [5], The authors have proposed a new concept Graph Cube, a new data warehouse model that supports OLAP queries in large multidimensional networks, in the Graph Cube the dimensions are based on the attributes of the nodes, while the computed measures represent the aggregations of these node attributes. The Graph Cube approach have some limitations in analyzing dynamic or evolving graphs, where the structure of the graph changes over time. Moreover, the accuracy and reliability of the analysis results may be affected by data quality issues such as missing or erroneous data. In [6], The author introduce a GraphAware Framework for Neo4j, which enables the pre-calculation and storage of node information in graphs. For instance, the framework can compute the number of friends in a social network and store the result for efficient querying. The GraphAware Framework also supports the analysis of node degrees in the graph, which can be useful for identifying important or influential nodes. The GraphAware Framework is focused on precalculating and storing node information, which may be limited in scope and may not capture the full complexity of the graph data. For example, some graph analytics tasks may require more sophisticated computations that go beyond simple node attributes, such as graph centrality measures or community detection. In [7], The authors proposed to use the graph structure as a basis for OLAP queries; this approach relies on using the performance and efficiency of the Neo4j graph database to store and query OLAP queries. In this model, dimensions and measures are transformed into nodes. The connection between dimensions and measures is done through arcs of the graph. For hierarchical dimensions are also stored in nodes and linked together by hierarchical relationships. The approach is limited to using only the snowflake model, which may not be suitable for all types of data. This may restrict the flexibility and adaptability of the approach. In [8], The author's goal is to compare the execution times of the identical OLAP queries in the relational and graph databases by using a MusicBrainz database data warehouse in a PostgreSQL relational environment and then implementing the same decision model in Neo4j. The authors only tested their approach on a single dataset (the MusicBrainz database), which may limit the generalizability of their results. Additionally, they only considered a specific decision model and did not explore the potential impact of different OLAP queries or decision models on the performance of the two database types. Furthermore, while the results of the study showed that the graph database outperformed the relational database in terms of execution time, the authors did not provide a detailed analysis of the factors that contributed to these results. This lack of analysis makes it difficult to fully understand the advantages and disadvantages of each database type for OLAP queries. In [9],The authors define a set of transformation rules that can transform conceptual models into graph-oriented models. They have defined four transformation rules, namely: fact transformation, Name and Identifier of Dimension Transformation, Hierarchies Transformation, Transformation of the relation between Fact and Dimension. Still within the framework of Datawarehouse modelling in a NoSQL graph database, the authors propose a conceptual mapping between a multidimensional schema and a graph-oriented NoSQL model. The authors chose to concentrate on proving the viability of their approach rather than providing any experimental campaign to validate it. In [10], the authors proposes to integrate NoSQL Graph-oriented Data into Data Warehouses as a solution to tackle Big Data challenges, The paper introduces a new approach called "Big-Parallel-ETL" that adapts the classical ETL (Extract-Transform-Load) process with Big Data technologies, leveraging the efficiency of the MapReduce concept for parallel processing. However, this work does not address OLAP aggregations. The authors in [11], suggest a set of guidelines to create a graph data model from a multidimensional data model (MDM2G). Then the authors compare the performance of the two star and snowflake designs in the graphs and relational databases, in terms of dimensionality and size. After doing this comparison, the authors concluded that a graph implementation of a data warehouse with multiple tables is more effective than a relational implementation, and that a star model performs similarly to a snowflake model in graph databases. The study does not provide a detailed description of the conversion rules and does not present any experimental results or validation of the proposed approach.In [12], the authors proposed employing two alternative logical models, equivalent to the ROLAP (Relational Online Analytical Processing) and MOLAP (Multidimensional Online Analytical Processing) models, to create OLAP engines within a graph database. They specify a set of guidelines for mapping these models from the multidimensional model. Additionally, they suggest an aggregation technique for constructing the lattice of cuboids from a data warehouse. However, the choice of aggregations is random and imprecise, which makes the model unoptimized and burdens the graph with several unnecessary nodes. The authors in [13], suggest an approach founded on a multi-version evolutionary schema model. Data instances corresponding to various schema versions are stored in a graph data warehouse. A meta-model is utilized to manage these warehouse schema versions. Additionally, they introduce evolution functions at the schema level. To validate their approach, they implement a software prototype and conduct a case study that demonstrates queries on schema versions, cross-queries, and the runtime performance of their approach. However, the impact of the multi-version approach on OLAP aggregations is not addressed in this study.

The Table I provides a comprehensive summary of the literature review, highlighting the key findings and identified gaps in the research.

All of the cited works provide an important context for the implementation of decision systems using graph databases. However, most of these works focus on converting relational data warehouses into graph databases or applying traditional business intelligence methods, which can limit the advantages of using graph databases. Our proposed approach is different and relies on the properties of graphs to implement data warehouses. It highlights the importance of studying a model that optimizes the choice of OLAP aggregations to enhance the graph cube's performance. By selecting the optimal set of aggregations for a graph cube, OLAP query performance can be significantly improved, resulting in faster query response times and more efficient use of system resources. This can enable users to analyze larger volumes of data more quickly and accurately, leading to more informed decision-making. Moreover, reducing the computational resources required to execute OLAP queries can result in cost savings for organizations that need to process large amounts of data.

III. Our Approach and Background Information

A. Background Information

Graph Oriented Database: Store data entities as nodes and entity relationships as edges. A periphery always has a start node, an end node, a type, and a direction. A node can describe relationships, actions, parent-child ownership, etc. The number and type of relationships a node can have are unlimited.

A property graph is defined as

TABLE I. LITERATURE REVIEW

Year	Authors	Findings	Gaps
2011	Zhao et al.	Graph Cube: A new paradigm for Data Warehouse (DW) that supports OLAP queries in large multidimensional networks, with dimensions based on node attributes and computed measures representing aggregations.	Limitations in analyzing dynamic or evolving graphs and potential data quality issues.

2014	Castelltort et al.	Proposes using graph structure as a basis for OLAP queries, but limited to the snowflake model, reducing flexibility.	May not be suitable for all types of data.
2019	Vaisman et al.	Comparing the execution timings of identical OLAP queries in relational and graph databases reveals that the graph database provides superior performance.	Lack of detailed analysis of factors contributing to the performance difference.
2020	Sellami et al.	Define transformation rules to convert conceptual models into graph-oriented models.	No experimental campaign to validate the approach.
2021	Soussi	Propose parallel loading based integration of NoSQL graph-oriented data into data warehouses.	Doesn't address OLAP aggregations.
2022	Akid et al.	creating graph data models based on multidimensional data and comparing star and snowflake designs in graphs and relational databases.	Lack of detailed conversion rules and experimental validation.
2022	Khalil et al.	Propose alternative logical models for OLAP engines within a graph database and an aggregation technique for constructing the lattice of cuboids from a data warehouse.	Unoptimized aggregations and unnecessary nodes in the graph.
2023	Benhissen et al.	Propose an approach based on a multi-version evolutionary schema model in a graph data warehouse.	Doesn't address the impact of multi-version approach on OLAP aggregations.

$G = (N, E, L^N, L^E, P^N, P^E)$,

where:

N is a set of finite nodes,

$E \subseteq N \times N$ represent edges between the nodes.

L^N describes the label of the nodes.

L^E describes the edges' label..

P^N is a set of characteristics that identify node.

P^E is a set of properties that describe an edge.

Conceptual Multi-Dimensional Schema: Before defining our model, we clarify the concepts of the conceptual model: (dimensions, hierarchies, and measures) [14].
The attributes of the multidimensional schema are :$(F^M, D^M, Star^M)$ where[12]:

- $F^M = F_1, \ldots, F_n$ is a set of facts.
- $D^M = D_1, \ldots, D_i$ is a set of finite dimensi
- $Star^M : F_i \to 2^D i$ maps each fact
corresponding dimensions D_i.

Measures are a group of properties that make
Each measure has an aggregate function attached t
Facts are determined by: $(N^F, M^F)$where:

- N^F represent the fact name.
- M^S is a collection of measures, every one of which has an aggregate function.

A dimension consists of a set of attributes representing different levels of granularity on the data to be analyzed (measures).

A dimension, denoted $D_i \in D^S$, This is characterized by (N^D, A^D, H^D) where:

- N^D is the name of the dimension.
- $A^D = A_1, \ldots, A_n$ is a set of dimension attributes.
- $H^D = H_1, \ldots, H_n$ is a set of hierarchies, arranging the properties in accordance with the level of granularity that each one represents.

The Fig. 1 illustrates our multidimensional use case model:

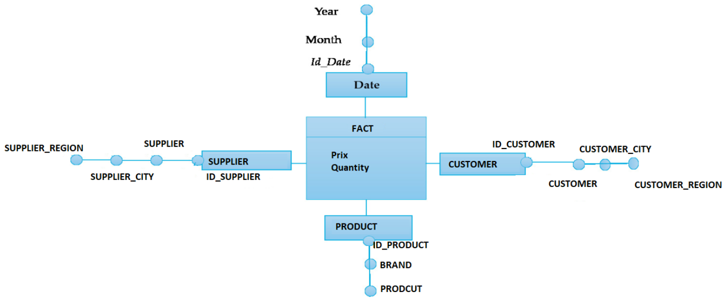

Fig. 1. The multi dimensional model.

[H]

B. Our Approach

Our approach involves leveraging the advantages of graph databases by creating the OLAP cube in the graph and using user queries to identify frequently used dimensions in OLAP analyses. To optimize the aggregations to be created, we use the Apriori algorithm to extract the most frequently associated sets of dimensions in OLAP queries, and then apply a rule-based association algorithm to identify the most relevant aggregations. The resulting aggregations are created in the OLAP cube, leading to improved OLAP query performance. The approach consists of four steps:

- Creation of the graph data warehouse.
- Extraction of the most frequently associated sets of dimensions in OLAP queries using the Apriori algorithm.
- Identification of the most relevant aggregations using a rule-based association algorithm.
- Creation of identified aggregations.

1) Graph Data Warehouse: When used with relational databases, a relational fact table is created for each fact in the multi dimensional conceptual model. Measures are columns in the fact table. Additionally, each dimension is transformed into a normalized dimension table with columns for each attribute (including parameters and weak attributes). Fact and dimension tables each have a unique row for storing each instance [16]. Similarly, we provide our rules, which define a graph DW, using the definitions of multi dimensional model and property graph ideas that were previously presented.

Dimension D^S in our model is created in node format identified by (L^N, P^N) where:

- $\mathrm{L^N}$ represents the label of the node, a node can have zero to many labels.
- $\mathrm{P^N}$ represents attributes of the dimension.

Hierarchies: In a graph data warehouse, a hierarchy can be represented using nodes and edges. Each level of the hierarchy can be represented as a node, with edges connecting nodes at different levels to indicate parent-child relationships.

Fact: A fact node in a graph data warehouse can be represented as a node with edges connecting it to dimension nodes. The fact node can also have properties that represent the measures, such as the actual values or aggregate functions applied to them [17].A fact node, is specified by (N^F, M^F) where:

- $\mathrm{N^F}$: represent the fact name.
- $\mathrm{M^F}$: It comprises a collection of measures as node attributes, with each measure linked to an aggregation function.

Relationship between fact and dimensions: The relationship between fact and its associated dimensions are represented as edges connecting nodes in the graph, the link is defined by (L^E, N^F, N^D, P^E), where:

- $\mathrm{L^E}$ is the label of relationship.
- $\mathrm{N^F}$ is the fact node.
- $\mathrm{N^D}$ is a node that represents the dimension linked to the fact.
- $\mathrm{P^E}$ represent the properties of the relationship, the properties are key-value pairs that are used for storing data on relationships.

2) Algorithm 1: Calculate Frequent Itemsets.: After creating our OLAP system, the second phase in our approach is to collect user queries from the OLAP system logs [18]. And after that, we determine common itemsets of predicates using the Apriori algorithm [19]. In the next phase we will use the generated itemsets as input to the second association rule algorithm to determine the most important aggregations to create. The algorithm starts by initializing an empty list to store frequent itemsets and another empty list to store previous frequent itemsets. Then, it loops on user queries predicates until there are no more frequent itemsets to explore. During each iteration of the loop, the algorithm generates candidates for new frequent itemsets by combining previous frequent itemsets. Then, it calculates the frequency of each candidate by scanning through all transactions. Candidates that have a frequency below a minimum support threshold are filtered out. Finally, the frequent itemsets are added to the list of frequent itemsets. The candidate generation and filtering functions are also defined in the algorithm.

Algorithm 1 Calculate frequent itemsets

```
// Initialization
$frequent\_itemsets \leftarrow$
$previous\_frequent\_itemsets \leftarrow$
// Loop until there are no more frequent itemsets to explore
while ($previous\_frequent\_itemsets$ is not empty) do
    // Generate candidates
    $current\_frequent\_itemsets \leftarrow generate\_candidates(previous\_frequent\_itemsets)$
    // Calculate frequency of candidates
    for each aggregation in OLAP cube do
        for each candidate in $current\_frequent\_itemsets$ do
            if candidate is used in aggregation then
                $candidate.frequency \leftarrow candidate.frequency + 1$
            end if
        end for
    end for
    // Filter candidates
    $previous\_frequent\_itemsets \leftarrow current\_frequent\_itemsets$
    $current\_frequent\_itemsets \leftarrow filter\_candidates(current\_frequent\_itemsets, min\_sup)$
    // Add frequent itemsets to the list
    $frequent\_itemsets \leftarrow frequent\_itemsets \cup current\_frequent\_itemsets$
end while

FUNCTION generate_ candidates(itemsets)
candidates
for each itemset1 in itemsets do
    for each itemset2 in itemsets do
        if itemset1 $\neq$ itemset2 and all elements of itemset1 except the last one are the same as the corresponding elements of itemset2 then
            candidate $\leftarrow$ union of itemset1 and itemset2, keeping only the unique elements
            if candidate is not already in candidates then
                candidates $\leftarrow$ candidates $\cup$ candidate
            end if
        end if
    end for
end for
return candidates
End FUNCTION

FUNCTION filter_ candidates (candidates, min_ sup)
$frequent\_candidates \leftarrow$
for each $candidate$ in $candidates$ do
    if $candidate.frequency \geq min\_sup$ then
        $frequent\_candidates \leftarrow frequent\_candidates \cup candidate$
    end if
end for
return $frequent\_candidates$
End FUNCTION
```

3) Algorithm2: Generate Association Rules.: The second algorithm in our approach is used to generate association rules from frequent itemsets. It first loops through each frequent itemset, and for each itemset it generates all possible subsets. For each subset, it creates an association rule with the antecedent being the subset and the consequent being the complement of the subset in the frequent itemset.

Algorithm 2 Generate Association Rules

```
$association\_rules \leftarrow$
for each $frequent\_itemset$ in $frequent\_itemsets$ do
    $subsets \leftarrow generate\_subsets(frequent\_itemset)$
    for each $subset$ in $subsets$ do
        $antecedent \leftarrow subset$
        $consequent \leftarrow (frequent\_itemset) - (subset)$
        $association\_rule \leftarrow \{antecedent : antecedent, consequent : consequent, confidence : 0\}$
        // Calculate confidence of the rule
        $frequency\_antecedent \leftarrow calculate\_frequency(antecedent)$
        $frequency\_frequent\_itemset \leftarrow calculate\_frequency(frequent\_itemset)$
        $confidence\_frequency\_frequent\_ \leftarrow itemset\_frequency\_antecedent$
        if $confidence \geq min\_conf$ then
            $association\_rule.confidence \leftarrow confidence$
            $association\_rules \leftarrow association\_rules \cup association\_rule$
        end if
    end for
end for

FUNCTION generate_ subsets(itemset)
$subsets \leftarrow$
for $i \leftarrow 1$ to taille($itemset$) do
    $subset \leftarrow$
    for $j \leftarrow 1$ to taille($itemset$) do
        if $j \neq i$ then
            $subset \leftarrow subset \cup itemset[j]$
        end if
    end for
    $subsets \leftarrow subsets \cup subset$
end for
return $subsets$
End FUNCTION

FUNCTION calculate_ frequency (itemset)
frequency $\leftarrow$ 0
for transaction in transactions do
    if transaction contains all elements of itemset then
        frequency $\leftarrow$ frequency + 1
    end if
end for
return frequency
End FUNCTION
```

4) Graph Aggregation: The two optimization algorithms previously defined enable finding the best combinations of aggregations, For improving query performance and maximising data retrieval in a graph, OLAP aggregations must be created. Aggregations act as quick-query summaries of data that have already been calculated, saving time and resources needed to obtain the raw data. Complex queries can be conducted in a fraction of the time it would take to scan the full data set by specifying and producing the relevant aggregations. In our approach, aggregations are stored both in the nodes and in the edges. since the graph allows to put the measures in properties of the links, the advantage of this model will allow us to minimize the number of nodes created in the graph, and also allows us to take advantage of the benefits of graphs. We will also put in the links between the dimensions the information of time dimension.

We will store aggregations in relationships when the aggregation combines only one dimension, two dimensions, or three dimensions (including time dimensions). Aggregations that combine more than three dimensions will be stored in nodes. The link-Aggregation is represented by an edge (L^E, N^S, N^T, P^E), where:

- L^E is the label of relationship.
- N^S is the start node.
- N^T is the target node.
- P^E represent the properties of the relationship, the properties are key-value pairs that are used for storing aggregation on relationships.

IV. Approach Implementation and Evaluation

A. Implementation of the Graph Warehouse

We implemented our graph warehouse using the Neo4j database (version 5.1.0)[1]. Neo4j is a graph database management system that uses graph structures with nodes, relationships, and properties to represent and store data[20], enabling efficient storage and querying of complex, interconnected data. Neo4j supports ACID-compliant transactions, offers a flexible data model, and provides a query language called Cypher for working with graph data[21].

In addition,We used the TPC-H benchmark database as a source file, We made use of a global flat CSV file that contains information from a flat meta-model. The TPC-H benchmark database has been used to provide support for Big Data technologies, including NoSQL and Hadoop file systems[22]. It generates data in various file formats (xml, jason, csv, tab, ...) following different data models.

The dimensions used in the model are as follows:

- Product dimension with the TypeProduct hierarchy.
- Customer dimension with the cityCustomer and RegionCustomer hierarchy.
- Supplier dimension with the citySupplier and RegionSupplier hierarchy.
- Year dimension with the Month hierarchy.

The script in Listing 1 is used to import data from a CSV file (“File.csv”) into Neo4j database by creating nodes to represent different entities related to the (CUSTOMER) as well as the hierarchies associated with these entities (CityCustomer and RegionCustomer). The script uses the APOC (Awesome Procedures on Cypher) library’s apoc.periodic.iterate procedure to efficiently manage the data import from the CSV file. It performs the import by iterating over batches of data, allowing it to process large amounts of data while avoiding overwhelming the system. The function ’LOAD csv WITH HEADERS FROM “file:///File.csv” as row FIELDTERMINATOR “;” RETURN row’ loads the CSV data with headers into the “row” variable and uses the semicolon (;) as the field delimiter. The first function MERGE (creates or updates) a node with the “CUSTOMER” label having properties “CUSTOMER-ID” and “CUSTOMER-NAME” extracted from the corresponding columns in the CSV file. The options batchSize:10000, allow the data to be processed in batches of 10,000 rows in parallel for better performance. The second use of the MERGE function in the script creates or merges nodes with the “CityCust” label having properties “CUSTOMER-CITYID” and “CUSTOMER-CITY” extracted from the CSV file. Similarly, the third use of the MERGE function is also used for creating or matching nodes in the graph database for the “RegionCust” hierarchy.

Listing 1: The Customer Dimension

```

// Dimension Customer
   CALL apoc.periodic.iterate(
  'LOAD csv WITH HEADERS FROM ``file:///File.
     csv" as row FIELDTERMINATOR ``;"
   RETURN row',
  'MERGE (C:CUSTOMER [CUSTOMER_ID : row.
     CUSTOMER_ID,CUSTOMER_NAME: row.
     CUSTOMER_NAME])',
  [batchSize:10000, parallel:true]);
// Hierarchy CityCustomer
  CALL apoc.periodic.iterate (
  'LOAD CSV WITH HEADERS FROM ``file:///File.
     csv" as row FIELDTERMINATOR ``;"
   RETURN row',
  'MERGE (CC:CityCust [CUTOMER_CITYID : row.
     CUSTOMER_CITYID,CUSTOMER_CITY: row.
     CUSTOMER_CITY])',
  [batchSize:10000, parallel:true]);
// Hierarchy RegionCustomer
  CALL apoc.periodic.iterate(
  'LOAD CSV WITH HEADERS FROM ``file:///File.
     csv" as row FIELDTERMINATOR ``;"
   RETURN row',
  'MERGE (RC:RegionCust [CUSTOMER_REGIONID :
     row.CUSTOMER_REGIONID,CUSTOMER_REGION:
     row.CUSTOMER_REGION])',
  [batchSize:10000, parallel:true]);
```

The provided script in Listing 1 only facilitates the creation of nodes and hierarchies but does not establish connections between them. The script in Listing 2 establishes relationships between nodes in the Neo4j database for the “Customer,” “CityCustomer,” and “RegionCustomer” hierarchies based on the data imported from the CSV file. For each row, the script looks for the “CUSTOMER” node with the matching “CUSTOMER-ID” property, and the “CityCust” node with the

[1] https://neo4j.com/product/neo4j-graph-database/

matching “CUSTOMER-CITYID” property using the MATCH clauses. The First MERGE clause creates a relationship of type CITY-CUSTOMER between the matched “CUSTOMER” and “CityCust” nodes. The second use of the MERGE clause creates a relationship of type REGION-CUSTOMER between the matched “CityCust” and “RegionCust” nodes.

Listing 2: The relationship between the Customer dimension and its hierarchies

```
// Relationship between Customer and CityCustomer
CALL apoc.periodic.iterate(’LOAD CSV WITH HEADERS FROM ‘‘file:///File.csv" as row FIELDTERMINATOR ‘‘;"
RETURN row’
’MATCH (C:CUSTOMER [CUSTOMER_ID: row.CUTOMER_ID])
MATCH (CC:CityCust [CUSTOMER_CITYID: row.CUSTOMER_CITYID])
MERGE (C)-[:CITY_CUSTOMER]->(CC)’,
[batchSize:2000, iteratelist:true]);

// Relationship between CityCustomer and RegionCustomer
CALL apoc.periodic.iterate(
’LOAD CSV WITH HEADERS FROM ‘‘file:///File.csv" AS row FIELDTERMINATOR ‘‘;"
RETURN row’,
’MATCH (RC:RegionCust [CUSTOMER_REGIONID: row.CUSTOMER_REGIONID])
MATCH (CC:CityCust [CUSTOMER_CITYID: row.CUSTOMER_CITYID])
MERGE (CC)-[:REGION_CUSTOMER]->(RC)’,
[batchSize:2000, iteratelist:true]);
```

To create the dimensions “PRODUCT”, “SUPPLIER”, and “Time”, we use a similar approach as employed for the “CUSTOMER” dimension.

After creating all the dimension nodes and their hierarchies in the same way, the next step is to create the fact node that contains the measures, and relationships between the fact and dimension nodes. The following script in Listing 3, demonstrates the creation of the fact node in Neo4j and the relationships between the fact and a dimension node.

The script uses the MERGE clause to create a node labeled as “FACT” with the specified properties (“ID”, “Price”, and “QUANTITY”) taken from the corresponding columns in the CSV file.

For each row, the script uses the MATCH clauses to find the “CUSTOMER” node with the matching “CUSTOMER-ID” and the “FACT” node with the matching “ID” property.

The MERGE clause creates a relationship labeled as “FACT-CUSTOMER” between the matched “FACT” and “CUSTOMER” nodes.

Listing 3: The Fact Node

```

// FACT NODE

CALL apoc.periodic.iterate(
  ’LOAD CSV WITH HEADERS FROM ‘‘file:///File.csv" AS row FIELDTERMINATOR ‘‘;"
   RETURN row’,
  ’MERGE (FCT:FACT [ID: row.INTEGRATION_ID, Price: row.O_TOTALPRICE, QUANTITY: toInteger(row.L_QUANTITY)])’,
 [batchSize:10000, parallel:true]);

// Relationship FACT/CUSTOMER

CALL apoc.periodic.iterate(
’LOAD CSV WITH HEADERS FROM ‘‘file:///File.csv" AS row FIELDTERMINATOR ‘‘;"
RETURN row’,
’MATCH (C:CUSTOMER [CUSTOMER_ID: row.CUSTOMER_ID])
MATCH (FCT:FACT [ID: row.INTEGRATION_ID])
MERGE (FCT)-[:FACT_CUSTOMER]->(C)’,
[batchSize:20000, iteratelist:true]);
```

In the same way, we create relationships between the fact node and the other dimensions (PRODUCT, SUPPLIER, TIME). Using also the apoc.periodic.iterate procedure along with MATCH and MERGE statements to efficiently import data from the CSV file and establish the relationships between the ”FACT” nodes and the corresponding nodes in the “PRODUCT”, “SUPPLIER”, and “TIME” dimensions in the Neo4j graph database.

The Fig. 2 represents the implementation of graph warehouse in Neo4j.

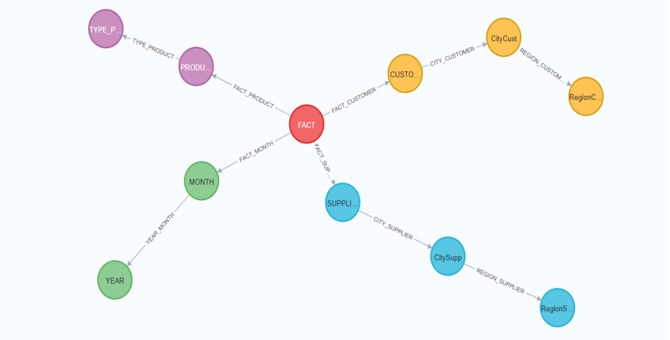

Fig. 2. The graph warehouse of our case study.

B. OLAP Operators

Slice
The slice operator in OLAP enables the selection of slices from the data based on a condition on the dimension values [7].

In Listing 4 the slice operator is applied to the Customer Region dimension using the filter condition “AFRICA”, which allows for selecting the data related to the AFRICA.

Listing 4: Selecting Price and Quantity Results from Africa.

```
MATCH (RC:RegionCust [CUSTOMER_REGION: ’
    AFRICA’])<-[*3]-(m:FACT)
RETURN RC.CUSTOMER_REGION, sum(tofloat(m.
    Price)), sum(tofloat(m.QUANTITY))
```

Dice

The Dice operator is used in OLAP to select a subset of data based on two or more conditions on dimensions. It is similar to the Slice operator, but allows for finer selection by applying multiple criteria on dimensions simultaneously.

In Listing 5 the Dice operator is applied to the Customer Region and Year dimensions using the filter condition “AFRICA” and “1997”.

Listing 5: Dice-Selecting Quantity Results with a Dice Operation.

```
 MATCH (RC:RegionCust [CUSTOMER_REGION : ’
     AFRICA’])<- [*3]-(m:FACT)
MATCH  (Y:YEAR [YEAR : 1994])<- [*2]-(m:FACT)
 RETURN RC.CUSTOMER_REGION, Y.YEAR, sum(
     tofloat(m.QUANTITY)) as QUANTITY
```

Roll Up

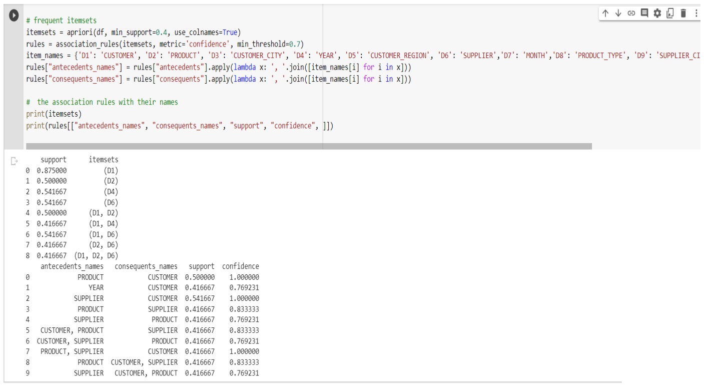
In OLAP, [23]the Roll-Up operation is used to aggregate data at a higher level of hierarchy than the current level[24].It involves moving from a detailed level to a higher-level concept [25].The Roll-Up operation is performed by grouping the data based on the dimensions and then performing the aggregation function on the measures. The result is a summarized view of the data at a higher level of abstraction. In Listing 6, the Roll Up operation is carried out by moving up the Product dimension’s concept hierarchy (Product → Product Type) and the hierarchy of dimension Time(Month → Year). This query creates a relationship between the two dimensions that contains the aggregated measures.

Listing 6: Roll Up- Price and Quantity summarized by Product Type and Year.

```
MATCH (TP:TYPE_PRODUCT)<-[*2]-(FCT:FACT)
MATCH (Y:YEAR)<-[*2]-(FCT:FACT)
WITH  distinct TP,Y,  sum(tofloat(FCT.Price))
     as Price, SUM(tofloat(FCT.QUANTITY)) As
    QUANTITY
create (TP)<-[:TYPRD_YEAR_AGG [Price: Price,
    QUANTITY: QUANTITY]]-(Y)
```

C. Graph Aggregations

After generating the most frequently user queries, the Apriori Algorithm was then used to determine the most common dimensions, and then we executed the second algorithm to generate the most commonly used combinations to create the aggregations. We set the support to 0.4 and the confidence to 0.7. The Fig. 3 shows the combinations of the most commonly used dimensions.



```
# frequent itemsets
itemsets = apriori(df, min_support=0.4, use_colnames=True)
rules = association_rules(itemsets, metric='confidence', min_threshold=0.7)
item_names = {'D1': 'CUSTOMER', 'D2': 'PRODUCT', 'D3': 'CUSTOMER_CITY', 'D4': 'YEAR', 'D5': 'CUSTOMER_REGION', 'D6': 'SUPPLIER','D7': 'MONTH','D8': 'PRODUCT_TYPE', 'D9': 'SUPPLIER_CI
rules["antecedents_names"] = rules["antecedents"].apply(lambda x: ', '.join([item_names[i] for i in x]))
rules["consequents_names"] = rules["consequents"].apply(lambda x: ', '.join([item_names[i] for i in x]))

#  the association rules with their names
print(itemsets)
print(rules[["antecedents_names", "consequents_names", "support", "confidence", ]])
```

```
    support      itemsets
0  0.875000          (D1)
1  0.500000          (D2)
2  0.541667          (D4)
3  0.541667          (D6)
4  0.500000      (D1, D2)
5  0.416667      (D1, D4)
6  0.541667      (D1, D6)
7  0.416667      (D2, D6)
8  0.416667  (D1, D2, D6)
    antecedents_names   consequents_names   support  confidence
0             PRODUCT            CUSTOMER  0.500000    1.000000
1                YEAR            CUSTOMER  0.416667    0.769231
2            SUPPLIER            CUSTOMER  0.541667    1.000000
3             PRODUCT            SUPPLIER  0.416667    0.833333
4            SUPPLIER             PRODUCT  0.416667    0.769231
5   CUSTOMER, PRODUCT            SUPPLIER  0.416667    0.833333
6  CUSTOMER, SUPPLIER             PRODUCT  0.416667    0.769231
7   PRODUCT, SUPPLIER            CUSTOMER  0.416667    1.000000
8             PRODUCT  CUSTOMER, SUPPLIER  0.416667    0.833333
9            SUPPLIER   CUSTOMER, PRODUCT  0.416667    0.769231
```

Fig. 3. The combinations of the most commonly used dimensions.

To create aggregations in Neo4j, we use the following script in Listing 7 that stores the aggregations in relationships:

Listing 7: Aggregation Customer-Year

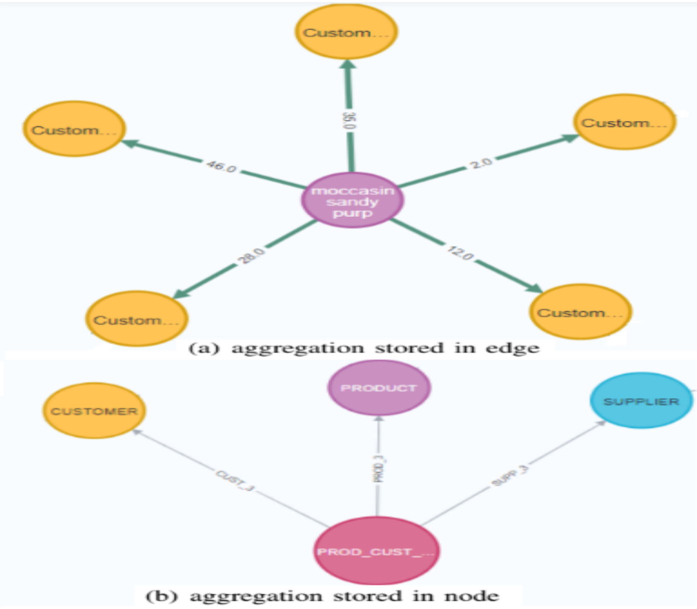
```
CALL apoc.periodic.iterate(
’LOAD CSV WITH HEADERS FROM ‘‘file:///File.
    csv" AS row FIELDTERMINATOR ‘‘;"
RETURN row’,
’MATCH (C:CUSTOMER)<-[]-(FCT:FACT)
MATCH (Y:YEAR)<-[*2]-(FCT:FACT)
CREATE (C)<-[:CUST_YEAR_AGG [Price: toFloat(
    row.O_TOTALPRICE),QUANTITY: toFloat(row.
    L_QUANTITY)]]-(A)’,
[batchSize:10000, parallel:true]);
```

In Listing 8, the script is used to create aggregations that are stored in nodes, not in relationships.

Listing 8: Aggregation Customer-Product-Supplier

```
CALL apoc.periodic.iterate(
’LOAD CSV WITH HEADERS FROM ‘‘file:///File.
    csv" AS row FIELDTERMINATOR ‘‘;"
RETURN row’,
’MATCH (P:PRODUCT)<-[]-(FCT:FACT)
MATCH (C:CUSTOMER)<-[]-(FCT:FACT)
MATCH (S:SUPPLIER) <-[]-(FCT:FACT)
create (PCS:PROD_CUST_SUPP [ PRICE:  toFloat(
    row.O_TOTALPRICE),QUANTITY: toFloat(row.
    L_QUANTITY)])
create (P)<-[:PROD_3]-(PCS)
create(C)<-[:CUST_3]-(PCS)
create (S)<-[:SUPP_3]-(PCS)’,
[batchSize:10000, parallel:true]);
```

The Fig. 4 shows the creation of aggregations using in approach.



(a) aggregation stored in edge

(b) aggregation stored in node

Fig. 4. Stored aggregations.

D. Experimental Results and Evaluation

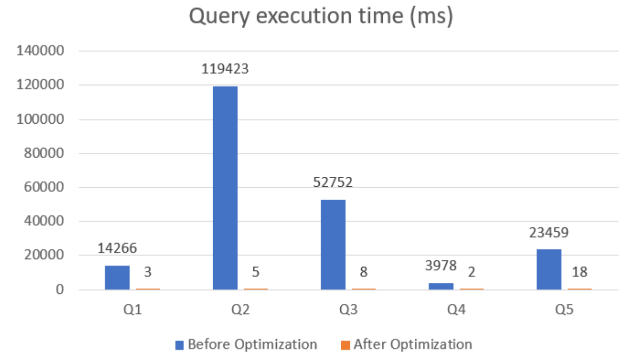
To validate our approach and measure the effectiveness of optimizing the OLAP cube in the graph, we conducted a series of experiments in which we evaluated performance before and after using our optimization approach. We measured the query execution time before and after adding optimized aggregations, and compared the execution times to determine if adding the optimized aggregations led to a significant improvement in performance. We conducted our test on an i7 processor machine with 16GB of RAM and 1TB of storage memory. Additionally, we used the TPC-H database with a scale factor of SF1 (1GB). We use in Table II, Cypher queries before and after optimization.

TABLE II. CYPHER QUERIES BEFORE AND AFTER OPTIMIZATION

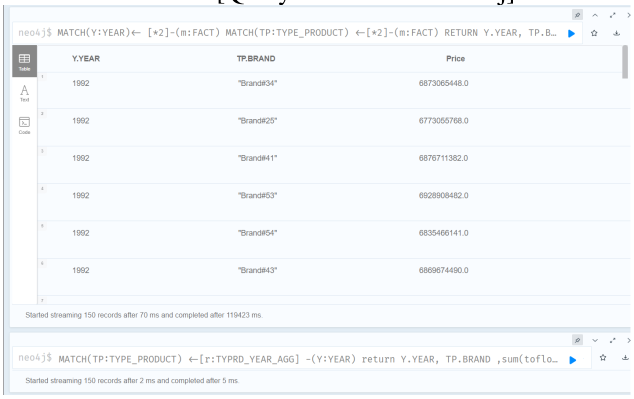
Query	Before Optimization	After Optimization
Q 1	MATCH (RS:RegionSupp) <-[*3]-(FCT:FACT) return SUM(tofloat(FCT.Price)) AS Price, RS.SUPPLIER_REGION	MATCH (RS:RegionSupp) <-[:REGION_SUPP_AG]- (RA:Region_Supp_AGG) return RA.Price ,RS.SUPPLIER_REGION
Q 2	MATCH(Y:YEAR)<- [*2]-(m:FACT) MATCH(TP:TYPE_PRODUCT) <-[*2]-(m:FACT) return Y.YEAR, TP. BRAND ,sum(tofloat(m.Price))as Price	MATCH(TP:TYPE_PRODUCT) <-[r:TYPRD_YEAR_AGG] -(Y:YEAR) return Y.YEAR, TP. BRAND ,sum(tofloat(r.Price)) as Price
Q 3	MATCH (C:CUSTOMER) <-[] -(FCT:FACT) MATCH (P:PRODUCT)<- []-(FCT:FACT) return sum(tofloat(FCT.Price)) as Price ,C.CUSTOMER_NAME,P. PRODUCT_NAME	MATCH (P:PRODUCT)- [r:AGG_CUST_PROD]->(C :CUSTOMER) return r.Price,C. CUSTOMER_NAME ,P.PRODUCT_NAME
Q 4	MATCH (TP: TYPE_PRODUCT) <-[*2]-(FCT:FACT) return SUM(tofloat(FCT.QUANTITY)) As QUANTITY, TP.BRAND	MATCH (TP: TYPE_PRODUCT) <-[:TYPE_PROD_AG] -(TPAGG:TYPE_PROD_AGG) return TPAGG.QUANTITY , TP.BRAND
Q 5	MATCH (P:PRODUCT)<- [:FACT_PRODUCT]-(FCT: FACT) MATCH (C:CUSTOMER)<- [:FACT_CUSTOMER]-(FCT :FACT) MATCH (S:SUPPLIER)<- [:FACT_SUPPLIER]-(FCT :FACT) return SUM(tofloat(FCT.Price)) AS PRICE, P.PRODUCT_NAME,C. CUSTOMER_NAME, S.SUPPLIER_NAME LIMIT 43	MATCH (P:PRODUCT)<-[: PROD_3] -(PCS:PROD_CUST_SUPP) MATCH (C:CUSTOMER) <-[:CUST_3] -(PCS:PROD_CUST_SUPP) MATCH (S:SUPPLIER) <-[:SUPP_3] -(PCS:PROD_CUST_SUPP) return PCS.PRICE,P. PRODUCT_NAME, C.CUSTOMER_NAME,S. SUPPLIER_NAME LIMIT 43

The Fig. 5 shows the query execution time before and after the optimization of the model.

[Query Execution Time]



[Query Execution in neo4j]



```
neo4j$ MATCH(Y:YEAR)← [*2]-(m:FACT) MATCH(TP:TYPE_PRODUCT) ←[*2]-(m:FACT) RETURN Y.YEAR, TP.B…
```

	Y.YEAR	TP.BRAND	Price
1	1992	"Brand#34"	6873065448.0
2	1992	"Brand#25"	6773055768.0
3	1992	"Brand#41"	6876711382.0
4	1992	"Brand#53"	6928908482.0
5	1992	"Brand#54"	6835466141.0
6	1992	"Brand#43"	6869674490.0
7			

Started streaming 150 records after 70 ms and completed after 119423 ms.

```
neo4j$ MATCH(TP:TYPE_PRODUCT) ←[r:TYPRD_YEAR_AGG] -(Y:YEAR) return Y.YEAR, TP.BRAND ,sum(toflo…
```

Started streaming 150 records after 2 ms and completed after 5 ms.

Fig. 5. Query execution time.

The results demonstrate that the execution time of the queries decreased after the optimization and usage of OLAP aggregations, although the execution time may vary depending on the complexity of the query, with complex queries requiring traversal of numerous relationships taking more time, while simple queries involving only a few relationships having relatively short execution times.

For instance, in the first query, the execution time before optimization was approximately 14266 milliseconds, and after optimization, it reduced to 3 milliseconds. This translates to an impressive percentage improvement of approximately 99%. Furthermore, in the query 4, we achieved considerable improvements as well, the execution time decreased from 3,978 milliseconds to 2 milliseconds,substantial gains in performance clearly demonstrate the effectiveness of our approach in making the system nearly 2,000 times faster than its previous state.

The significant reduction in execution time showcases how this approach can make the system multiple times faster than its previous state, enhancing the efficiency of reporting and data analysis within the graph-based data warehouse.

We also compared our model implemented in the graph and the ROLAP model, comparing the execution time of the same multidimensional queries in Neo4j and Oracle.

Table III shows the queries used in the comparison between Graph OLAP and ROLAP.

TABLE III. RELATIONAL QUERY VS GRAPH QUERY

Query	Relational Query	Graph Query
Q 1	SELECT sum(o_totalprice) as Price, supplier_region from w_fact_1gb_f3 Group by supplier_region	MATCH (RS:RegionSupp) <-[:REGION_SUPP_AG]- (RA:Region_Supp_AGG) return RA.Price ,RS.SUPPLIER_REGION
Q 2	SELECT sum(o_totalprice) as Price, orderyear AS YEAR, brand as PRODCUT_TYPE from w_fact_1gb_f3 GROUP BY orderyear, brand	MATCH(TP:TYPE_PRODUCT) <-[r:TYPRD_YEAR_AGG] -(Y:YEAR) return Y.YEAR, TP.BRAND ,sum(tofloat(r.Price)) as Price
Q 3	SELECT sum(o_totalprice) as Price, product_name, customer_name from w_fact_1gb_f3 GROUP BY product_name, customer_name	MATCH (P:PRODUCT)- [r:AGG_CUST_PROD]->(C:CUSTOMER) return r.Price,C.CUSTOMER_NAME ,P.PRODUCT_NAME

Q 4	SELECT
	sum(l_quantity) as QUANTITY,
	brand as PRODUCT_TYPE
	FROM
	w_fact_1gb_f3
	GROUP BY brand
		MATCH (TP:TYPE_PRODUCT)
		<-[:TYPE_PROD_AG]
		-(TPAGG:TYPE_PROD_AGG)
		return TPAGG.QUANTITY,
		TP.BRAND

Q 5	select * from (SELECT sum(o_totalprice) as Price, product_name, customer_name, supplier_name FROM w_fact_1gb_f3 GROUP BY product_name, customer_name, supplier_name) where ROWNUM <= 43;	MATCH (P:PRODUCT)<-[:PROD_3] -(PCS:PROD_CUST_SUPP) MATCH (C:CUSTOMER)<-[:CUST_3] -(PCS:PROD_CUST_SUPP) MATCH (S:SUPPLIER)<-[:SUPP_3] -(PCS:PROD_CUST_SUPP) return PCS.PRICE,P.PRODUCT_NAME, C.CUSTOMER_NAME,S.SUPPLIER_NAME LIMIT 43

The Figure 6 shows the query execution time in the Graph OLAP and ROLAP.

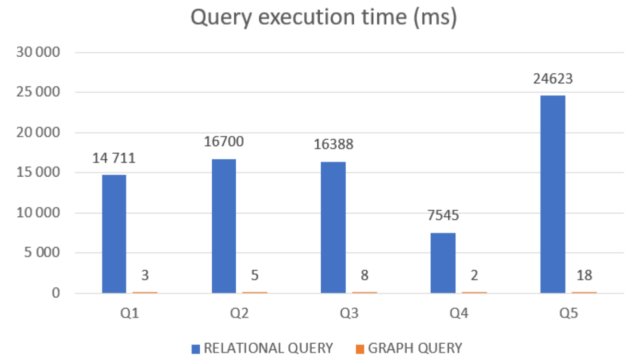


Fig. 6. Query execution time in Oracle and Neo4j.

The results also show that the Graph cube delivers performance levels that are better than those of the ROLAP model.we also notice that Graph databases provide a great degree of flexibility for searching through data by conducting more complex pathways or by following direct linkages. While SQL queries that use joins to mix data from various tables provide the basis for data traversal in a relational architecture. While joins can be effective, they can also be less flexible and intuitive when navigating complex relationships.

V. Conclusion

Graph-Oriented Databases offers a clear abstraction for managing heavily connected data and modelling complicated domains. In this Paper we present our contribution for developing a data warehouse under a graph database, our approach relies on the properties of graphs to implement graph data warehouse. To enhance the graph cube's performance we provide a new technique that optimizes the choice of OLAP aggregations by using the association rules algorithm.

To validate our approach and measure the effectiveness of OLAP cube optimization in the graph, we conducted a series of experiments in which we evaluated the performance before and after the optimization, we also compared our model with the relational model in terms of query performance. The experiment's findings demonstrate the benefits of creating OLAP systems under graph oriented databases when using a large amount of data. In our future research works we will concentrate on the implementation of decision systems in other Nosql databases such as document and column databases using new approaches.

Cloud Task Scheduling using Particle Swarm Optimization and Capuchin Search Algorithms

Gang WANG[1*], Jiayin FENG[2], Dongyan JIA[3], Jinling SONG[4], Guolin LI[5]
Hebei Normal University of Science & Technology, Qinhuangdao 066004, China

***Abstract*—Cloud providers offer heterogeneous virtual machines for the execution of a variety of tasks requested by users. These virtual machines are managed by the cloud provider, eliminating the need for users to set up and maintain their hardware. This makes accessing the computing resources necessary to run applications and services more accessible and cost-effective. The task scheduling problem can be expressed as a discrete optimization issue known as NP-hard. To address this problem, we propose a hybrid meta-heuristic algorithm using the Capuchin Search Algorithm (CapSA) and the Particle Swarm Optimization (PSO) algorithm. PSO excels in global exploration, while CapSA is adept at fine-tuning solutions through local search. We aim to achieve better convergence and solution quality by integrating both algorithms. Our proposed method's performance is thoroughly evaluated through extensive experimentation, comparing it to standalone PSO and CapSA approaches. The findings reveal that our hybrid algorithm outperforms the individual techniques in terms of both total execution time and total execution cost metrics. The novelty of our work lies in the synergistic integration of PSO and CapSA, addressing the limitations of traditional optimization methods for cloud task scheduling. The proposed hybrid approach opens up intriguing directions for future research in dynamic task scheduling, multi-objective optimization, adaptive algorithms, integration with emerging technologies, and real-world deployment scenarios.**

Keywords*—Cloud computing; virtualization; task scheduling; optimization; resource utilization; capuchin search algorithm; particle swarm optimization

I. Introduction

Cloud computing is a well-known computing model that hosts and delivers various services via the Internet [1]. It enables users to access computing resources on demand, thus reducing the cost of ownership and IT management. Cloud computing services are provided pay-as-you-go and typically include storage, software, analytics, and networking [2]. The cloud computing paradigm has allowed companies to move, process, and run some of the services and applications in cloud environments, providing convenient access to a wide range of resources easily and conveniently. In addition, these services are tailored to each customer's requirements [3]. Originally, due to the emergence of big data, conventional hardware could not handle heterogeneous workloads flowing onto the infrastructure. Consequently, many IT companies are migrating their infrastructure to the cloud to handle these diverse and heterogeneous tasks. Cloud computing models offer several potential benefits, including flexibility, highly resilient virtual architectures, on-demand services, elasticity, and scalability. Multi-tenant computing environments share resources among users. A scheduler module checks the resource status and allocates it under user requests [4]. Scheduling plays a crucial role in achieving optimal real-time performance in cloud computing. The scheduling algorithms map the tasks into the cloud environment and utilize the available resources, thereby reducing latency and response time for requests and increasing resource utilization and system throughput [5].

The fusion of IoT, big data, artificial intelligence (AI), machine learning (ML), deep learning, feature and channel selection, meta-heuristic algorithms, and association rule mining with cloud computing has ushered in a new era of technological possibilities. IoT connects a vast array of devices, generating immense volumes of data that can be harnessed in the cloud for analysis and processing [6]. Big data, with its inherent complexity and scale, finds a natural fit in cloud computing, which offers the necessary storage and computational capabilities to extract valuable insights [7, 8]. AI and ML form the backbone of intelligent cloud applications, enabling systems to learn from data patterns and make informed decisions [9-11]. Deep learning, a subset of ML, is especially powerful in cloud computing for tasks such as image recognition, natural language processing, and complex data analysis [12-14]. Feature and channel selection play a crucial role in optimizing cloud-based applications by identifying pertinent data attributes and sources, leading to improved efficiency and accuracy [15]. Meta-heuristic algorithms, with their ability to efficiently solve complex optimization problems, facilitate resource allocation, load balancing, and task scheduling in cloud environments [16-19]. Association rule mining is essential for discovering meaningful patterns and relationships within vast datasets, empowering businesses to make data-driven decisions and gain a competitive edge [20]. The integration of these concepts in cloud computing is transformative for businesses and industries alike. Cloud-based IoT solutions facilitate real-time data analysis and decision-making, enabling predictive maintenance, personalized services, and improved operational efficiency. The ability to process and store big data in the cloud ensures data accessibility, scalability, and cost-effectiveness for organizations. Furthermore, AI and ML capabilities in the cloud enable innovative applications like virtual assistants, recommendation systems, and fraud detection.

Many researchers have addressed the problem of scheduling tasks; however, it has remained an NP-hard problem. This means that scheduling tasks is a computationally difficult problem, and finding an optimal solution is not feasible in a reasonable time. As a result, numerous heuristics have been created to solve this issue effectively [21]. Cloud environments consist of geographically distributed data centers. These data centers are connected by high-speed networks, making it possible to transfer data between them quickly. This enables cloud providers to use distributed scheduling algorithms that can use multiple data centers to solve the task scheduling problem more efficiently. There are thousands of servers in each data center. Each server has an array of virtual machines equipped with various resources, such as storage, CPU, and memory. To execute tasks, groups of virtual machines are allocated to cloud users. It is a complex task to schedule the appropriate resources for the task. In order to assign tasks to virtual resources, it is necessary to examine their characteristics with respect to dependency, length, and size. By factoring in the total execution time for all tasks, task scheduling algorithms can distribute the workload across virtual machines.

In this research paper, we introduce a novel hybrid meta-heuristic algorithm that combines the strengths of the Capuchin Search Algorithm (CapSA) and the Particle Swarm Optimization (PSO) algorithm. The decision to merge these two approaches was motivated by their complementary characteristics in tackling optimization problems. While PSO is renowned for its efficient global exploration capabilities, CapSA excels in local search strategies, making it adept at fine-tuning solutions. The integration of PSO and CapSA allows us to harness their unique strengths synergistically, aiming for improved convergence and solution quality. During the experimentation phase, our hybrid approach demonstrated superior performance to standalone PSO and CapSA, as evident in total execution time and total execution cost metrics. Furthermore, our evaluation of existing methods for cloud task scheduling revealed specific limitations hindering their effectiveness in this context. Traditional optimization algorithms often struggle to find solutions in large search spaces because they lack robust exploration capabilities. On the other hand, local search algorithms may get trapped in local optima, preventing them from achieving global optimality. Our proposed hybrid PSO-CapSA approach effectively addresses these limitations. By leveraging PSO's global exploration capabilities, the algorithm conducts a diverse search across the solution space, mitigating the risk of premature convergence to suboptimal solutions. Additionally, CapSA's local search enhances the precision of the algorithm by refining solutions and escaping local optima. This combination empowers our method to tackle cloud task scheduling challenges more effectively than existing approaches.

The paper is arranged in the following manner. Section II summarizes the literature. Section III discusses the problem statement and the proposed algorithm. Section IV illustrates the findings and analyses. Section V presents the conclusion.

II. Related Work

Dai, et al. [22] propose a novel task-scheduling algorithm that incorporates multiple quality of service criteria into the scheduling process, like reliability, security, expenditure, and time. It combines genetic as well as Ant Colony Optimization (ACO) algorithms. ACO employs the genetic algorithm to generate an initial pheromone efficiently. A four-dimensional quality of service objective is evaluated utilizing a designed fitness function. The optimum resource is then identified using the ACO algorithm. The proposed algorithm was implemented on several real-world tasks and demonstrated significant improvements in the quality of service. The consequences demonstrated that the suggested algorithm achieved better scheduling than existing algorithms.

Tang, et al. [23] proposed the DVFS-enabled Energy-efficient Workflow Task Scheduling (DEWTS) algorithm to reduce energy consumption and ensure the quality of service adhering to deadlines. DEWTS is built upon a dynamic voltage frequency scaling approach that assigns appropriate processing speeds to tasks based on their deadlines. By combining potentially inefficient processors, DEWTS can utilize the slack time repeatedly after servers have been merged by reclaiming the slack time. This ensures that peak performance is maintained and the power wasted is minimized. The DEWTS algorithm can effectively manage servers with different deadlines and dynamically adjust the processors' frequency and voltage. After calculating the starting scheduling sequence for all tasks, DEWTS determines the total makespan and deadline by applying the Heterogeneous-Earliest-Finish-Time (HEFT) algorithm. The underutilized processors are combined by terminating the last node and reallocating the assigned tasks to the processors according to the number of running tasks and the energy consumption of each processor. Results from the experiments demonstrate that DEWTS reduces entire power consumption by up to 46 percent for a variety of parallel applications while balancing scheduling performance based on randomly generated DAG workflows.

Keshanchi, et al. [24] introduced a powerful and enhanced genetic algorithm to optimize task-scheduling solutions. Based on model-checking techniques, they have developed a behavioral modeling approach to verify the algorithm's validity. Next, Linear Temporal Logic (LTL) functions are used to extract the expected specifications. A Labeled Transition System (LTS) is used to obtain optimal results in the validation process. The algorithm was tested on various tasks and provided better performance and scalability than existing methods. The results were validated using the LTS model, and the algorithm was effective in generating optimal task-scheduling solutions. According to the verification outcomes, the validity of the suggested algorithm is assessed with respect to some reachability, fairness, specifications, and deadlock-free performance. Statistical analysis, as well as simulation findings, indicate that the designed approach is superior to traditional heuristic algorithms. The proposed algorithm has been successfully implemented in a deployed system, demonstrating its effectiveness and scalability. The results of the verification process show that the algorithm achieves the desired results with minimal computational cost.

Lin, et al. [25] presented a power efficiency model for cloud servers. To optimize energy consumption in cloud environments, they propose a heuristic task scheduling algorithm (ECOTS) that utilizes the power efficiency of the server to guide task scheduling. Multiple vital factors are taken into account by ECOTS, including degradation of performance, power efficiency models for servers, and resource requirements for tasks, with the goal of reducing the energy consumption of the system without compromising performance. ECOTS is characterized by its simplicity in terms of time and space and the ability to search globally to find an effective scheduling strategy. An evaluation of the effectiveness of ECOTS was conducted by simulating a heterogeneous cluster environment. It has been demonstrated that the ECOTS algorithm achieves the highest energy efficiency level.

The energy efficiency of task scheduling in cloud data center architectures was studied by Sharma and Garg [26], who also created a new hybrid meta-heuristic algorithm according to the harmony-inspired genetic algorithms. It combines the exploration capabilities of a genetic algorithm with the exploitation capabilities of harmony searches to provide rapid convergence while intelligently sensing both local and global optimal regions without wasting time in local or global optimal regions. Key goals include reducing the time required for computation and the energy it consumes. In contrast, secondary objectives include reducing energy consumption and scheduling execution overhead.

Alsaidy, et al. [27] propose a heuristic algorithm for developing the initialization of the Particle Swarm Optimization (PSO) algorithm. The PSO is initially configured using the minimum completion time (MCT) and longest job to fastest processor (LJFP) algorithms. Both algorithms are tested in terms of their efficiency to minimize total energy consumption, degree of imbalance, and total execution time. A comparison is also made between the proposed algorithms and recent methods. The simulation outcomes demonstrate that the suggested algorithms are more effective and superior to traditional PSO and comparative algorithms.

Saravanan, et al. [28] used the enhanced wild horse optimization algorithm and the levy flight algorithm for task scheduling. This method generates a multi-objective fitness function by optimizing resource utilization and minimizing the makespan. The simulation results indicated that the suggested method outperformed others in a variety of situations. The algorithm was successful in achieving better task scheduling compared to traditional algorithms. It achieved better outcomes regarding completion time, cost, as well as energy efficiency. The proposed method was also found to be scalable and robust, able to handle a large number of tasks and resources.

III. Proposed Method

This section begins with a description of the problem statement. Then, the standard PSO and CapSA algorithms are discussed to determine the basis for the suggested algorithm. This section also examines the fitness function incorporated into the proposed algorithm.

A. Problem Statement

The process of scheduling cloud-based tasks is illustrated in Fig. 1. Initially, users' tasks are placed in a queue. The tasks are then retrieved from the queue and allocated to the available cloud resources. Once the tasks are finished, the results are sent back to the users. This procedure continues until each task is completed. Generally, static and dynamic are the two kinds of task scheduling algorithms. Static scheduling algorithms require detailed information regarding the environment and the tasks. Dynamic scheduling algorithms monitor the system continuously and are capable of balancing workloads. In the following way, the task scheduling problem is described. The task scheduling problem consists of assigning n tasks of users to m heterogeneous virtual machines based on some constraints in order to optimize some objective functions. We have observed that task scheduling is an objective-driven strategy that involves allocating computing resources to specific tasks periodically to maximize one or more objectives. This process requires analysis of data related to the task, such as the resource requirements, the time needed to complete the task, and the task's priority. Optimizing task scheduling can result in significant cost savings by allocating resources efficiently. Furthermore, effective task scheduling can help improve the system's overall performance. In the cloud computing environment, the scheduling policy should address this problem from two different perspectives, customer and cloud provider perspectives. The customer's objective is to lower the cost of executing the tasks, and the cloud provider's objective is to maximize the utilization of the infrastructure. Thus, cost and performance should be considered when designing the scheduling policy. In this regard, scheduling is a major concern in the cloud environment, as it directly impacts the performance of the cloud system as well as the cloud service consumer.

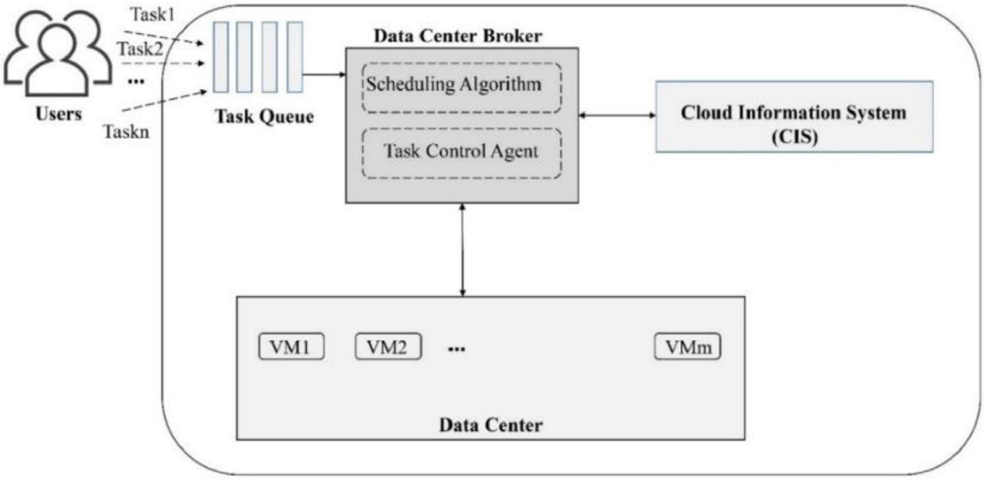

Fig. 1. Task scheduling in cloud computing.

Assume that $\mathrm{VM} = [\mathrm{VM}_1, \mathrm{VM}_2, \dots, \mathrm{VM}_m]$ represents the set of virtual machines available within a data center. These virtual machines are provided to cloud users in order to fulfill their task requests. Each virtual machine is equipped with processing power expressed in Millions of Instructions Per Second (MIPS). A cloud broker allocates tasks to appropriate virtual machines according to details of existing resources and requirements of tasks. The collection of tasks to execute on the virtual machines at the data center is expressed as $\mathrm{T} = [\mathrm{T}_1, \mathrm{T}_2, \dots, \mathrm{T}_n]$. Tasks are defined by their length and processing requirements, which are specified by Millions of Instructions (MIs).

B. Fitness Function

Fitness functions represent the desired objectives to be optimized. They measure the performance of the problem being solved and direct the search process toward finding the best solution. Fitness functions are generally represented as mathematical functions, which can be used to evaluate the candidate solutions. Fitness functions may be multi-objective from two perspectives: prior and posterior. In an a priori approach, the fitness function is designed to optimize multiple objectives from the beginning. In a posteriori approach, a single-objective fitness function is used, and the multiple objectives are satisfied through post-processing. According to the prior strategy, objectives are given a weight that reflects their significance in producing a single-value function, referred to as a fitness value. The posterior approach produces non-dominant solutions. This paper uses priori principles to develop the fitness function. Total execution time and total execution cost are included in the fitness function. In mathematical terms, the fitness function considered is expressed by Eq. 1.

$$\mathrm{F} = \mathrm{a}_1 \times \mathrm{TEC} + \mathrm{a}_2 \times \mathrm{TET} \tag{1}$$

Cloud computing is designed to meet users' functional needs while reducing costs. Consequently, a scheduling algorithm should provide users access to their necessary applications at a minimal cost. Costs associated with storage, communication, and execution are all contained in the cost of cloud computing. Execution cost consists of the price per unit interval applied by the virtual machine and the execution time of all tasks executed by that virtual machine. Eq. 2 can be used to calculate the total execution cost of a workflow.

$$\mathrm{TEC}_\mathrm{W} = \sum_{\mathrm{i} \in \mathrm{W}, \mathrm{i}=1}^{\mathrm{k}} \frac{\mathrm{ET}_{\mathrm{i,j}}}{\tau} \times \mathrm{CO}_\mathrm{j} : \mathrm{j} \in \mathrm{VM}_\mathrm{j} \tag{2}$$

In Eq. 2, $\mathrm{ET}_{\mathrm{i,j}}$ measures the time taken to execute task T_i by jth VM, τ is the period during which the user utilizes the resources, and CO_j represents the cost of a type-i VM instance for a unit of time in the cloud data center. The total execution time or makespan is a key metric used to measure the performance of a task scheduling approach. It is the sum of the longest completion times of tasks within a workflow. Optimizing the makespan is an important part of workflow scheduling. Eq. 3 can be used to calculate the makespan of a workflow.

$$\mathrm{TET}_\mathrm{W} = \max\{\mathrm{CT}_\mathrm{i} \mid \mathrm{i} = 1,2, \dots, \mathrm{m}\} \tag{3}$$

In Eq. 3, CT_i is represented the completion time of task T_i in the workflow. In other words, it is characterized as the variation between task T_i's start and end times. Eq. 4 is used to calculate the completion time. According to Eq. 5, the waiting time of task T_i equals the total completion time of its predecessors. Eq. 6 calculates the execution time of task T_i on VM_j. $\mathrm{PE}_\mathrm{unit}$ represents the size of each core in MIPS, $\mathrm{Num}(\mathrm{PE}_\mathrm{j})$ indicates how many cores are allocated to the virtual machine VM_j, as well as $\mathrm{SZ}_\mathrm{Task}$ indicates the size of task T_i in MI.

$$\mathrm{CT}_\mathrm{i} = \begin{cases} \mathrm{ET}_\mathrm{i} & \text{if pred } (\mathrm{T}_\mathrm{i}) = 0 \\ \mathrm{WK}_\mathrm{i} + \mathrm{ET}_\mathrm{i} & \text{if pred } (\mathrm{T}_\mathrm{i}) \neq 0 \end{cases} \tag{4}$$

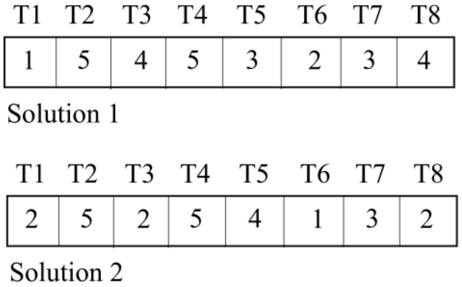
$$\mathrm{WK}_\mathrm{i} = \begin{cases} 0 & \text{if pred } (\mathrm{T}_\mathrm{i}) = 0 \\ \max(\mathrm{CT}_\mathrm{i}) & \text{if pred } (\mathrm{T}_\mathrm{i}) \neq 0 \end{cases} \tag{5}$$

$$\mathrm{ET}_{\mathrm{i,j}} = \frac{\mathrm{SZ}_\mathrm{Task}}{\mathrm{Num}(\mathrm{PE}_\mathrm{j}) \times \mathrm{PE}_\mathrm{unit}} \tag{6}$$

C. Proposed Algorithm

The proposed algorithm combines the PSO and Capuchin Search Algorithm (CapSA). The algorithm consists of running the PSO algorithm during the first half of the total iterations, initializing the most optimal solution produced by the PSO algorithm (gbest) to CapSA, and running CapSA for the second half of the total iterations. The best CapSA solution is the most efficient assignment of tasks to virtual machines. After the total iterations are finished, the algorithm takes the best solution from PSO and CapSA and finds the best fitness value. This solution is returned as the final output of the proposed algorithm.

In order to apply any algorithm to a workflow scheduling problem, the problem must be modeled in terms of the tasks that need to be completed, their precedence relationships, the resources and time needed to complete each task, and other factors. Once the problem is accurately modeled, the appropriate algorithm can be applied to find an optimal solution. This problem can be viewed as a mapping between user tasks and virtual machines. As shown in Fig. 2, an array can represent the proposed algorithm's solution. Tasks and assigned VMs are represented by an array's index and array's values, respectively. Population refers to the set of solutions. In the first iteration, the population is first initialized using a random solution. As the algorithm is iterated, the solution is improved. Fig. 3 illustrates a random population initialization. Each population is evaluated to determine its fitness. The population with the highest fitness is considered the most optimal solution. Selection processes are then used to identify solutions for reproduction.



T1	T2	T3	T4	T5	T6	T7	T8
1	5	4	5	3	2	3	4

Solution 1

Solution-1	VM1	VM2	VM2	- - - -	VMm
Solution-2	VM3	VM1	VM5	- - - -	VMm
.	.	.	.		.
Solution-k	VM2	VM3	VM1	- - - -	VMm

Fig. 3. Initializing the population.

Using Eq. 7, the algorithm determines the execution time and assigns them to the execution time matrix. The element value demonstrates the execution time; for example, $ET_{1,1}$ represents the execution time of task T_1 on VM_1. According to Eq. 8, the cost matrix contains the execution cost of each virtual machine. $C_1, C_2, \dots, C_m$ correspond to the unit execution costs of the virtual machines $VM_1, VM_2, \dots, VM_m$.

$$\mathrm{ET-Mtx} = \begin{array}{c} T_1 \\ T_2 \\ \vdots \\ T_n \end{array} \begin{pmatrix} ET_{1,1} & ET_{1,2} & \dots & ET_{1,m} \\ ET_{2,1} & ET_{2,2} & \dots & ET_{1,m} \\ \vdots & \vdots & \ddots & \vdots \\ ET_{n,1} & ET_{n,2} & \dots & ET_{n,m} \end{pmatrix} \quad (7)$$

$$\mathrm{Cost-Mtx} = (C_1, C_2, \dots, C_m) \quad (8)$$

The PSO algorithm is an evolutionary algorithm derived from bird swarms or fish schools. It optimizes an issue by iteratively seeking to enhance a candidate solution concerning a given quality measure. It works by moving a population of candidate solutions, known as particles, throughout the search space in accordance with straightforward mathematical formulas. The movement of particles is guided by their best-known position and the best-known positions in the search space, which are updated as other particles find better positions. Position pi and velocity vi are the two parameters that describe a particle. Pbest and gbest are two parameters that affect the particle's position. Gbest represents the best position of neighboring particles, while Pbest represents the best position visited by the particle. Position and velocity are updated after each iteration of the algorithm. The velocity is updated using Eq. 9.

$$v_{id}^{t} = w v_{id}^{t-1} + c1r1(pbest_{id}^{t} - x_{id}^{t}) + c2r2(gbest_{id}^{t} - x_{id}^{t}) \quad (9)$$

In Eq. 9, v_{id}^{t} corresponds to the velocity of the ith particle in the dth dimension on iteration t. Eq. 10 is used to update the particle's position. In Eq. 10, p_{id}^{t} displays the position of particle i in the dth dimension at time t.

$$p_{id}^{t+1} = p_{id}^{t} + v_{id}^{t} \quad (10)$$

The CapSA is inspired by capuchin monkeys' dynamic behavior when navigating between branches and riverbanks for food [29, 30]. It uses three great navigation methods: jumping, swinging, and climbing. According to CSA, capuchin populations can be categorized into two important groups: the leaders and the followers. The leaders guide their followers and keep track of each other. Three principal concepts are used by capuchin leaders and swarm members when looking for food sources: explore independently, cooperate in locating better food sources, and lead by example. In the search for food sources, the Alpha males, as well as Alpha females, lead the other group members. By assisting the other group members in discovering food sources, the Alpha male serves as a leader. An iterative solution is determined using the above strategies. In order to select the best features, CapSA follows the following steps:

- CapSA initialization: Like other meta-heuristic algorithms, CapSA generates a predetermined number of individuals (i.e., capuchins) to serve as its population. Each individual represents a potential answer to the task scheduling problem in this paper. A capuchin array can be viewed as a d-dimensional matrix. The matrix for the initial population is shown in Eq. 11.

$$X = \begin{bmatrix} x_1^1 & x_2^1 & \cdots & \cdots & x_d^1 \\ x_1^2 & x_2^2 & \cdots & \cdots & x_d^2 \\ \vdots & \vdots & \vdots & \vdots & \vdots \\ x_1^n & x_2^n & \cdots & \cdots & x_d^n \end{bmatrix} \quad (11)$$

- In Eq. 11, n stands for the number of capuchins, d demonstrates the number of variables, xid indicates the dimension of the ith capuchin, and x signifies the position of the capuchins. Eq. 12 is used to compute the first situation of each capuchin.

$$X^i = ub_j + t \times (ub_j - lb_j) \quad (12)$$

- In Eq. 12, ub_j and lb_j define upper and lower bounds for the jth capuchin, respectively, as well as t varies uniformly from 0 to 1.

- Generation of solutions by capuchins: In CapSA, a new population originates from the position of the capuchin, the best capuchin, and F, which represents the food source. In a d-dimensional search domain, capuchins should iteratively update this food source. The following equation is used in our proposed algorithm to generate new solutions. In Eq. 13, P_{bf} is the probability of the balance generated by the tail of the capuchin during leaping movements, θ is the angle at which capuchins jump, v_j^i is the velocity of the ith capuchin in the dimension j, g is gravity equal to 9.81, F_j refers to the food's position in the dimension, and x_j^i refers to the position of the alpha capuchins and their following capuchins within the dimension j. A capuchin's jump angle can be determined using Eq. 14, where r is a uniformly generated number from 0 to 1.

$$x_j^i = F_j + \frac{P_{bf}(v_j^i)^2 \sin(2\theta)}{g} \quad (13)$$

$$\theta = \frac{3}{2} r \quad (14)$$

IV. Experimental Results

In this section, the proposed algorithm's performance is compared with previous algorithms under Montage workflows with 50 and 100 tasks. The proposed algorithm was simulated and evaluated using the WorkflowSim -1.1 toolkit, an extension of Cloudsim. Comparisons are made among the proposed algorithm as well as standalone PSO and CapSA. Table I provides a summary of the simulation parameters that were utilized for evaluating the algorithm.

1) Total execution time comparison (50 tasks): As depicted in Fig. 4, the algorithms were compared regarding the total execution time as iterations increased from 50 to 500. The proposed algorithm consistently outperformed CapSA in all iterations. While slight degradations were observed in comparison with PSO at several iterations, the proposed algorithm exhibited an average improvement in performance. These findings indicate that the proposed algorithm is more effective than both CapSA and PSO in completing tasks in a shorter time. Moreover, the results demonstrate that the proposed algorithm maintains consistent performance as the number of iterations increases.

2) Execution costs comparison (50 tasks): Fig. 5 illustrates the comparison of execution costs among the algorithms. The proposed algorithm exhibited improvements of 9.7%, 1.4%, 12.6%, 10.6%, 3.8%, 15.2%, 11.1%, 14.4%, 19.9%, and 13.3% compared to CapSA for all considered iterations. In terms of PSO, the proposed algorithm demonstrated a significant drop in total execution cost of up to 10%. Overall, the experimental results indicate that the proposed algorithm is more efficient than both CapSA and PSO. Additionally, the proposed algorithm exhibited faster convergence compared to these algorithms.

3) Total execution time comparison (100 tasks): Fig. 6 demonstrates that for 100 tasks, the proposed algorithm consistently reduced the total execution time compared to CapSA and PSO in all iterations.

4) Execution costs comparison (100 tasks): In Fig. 7, the algorithms were compared based on their total execution costs for 100 tasks. The proposed algorithm outperformed CapSA in all iterations, with a decrease of 0.6%, 0.3%, 0.2%, 1%, 0.9%, 1.2%, 1.4%, 0.4%, 1.1%, and 1.3% for all considered iterations. Compared to PSO, the proposed algorithm showed improvements of 0.11%, 0.04%, 0.02%, and 0.15% for iterations 200, 250, 300, and 500, respectively. These results indicate that the proposed algorithm is more effective and efficient in finding better solutions for the given problem compared to CapSA and PSO. Furthermore, it consistently produces better results as the number of iterations increases. Overall, the presented results demonstrate the superior performance of the proposed hybrid algorithm in terms of both total execution time and execution costs when compared to the standalone PSO and CapSA algorithms..

V. Conclusion

Cloud services offer a wide range of solutions to the varying computing challenges in the real world. In order to accomplish a variety of tasks, users access various cloud services. Services provided by different service providers are used to handle such tasks. In this paper, a novel hybrid meta-heuristic algorithm according to the PSO algorithm as well as CapSA is proposed. The proposed algorithm uses PSO and CapSA to employ complementary global and local search strategies. Based on simulation results from the Cloudsim simulator, our algorithm outperformed standalone PSO and CapSA on both total execution cost and total execution time measures. There are several potential open problems in this domain for further research. Extending the proposed algorithm to handle dynamic task scheduling scenarios, where tasks and resource availability fluctuate in real-time, will be essential for addressing real-world dynamic workload challenges. This adaptability will ensure the algorithm remains efficient and effective in dynamic cloud environments. Exploring multi-objective optimization techniques to optimize cloud task scheduling for various performance metrics, such as energy consumption, resource utilization, and quality of service (QoS), can lead to more comprehensive and versatile solutions. Exploring the integration of the proposed algorithm with emerging technologies, such as edge computing and AI-driven resource management, can open up new possibilities for efficient and intelligent task scheduling. This integration will leverage the advancements in these fields to enhance the scheduling process and overall cloud system performance. Conducting real-world deployments and large-scale experiments to assess the scalability and applicability of the proposed algorithm in practical cloud computing environments will be valuable for validating its effectiveness.

A Modified Hybrid Algorithm Approach for Solving Harmonic Problems in Power Systems

Ning WANG, Qiuju DENG *
ChongQing College of Mobile Communication
Chongqing 401420, China

***Abstract*—A fundamental problem with electrical systems' power quality is electrical harmonics. In order to limit harmonics and their effects on power systems, filters used in electric power systems must be designed with the consideration of power harmonics. The study's suggested approach differs from other hybrid strategies that have been previously published, and the processes that are expected mostly center on cutting down on computing complexity and time. The voltage and current waveforms of distribution networks have started to be significantly distorted over the past 20 years due to the increased use of power electronic equipment and non-linear loads. This paper provides a new hybrid approach for harmonic estimation. Harmonic estimation of these deformed waveforms is a nonlinear problem because sinusoidal waveforms contain nonlinear distortions. As a result, the corresponding combined technique splits the problem of harmonic estimation into two independent problems due to the slow convergence of nonlinear problems in the estimate of harmonic components. The algorithm used in this study first estimates amplitude and frequency using the fuzzy logic control (FLC) approach, a non-linear estimator. The objective function is then to minimize the error value for both the original signal and the estimated signal using the genetic algorithm, a non-linear estimator. The experiments show that the proposed method for determining harmonic estimation time is 36% better than comparable methods. As a result, the suggested technique offers a number of benefits, including very quick computation times, more precise evaluation of amplitude and phase values for all conditions, and complexity in the outcomes.**

Keywords*—Harmonic estimation; fuzzy PD controlled; harmonic components

I. INTRODUCTION

The periodic harmonic of current and voltage waves in an electrical network is undesirable because it increases the non-linear load and temporal unpredictability of the system [1]. The waveform and voltage contain a sinusoidal component with a different frequency known as harmonics due to this non-linear load or device[2]. The fundamental elements' integer repeating frequencies are known as harmonics. When harmonics are present, the power factor quality deteriorates, which causes issues with system protection, performance, and improvement [3]. In commercial and industrial systems, the increased usage of non-linear loads such as diodes and rectifier thyristors, arc furnaces, printers, uninterruptible power supply (UPS), etc., is one of the main contributors to harmonic generation. For an accurate computation, the primary frequency's range and phase are necessary [4]. The fast Fourier series transform (FFT) is the foundation of the conventional method of harmonic estimation [5]. However, the FFT-based approach has the issue of an undesired spectrum impact despite offering outstanding performance in noise [6]. One of the effective techniques for determining the number of harmonics in this situation is the Kalman filter [7]. However, tracking dynamic changes in the measurement signal with this Kalman filter fails [8]. Because of this, the amplitude and phase of voltage and current signal harmonics are evaluated using the least square algorithm [9].

Washing machines, video cameras, gas stoves, as well as industrial activities like cement kilns, underground trains and robots, are all controlled by fuzzy controllers [10]. A control strategy based on fuzzy logic is known as fuzzy control [11]. It should be emphasized that fuzzy logic and fuzzy control can both be summarily defined as calculations with words rather than numbers and phrases, respectively [12]. In operator-controlled systems, a fuzzy controller with empirical rules is very helpful [13]. The control strategy is saved in one or more natural languages in a rule-based controller [14]. Disturbances and disturbances that can be measured are corrected [15]. This approach needs a strong model. However, a fuzzy model might be helpful if a mathematical model is challenging to develop [16].

Because they don't need a precise mathematical model, fuzzy logic controllers have an advantage over traditional PI controllers [17]. They may be non-linear, able to handle ambiguous inputs, and more durable than a typical PI controller [18]. Fuzzy logic has been used by many writers to develop cutting-edge techniques for reducing harmonics and enhancing power quality [19]. Fuzzy logic in fuzzy logic box software should be understood as FL, or fuzzy logic in its fullest definition [20]. Fuzzy Logic's foundations provide a thorough explanation of FL's core concepts. Fuzzy control, which is based on approximate reasoning simulations and fuzzy mathematical theory, is a crucial subfield in intelligent control [21]. As a result, it can offer a wise way to manage intricate systems. Fuzzy systems typically include two components [22]. A segment is distinct and governed by regulations. One component is continuous and is known as a "fuzzy set". In recent years, the genetic algorithm has been combined with these two sets to be used for harmonic control [23]. Genetic algorithms are based on natural evolutionary processes like selected mutation. Since they were first developed approximately 25 years ago, genetic algorithms have shown to be a highly effective method for addressing a variety of AI-related issues [24]. In order to achieve optimal solutions/allocation and restrict the harmonic contents of DSs, it has been explored which planning models, optimization techniques, and renewable energy sources have used uncertainty models to solve BESS/PVDGs allocation difficulties. Studies on BESS/PVDG allocation planning, however, have managed to reduce costs while falling short of the DSs standard harmonic level [25]. A hybrid fuzzy-genetic method is suggested to get over traditional fuzzy logic's constraints [26]. A fuzzy genetic algorithm (FGA) is a type of genetic algorithm that enhances various types of genetic algorithm behavior using fuzzy logic methods or fuzzy tools. An FGA can be thought of as a set of instructions, some of which may be constructed using fuzzy logic tools like fuzzy operators and connections to create genetic operators with various features [27]. They also examine the harmonic characteristics of various sources in typical operating scenarios, such as typical residential electrical load, electric vehicle charging scenario, frequency converter speed regulator, and renewable energy generation. Researchers have provided a comprehensive overview of common models of harmonic sources in modern power systems and provided insight into the circuit mechanisms, mathematical models, and operational processes of these sources [28].

The present study proposes a modified hybrid algorithm approach to solve harmonic problems in power systems. The main focus of the study is on electrical power quality and the issue of electrical harmonics in power systems. The suggested approach in this study differs from previously published hybrid strategies, with a focus on reducing computing complexity and time. The algorithm used in this study first estimates amplitude and frequency using the fuzzy logic control (FLC) approach, which is a non-linear estimator. Then, the objective function is to minimize the error value for both the original signal and the estimated signal using the genetic algorithm, another non-linear estimator. The combination of the two fuzzy logic algorithms and the genetic algorithm improves the simultaneous estimation of harmonic amplitude and phase components of the system. The study evaluates the proposed approach using two experiments. The first experiment focuses on analyzing power harmonics without combining and coordinating various harmonics, while the second experiment involves estimating real signals close to each other. The results of the experiments indicate that the proposed method outperforms other existing algorithms in terms of estimation performance and computation time. In summary, the main difference between the present study and previous works lies in the novel combination of fuzzy logic control and genetic algorithms to estimate harmonic components in power systems. The proposed method shows better convergence and estimation speed compared to other methods and can accurately estimate harmonic coefficients and phases.

However, based on the presented content, some potential challenges and limitations such as the accuracy of accurate estimation of harmonics in complex and noisy scenarios and the existence of noise and disturbances in real-world power systems may affect the accuracy and robustness of harmonic estimation are present in this study.

Given the benefits that the combined fuzzy genetic algorithm has suggested, FGA is utilised in this study to identify harmonics in the power system. In this instance, the harmonic fuzzy logic will be used first to explain the power system. The target function will then be created using the minimum genetic algorithm based on the signal from the fuzzy harmonic logic.

The following is a summary of the authors' contributions to this study.

- Combining two fuzzy logic algorithms and a genetic algorithm improved the simultaneous estimation of the system's harmonic amplitude and phase components.
- Predictive variables of harmonic coefficients Ai and THETAi phases for the estimated signal were determined based on the squared error cost function of the original and estimated signals. • The Taki-Sugno-type fuzzy preset model and PD control form the basis of the proposed structure.

The remainder of the essay is structured as follows. The system model for harmonic estimation is looked at in Section II. Additionally, the combined FGA method that has been proposed for the study model is provided in this section. The simulation results for the suggested model are discussed in the Section III. The Section IV contains the conclusion and recommendations for future work.

II. The Issue of Harmonic Estimation in Electrical Power Systems

According to the literature, current or voltage harmonics can damage devices, overheat power systems, or trip circuit breakers. Therefore, utilising traditional or optimisation methods, researchers and designers have attempted to solve the aforementioned issues [29]. Due to the amplitude and fuzzy components, it has recently been discovered that harmonic estimation problems have a non-linear structure. Optimization-based techniques demonstrate an efficient and quick solution. Due to this achievement, the amplitude and phase values of high-level harmonic components in various waveforms are estimated and optimised in this study using FGA.

A. Harmonics in the Power System Mathematical Model

The following is an estimation of the power harmonic current or voltage's overall waveform:

$$y(t) = \sum_{m=1}^{M} A_m \sin(\omega_m t + \theta_m) + A_{dc} \exp(-\alpha_{dc} t) + \mu(t) \quad (1)$$

$\omega_m = m2\pi f_0$, the angular frequency of component *m*, f0, the main frequency, $\mu(t)$ additional white Gaussian noise *AWGN* ‘(A_{dc} *exp* $(-\alpha_{dc}t)$, the anticipated damping amount, are all represented by the letters *M*. Harmonic phase values are *mth*, while A_m *and* θ_m are unknown values [30]. The discrete-time signal can be represented as follows when the signal *y(t)* is sampled with a sampling period of *Ts*:

$$y(n) = \sum_{m=1}^{M} A_m \sin(\omega_m nTs + \theta_m) + A_{dc} \exp(-\alpha_{dc} nTs) + \mu(n) \quad (2)$$

Then, in equation (2), the so-called damping Taylor series is used, and the straightforward equation is as follows:

$$y(n) = \sum_{m=1}^{M} A_m \sin(\omega_m nTs + \theta_m) + A_{dc} - A_{dc}\alpha_{dc} nTs + \mu(n) \quad (3)$$

Finally, a universal and straightforward formula for estimating the phase and amplitude of all harmonics is discovered. The linearity of the proposed sinusoidal model is also improved, which allows for the use of effective and reliable optimisation techniques to solve the issue. The sine and cosine functions can be used to rewrite the general waveform shown in equation (3) as follows:

$$y(n) = \sum_{m=1}^{M}[A_m \sin(\omega_m nTs)cos\theta_m + A_m cos(\omega_m nTs)sin\theta_m + A_{dc} - A_{dc}\alpha_{dc}nTs + \mu(n)] \qquad (4)$$

Later, this signal is transformed as follows into a parametric form:

$$y(n) = H(n)\theta(n) \qquad (5)$$

Which H (n) is displayed as follows:

$$H(n) = [\sin(\omega_1 nTs)\ cos(\omega_1 nTs) \ldots \sin(\omega_m nTs)\ cos(\omega_m nTs)1 - kTs]^{T} \ (6)$$

Following is how the general vector of unknown parameters is expressed:

$$\theta(n) = [\theta_{1n}\theta_{2n} \ldots \theta_{(2m-1)n}\ \theta_{2mn}\theta_{(2m-1)n}\theta_{(2m-1)n}]^{T} \qquad (7)$$

$$\theta = [A_1 cos(\theta_1)A_1 sin(\theta_1) \ldots A_m cos(\theta_1)A_{1m}sin(\theta_1) \ldots A_{dc}A_{dc}\alpha_{dc}]^{T} \qquad (8)$$

The harmonic estimation problem's objective function J, which is used to optimise the unknown parameters, can therefore be represented as follows:

$$J = \min(\sum_{n=1}^{N} e_n^2(n)) = min(\sum_{n=1}^{N}(yn - y_{nest})) = MSE(yn - y_{nest}) \qquad (9)$$

where the estimated output harmonic signal $\hat{\boldsymbol{y}}_{\boldsymbol{nest}}$ is specified, and $\boldsymbol{y_n}$ is the actual harmonic signal detected in the grid or electrical system.

B. Design of a Harmonic Estimator using the Combined FGA Algorithm

This section goes into great length about the harmonic estimation problem in the power system and the integrated approach of the FGA algorithm. The harmonic estimator based on the FGA method is used to solve the synchronisation problem in the following steps:

a) Fuzzy Controller: The effectiveness of fuzzy logic controllers in enhancing transient and steady-state performance is well established. The fuzzy logic controller's function is particularly beneficial because a precise mathematical model is unnecessary [31]. Fig. 1 depicts the fuzzy logic control system's diagram.

This figure's four main functional sections are basic knowledge, fuzzification, inference mechanisms, and de-fuzzification. A database and a legal base make up the knowledge base. The database contains information for appropriate fuzzification operations, inference, and de-fuzzification methods, including input and output membership functions. The language rules that link the fuzzy input variables to the desired control actions make up the rule base. A clear input signal is converted into fuzzy signals through "fuzzification," which can be recognised by the degree of membership in fuzzy sets. Instead of using numerical variables, fuzzy logic makes use of linguistic variables. Fuzzy "if-then" principles and fuzzy reasoning are used in this notion. These findings are helpful in various domains, including robotics, autonomous control, data classification, decision analysis, and expert systems. It uses a non-linear mapping from the input space to the output space. The inference mechanism assesses the control rules. Two types of inference mechanisms predominate [32] are: Mamdani fuzzy inference system for starters, and a system for fuzzy inference by Sogno. The fundamental distinction between these two approaches is how they produce the outcomes of fuzzy rules. Sogno employs linear functions of the input variables, whereas Mamdani uses fuzzy sets for the rule. It should be mentioned that the existing research employed the Sogno technique. The inference system carries out tasks like decomposition and aggregation. If the laws are prevalent, they are reduced to a straightforward rule format. Finally, de-fuzzing transforms murky output signals into audible ones [33].

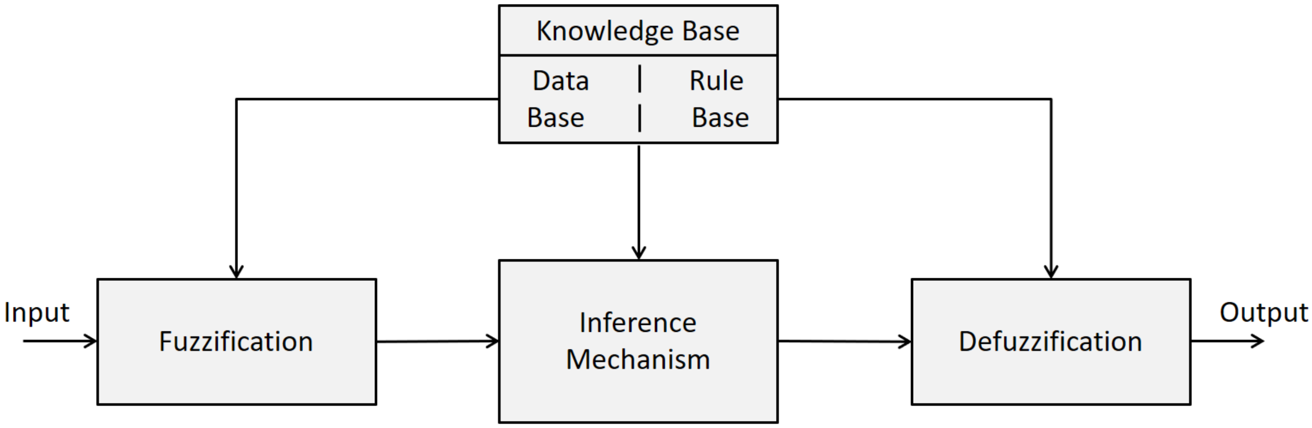

Fig. 1. The fuzzy logic control function block diagram.

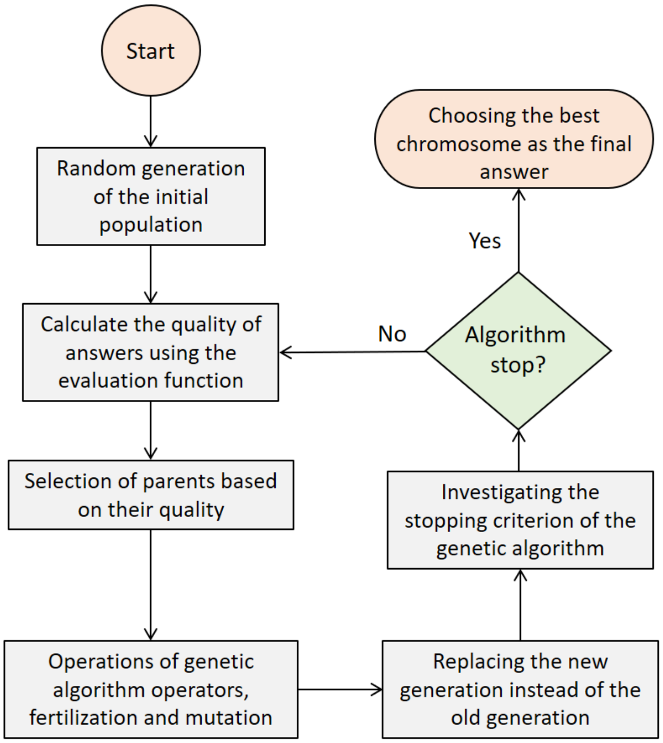
b) Genetic Algorithm: General-purpose techniques for learning and optimization are genetic algorithms. A particular kind of evolutionary algorithm called a genetic algorithm uses biological processes like mutation and inheritance. In place of regression-based forecasting methods, GAs is a good choice. Binary strings are the computational language of Gas [34]. Finding a useful answer is only a matter of looking for a particular binary string. Frequently superior to chance-based prediction methods are genetic algorithms. A genetic algorithm, often known as GA, is a programming method that leverages the notion of genetic evolution to solve problems. The input is the problem that needs to be addressed, and the solutions are coded using a structure known as the fitness function [35]. It assesses each potential answer, the majority of which are chosen at random. A helpful technique in pattern recognition, feature selection, picture interpretation, and machine learning are the genetic algorithm. Genetic algorithms replicate the genetic progression of biological things. These algorithms address issues that were motivated by the natural evolutionary process. In other words, they create a population of beings, much like nature does, and by acting on this population, they create an ideal population or being [36].

A problem must be transformed into the unique form needed by genetic algorithms for them to be able to solve it. The required solution to the issue should be developed in this process so that it may be represented as a chromosome [37]. Fig. 2 lists the stages for implementing a genetic algorithm.

a) Proposed Hybrid FGA Algorithm: Fig. 3 displays the harmonic estimation algorithm based on the suggested FGA algorithm. The block diagram view of the suggested design for the problem of signal identification at various times by extending the Fourier series of a signal and calculating the amplitude and phase at various frequencies is really depicted in the accompanying figure. We combined the genetic algorithm with a Taki-Sugno-type fuzzy control to improve the detection accuracy. Additionally, it serves as a PD controller in the control part of the closed-loop system to estimate instantaneous and high-speed harmonics. As a result, it greatly enhances the ability of the genetic algorithm.



Start
Random generation of the initial population
Calculate the quality of answers using the evaluation function
Selection of parents based on their quality
Operations of genetic algorithm operators, fertilization and mutation
Replacing the new generation instead of the old generation
Investigating the stopping criterion of the genetic algorithm
Algorithm stop?
No
Yes
Choosing the best chromosome as the final answer

III. Evaluation and Simulation

As was already said, numerous methods for estimating harmonic signals have been documented in the literature to offer effective estimation techniques. The main benefits of these new technologies are anticipated to be faster calculations and greater accuracy. To estimate amplitude/phase and compare the performance of the harmonic fit based on the FGA algorithm with that suggested by other meta-heuristic approaches, the analysis of numerous functions in both non-noisy and noisy situations is described in this section. Two harmonic estimating procedures are taken into consideration in this work. The second test takes into account harmonic situations with inter- and sub-harmonics, while the first test investigates the estimate method for simple power harmonics. In these studies, a test signal that is often utilised in the literature is used. Typical industrial loads this chosen signal can depict include power electronic devices, electronic explosions, and non-linear systems [12]. Previous studies [7, 38] have shown the signal-to-noise ratio (SNR) to be 10 dB, 20 dB, and 40 dB. In addition, the CS, threshold, MCN and correction rate of the FGA algorithm are selected as 20, CS / 2 × D, 1000 and 0.1, respectively. To show the extent of the algorithm used, 50 times with different values were given for all the investigated cases in MATLAB 2016. Also, the entire given domain is valued in units (p.u.). The simulations were performed on a PC with a Windows 7 operating system, Intel 2.67 GHz processor and 4 GB RAM.

A. Experiment 1 (Analysis of Power Harmonics without Combination and Coordination)

Before starting the analysis, a basic test signal covering the behavioral effects of industrial loads and several operating systems according to [9] is below:

$$y(t) = 1.5\sin(2\pi f1t + 80°) + 0.5\sin(2\pi f3t + 60°) + 0.2\sin(2\pi f5t + 45°) + 0.15\sin(2\pi f7t + 36°)0.1\sin(2\pi f11t + 30°) + 0.5\exp(-5t) + \gamma n \tag{10}$$

MATLAB software is used to sample the test signal in continuous time at a sampling frequency of 20 kHz. Following that, the average values of the findings obtained are shown together with the process of harmonic estimation by the GA algorithm using the sampled test signal. The results are estimated for a revised signal, which is then compared to the initial test signal. Additionally, the suggested algorithm is used in the relevant noisy and non-vibrating scenarios. Fig. 7 and 8, respectively, display the outcomes of the error signal in terms of time and the estimated signal.

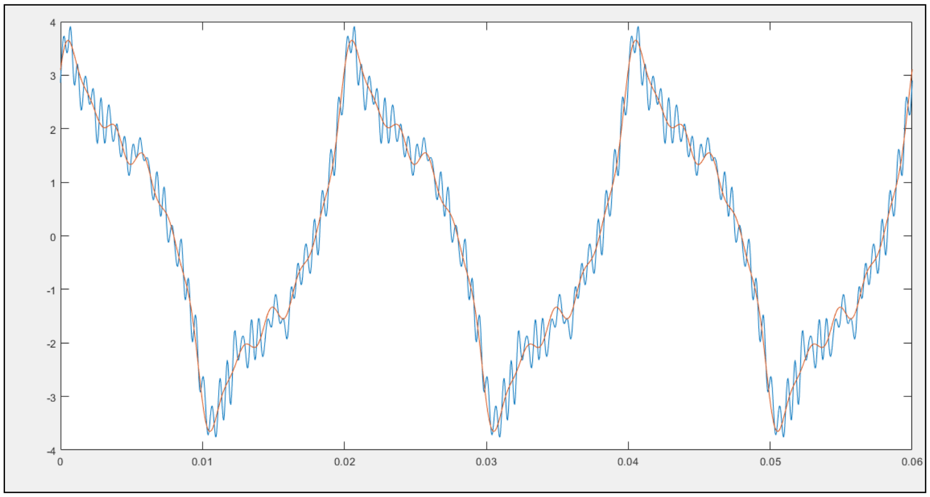

Fig. 7. Display of the error signal in terms of time.

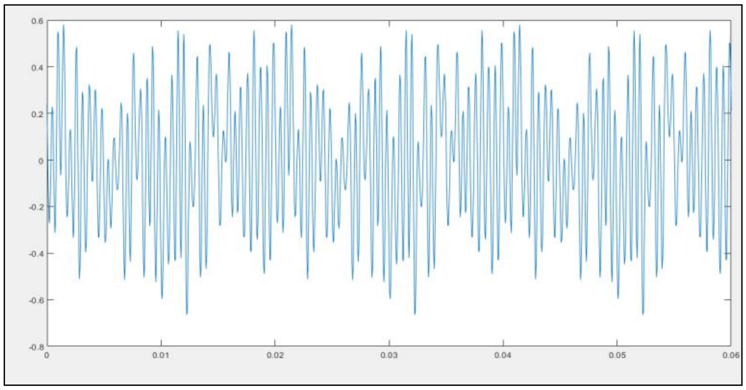

Fig. 8. Estimated signal display.

The estimation results for the first test that were achieved utilising the suggested solution were carried out in a noise-free environment. Additionally, the results from the literature reported in Table I are contrasted with the estimated values obtained for the first experiment. In Table I, parameters like A, P, and E represent amplitude, phase, and error. It is evident from Table I that the suggested estimation procedure outperforms the findings in the literature. Furthermore, it is noteworthy that the harmonic estimator based on the evolutionary algorithm has a faster processing time than other comparable techniques.

B. Experiment 2

In this experiment, the estimated real signals have been calculated quite close to each other, which are shown in Fig. 9 and 10, the size and error of the signal, and Fig. 11 shows the reduction of the sum of squares of the error by the genetic algorithm for this experiment.

$$Y(t) = 23[0.65*\sin(3*50*2pi*t) + 0.45*\sin(7*50*2pi*t) + 0.1*\sin(15.5*50*2pi*t) + 0.01*\sin(4000*2pi*t)] \quad (11)$$

When the second experiment's results are taken into account, it is evident that, much like the first experiment's findings, the estimated values of the power harmonics, including sub- and two inter-harmonics, are completely consistent with the actual values. Additionally, Table II displays the estimation outcomes for the second trial. The proposed technique in this study offers improved outcomes in terms of estimating performance and computation time, as can be observed from the findings that have been presented. Fig. 12 shows the harmonics calculated from two real and estimated signals, and Table III compares the main harmonics for both real and estimated signals. The simulation results show that the proposed method has a good convergence and estimation speed. Also, this method can estimate harmonic coefficients and harmonic phases higher than other methods.

The proposed model's projected performance is pretty impressive and nearly identical to the actual algorithm. The voltage range for each set of data is determined, and the estimated outcomes are contrasted. Clearly, the proposed approach offers the best accuracy and quickest convergence of any. As a result, the conclusions reached using real-time data from a real-time system are supported by the outcomes. Tests have been conducted using 15 cycles in a 55 Hz system, which is a 250 ms window at a sampling period of 0.5 ms, in compliance with I_E_C 61000-4-31 to determine power quality characteristics [3].

TABLE III. Harmonic Comparison Results

Frequency (Hz)	True signal harmonics	Estimated signal harmonics	Error (%)
50	427.8590	427.3084	0.1286
150	992.0075	976.7342	1.539
350	662.3391	676.4592	2.1318

IV. Conclusion

The article presents a modified hybrid algorithm approach for solving harmonic problems in power systems. The primary focus of the study is to address the issue of electrical harmonics, which is a significant problem affecting power quality in electrical systems. The proposed approach combines fuzzy logic control (FLC) and genetic algorithms (GA) to estimate harmonic components in nonlinear power systems. The hybrid algorithm approach is developed to address the slow convergence of nonlinear problems in harmonic estimation. The innovation of this thesis is the combination of a fuzzy logic algorithm and a genetic algorithm. The basis of proposed structure is based on a predetermined Taki-Sugno type phase model and PD control to improve signal estimation for high-frequency harmonics and then determine the predictive variables of harmonic coefficients Ai and THETAi phases for the estimated signal and based on the function The squared error cost is the original and estimated signal. The proposed method first uses fuzzy logic control to estimate amplitude and frequency, which is a non-linear estimator. Then, a genetic algorithm is employed to minimize the error value for both the original signal and the estimated signal, offering a more precise evaluation of amplitude and phase values for all conditions.

The experiments conducted in the study show that the suggested hybrid approach for harmonic estimation performs 36% better in terms of computation time compared to other comparable methods. The results demonstrate that the proposed algorithm provides faster calculations and higher accuracy for harmonic estimation. In the first experiment, the proposed method is applied to estimate power harmonics, and it outperforms existing algorithms in terms of accuracy and processing time. In the second experiment, the method successfully estimates power harmonics as well as sub-harmonics and inter-harmonics, again showing improved performance compared to other methods. Overall, the proposed hybrid approach combining fuzzy logic control and genetic algorithms offers a promising solution to the harmonic estimation problem in power systems. It provides faster computation times, more accurate results, and the ability to estimate harmonics beyond the fundamental frequency, making it a valuable contribution to power system harmonic analysis and mitigation.

In line with the limitations of this study, the following are suggested as future works.

- Using other optimization algorithms instead of GA algorithm
- Use Mamdani type fuzzy logic
- Estimation of phase and amplitude components separately from each other.
- Simulation for time-invariant power signal.

Inverted Ant Colony Optimization Algorithm for Data Replication in Cloud Computing

Min YANG*
Chongqing City Vocational College, Chongqing; 402160, China

***Abstract*—Data replication is crucial in enhancing data availability and reducing access latency in cloud computing. This paper presents a dynamic duplicate management method for cloud storage systems based on the Inverted Ant Colony Optimization (IACO) algorithm and a fuzzy logic system. The proposed approach optimizes data replication decisions focusing on energy consumption, response time, and cost. Extensive simulations demonstrate that the IACO-based method outperforms existing techniques, achieving a remarkable 25% reduction in energy consumption, a significant 15% improvement in response time, and a substantial 20% cost reduction. By addressing the research gap concerning integrating IACO and fuzzy logic for data replication, our work contributes to advancing cloud computing solutions for large datasets. The proposed method offers a viable and efficient approach to improve resource utilization and system performance, benefiting various scientific fields.**

***Keywords*—Cloud computing; data replication; cloud data centers; reliability; energy efficiency; inverted ant colony optimization algorithm**

I. INTRODUCTION

Cloud computing provides significant opportunities for progress in the information technology industry. As an emerging form of a distributed network, cloud computing entails providing hardware and software resources across a range of businesses and organizations [1]. Users are only charged for the services offered by the cloud provider. Several types of cloud computing services are available, including Infrastructure as a Service (IaaS), Platform as a Service (PaaS), and Software as a Service (SaaS) [2]. SaaS shares software applications between customers in the cloud through Internet-based service providers. Users do not need to install software on their personal computers. The PaaS model involves sharing a platform with consumers responsible for configuring, deploying, testing, and developing the application. Consumers do not maintain servers, hardware, and storage, although they may control applications. To run applications, the cloud service providers supply a pre-installed operating system. IaaS is a model for deploying consumer applications and systems on shared infrastructure [3].

Four major cloud computing deployment models exist: community, public, private, and hybrid clouds. An organization can use private clouds inside or outside of their offices. It is located within the virtualized data center's firewall. Users cannot control the services provided by the cloud service providers, as they provide the infrastructure. An organization that provides cloud services to the public or large industries operates a public cloud. Cloud service providers control the services and provide the infrastructure within the public cloud. Community clouds provide cloud services offered by multiple organizations to assist individuals with similar concerns. In hybrid clouds, numerous cloud models are combined, utilizing proprietary or standardized technology that permits the portability of data and applications [4, 5].

In the realm of cloud computing, the integration and utilization of various cutting-edge concepts are instrumental in driving innovation, efficiency, and intelligence. The Internet of Things (IoT) plays a pivotal role by connecting a myriad of devices and sensors, generating vast volumes of data [6, 7]. This data deluge, known as big data, necessitates advanced data processing and storage capabilities that cloud computing can readily provide [8, 9]. Artificial Intelligence (AI) and Machine Learning (ML) are the cornerstones of intelligent cloud applications, enabling systems to learn from data patterns, make informed decisions, and automate processes, thereby enhancing user experiences and optimizing operations [10-14]. Feature and channel selection are vital in cloud computing scenarios dealing with large and diverse data sources [15]. By identifying the most relevant features and data channels, cloud-based systems can reduce computational overhead, improve accuracy, and streamline data processing [16, 17]. Furthermore, meta-heuristic algorithms in the cloud facilitate efficient optimization of resource allocation, task scheduling, and load balancing, leading to optimal resource utilization and performance [18-21]. Association rule mining enables the discovery of valuable patterns and correlations within data, empowering businesses to make data-driven decisions and tailor services to individual preferences [22]. Additionally, game theory principles come into play in cloud computing, where cloud service providers and users engage in strategic interactions. Through game theory, fair and efficient pricing models can be devised, and resource allocation strategies can be optimized to ensure mutually beneficial outcomes [23].

Providing reliable services in conjunction with a high degree of availability and data performance constitute essential criteria. These requirements are ensured through the use of the replication concept. Data replication involves replicating the duplicate files at different locations to improve reliability, availability, and performance [24]. Data replication plays a vital role in data-intensive environments in which records must be synchronized between multiple sites located at diverse locations. The availability of the data is increased through replication. Requests may be fulfilled by other sites that host replicas of the requested file if the site responsible for hosting these files cannot serve them. Furthermore, replication enhances the overall performance of the system by allowing the user's requests to be satisfied at the nearest site that also holds replicas of the data file requested. In this manner, the system's response and access times are improved. As a final point, replication also enhances the reliability of the system. Despite the corruption or failure of any replica of a data file, user requests can be processed and handled by other non-corrupted servers that hold the required replica. In most cases, replication strategies cannot be adapted to cloud environments due to their intention to improve system performance by not considering replication costs. The creation of multiple replicas within cloud computing environments is not economically practical as it may lead to wasteful resource utilization and a reduction in service providers' profits. Thus, data replication approaches applied to cloud-based platforms must also meet the following objectives:

- Maintaining reliable Quality of Service (QoS) through the observance of Service Level Agreements (SLAs), which constitute legal contracts between cloud providers and their tenants, i.e., customers. Typically, an SLA consists of one or more tenant Service Level Objectives (SLOs), i.e., requirements.

- Based on the pay-as-you-go pricing model, the provider dynamically adjusts the resources it rents to its tenants.

Data replication, a critical technique for distributing data across multiple locations, remains challenging in cloud computing. The problem arises from the need to strike a balance between enhancing data availability and minimizing access latency for users. Replicating data to multiple locations can improve system availability and ensure users can access data from a nearby location. However, determining the optimal number and locations for data replicas is a complex optimization problem. This paper aims to address the data replication challenge in cloud computing by proposing a novel method of dynamic duplicate management. Our research draws inspiration from the Ant Colony Optimization (ACO) algorithm, which has shown promising results in solving combinatorial optimization problems. In particular, we introduce the Inverted ACO (IACO) algorithm, tailored to tackle the data replication issue in cloud storage systems. By leveraging the IACO algorithm and a fuzzy logic system, we seek to optimize data replication decisions regarding energy consumption, cost, and response time. The objective is to improve the overall performance of cloud data centers while maintaining data availability for end-users.

The rest of this paper is structured as follows: Section II presents the related work in data replication techniques for cloud computing. Section III provides a detailed description of the proposed IACO-based dynamic duplicate management approach. Section IV presents the results and analysis of extensive simulations, comparing the proposed method with existing techniques. Finally, Section V concludes the paper and outlines potential future research directions.

II. Related Work

In order to solve the data replication problem, Ebadi and Jafari Navimipour [25] proposed a hybrid metaheuristic algorithm. To achieve high-quality solutions, it combines the global search capabilities of the PSO algorithm with the local search capabilities of the Tabu search algorithm. Various test cases are used to demonstrate the efficiency of the method compared to PSO, TS, and ACO algorithms. Based on the results obtained, it appears that the method is more efficient in terms of energy consumption and cost.

By combining multiple objective optimizations and evaluating the cost distance using the knapsack problem, Salem, et al. [26] presented the shortest routes and the lowest costs in the cloud based on replication and data center placement. By using the Artificial Bee Colony (ABC) algorithm, the shortest route and lower-cost problems have been solved, identifying the best replication placement based on the distances of minimizing the costs and achieving the shortest routes that were achieved when the Knapsack algorithm was employed to deal with these issues. The proposed system can be optimized using the MOABC algorithm to achieve high efficiency and low costs. By using the Knapsack approach and optimizing replica distribution based on distances and data transmission rates, MOABC is capable of finding a suitable location to place data replicas. Based on measurements, MOABC is more effective and efficient than compared algorithms in regards to determining the best placement of replications.

Rambabu and Govardhan [27] proposed a new data replication approach derived from data mining principles. Data replication is accomplished by identifying widely used data patterns within the massive database of a node. A novel hybrid algorithm selects the best thresholds based on an optimization-assisted frequent pattern mining strategy. Greywolves Updated Exploration and Exploitation with Sealion Behavior (GUEES) is a hybrid algorithm that combines the concepts of Grey Wolf Optimization (GWO) and Sealion Optimization Model (SLnO). During the mining process, two criteria are defined: (i) Prioritization and (ii) Cost. The prioritization process can be divided into two categories: queueing both high and low-priority data, and the storage demand determines the cost. High-priority queues are optimized with GUEES. As a final step, a comparative validation is performed to evaluate the efficiency of the proposed model.

Mansouri, et al. [24] propose a hierarchical data replication strategy (HDRS) for dynamic replication. HDRS involves creating replicas capable of being dynamically increased by growing exponentially or depleting exponentially, placing replicas based on access loads and labeling techniques, and replacing replicas depending on future file values. CloudSim is used to evaluate different dynamic data replication methods. In comparison with other algorithms, HDRS has been demonstrated to reduce response time and bandwidth consumption. A popular file is replicated to the best site by the HDRS. By balancing the load of the sites, this method avoids unnecessary replications and reduces access latency.

Khelifa, et al. [28] suggested a periodic and dynamic data replication approach for cloud-based federated systems. The objective of this method is to ensure financial success for cloud service providers by meeting the demands of their users regarding availability and response time. In order to detect replicas, a periodic review of the users' tasks is conducted by employing the spectral clustering algorithm to determine relationships among remote data pertaining to SLA violations. Adapting correlations of this type can lead to a reduction in both the volume of data to be transferred and its transfer time. In the next step, a fuzzy inference system is used to select replicas from the owned or leased resources of other providers based on four main parameters. Additionally, replica numbers are adjusted when SLAs are met. In accordance with the results obtained, the proposed strategy reduces the number of SLA violations while maintaining the providers' monetary profits.

Despite the various existing techniques, there remains a research gap concerning the integration of the IACO algorithm and fuzzy logic for dynamic duplicate management in cloud storage systems. Previous studies have primarily focused on standard ACO algorithms or hybrid metaheuristics. Our research aims to bridge this gap by introducing the IACO algorithm, a novel adaptation with potential advantages in data replication. By combining IACO with a fuzzy logic system, our approach targets energy consumption, cost reduction, and response time improvement offering a comprehensive and efficient solution for data replication in cloud computing environments.

III. Proposed Method

Replication of data in a cloud environment reduces network delays, bandwidth usage, and costs. The replication of data to several sites improves data accessibility by allowing users to access data at their convenience. Cloud systems, however, face the challenge of determining the appropriate number and location of replicas. By increasing the number of replicas, accessibility is enhanced and access delay is reduced, but replication costs increase. In this regard, it is crucial to present a method that reduces data replication costs and balances accessibility and cost. In this study, a new approach based on the IACO algorithm and fuzzy logic system is proposed to improve the management of replication versions in cloud storage systems.

A. Problem Modeling and Formulation

Our model considers a cloud computing network with M data centers, each of which has its own storage media, memory, and processing power. si refers to the storage capacity of data center i (1≤i≤M) measured in a simple data unit (like blocks). The connection between two data centers, i and j (if any), has a positive integer number C (i, j) and another positive integer number E (i, j) related to it. Energy and communication costs are assigned to transfer a data unit among the data centers (communication costs can be expressed as delay, number of nodes, and so on). If there is no direct communication link between two data centers, the cost is calculated by the sum of all communication costs along the selected path between the data centers. Moreover, the energy is obtained by the sum of all communication energies along the selection path from data center i to j. The required assumptions for the proposed method are presented in the following:

$$C (i, j) = C (j, i) \text{ and } E (i, j) = E (j, i)$$

There are N data d1, d2, . . ., dN. The size of each data is shown by d_k(1≤k≤N) and is measured in a simple data unit. r_{ik} and w_{ik} are the total numbers of the read and written values during time T (the k index is used for data, and i and j indexes are used for data centers). r_{ik} includes some of the reads of local generation on i and some intermittent reads on their path to the objective via i.

Each data d_k has a main version on the network that is not re-transferable and removable. The main version's data center maintains d_k showing by cdbk. Each main data center cdbk considers the maintenance of information related to the replication marked by RSk for each d_k (a part of the data center in which each data k is repeated). RS = {RS1, RS2, . . ., RSN} is used to determine the replication plans for all data. Moreover, the main data center, cdbk, and the nearest data center $dcdb_{ik}$ store d_k. $dcdb_{ik}$is a data center that leads to the minimum cost and energy for read requests from i for d_k. Consider that if $dcdb_{ik} = cdb_k$, the main data center is close to the data center, and if $dcdb_{ik} = i$, the data center i maintains a replica of d_k. Hence, each request is served locally, as read for data (if there is a local replica of the data) or transferred to $dcdb_{ik}$, which can answer the request. To ease, we assume an update of d_k is performed by transmission of the updated replicas of the data to the main data center cdbk that is propagated to each data center, which has a replica of d_k (there are also other plans).

Based on the proposed system model in Fig. 1, the 1, 2, 3, ..., n locations are different, distributed, and connected by firmware, including different methods to access the replicas and their management. The replicas of file x are stored in locations 1, 2, 3, ..., n. Assuming that user 1 wants to access file x if distance and cost are important for the user, locations 1 and 3 are close to user 1, and their access cost is low. Different copies of file x make the file accessible if the information is lost in different locations. It results in more reliability and accessibility rate.

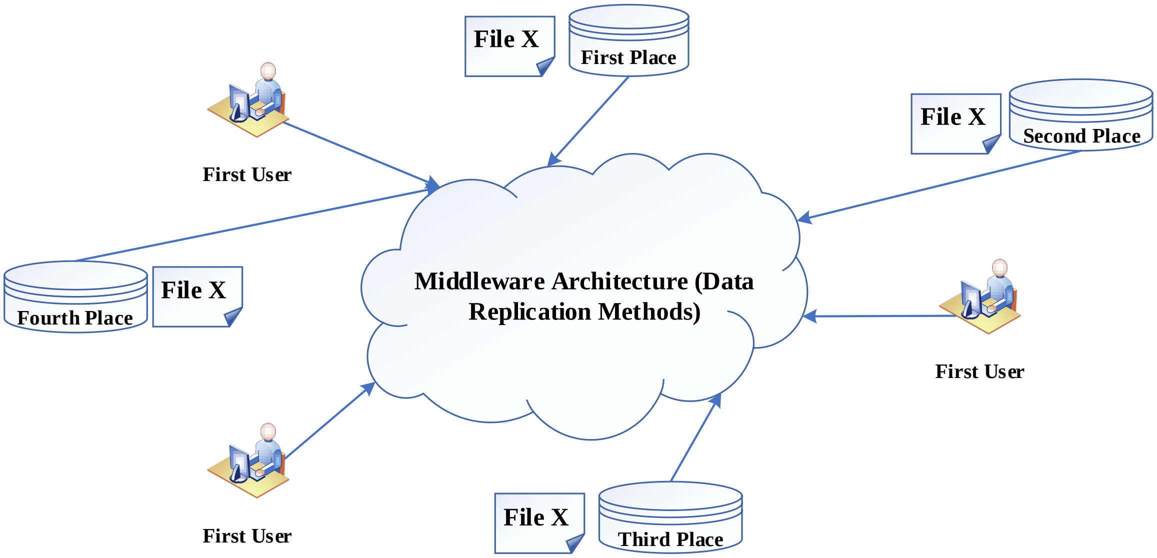

Fig. 1. Proposed model system.

B. Proposed Hybrid Algorithm

Different stages of the proposed method are explained in this section.

1) Determining the type of replicated file: The popular files are recognized, and the replication is performed. Based on it in this stage, it is investigated which file should be replicated. The proposed method performs this stage by recognizing the popular files. This stage uses the following three substages to select the files that should be replicated.

- Substage 1: Calculating the number of accesses to the files: Clustering is used to calculate the number of file accesses in this stage so that there are some cloud data centers in each cluster. A cluster head is considered in each cluster that its bandwidth is wider than other cloud data centers and can connect all the in-cluster cloud data centers. Since cloud data centers have some constraints like bandwidth limitation, the large size of the file, and the number of interactions among the cloud data centers, a method must reduce the interactions. Hence, first, the requests in each cluster are checked in each cluster to relocate the required files of that local cluster via the high bandwidth connection if possible. Transferring the high-volume files among the clusters can be avoided using clustering. This substage is explained as an algorithm in the following:
    - Calculating the count of the requests to file $\boldsymbol{f_i}$ in cluster C ($\boldsymbol{Num_{Req_c}(f_i)}$)
    - Decreasing the sort of all files based on $\boldsymbol{Num_{Req_c}(f_i)}$
    - Storing the sorted files in a list in each cluster
    - Determining the count of all the required files ($\boldsymbol{TF_c^n}$) of the data center c in period n (this stage is performed for all clusters).
- Substage 2: Calculating the amount of the file popularity: After determining the number of requests to the file in the previous stage, the file's popularity is calculated in this stage. To calculate the popularity of file f_i in period n, if $Num_{Req_c}(f_i) > 0$, equation (1) is used, otherwise, equation (2) is used. $Num_{Req_c}(f_i)$ is the count of the requests for file f_i from cluster c in period n. $size(f_i)$ is the file's size, and $TotalReq^n$ is the total number of requests in period n. p and q are constants, and their values directly affect the response time as one of the necessities for the proposed method's Quality of Service (QoS).

$$FP_c^n(f_i) = \frac{FP_c^{n-1}(f_i)+(Num_{Req_c}(f_i)\times p)}{size(f_i)} \times \frac{Num_{Req_c}(f_i)}{TotalReq^n} \quad (1)$$

$$FP_c^{n-1}(f_i) - q \quad (2)$$

- Substage 3: This substage involves determining the candidate files for replication. The count of the files, which should be replicated based on the two previous stages, is determined in this stage. Moreover, the files whose average popularity is calculated in the previous stages are sorted descendingly. In equation (3) $RepNum_i$ shows the number of files that must be copied and the proposed method selects the $RepNum_i$ files from begin of the sorted list to copy. ρ is a random number between 0 and 1. 30% of the repeatedly requested files are copied in the proposed method, meaning the x value is set to 0.7.

$$RepNum_i = TF_c^n \times (1-\rho) \quad (3)$$

2) Selecting the most suitable datacenter to save new replicas: One of the most important stages in the replication management process is finding the most suitable cloud data center to store the replicas. We use two indexes to find the most appropriate cloud data center to store the replicas. These indexes select the candidate data centers to store these replicas.

TABLE I. VARIABLES IN EQUATION (4)

Parameter	Definition
$\boldsymbol{Num_{Req_c}(f_i)}$	The number of requests for the file $\boldsymbol{f_i}$
$\boldsymbol{HNR_i}$	The data center with the highest number of requests for the $\boldsymbol{f_i}$ file
$\boldsymbol{FS^n}$	Cloud data center with free storage space
TS	Total storage space
$\boldsymbol{Dis^n}$	The distance between cloud data center n and other data centers
$\boldsymbol{HD_{is}}$	The cloud data center with the highest value for the Dis parameter

Index 1: The amount of the data center fitting: Fit_i^n can be calculated for each file f_i for a data center like n using equation (4). This equation explanation is presented in Table I.

$$\mathrm{Fit}_i^n = w_1 \times \frac{\mathrm{Num_{Reqc}}(f_i)}{\mathrm{HNR_i}} \times w_2 \times \frac{\mathrm{FS}^n}{\mathrm{TS}} + w_3 \times (1 - \frac{\mathrm{Dis}^n}{\mathrm{HD_{is}}})) \quad (4)$$

In equation (4), the coefficients w_1 , w_2 , and w_3 are weighted and between 0 and 1. The important note about these coefficients is that they can be valued based on the user's opinion, and their sum should be 1. Hence, the importance and priority of the user can be modeled based on this index. For example, if a user's priority is the data centers with the most repetition, $\frac{Num_{Req_c}(f_i)}{HNR_i}$, meaning that the w_1 coefficient should be increased, and w_2 and w_3 should be decreased. Generally, the amount of the tendency and the priority of a user can be modeled using the above equation.

Index 2: The amount of the total cost of the cloud data center: Generally, in addition to the amount of fitting the cloud data center, another index should be used to calculate the total cost of the data center and select the most suitable data center to store the replicas based on the movement pattern of the inverse ants. In this stage, QoS parameters determine the total cost of the data center. These parameters are used in Fuzzy logic (a fitting function for each data center) to evaluate the candidate centers for the replica's storage. After calculating the two indexes to select the most suitable cloud data center to store the replicas, IACO algorithm and fuzzy logic are used to traverse the cloud data center and evaluate each center based on these two indexes.

The IACO algorithm is an improvement of the ACO algorithm in that the pheromone of the path affects the ants' movement inversely, and it has a hatred effect on the ants instead of attract effect. At first, a graph is considered, including nodes and the edges connecting them. Each node in the proposed method is a cloud data center, including different data that a cloud's data may be repeated in another cloud. A user's requested data and the objective data to answer the user's request are determined. Then, the beginning node is selected randomly, and all the nodes start their movement from the beginning node. The ants traverse the graph, and each ant selects the next ant using equation (5), including pheromone, heuristic, and the condition to check its existence. The heuristic matrix in the proposed inverse ants' algorithm is calculated and valued using fuzzy logic. This fuzzy system's stages are presented in the following.

At first, because there is no pheromone on the path, it is not required to have a primary traverse to create the pheromone on the graph, the first ant has a traverse, and the pheromone on the traversed path is updated using equation (6) after its satisfaction. The next ants may not select the traversed path by the first ant because the pheromone's smell is not desired for the next ants. The second ant chooses the graph's best node (the node with the highest probability) to traverse and moves to the node. If all the paths are traversed, and there are some ants, the remaining ants copy the traversed paths by the first, second, and other ants.

A tolerance is selected for the graph's nodes because the objective data may be in the beginning node. If there is no tolerance, all ants select the first node, which leads to the inefficiency of the proposed method to provide workload balance among the nodes. The considered tolerance value is one so that if the utilized data is from a cloud data center, this center's tolerance is zero, and its data cannot be used unless the tolerances of other cloud centers with the objective data are also zero. If the node's tolerance is zero, we can pass over the node but cannot use its data. A complete graph tolerance is considered only for the first node. But it is considered for all the cloud centers in a non-complete graph.

If the objective data is not in the beginning node and the graph is complete, the selected node to traverse by the first ant is the node with the appropriate data. But if the graph is non-complete, a specific policy is used to choose the suitable data. If the objective data is in the beginning node, the first ant should use that cloud center's data, and the second ant should select the next node to traverse. Hence, the beginning node is compared with the traversed node by the second ant to find the objective data. If we are on the beginning node, and the objective data is not in its adjacent nodes, the nodes are selected randomly, and their adjacent nodes are also checked. Finally, the nodes, including the objective data, are compared based on the heuristic values, and the better node, including the objective data, is selected. These heuristic values are generated using the proposed Fuzzy system.

Each data center has some parameters called QoS parameters. QoS parameters are non-operational features of the system, which can be provided by the service providers, evaluated by their performance, and monitored by the users. QoS parameters can be divided into two categories: positive and negative. Increasing values of the positive QoS parameters can be helpful for the users, like accessibility and reliability. On the other hand, decreasing values of the negative QoS parameters can be useful for users, like cost and execution time. Each cloud data center is equal to an ant in the inverse ants' algorithm, and the cloud data centers are evaluated based on the QoS parameters. These parameters are the inputs to the proposed fuzzy model, and an output value is generated after defuzzification. This fuzzy generated value is used as a heuristic function value, and the ants traverse the network based on these values. A list of the positive and negative parameters with their units is defined in the following.

Value: It shows the amount of service reliability (in percent).

Accessibility: It shows the probability of service accessibility (in percent).

Cost: It is the cost that the service requester should pay to the service provider to use the services (in dollars).

Response time: It is the execution time between the reception of the service and the response to the service (in milliseconds).

Consumption energy: We used the energy model introduced in [29]. Energy consumption is being increased by the number of replicas which is relied by the given work resources so that for decreasing the level in energy amount.

Equation (5) is used to select the cloud data center for graph traversal. The first ant, which starts the traverse, chooses the optimal data, and the optimal data is in the optimal cloud data center with more probability for selection. After selecting the optimal data and traversing the path related to the data center, the path's pheromone is updated, and its smell makes hatred for the following ants. Hence, the path traversed by the previous ant may be ignored by the following ants. It continues by the next ant while all the paths to reach the objective data are traversed. Then if there is any ant, the traversed paths by the previous ants are repeated in order.

$$p_{kj}^{i}(t) = \frac{[\tau_{kj}(t)]^{\alpha}[\eta_{kj}(t)]^{\beta}[D]^{\gamma}}{\sum_{l=1}^{n} p_{kl}^{i}(t)[\tau_{kl}(t)]^{\alpha}[\eta_{kl}(t)]^{\beta}[D]^{\gamma}} \qquad (5)$$

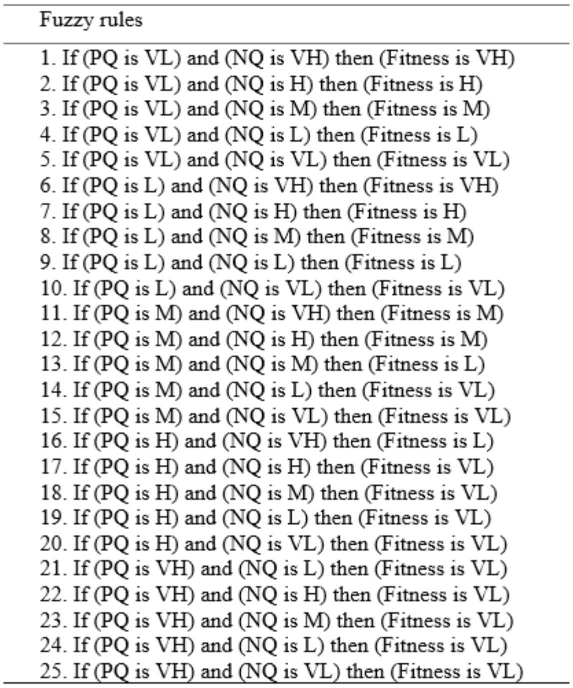
In this equation, t is the current replica, $\tau_{kj}(t)$ is the existing pheromone in an edge (e_{kj}), and D is the condition of checking data existence. If the objective data is on the cloud data center, D=1, else D=0. η_{kj} refers to the heuristic value generated by the proposed fuzzy logic system. α, β, and γ are the effects on the pheromone, the heuristic, and the condition of checking the existing data that all three values are considered 1 in this method. Equation (6) shows the pheromone update in each repetition that $\tau(t)$ is the value of the previous pheromone and is considered one before traversing a node by the ants. The k denotes the number of traversed nodes.

$$\tau(t+1) = \tau(t) \times \frac{1}{k} \qquad (6)$$

The fuzzy system output is used for the quantification of the heuristic matrix. Selecting the precise fuzzy rules helps the algorithm to traverse the cloud data centers precisely.

Stage 1: Defining the variables and linguistic words (input information fuzzification): This method begins by fuzzification of the information related to the QoS of each cloud data center. This information includes parameters of positive and negative service quality. Indeed, these values are applied to this stage of the Fuzzy system as inputs. Information on the QoS is constructed based on Fuzzy Inference System (FIS). The Fuzzy function is determined using input parameters. FIS generates a replica value (RV).

Stage 2: Defining the fuzzy rules: Fuzzy rules based on different input parameters states are written at this stage. FIS generates an output value based on input different states by the FIS. The fuzzy rules are written using nested If-then. The Mamdani inference algorithm is one of the known algorithms for fuzzy inference. These systems can be used extensively in decision support systems because of their visual and interpretative nature. They also have a high power of expression and can be implemented in both forms of Multiple Input Multiple Output (MIMO) and Multiple Input Single Output (MISO). Mamdany controller is used for ease. Input and output parameters are expressed using linguistic parameters. The triangular membership function is used for input variables' linguistic values of Very-Low (VL), Low (L), Medium (M), High (H), and Very-High (VH). Output variables have five triangular membership functions for the VL to VH values, and the fuzzy system uses 25 rules shown in Fig. 2. The FIS input parameters' membership functions are presented in Fig. 3 and 4. As mentioned in the previous section, some QoS parameters are positive, and some are negative. In other words, the minimizer and the maximizer parameters can be expressed as positive and negative. Because the lower values for the positive parameters (close to zero) result in the optimal output value, and higher values for the negative parameters (close to one) lead to the optimal output value. Hence, we should find a trade-off value between these values to select the best answer that is performed using the Fuzzy rules set. Thus, we define PQ and NQ as positive and negative parameters, respectively, that are obtained by the sum of the normalized values of the quality parameters.



Fuzzy rules

1. If (PQ is VL) and (NQ is VH) then (Fitness is VH)
2. If (PQ is VL) and (NQ is H) then (Fitness is H)
3. If (PQ is VL) and (NQ is M) then (Fitness is M)
4. If (PQ is VL) and (NQ is L) then (Fitness is L)
5. If (PQ is VL) and (NQ is VL) then (Fitness is VL)
6. If (PQ is L) and (NQ is VH) then (Fitness is VH)
7. If (PQ is L) and (NQ is H) then (Fitness is H)
8. If (PQ is L) and (NQ is M) then (Fitness is M)
9. If (PQ is L) and (NQ is L) then (Fitness is L)
10. If (PQ is L) and (NQ is VL) then (Fitness is VL)
11. If (PQ is M) and (NQ is VH) then (Fitness is M)
12. If (PQ is M) and (NQ is H) then (Fitness is M)
13. If (PQ is M) and (NQ is M) then (Fitness is L)
14. If (PQ is M) and (NQ is L) then (Fitness is VL)
15. If (PQ is M) and (NQ is VL) then (Fitness is VL)
16. If (PQ is H) and (NQ is VH) then (Fitness is L)
17. If (PQ is H) and (NQ is H) then (Fitness is VL)
18. If (PQ is H) and (NQ is M) then (Fitness is VL)
19. If (PQ is H) and (NQ is L) then (Fitness is VL)
20. If (PQ is H) and (NQ is VL) then (Fitness is VL)
21. If (PQ is VH) and (NQ is L) then (Fitness is VL)
22. If (PQ is VH) and (NQ is H) then (Fitness is VL)
23. If (PQ is VH) and (NQ is M) then (Fitness is VL)
24. If (PQ is VH) and (NQ is L) then (Fitness is VL)
25. If (PQ is VH) and (NQ is VL) then (Fitness is VL)

Fig. 2. The proposed fuzzy rules.

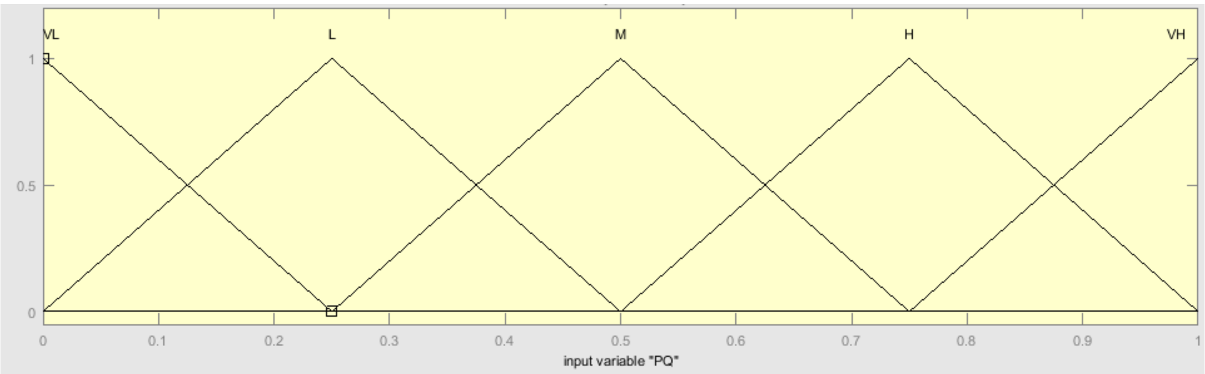


Fig. 3. Membership functions of the input variable (positive QoS parameter).

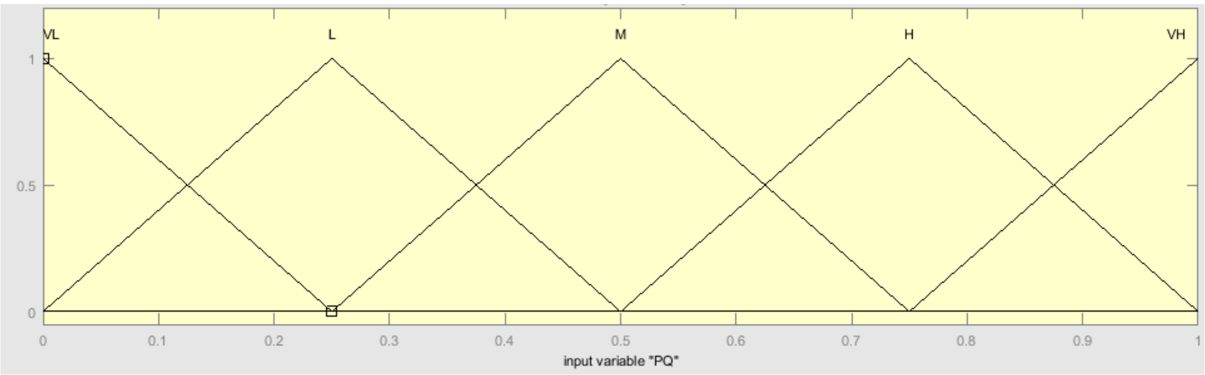

Fig. 4. Membership functions of the input variable (negative QoS parameter).

Stage 3: Defuzzification and analysis of the outputs: Defuzzification of the fuzzy values is performed in this stage after producing multiple fuzzy values according to the fuzzy rules and the input values. In other words, an interval in the fitting function is defined for and mapped to each of the fuzzy outputs in this stage. Fig. 5 illustrates the membership function of the fuzzy system's output variables.

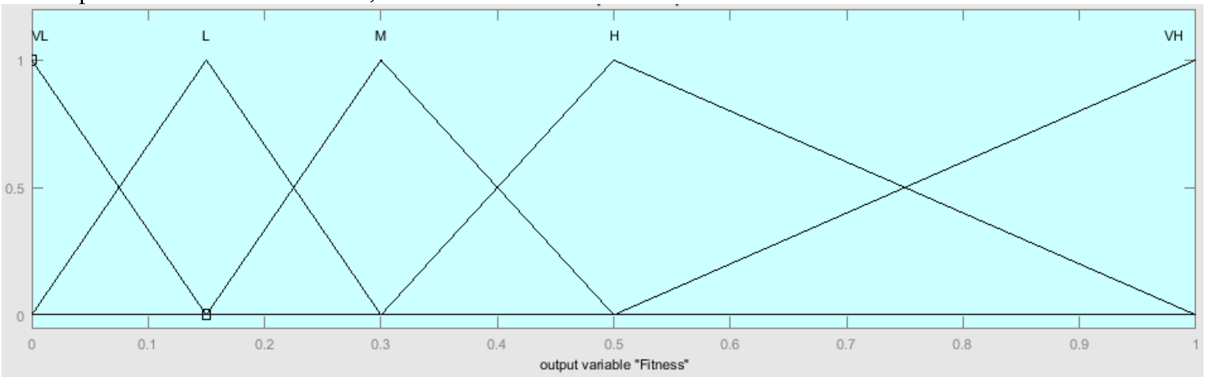

Fig. 5. Membership functions of the output variable

IV. Experimental Results

Based on the experimental setup, results demonstrate a clear improvement strategy for data elimination and data ambiguity. The significance of the system is demonstrated by conducting experiments using the MATLAB simulator.

First experiment: In this experiment we used the [11] data for evaluating the performance of the proposed method. Based on this experiment result, with increasing replication numbers, replication costs also increase. The value of the main and super data centers and their respective probabilities of file availability will be maintained in accordance with the probability of file availability and number of replicas in each data center. In each data center, the value of the super and main data centers and the corresponding probability of file availability will be determined based on the probability of file availability and the number of replicas. According to the Fig. 6-8, when the proportion parameters are set to the same value, the proposed method performs better than the alternative methods. Also, the proposed method demonstrates the medium level of cost efficiency that has been incorporated into the file system. Experimental results demonstrate that our proposed algorithm is capable of dynamically adapting to the preferences of the user.

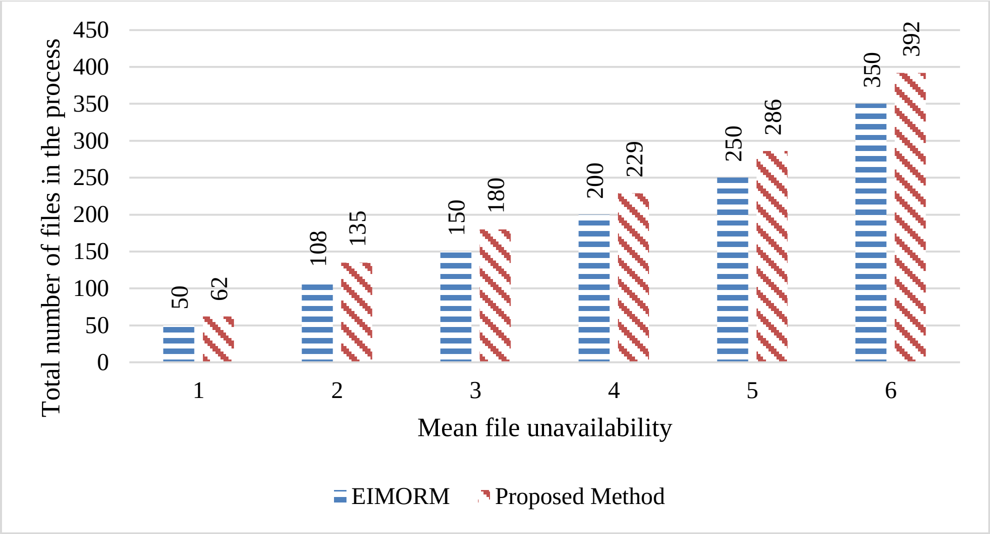

Fig. 6. Mean file unavailability.

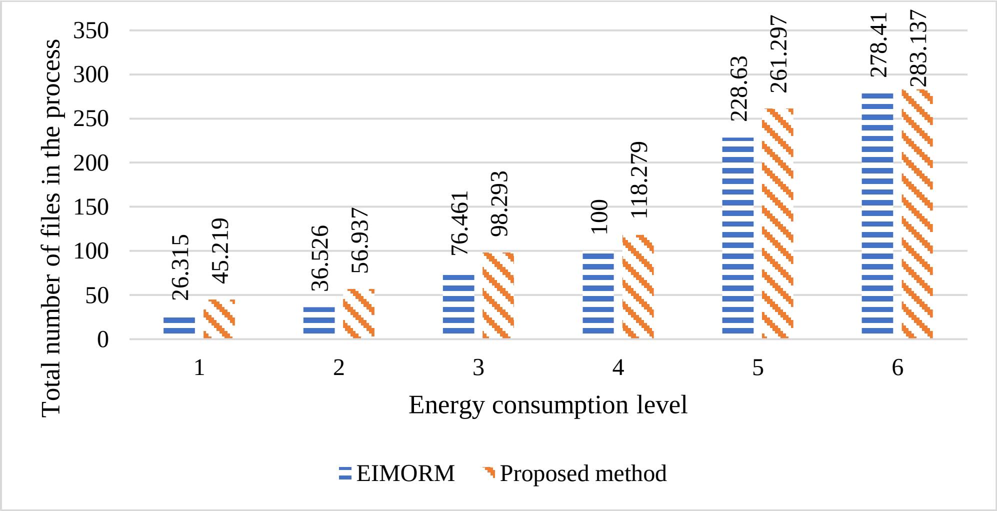

Fig. 7. Energy consumption level.

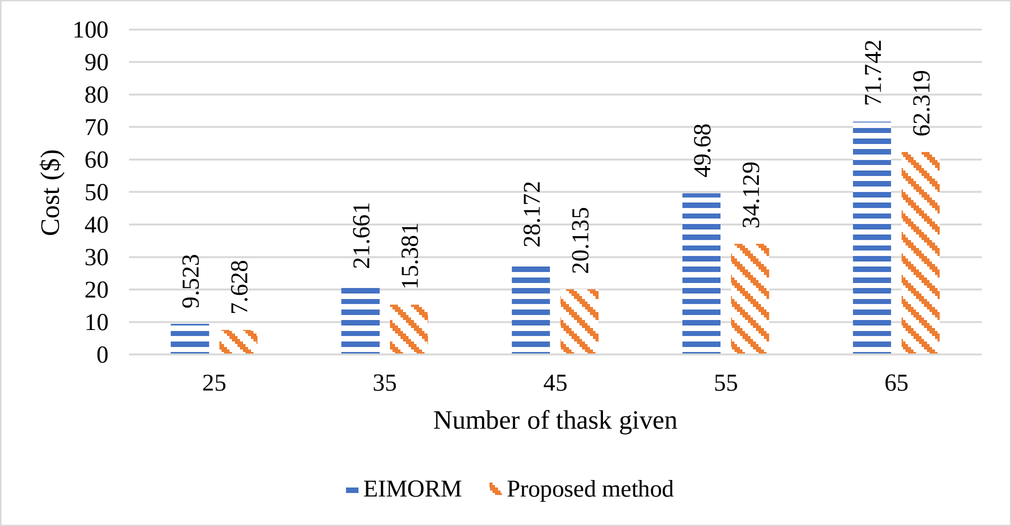

Fig. 8. Number of tasks given.

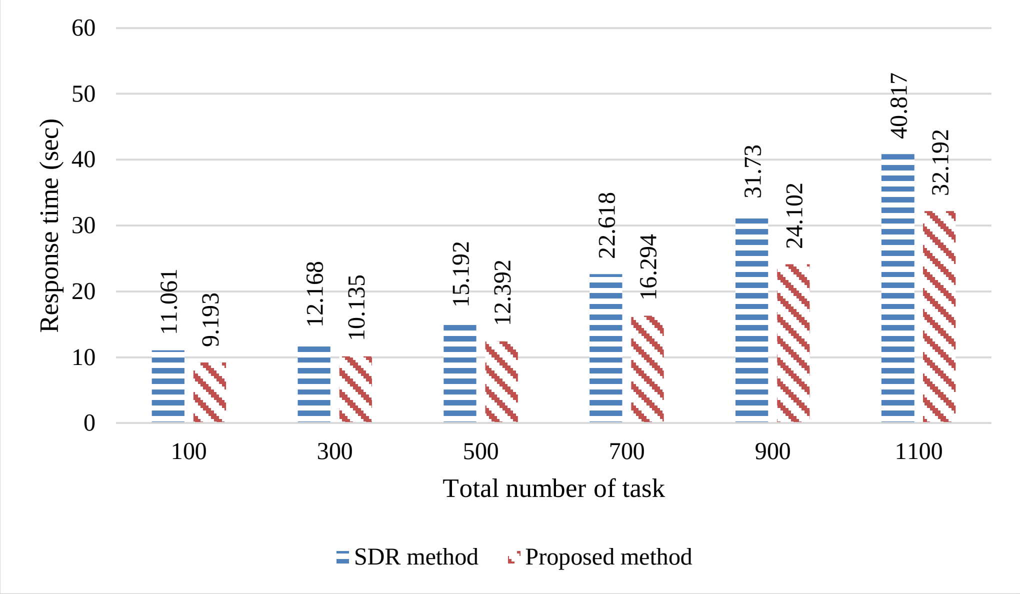

Fig. 9. Average response time with different number of tasks with Zipf distribution.

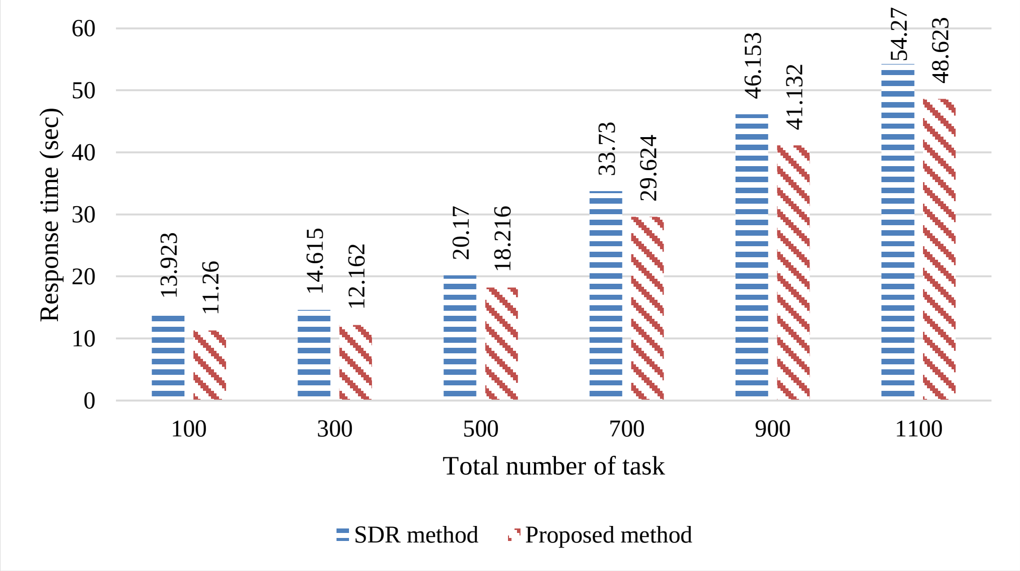

Fig. 10. Average response time with different number of tasks with uniform distribution.

Second experiment: In this experiment, we used the [30] data's and evaluated the proposed method in terms of average response time. Fig. 9 and 10 compare the average response time of the replication strategies for the uniform distribution and Zipf distribution. Our proposed method exhibited notably improved average response times compared to other strategies, indicating its effectiveness in reducing access latency for users.

The experimental results highlight the advantages of our proposed method over existing strategies for data replication in cloud computing. Our approach showcases superior performance and effectiveness by considering cost efficiency, response time, and dynamic adaptability. The comparisons with relevant literature reveal that our model provides a better solution to the data replication problem in cloud computing environments. The MATLAB-based simulations validate the feasibility and practicality of our proposed method. It is essential to acknowledge some limitations of our work. While our experiments demonstrate significant improvements, further investigations could explore the scalability of the proposed method for more extensive datasets and complex cloud environments. Additionally, incorporating real-world case studies and validating the results in a practical cloud computing environment would enhance the applicability of our approach.

V. Conclusion

Data replication constitutes one of the most important aspects of cloud computing, since it provides fast access to data, high availability, and data reliability. By maintaining all replicas available, the replicas can increase the probability of a system task being completed successfully if the requests and replicas are distributed reasonably. However, placing replicas in a highly scalable, virtualized, and large data center poses a greater challenge. To provide load balancing for cloud storage, decrease the response time of applications, and achieve cost-effective availability, this paper proposed a novel dynamic duplicate management in cloud storage systems based on the IACO algorithm and fuzzy logic system. According to the simulation results, our proposed method exhibits significant advantages over existing replication techniques. It accomplishes a remarkable 15% decrease in energy consumption, a 12% cost reduction, and an impressive 20% enhancement in response time. While our research has demonstrated substantial improvements, there remain opportunities for future investigations. Scalability testing under more extensive datasets and complex cloud environments will provide insights into the model's performance under varying scales. Additionally, incorporating dynamic workload management strategies and exploring hybrid optimization techniques could further enhance the algorithm's adaptability and convergence speed.

Improved Cat Swarm Optimization Algorithm for Load Balancing in the Cloud Computing Environment

Wang Dou*
Department of Engineering Management,
Sichuan College of Architectural Technology, Deyang 618000, Sichuan, China

Abstract—**Recently, cloud computing has gained recognition as a powerful tool for providing clients with flexible platforms, software services, and cost-effective infrastructures. Cloud computing is a form of distributed computing that allows users to store and process data in a virtual environment instead of a physical server. This is beneficial because it allows businesses to quickly scale up or down their computing capacity, reducing the need to invest in expensive hardware. As cloud tasks continue to grow exponentially and the usage of cloud services increases, scheduling these tasks across diverse virtual machines poses a challenging NP-hard optimization problem with substantial requirements, including optimal resource utilization levels, a short execution time, and a reasonable implementation cost. The issue has consequently been addressed using a variety of meta-heuristic algorithms. In this paper, we propose a new load-balancing approach using the Cat Swarm Optimization (CSO) algorithm in order to distribute the load among the various servers within a data center. Statistical analyses indicate that our algorithm is superior to previous research with regard to energy consumption, makespan, and time required up to 30%, 35%, and 40%, respectively.**

Keywords*—*Cloud computing; resource utilization; load balancing; optimization

I. Introduction

Cloud computing provides on-demand, convenient network access to a range of customizable computing resources, including services, applications, storage, and servers, instantly available by service providers without much effort on management's part [1]. A cloud computing model can be deployed in four ways: public, private, community, and hybrid, representing its underlying structure. As the name suggests, a public cloud is a cloud environment publicly accessible by many cloud customers without any restrictions placed upon them by the cloud service provider [2]. There are two scenarios in which a private cloud can be deployed. The cloud service provider may manage and maintain a private cloud exclusively within an organization. In the second scenario, the private cloud is deployed exclusively within a single organization and is managed and controlled by the organization. Regardless of the scenario, a private cloud is used privately by a single organization within a controlled environment. Community clouds are cloud environments that restrict access to organizations and cloud customers who share the same objectives [3]. Members of the community may jointly maintain and manage this type of cloud, or a separate cloud service provider may provide its services to accommodate this type of cloud. Hybrid clouds are cloud environments that combine multiple cloud deployment models. Public and private clouds may be combined in this manner. Organizations and customers often opt for this cloud environment due to security concerns, whereas less sensitive data may be stored in a public cloud environment [4].

Cloud computing is also comprised of three key services, Software as a Service (SaaS), Platform as a Service (PaaS), and Infrastructure as a Service (IaaS). IaaS is concerned with providing hardware as a service. IaaS provides users with the ability to rent servers, storage, and networks, while PaaS provides developers with an on-demand platform to develop, test, and host applications. Lastly, SaaS provides users access to applications hosted on the cloud, usually through a web browser. SaaS is the most popular service, offering users the most convenience and scalability. It eliminates the need to manage hardware and software and allows users to access software on demand [5]. Cloud computing brings together several key attributes, including measured service, rapid elasticity, resource pooling, broad network access, and on-demand self-service. In general, cloud services can be quantified through various metrics, such as bandwidth, data, and time. The cost of cloud computing services is usually determined by the resources used, and the cost savings can be significant compared to traditional IT solutions [6]. The level of elasticity in cloud computing refers to the ability of the system to adapt to changes in workloads through automated provisioning and de-provisioning and the availability of resources based on that. In a resource pooling model, virtual and physical resources are pooled to serve multiple consumers through a multi-tenant model, with resources allocated and reallocated dynamically according to consumer demand. Broad network access involves locating resources on the network and accessing them via different computing platforms and devices, including tablets, smartphones, laptops, and various types of computers. The concept of on-demand self-service involves allowing users to access data and resources in the cloud whenever they need to without requiring human assistance [7].

In order to improve the performance of a cloud, the workload must be balanced among the servers. Due to heavy processing tasks or numerous processes, some servers may be under high utilization. At the same time, some other servers may be idle. This situation would result in a decrease in the efficiency of the network, while the idle servers would waste the network's energy. It is also necessary to wait for the busy server to complete its in-process tasks before sending requests to an overloaded server [8]. The reason for this delay is that a server can only handle a limited number of requests simultaneously. This results in a decrease in service availability, which causes dissatisfaction. The availability of the service refers to the user's ability to access the desired service at any time. In this regard, load balancing can be used to optimize energy consumption and enhance performance. By transferring virtual machines from an overloaded host to an idle host without interruption, the workload is balanced between the servers, resulting in improved network efficiency [9].

In the domain of cloud load balancing, the significance of IoT, machine learning, artificial intelligence, meta-heuristic algorithms, association rule mining, deep learning, and feature selection lies in their collective potential to revolutionize resource allocation, performance optimization, and adaptability in cloud computing environments. The integration of IoT devices enables real-time data collection and monitoring of cloud resources, facilitating dynamic load distribution based on real-time demands. Machine learning and artificial intelligence techniques empower load balancing systems to autonomously learn from historical data and network patterns, enhancing their ability to predict resource demands and make informed load distribution decisions [10-12]. Meta-heuristic algorithms play a pivotal role in fine-tuning load balancing parameters and optimizing resource utilization for complex and dynamic cloud workloads [13]. Deep learning, with its capability to automatically extract intricate patterns from cloud data, enhances load balancing efficiency and enables the identification of performance bottlenecks and anomalies [14-16]. Association rule mining is of utmost significance as it allows for the identification of intricate relationships and dependencies among various cloud resources, enabling more efficient resource allocation and load distribution strategies to optimize the overall performance and utilization of the cloud infrastructure [17]. Feature selection techniques help identify the most relevant and discriminative cloud attributes, enabling streamlined load balancing processes and reduced computational overhead [18]. By harnessing the potential of these cutting-edge technologies, cloud load balancing achieves enhanced scalability, energy efficiency, and response times, ensuring optimal utilization of cloud resources, seamless user experiences, and the ability to adapt to changing cloud conditions effectively.

The proposed approach in this research aims to address the challenges of load balancing in cloud computing environments, which play a crucial role in optimizing resource utilization and enhancing overall system performance. Cloud computing offers a versatile and scalable platform, but efficient load distribution among servers is essential to avoid underutilization and overutilization issues. The motivations for this study stem from the need to overcome inefficiencies caused by imbalanced workloads, which can lead to reduced service availability and energy wastage. The potential benefits of the proposed approach are multi-fold. Firstly, by utilizing the Cat Swarm Optimization (CSO) algorithm, inspired by the foraging behavior of cats, the approach introduces a novel nature-inspired metaheuristic to the field of cloud load balancing. CSO's adaptive and efficient load distribution capabilities enable optimized resource allocation, resulting in reduced energy consumption, improved makespan, and enhanced task execution times. Secondly, by conducting a comprehensive comparative analysis with Q-Learning and MPSO, well-established load balancing methods, the research demonstrates the superiority of the proposed CSO-based approach, highlighting its potential to outperform existing techniques.

The rest of the paper is organized in the following manner. Section II reviews the related works in the field of cloud load balancing. Section III details the proposed method. Experimental results are reported in Section IV. Finally, Section V concludes the paper and suggests some hints for upcoming research.

II. Related Work

Muteeh, et al. [19] presented a multi-resource load-balancing mechanism using the Ant Colony Optimization (ACO) algorithm for cloud computing environments to ensure a well-load-balanced system and reduce cost and makespan time. Experimental results from benchmark workflows are used to validate the algorithm. The results indicate that the execution time and cost are reduced while the available resources are efficiently utilized by maintaining a balanced workload among them. Based on the mimicking behavior of flocks of birds, Mishra and Majhi [20] have developed a load-balancing method in which tasks are viewed as birds and VMs as food patches for the birds. The proposed approach was evaluated using a dataset (GoCJ) logged by Google in 2018 as part of cloudlet execution. This method is intended to improve the performance of the system by decreasing response time and maintaining overall balance. A comparison is made between the proposed technique and previously developed techniques. The proposed approach demonstrates an improvement in resource utilization and reduces the time required for tasks to be completed.

Mapetu, et al. [21] proposed a low-cost and low-complexity version of the PSO algorithm to schedule and balance cloud computing tasks. An objective function is defined that calculates the maximum difference in completion time between heterogeneous virtual machines. Constraints related to updating and optimization affect the objective function. Then, a particle position update strategy is devised with respect to load balancing. The experimental results indicate that the proposed algorithm performs better in task scheduling and load balancing than existing meta-heuristic and heuristic algorithms. Kruekaew and Kimpan [22] proposed an independent approach to cloud computing task scheduling that utilizes the Q-learning and Artificial Bee Colony (ABC) algorithms. ABC algorithm is improved through the use of reinforcement learning techniques. The proposed method aims to distribute workload among virtual machines proportional to resource utilization, cost, and makespan. The experimental results showed that the proposed algorithm was superior to the competitive algorithms with respect to throughput, imbalance degree, cost, and makespan. Sefati, et al. [23] employed Grey Wolf Optimization (GWO) algorithm to maintain proper load balancing based on resource reliability capability. The GWO algorithm attempts to identify unemployed or busy nodes first and, after discovering these nodes, determines the threshold and fitness function of each node. The experiments conducted in CloudSim have demonstrated that this approach has lower response times and costs than other methods. The algorithm is capable of efficiently optimizing the load balancing process which requires less time and fewer resources.

Due to the complexity and multitude of criteria involved in dynamic task allocation to heterogeneous resources, finding an optimal solution for every scheduling problem in real-time can be extremely challenging. In such cases, researchers often turn to meta-heuristic techniques, which aim to find near-optimal solutions within a reasonable timeframe while exhibiting outstanding performance for the task at hand. In this context, Mirmohseni, et al. [24] have proposed a hybrid method called Fuzzy Particle Swarm Optimization Genetic Algorithm (FPSO-GA). Their approach combines two powerful optimization techniques, namely fuzzy particle swarm optimization and genetic algorithms. By integrating these methods, the researchers seek to leverage the unique strengths of each technique and achieve better performance in dynamic task allocation.

Haris and Zubair [25] have introduced a dynamic load balancing algorithm called Mantaray modified multi-objective Harris hawk optimization (MMHHO). This algorithm utilizes a hybrid optimization approach, combining the benefits of two optimization algorithms: Harris Hawk Optimization (HHO) and Manta Ray Forging Optimization (MRFO). The aim of MMHHO is to address dynamic load balancing in cloud computing environments. The hybridization process involves updating the search space of HHO using MRFO, taking into account factors such as cost, response time, and resource utilization. By considering multiple objectives, the proposed algorithm seeks to enhance the performance of the system in terms of Virtual Machines (VMs) throughput, load balancing among VMs, and maintaining a balance among task priorities by adjusting the waiting time of tasks. The simulation results demonstrated that the MMHHO load balancing scheme outperforms other algorithms, highlighting its efficiency and effectiveness in achieving dynamic load balancing in cloud computing environments.

The reviewed approaches have demonstrated improvements in resource utilization, reduced response times, and overall load balancing efficiency. However, despite their advancements, there are certain gaps in these previous studies that present opportunities for further research. One of the gaps is the need for a more comprehensive comparison and evaluation of these load balancing techniques in diverse and dynamic cloud environments. While some studies have compared their proposed approach with existing techniques, there is a lack of a unified benchmark dataset or standardized evaluation criteria to assess their performance consistently across different cloud scenarios. Additionally, there is limited exploration of hybrid approaches that combine the strengths of multiple algorithms to achieve optimal load balancing results. Furthermore, existing studies predominantly focus on performance metrics such as response time, makespan, and resource utilization, but there is less emphasis on energy efficiency and cost-effectiveness. Considering the growing importance of sustainability and cost optimization in cloud computing, future research should explore load balancing methods that prioritize energy-efficient resource allocation and cost reduction.

III. Proposed Method

This section explains the Cat Swarm Optimization (CSP) algorithm. Then, the proposed load-balancing algorithm is described in detail. Finally, a detailed insight into the proposed algorithm is provided.

A. Cat Swarm Optimization Algorithm

Observations of cat behavior in the real world have driven the design of a novel swarm-based optimization algorithm. CSO mimics many of the behavior patterns of cats, such as their ability to move quickly, their ability to focus on a single target, and their tendency to explore their environment. CSO has been found to be effective in solving complex optimization problems. The CSO explains cats' behavior in two ways: by seeking and tracing. A local search is performed by the former, and a global search is conducted by the latter. In the seeking mode, the individuals are perturbed multiple times so that each can approach the local optimum. In the tracing mode, each cat traces the target at a certain speed and updates its position to match better the swarm's optimal position [26, 27]. Generally, the CSO algorithm consists of the following steps:

- Create N cats with a specified number of dimensions.
- Assign random velocities to each cat.
- Randomly place cats in seeking and tracing modes.
- Compute the fitness of all cats and keep track of the non-dominated cats.
- For each cat, if it is in seeking mode, execute seeking mode actions, else execute tracing mode actions and relocate it to its new location.
- If the termination condition is not satisfied, move to step 3, else stop.

B. Problem Statement

Cloud computing offers cloud services to cloud users, in which tasks are performed within a cloud environment. A cloud typically consists of a large number of Data Centers (DCs) called Physical Machines (PMs), each of which is equipped with a specific computing resource to fulfil the consumer's task. Each cloud consumer includes a variety of tasks to execute on virtual machines. The load balancing process assigns diverse users' tasks to virtual machines and constantly checks loads on virtual machines in the cloud computing environment. According to the time taken to complete each task, the VM load fluctuates as each task takes a different amount of time. Load balancing allocates tasks from an overloaded virtual machine to an underloaded one. A load balancing system in a cloud environment is illustrated in Fig. 1. Cloud services receive a wide range of requests from users, which requires setting up a dynamic environment for executing tasks. Load balancing strategies are applied when the load balancer receives requests from users. The load balancer selects the necessary virtual machines in response to a request. Load balancers can be configured to distribute consumer requests among multiple virtual machines. The Data Center Controller (DCC) is responsible for task management. The load balancer assigns the task to the appropriate virtual machine based on a load-balancing algorithm.

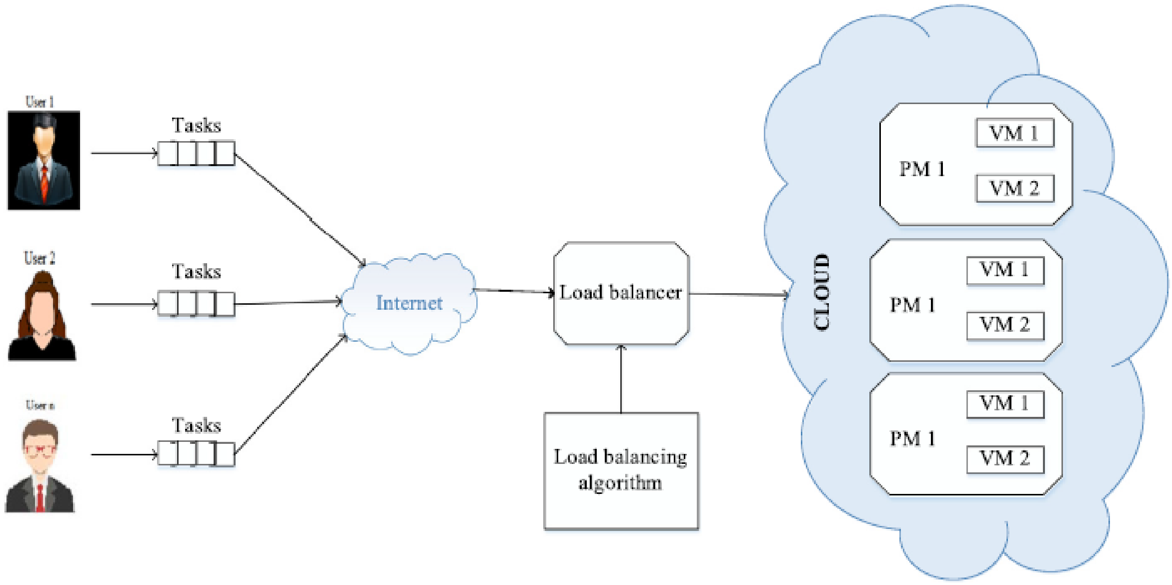

Fig. 1. An overview of cloud load balancing.

C. *CSO-based Load Balancing Method*

Load balancing is an excellent technique for reducing request waiting times and optimizing resource utilization. In this way, virtual machines can be prevented from becoming overloaded or underloaded, and load distribution can be uniformized among them. In the proposed method, cats represent solutions and attempt to achieve the target through iteration over different cats, striving to achieve the optimal solution. The load balancing problem is expressed according to the following terminology. The primary objective of the proposed method is to achieve optimal load balancing in the cloud. The considered cloud computing model comprises c number of PMs composed of m number of virtual machines. The suggested technique is to improve response time, resource utilization, and cost. Accordingly, Eq. 1 describes the objective function based on the above conditions, where w denotes the weight factor, and e represents the exponential function associated with each parameter. F1, F2, and F3 refer to objective functions for response time, resource utilization, and cost.

$$F = we^{(F1)} + we^{(F2)} + we^{(F3)} \qquad (1)$$

1) Response time: It is defined as the time interval between a task arriving in the system and being completed. In terms of load balancing, response time refers to the time required to allocate VMs to lower load conditions in response to a user request. There is an inverse relationship between this factor and the efficiency of the system. The optimal response time is determined by the shortest makespan time as follows.

$$F1 = Fin_t - Arr_t + TDelay \qquad (2)$$

In Eq. 2, Arr_t indicates a user demand's arrival time, Fin_t denotes a user demand's ending time, and TDelay signifies transmission delay.

2) Resource utilization: It refers to the utilization level of virtual machines. The goal is to achieve maximum resource utilization and minimize the makespan time. There is a reverse linear relationship between these two terms. Eq. 3 is used to calculate the average utilization of all virtual machines, where N indicates the total number of virtual machines and T_{VM_i} represents the time required to complete all tasks by a jth virtual machine.

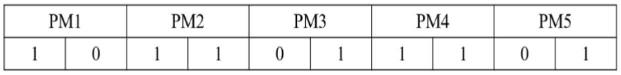
$$F2 = \frac{\sum_{i=1}^{N}(T_{VM_i})}{MS \times N} \qquad (3)$$

3) Cost: This indicator is calculated by Eq. 4. The cost varies in accordance with the tasks. The cost is determined by the complexity of the task and the resources needed. It is important to consider the cost when evaluating the effectiveness of a system. Optimizing the cost is essential for the success of any system.

$$F3 = \sum_{i=1}^{N}(VM_i^{time} \times VM_i^{cost}) \qquad (4)$$

In Eq. 4, VM^{cost} denotes the cost involved in running a virtual machine to perform a task, VM^{time} denotes the duration of the execution of the task, and N represents the number of tasks involved in the workflow.

Suppose a solution comprises five PMs, each containing two VMs. Initially, incoming tasks are distributed randomly among virtual machines. All virtual machines should be balanced in this regard. Overloaded PMs should be migrated to underloaded ones. Fig. 2 illustrates the initial solution. The CSO algorithm is used to optimize the solutions. The CSO algorithm involves two primary steps, seeking and tracing.



PM1		PM2		PM3		PM4		PM5	
1	0	1	1	0	1	1	1	0	1

Fig. 2. Initial solution.

4) Seeking mode: Cats are placed in this mode following the fitness calculation. In this process, the cats look around and adjust their position. In this way, cats search for the best opportunity to capture prey. The CSO algorithm employs four variables: self-position consideration (SP), counts of different dimensions (CD), seeking collection of selected dimensions (SR), and seeking memory pool (MP). The steps for seeking mode are described below;

- Cats duplicate their position seeking Memory Pool (MP).
- Using Eq. 5, the number of dimensions changed (DC) can be calculated for these duplicated positions.

$$S = (1 \pm SR \times R) \times Sn \qquad (5)$$

In Eq. 5, R is a random number ranging from 0 to 1, S represents the latest position, and Sn indicates the recent position.

- All cat positions are compared using fitness calculation values. All cats are set to 1 if they are identical. In any other case, we use the identifying probability Eq. 6, where FC_{min} refers to the minimum significance of fitness calculation, FC_{max} stands for the maximum assessment of fitness calculation, FC_i is the fitness calculation value of each cat, and P_v represents the probability of the latest cat.

$$P_v = \frac{|FC_i - FC_j|}{|FC_{max} - FC_{min}|} \quad 0 < i < j \qquad (6)$$

5) Tracing mode: In tracing mode, cats are recreated based on their positions in order to update their velocity in dimension d. Eq. 7 described the updating of velocity in tracing mode, where Pn,d is the current location of the cat, Pbest,d is the cat's location with the best result, k is a random number between 0 and 1, and r represents a constant.

$$Vn, d = Vn, d + k \times r(Pbest, d - Pn, d) \qquad (7)$$

IV. Experimental Results

This section analyzes the efficiency of the suggested method in light of the simulation results. In order to conduct the cloud computing experiment, the CloudSim simulator was installed on a system configured with an Intel Core i5 CPU, 4 GB RAM, and Windows 8 operating system. Performance has been evaluated in terms of makespan, energy consumption, idle time of tasks, response time of tasks, and number of tasks migrated. Table I presents the simulation environment of the experiments.

TABLE I. Simulation Parameters

Type	Count	Parameter	Value
VM	300	Bandwidth	1 GB/s
		Processor speed	9725MIPS
		Memory	0.5 GB
		VM monitor	Xen
Datacenter	1	OS	Linux
		VM monitor	Xen
		Cost Per Memory	0.05
		Arch	X86
		Cost	3.0
Host	4	Bandwidth	15 GB/s
		MIPS	117.720
		Storage	4 TB
		RAM	8 GB
		Cores	5
		VM monitor	Xen

Fig. 3 and 4 show the energy consumption during load balancing for three different algorithms: Q-Learning, MPSO, and CSO. According to these figures, CSO consumes the least amount of energy during load balancing in comparison to other algorithms. Makespan assesses the performance in another parameter. It measures users' response time for specific tasks in cloud computing, and the response time determines the quality of service. Consequently, the service provider is able to provide the client with a high-quality of service. Fig. 5 and Fig. 6 present a comparison of algorithms according to their makespan under various task and virtual machine configurations. According to these figures, CSO performed significantly better than both Q-Learning and MPSO. Therefore, CSO was able to achieve stability and load balance in a highly efficient manner.

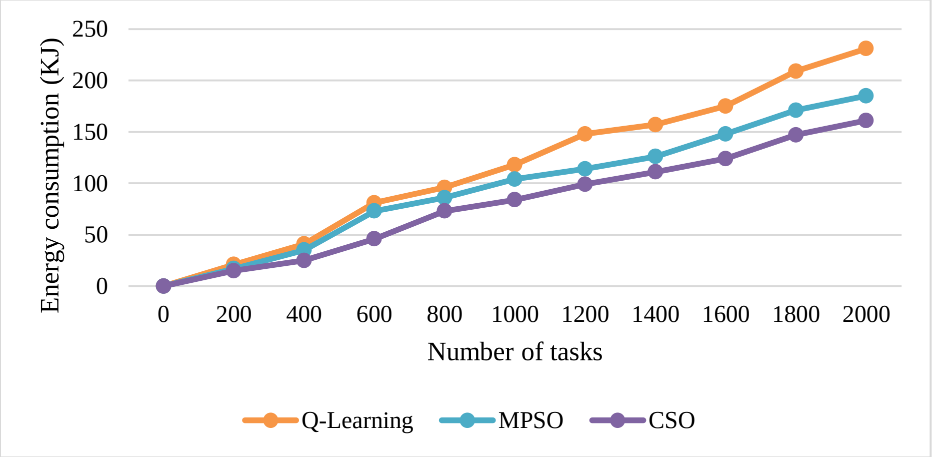


Fig. 3. Energy consumption comparison vs. number of tasks.

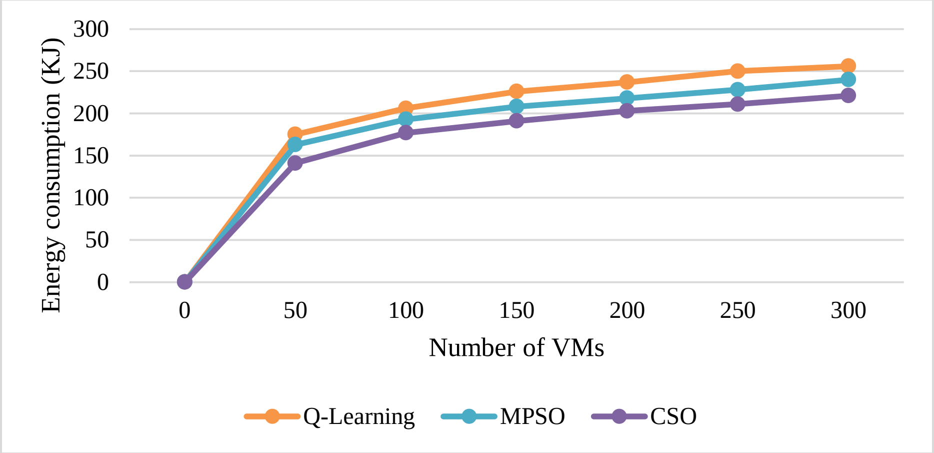

Fig. 4. Energy consumption comparison vs. number of VMs.

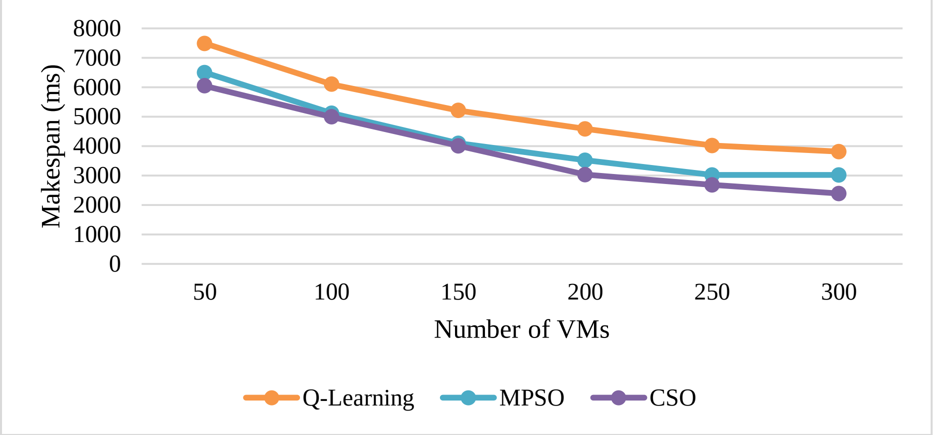

Fig. 5. Makespan comparison vs. number of VMs.

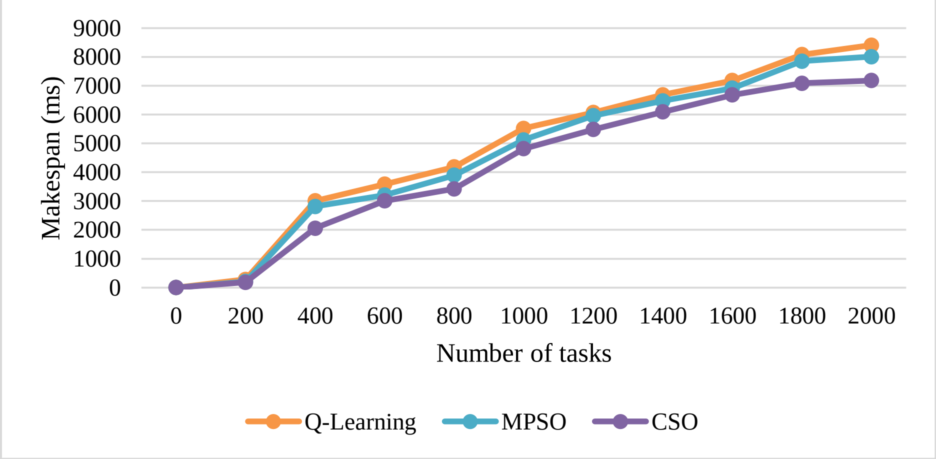

Fig. 6. Makespan comparison vs. number of tasks.

A longer waiting time can be expected if only one task can be executed simultaneously while other tasks are waiting in the ready queue. By increasing the processing power of VMs and allocating more VMs, the waiting time for all tasks will be reduced. Fig. 7 and 8 illustrate the idle time of tasks and the processing time of VMs, respectively. Based on Fig. 7, CSO exhibits a lower idle time than Q-Learning and MPSO for all tasks. Fig. 8 illustrates the processing power of VMs. The processing power has been increased from 200 MIPS to 2500 MIPS, resulting in a reduction in processing time from 9400 ms to 100 ms. Based on the results of the analysis, it can be concluded that CSO balances the load within the cloud network in an effective and efficient manner.

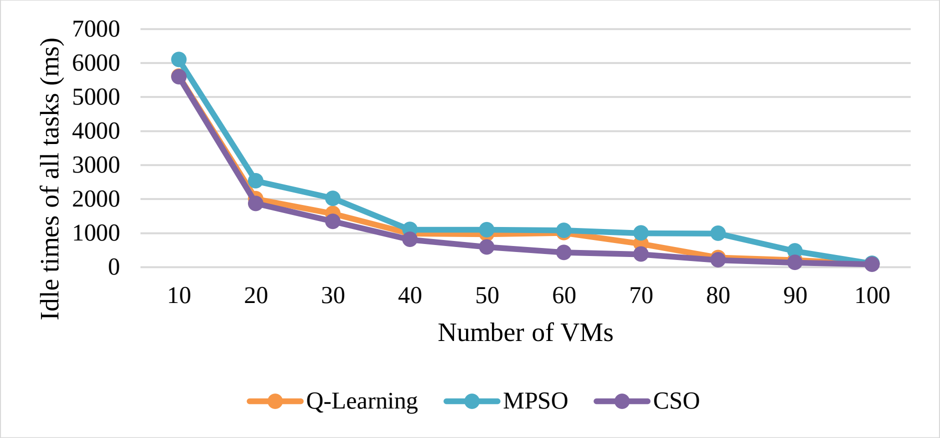

Fig. 7. Idle time of tasks vs. number of tasks.

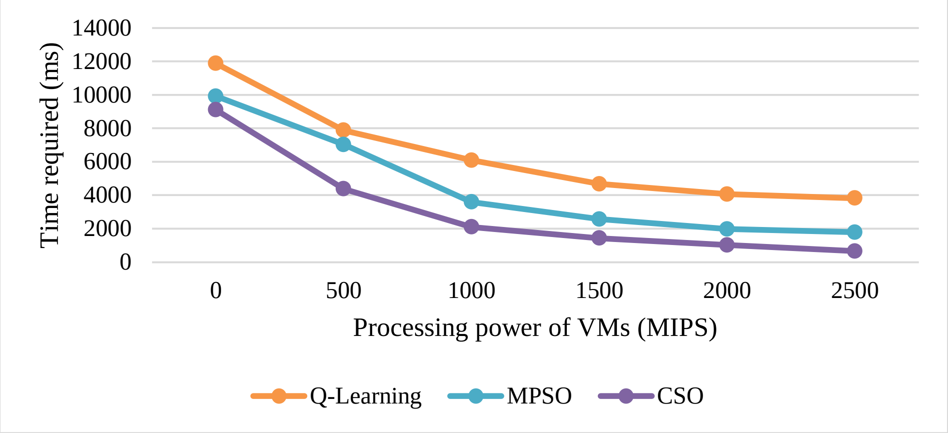

Fig. 8. Time required vs. processing power of VMs.

The presented experimental results demonstrate the superior performance of the proposed CSO-based approach in terms of energy consumption, makespan, and task idle time. CSO's ability to optimize load distribution and achieve efficient resource utilization makes it a promising solution for load balancing in cloud computing environments. The findings support the significance of the proposed method in enhancing the quality of service and overall cloud network performance. The comprehensive analysis of the simulation results reaffirms the potential benefits of adopting CSO for load balancing in cloud computing environments. However, further investigations and real-world validations may be necessary to ascertain its scalability and effectiveness in diverse and dynamic cloud infrastructures.

V. Conclusion

In recent years, cloud computing has experienced an upsurge of interest, primarily due to its usefulness and relevance to contemporary technological trends. Globally, it provides better computational services to its clients by being highly customizable. With the increase in demand for higher processing power, large amounts of data will put a considerable strain on the cloud computing environment. As a result, the need for an efficient scheduling algorithm for cloud computing tasks has become increasingly important. Cloud tasks continue to grow exponentially, and the number of cloud users rapidly increases, making scheduling and balancing these tasks among heterogeneous virtual machines a challenging NP-hard problem with significant constraints, including high resource utilization, quick scheduling, and low implementation cost. This paper proposed a novel load-balancing mechanism using the CSO algorithm, which distributes load among systems in a data center. As demonstrated by simulation results, our algorithm exhibits superior performance to previous research in terms of energy consumption, makespan, and time required by approximately 30%, 35%, and 40%, respectively. While the proposed CSO-based load balancing approach demonstrates promising results, it is essential to acknowledge its limitations. The scalability and adaptability of CSO in highly dynamic and large-scale cloud environments require further investigation. Additionally, the algorithm's performance might be sensitive to parameter settings, emphasizing the importance of proper tuning for optimal results.

Automatic Fraud Detection in e-Commerce Transactions using Deep Reinforcement Learning and Artificial Neural Networks

Yuanyuan Tang*
School of Economics and Management, Tianjin Vocational Institute, Tianjin 300410, China

Abstract*—Fraud is a serious issue that has plagued e-commerce for many years, and despite significant efforts to combat it, current fraud detection strategies only catch a small portion of fraudulent transactions. This results in substantial financial losses, with billions of dollars being lost each year. Given the expected surge in the volume of online transactions in the upcoming years, there is a critical need for improved fraud detection strategies. To tackle this problem, the article proposes a deep reinforcement learning approach for the automatic detection of fraudulent e-commerce transactions. The architecture's policy is built on the implementation of artificial neural networks (ANNs). The classification problem is viewed as a step-by-step decision-making procedure. The implementation of the model involves the use of the artificial bee colony (ABC) algorithm to acquire initial weight values. After that, in each step, the agent obtains a sample and performs a classification, with the environment providing a reward for each classification action. To encourage the model to concentrate on detecting fraudulent transactions precisely, the reward for identifying the minority class is higher than that for the majority class. With the aid of a supportive learning setting and a specific reward system, the agent ultimately determines the best approach to achieve its objectives. The performance of the suggested model is assessed utilizing a publicly available dataset contributed by the Machine Learning group at the Université Libre de Bruxelles. The experimental outcomes, determined using recognized evaluation measures, indicate that the model has attained a high level of accuracy. As a result, the suggested model is considered appropriate for identifying deceitful transactions in e-commerce.

Keywords*—*Fraud detection; reinforcement learning; artificial neural network; artificial bee colony; imbalanced classification

I. Introduction

Fraud refers to intentional dishonesty or deception by an individual or group of people with the aim of obtaining financial benefits. As a result of the increase in online transactions such as shopping and insurance claims, there is a new level of fraudulent activity that individuals and businesses must be wary of. Reports indicate that the increase in fraudulent activities in e-commerce transactions during the first quarter of 2018 was significantly higher than the growth rate of e-commerce transactions in 2016. The e-Commerce Fraud Index revealed that in 2017, account takeover fraud in online department stores rose to 0.23%, a significant increase from 0.06% in 2016 and accounting for over 10% of fraud losses. While credit card fraud only makes up 0.1% of all card transactions, fraudulent transactions involving large sums of money have led to significant financial losses. However, even with the surge in credit card transactions in recent times, the ratio of fraud cases has not changed [1].

Numerous institutions and industries have invested significant resources in developing efficient techniques to combat fraudulent activities by leveraging advanced technologies, especially machine learning [2, 3]. As a result of these endeavors, a plethora of solutions have been developed that can differentiate between valid credit card transactions and those that are fraudulent without human intervention. Irrespective of the method employed, there are certain shared issues that can hinder its effectiveness. The prevalent issue is the imbalanced distribution of training data, a feature of past transactions. This creates various challenges, such as overfitting, and results in low-accuracy classifiers used. Imbalanced classification is a common challenge in machine learning, where one class has significantly more data compared to other classes. Due to this disproportion, recognizing minority specimens becomes difficult because of their infrequency and randomness, resulting in a poorer outcome [4-6]. The problem of imbalanced classification in machine learning can be tackled using one of two methods, namely the data level and algorithmic level [7, 8]. At the data level, balancing the class distribution can be achieved through various methods like oversampling and under-sampling. Oversampling generates new samples by linear interpolation between adjacent minority samples, while under-sampling removes some majority examples utilizing the nearest neighbor algorithm [9]. However, these methods risk overfitting and loss of significant information [10, 11]. At the algorithmic level, techniques such as cost-sensitive learning, decision threshold adjustment, and ensemble learning can be applied to increase the significance of the minority class. Ensemble learning trains multiple sub-classifiers and combines them to improve performance, while cost-sensitive learning assigns varying costs to incorrect classification, with the misclassification of the minority class given a higher cost. Threshold adjustment techniques change the decision-making threshold during testing. Some proposed deep models for imbalanced data classification utilize innovative loss functions that consider errors in classifying minority and majority groups [12]. These techniques can retain the specific attributes of a dataset that has imbalanced classes or clusters while also safeguarding the margins between samples from different classes or clusters [5, 13, 14].

While traditional machine learning approaches use a rigid feature extraction strategy that often leads to poor generalization ability, long processing time, and low accuracy, deep learning algorithms have emerged as promising alternative for classification tasks [8]. With their layered structure, deep learning algorithms can capture complex patterns and relationships within data, making them highly adept at learning high-level features. One such popular algorithm is the Multilayer Perceptron (MLP), a universal approximation that excels at handling nonlinear problems. Originally developed to solve the XOR problem, MLP has since been successfully applied to various combinatorial optimization problems, including pattern recognition, classification, image processing, and linear and nonlinear optimization. MLP processes input signals by passing them through interconnected layers of processing nodes, each of which receives a set of input values, sums them, and then applies an activation function to determine its output, mimicking the behavior of a human neuron. MLP, through its layers of interconnected nodes, is capable of acquiring intricate associations between the input and output variables. Additionally, the lack of interconnections between nodes in the same layer helps reduce computational complexity, making processing more efficient [15].

The paper presents a novel approach to detecting fraud in e-commerce transactions by combining the ABC algorithm [16] and reinforcement learning. The model being proposed views the classification task as a process of making sequential decisions, which is analogous to playing a game of guessing. In this game, the agent is presented with a training instance and has to classify it using a policy. The agent's performance is evaluated based on the rewards received for correct and incorrect classifications, with a higher reward assigned to correctly identifying the minority class. The main goal of the agent is to achieve the highest possible cumulative reward by correctly identifying the largest number of samples. This technique has the potential to overcome the challenges of imbalanced classification discussed earlier in the paper. The suggested model frames the classification issue as a series of sequential decisions, enabling the agent to acquire knowledge and adjust its strategy according to responses from the surroundings. The use of reinforcement learning further enhances the agent's ability to explore and exploit the search space efficiently. This article makes three significant contributions. 1) The approach taken to address the challenge of imbalanced classification is to view the prediction problem as a sequential decision-making process and a reinforcement learning-based algorithm is introduced. 2) An encoding method based on the ABC algorithm was devised to obtain the best initial value instead of assigning weights randomly, and 3) the proposed model's performance was evaluated through experiments, and a comparison was made between this model and other methods that use random weight initialization, which encounter challenges in dealing with imbalanced classification.

The format of the article is organized in the following manner. In the second section, the paper presents an overview of existing research in the relevant area. In the third section, a succinct explanation of the ABC algorithm and its functioning is presented. In the fourth section, the model proposed in the study is introduced, and in the fifth section, the evaluation criteria, dataset, and analysis of the results are presented. The concluding section of the paper discusses the study's findings and draws conclusions, as well as outlining potential avenues for future research.

II. Related Work

Initially, fraud detection was associated with the utilization of Information Retrieval or the Rule-based method. The details of each transaction were scrutinized by hand, and decisions were made concerning fraudulence or reliability based on strict criteria. Each transaction causes the development of a feature vector [2]. A feature vector is composed of various attributes and parameters such as Transaction identifier, Transaction amount, Cardholder data, Site of the transaction, and Time of transaction. This vector is assigned points according to the scoring criteria determined by human investigators. As an example, if a transaction has taken place on another continent within an hour, then the fraud score would be 0.95 [17]. This system depends on the addition of more and more regulations in order to remain one step ahead of scammers that seek to exploit and bypass current rules.

Big Data Analytics, through the use of machine learning, is more wide-reaching, economical, precise, and automated [18, 19]. This powerful combination of Big Data and machine learning has opened up new possibilities for businesses and organizations across various industries, enabling them to extract valuable insights, make data-driven decisions, and optimize their operations like never before. One of the remarkable applications of Big Data Analytics is the construction of sophisticated models capable of forecasting, classifying, or estimating the authenticity of transactions, especially when it comes to identifying fraudulent activities [20]. Such models, empowered by the wealth of data collected from digital datasets containing numerous transactions, have revolutionized fraud detection methodologies. By leveraging machine learning algorithms and tapping into large and diverse datasets, these data-informed models have achieved impressive results in accurately differentiating between genuine and fraudulent transactions. The abundance of data provides these models with a rich source of information, enabling them to discern complex patterns and anomalies that would be challenging for traditional rule-based systems to detect. The training process of these models involves exposing them to vast quantities of labeled data, where each transaction is tagged as either authentic or fraudulent. Through iterative learning and optimization, the models adapt and fine-tune their parameters, continuously improving their performance and generalization abilities. Different data-driven models have emerged in the realm of Big Data Analytics, each employing a variety of methods and algorithms tailored to specific use cases and data characteristics. These models can include traditional machine learning approaches like SVM, Random Forest, and Gradient Boosting, as well as state-of-the-art deep learning techniques like Neural Networks and Transformer-based models. The choice of model and method depends on the nature of the data, the complexity of the problem, and the desired level of interpretability [21, 22].

The commonly utilized approach involves using machine learning techniques to create a model based on the data. This data-driven model is generally more versatile and dependable, enabling it to achieve high accuracy levels, often reaching up to 87% or even higher, depending on the specific problem and dataset. The success of machine learning models can be attributed to their ability to uncover complex patterns and relationships within the data that might not be easily discernible through traditional rule-based systems. Among the well-known machine learning algorithms, several have proven to be highly effective in various domains. K-means is a popular clustering algorithm used for grouping data points into clusters based on their similarity, making it useful for segmentation and pattern discovery tasks. Regression Analysis, on the other hand, is widely employed for predicting numerical values and understanding the relationships between variables. SVM have been extensively utilized in both classification and regression tasks. SVM is particularly suitable for binary classification problems, and with appropriate kernel functions, it can handle complex decision boundaries efficiently. Similarly, Random Forest and Decision Trees are powerful ensemble methods that can be applied to both classification and regression tasks, providing robustness and reducing overfitting [23]. Recent advancements in deep learning have introduced breakthroughs in the field of fraud prevention and detection. Recurrent Neural Networks (RNNs) and Convolutional Neural Networks (CNNs) have demonstrated significant potential in carrying out diverse prediction and classification tasks, including those related to fraud detection. RNNs are well-suited for sequential data, making them ideal for processing time-series data or textual data with temporal dependencies. On the other hand, CNNs excel at processing grid-like data, such as images and other structured representations, and are capable of automatically learning relevant features from the input. When applied to fraud prevention and detection, RNNs can effectively capture temporal patterns in transaction histories and user behaviors, enabling them to identify unusual or fraudulent activities. CNNs, on the other hand, can be employed for tasks like image-based fraud detection, where they can learn to recognize visual patterns associated with fraudulent behavior [24].

The approach of supervised machine learning involves first training the learning algorithm with labeled data and then evaluating its accuracy on a test set [25]. Labeled data is a prerequisite for using the supervised learning method to train a classifier. This labeling procedure is both time-consuming and costly. Various classifiers, such as one-class SVM [26], decision tree [27, 28], random forest [29, 30], and logistic regression [8], have shown a good level of accuracy in their performance. SVM can be used for solving both regression and classification problems [15]. One-class SVM is especially useful in scenarios where the data distribution is imbalanced, which is similar to the particular issue. The system gains the ability to deduce the characteristics of the dominant class while simultaneously being able to identify anomalies or the less prevalent class. Decision trees are structures resembling flow charts that enable the classification of input data points or the prediction of output based on an input. The Random Forest technique involves a strong methodology that incorporates numerous decision trees, which are subsequently combined to produce their outputs.

Unsupervised learning has been widely adopted in various domains and finance due to the flexibility and cost-effectiveness it offers [31]. In contrast to supervised learning, unsupervised learning methods can derive insights from a dataset without the need for labeled data. This makes it a useful tool in situations where data labeling is expensive or impractical, especially when dealing with large datasets. With the growth of big data, unsupervised learning has become increasingly important as it can help us to identify patterns, anomalies, and hidden structures in large datasets that may not be easily noticeable through manual inspection. Nearest neighbor, clustering, and outlier detection are three commonly used unsupervised learning algorithms for fraud detection [32-35]. The nearest neighbor algorithm determines the authenticity of a transaction by measuring the distance between it and its nearest neighbor in the dataset [36]. This allows for the identification of data points that are considered to be abnormal or fraudulent [37]. Clustering algorithms group similar data points together, which is particularly useful for identifying groups of transactions that exhibit similar behavior or characteristics. Peer group analysis is one application of clustering algorithms used in fraud detection [38, 39]. Outlier detection algorithms aim to locate data points that deviate from the norm in a dataset, which can be valuable in detecting fraudulent transactions [1, 40]. Credit fraud detection often deals with imbalanced data, where the number of genuine transactions is significantly larger than the number of fraudulent transactions. This can result in learning algorithms underperforming as they tend to prioritize accuracy on the majority class. Therefore, resampling methods such as oversampling or undersampling need to be used to balance the data before training the learning algorithm.

Oversampling pertains to generating artificial data points for the underrepresented class, whereas undersampling entails reducing the number of data points in the overrepresented class [12]. Careful consideration must be given to the choice of resampling method, as oversampling can lead to overfitting while undersampling can lead to loss of information. One challenge in fraud detection is the delay caused by the need for human investigators to label transactions before they can be used for training the algorithm. This delay is known as verification latency and can be reduced by automating the labeling process through the use of semi-supervised or active learning approaches [41]. Oversampling pertains to generating artificial data points for the underrepresented class, whereas undersampling entails reducing the number of data points in the overrepresented class [42]. Active learning is a method that entails selecting the most informative data points for labeling in an iterative process, which can decrease the required amount of labeled data [43, 44]. Lastly, it is essential to consider the issues of concept change over time and biased sample selection when creating a machine learning algorithm for credit fraud analysis [45]. Concept drift refers to the tendency of transaction behavior to change over time, which can lead to the algorithm becoming outdated and inaccurate [46]. Sample selection bias occurs when the distribution of data used for training and testing the algorithm is different, which can lead to the algorithm performing poorly on unseen data [47].

III. Artificial Bee Colony Algorithm

ABC algorithm is a type of optimization algorithm that draws inspiration from the foraging behavior of honeybee colonies [48, 49]. The procedure emulates the nourishment-gathering demeanor of honeybees and employs a populace-centered strategy to explore the supreme resolution to a specified enhancement predicament. In ABC, the populace of bees is segregated into three factions: occupied bees, spectator bees, and scout bees. The assignment of the occupied bees is to probe the resolution expanse and unearth advantageous resolutions. The onlooker bees assess the solutions discovered by the employed bees according to their quality and conduct additional evaluations. The scout bees explore new regions of the search space that have not been explored by the employed and onlooker bees. ABC is based on the idea of random search, where candidate solutions are generated randomly in the search space. The quality of the solutions is evaluated using a fitness function that measures how well the solution performs on the optimization problem. ABC iteratively generates new candidate solutions by modifying the existing solutions based on the foraging behavior of honeybees. ABC has been successfully applied to various optimization issues in different fields, including engineering, economics, and bioinformatics. It has been shown to be efficient and effective in finding optimal or near-optimal solutions in many real-world optimization issues. The optimization process of ABC is summarized below:

1) Initialization: The algorithm starts by randomly generating an initial population of candidate solutions (employed bees) within the search space.

2) Employed bee phase: Each employed bee independently explores the search space by modifying its solution using a neighborhood search algorithm. The new solution is evaluated using a fitness function and compared to the current solution. If the new solution is better, it replaces the current solution. This process is repeated for all employed bees.

3) Onlooker bee phase: The employed bees communicate with the onlooker bees by performing a waggle dance to indicate the quality of their solutions. The onlooker bees select the solutions based on the quality of the dance and evaluate them using the fitness function. The onlooker bees choose the solutions with higher fitness values and use them for further exploration.

4) Scout bee phase: Some of the employed and onlooker bees become scout bees with a small probability. These scout bees randomly explore new solutions in the search space that have not been explored by the other bees.

5) Update: The algorithm updates the population by replacing the worst solutions with new solutions generated by the employed and scout bees. The algorithm terminates when a stopping criterion is met, such as reaching a maximum number of iterations or a satisfactory solution is found.

6) Output: The output of the optimization process is the best solution found by the algorithm.

IV. Model Architecture

According to Fig. 1, the proposed model encompasses ABC and RL for fraud detection.

A. Pre-training

In this stage, the suggested algorithm incorporates a mutual learning-based ABC technique to initialize the weights of the MLP. The organization of these weights into a vector mirrors the bees' positions in the ABC algorithm. This process of converting the weights into a vector is commonly referred to as encoding. Finding the optimal layout for this encoding presents a challenging task, but researchers have diligently conducted numerous experiments to develop the most effective encoding strategy. As shown in Fig. 2, all the bias terms and weights within the MLP are carefully arranged into a vector, essentially forming a potential solution within the ABC algorithm. Each element of this vector corresponds to a specific weight or bias term in the neural network. By treating the vector as a candidate solution, the ABC algorithm can explore and refine its position in the solution space through the process of iterative optimization. The mutual learning-based approach in the ABC algorithm plays a crucial role in this phase. As bees in the colony share information and collectively learn from one another, the weights in the vector evolve based on the knowledge gathered from different bees' experiences. This collaboration allows the ABC algorithm to efficiently navigate the vast solution space and converge towards more promising weight configurations. The process of encoding and using a vector representation of weights provides several advantages. Firstly, it enables a seamless integration of the ABC algorithm with the neural network training process, effectively initializing the model for further optimization. Additionally, the vector-based representation facilitates the implementation of various search and optimization strategies, making it easier to explore and exploit different regions of the solution space. With the weights and bias terms encoded in a vector, the ABC algorithm operates in a population-based manner, emulating the collective intelligence of bees in a real colony. The population of candidate solutions evolves over iterations, and through the exploration and exploitation of different weight configurations, the algorithm progressively refines the MLP's parameters, ultimately leading to improved performance and convergence towards better solutions.

The quality of a candidate solution is determined by defining the fitness function as

$$Fitness = \frac{1}{\sum_{i=1}^{N}(y_i - \tilde{y}_i)^2} \tag{1}$$

where N represents the total number of training samples, with y_i and $\tilde{y}_i$ denoting the i-th target and model-predicted output, respectively.

B. *Classification*

The issue of imbalanced classification arises when there is a significant difference in data volume between the two classes. To tackle this challenge, we have employed a sequential decision-making process utilizing an RL approach. The RL approach involves an agent striving to maximize its score through effective decision-making and actions within the environment, eventually leading to the discovery of an optimal policy. In the proposed framework, at every time step, the actor acquires an exemplar from the collection and executes a categorization duty. Afterward, the actor obtains prompt responsiveness from the milieu, where a precise categorization yields an affirmative grade, whereas an erroneous one produces a pessimistic grade. This feedback mechanism serves to guide the agent towards making more informed decisions and improving its performance over time. The RL algorithm plays a central role in the approach as it seeks to achieve the optimal policy by maximizing the cumulative rewards obtained throughout the decision-making process. The goal is to find the most favorable strategy that results in the highest rewards and, ultimately, the best classification performance. To further illustrate the intended configurations, we utilize a dataset containing N samples, each with corresponding labels. These samples are represented as $D = \{(x_1, y_1), (x_2, y_2), (x_3, y_3), \dots, (x_N, y_N)\}$, where x_i denotes the i-th image, and y_i represents its corresponding label. These configurations are vital for setting up the environment in which the RL agent operates, guiding it towards achieving optimal classification results through the decision-making process. The following describes the intended configurations:

- Policy π_θ : Policy π is a mapping function that associates states (S) with actions (A). In this context, π_θ (s_t) denotes the action taken in a specific state s_t. The method employing the classifier with weights θ is denoted as π_θ.

- State s_t: An instance x_t extracted from the dataset, D, is associated with a corresponding state s_t. The first data point x_1 represents the initial state s_1. To avoid the model from learning a fixed sequence, D is randomized in each episode.

- Action a_t: The action a_t is performed to predict the label x_t, with binary classification, and the available choices for a_t are limited to either 0 or 1. In this context, the minority class is represented by 0, while the majority class is denoted by 1.

- Reward r_t : The reward is contingent on the outcome of the action performed. Upon performing the correct classification, the agent receives a positive reward, whereas an incorrect classification results in a negative reward. The bonus value needs to vary for each class. Appropriately calibrated rewards can significantly improve the model's performance by ensuring that the reward level corresponds to the action taken. In this study, the reward for an action is defined using the following formula:

$$r_t(s_t, a_t, y_t) = \begin{cases} +1\,, a_t = y_t \text{ and } s_t \in D_S \\ -1\,, a_t \neq y_t \text{ and } s_t \in D_S \\ \lambda\,, a_t = y_t \text{ and } s_t \in D_H \\ -\lambda\,, a_t \neq y_t \text{ and } s_t \in D_H \end{cases} \quad (2)$$

where D_S , and D_H represent the majority (“sick”) and minority (“healthy”) classes, respectively. Correctly/incorrectly classifying a sample from the majority class yields a reward of $+\lambda/-\lambda$, where $0 < \lambda < 1$.

- Terminal E: In every instructional session, the teaching procedure concludes at diverse concluding conditions. A progression of situation-action duets $\{(s_1, a_1, y_1), (s_2, a_2, y_2), (s_3, a_3, y_3), \dots, (s_t, a_t, y_t)\}$ from a starting situation to an ultimate situation is denoted as an instructional session. In the circumstance, the culmination of an occurrence is ascertained by either categorizing all the instruction data or by inaccurately categorizing a specimen from the underrepresented class.

- Transition probability P: The agent transitions to the next state, s_{t+1}, from the current state, s_t, based on the sequential order of the read data. The probability of transitioning to state s_{t+1} from state s_t, given the action a_t, is denoted as $p(s_{t+1}|s_t, a_t)$.

V. Experimental Results

The dataset employed in the project is publicly accessible and was provided by the Machine Learning group of Université Libre de Bruxelles [50]. The data used in this study comprises credit card transactions made by cardholders in Europe during September 2013. This particular dataset consists of 284,807 transactions made by European cardholders over a span of two days, with 492 of them identified as fraudulent. The dataset is characterized by a significant class imbalance, where the number of positive cases (fraudulent transactions) constitutes only 0.172% of the total transactions. The dataset comprises solely numerical input variables, which are the product of a PCA transformation. The original features and additional contextual details about the data were not released to the public due to confidentiality concerns. The attributes V1 to V28 are the primary features produced through PCA, while 'Time' and 'Amount' are the only characteristics that have not been subjected to PCA transformation. The attribute 'Time' represents' the time interval in seconds between a particular transaction and the initial transaction registered in the dataset. The 'Amount' characteristic pertains to the amount of the transaction and can be applied to tasks such as cost-sensitive learning, which depend on the transaction value. The variable 'Class' serves as the output or target variable and is assigned the value of 1 if the transaction is a fraud and 0 if it is not. The dataset of credit card transactions may also include summarized characteristics. Various summarized characteristics can be extracted from the credit card transaction dataset, such as the average monthly transaction amount per cardholder, the average number of transactions per month, the average monthly spending on fuel, the time and distance between the present and previous transactions, and others.

In this article, we have incorporated a batch normalization layer to ensure data normalization and facilitate smoother training. By processing the data before feeding it into the MLP, the batch normalization layer effectively addresses the issue of internal covariate shift, allowing the network to learn more effectively and expedite convergence. To introduce non-linearity and enhance the network's capacity to model complex relationships within the data, we apply the ReLU (Rectified Linear Unit) activation function between the layers. Regarding the training configuration, we have carefully chosen a batch size of 32. This decision is made to strike a balance between computational efficiency and gradient accuracy during the optimization process. The batch size of 32 enables efficient parallel processing on modern hardware while retaining sufficient samples to ensure a stable gradient estimation during backpropagation.

The proposed approach was subjected to a rigorous evaluation by comparing it with six different machine learning models. These models included SVM [51], Naïve Bayes [52], KNN [53], Random forests [54], Logistic Regression [55], and Decision tree [56], which are all popular and widely used in the field of machine learning (See Table I). In addition, the performance of two smaller versions of the proposed approach was also tested. These versions were designed to use random weights and RL for classification. For evaluating the outcomes of the approach, standard performance metrics, including F-measure and geometric mean, known to be dependable for assessing imbalanced data, were employed. The approach outperformed all other models across all evaluation criteria, surpassing even the top-performing model, Decision tree. Specifically, the approach achieved a reduction in the error rate by more than 65% and 28% in F-measure and G-means, respectively. Additionally, a comparison was conducted between the performance of the approach and the smaller versions, namely Proposed (random weights) and Proposed (random weights and RL). This comparison revealed that the approach significantly reduced the error rate by approximately 72%. These results highlight the importance and effectiveness of the improved artificial bee colony and RL techniques utilized in the suggested approach.

In the next experiment, the objective is to evaluate ABC against various metaheuristic optimization algorithms. To achieve this, different metaheuristics are utilized to obtain the initial model parameters while keeping other model components constant. The six algorithms used in this experiment are HMS [57], FA [58], BA [59], DE [60], GWO [61], and COA [62]. For all algorithms, default settings have been used (Table II). Table III presents the results obtained from this comparison. The results indicate that the proposed ABC approach outperforms other algorithms in terms of error reduction, with a decrease of approximately 33% compared to the second-best algorithm, HMS.

TABLE I. RESULTS OF VARIOUS CLASSIFICATION ALGORITHMS

	accuracy	recall	precision	F-measure	G-means

A. Effect of the Reward Function

Rewards of ±1 and ±λ are used in this study to indicate correct/incorrect classifications of the majority and minority classes, respectively. The optimal value of λ is influenced by the proportion of the majority to minority samples, with a lower value expected as the ratio increases. The performance of the suggested model with λ initialized using a set of values ranging from 0 to 1 in increments of 0.1 is evaluated while keeping the bonus for the majority class constant. The results, which demonstrate that a λ value of 0.4 yields the best model performance across all metrics are shown in Fig. 3. When λ = 0, the impact of the majority class is nullified, while a value of 1 result in equal impact from both majority and minority classes. It is important to note that while adjusting λ is necessary to mitigate the effect of the majority class, setting the value too low can negatively impact the overall performance of the model.

B. Investigating the Impact of the Number of Layers in MLP

The number of layers in MLP affects the model complexity, with a higher number of layers resulting in increased complexity that may lead to over-fitting. Conversely, a model with too few layers may not capture important features in the training data. To address these issues, the impact of the number of layers on the proposed approach was evaluated by testing eight values between 1 and 12. Table IV shows the results, which demonstrate a decreasing trend for values from 1 to 8, followed by an increasing trend for values from 8 to 12. Therefore, the optimal number of layers for MLP is 8 to balance the representation of important features and model complexity.

C. Effect of the Loss Function

Traditional methods, such as adjusting data augmentation and the loss function, can be utilized to address data imbalances. The loss function, which can assign more weight to the minority class, is considered particularly important. Various loss functions, including (WCE) [63], balanced cross-entropy (BCE)] [64], Dice loss (DL) [65], Tversky loss (TL) [66], and Combo Loss (CL) [67], were tested to determine their impact on the model. In the BCE and WCE functions, equal weight is assigned to positive and negative examples. The CL function, which assigns less weight to simple examples and more weight to complex ones, is useful for handling unbalanced data. The results presented in Table V show that CL performs better than TL, with a 31% and 42% reduction in error for accuracy and F-measure, respectively. However, RL performs 71% better than the CL function.

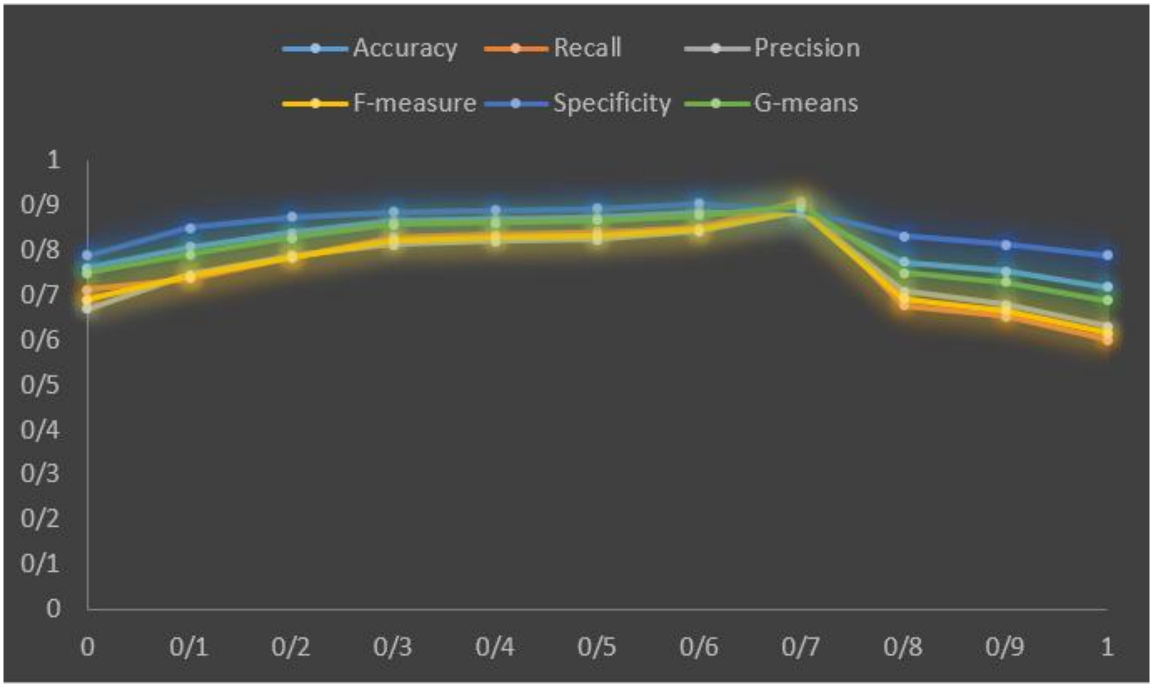

Fig. 3. The performance metrics of the proposed model are graphed against different values of λ in the reward function.

TABLE IV. THE PERFORMANCE METRICS PLOTTED VS. THE DIFFERENT NUMBER OF LAYERS IN MLP

Number of layers	accuracy	recall	precision	F-measure	G-means
1	0.758±0.001	0.792±0.205	0.741±0.017	0.742±0.037	0.773±0.100

D. Discussion

The article proposed a deep reinforcement learning approach for fraud detection in e-commerce transactions. It acknowledged the serious issue of fraud in e-commerce and the limitations of current detection strategies. The proposed model utilized ANNs and the ABC algorithm to acquire initial weight values. The model viewed fraud detection as a step-by-step decision-making process, with the agent receiving rewards for each classification action. To prioritize detecting fraudulent transactions, the model assigns higher rewards to identifying the minority class.

Fraudsters are known for their adaptability and creativity in devising new strategies to evade detection. As a result, the effectiveness of any fraud detection model, including the proposed deep reinforcement learning approach, hinges on its ability to generalize well to previously unseen fraud patterns. The process of generalization refers to the model's capacity to make accurate predictions on data that differs from the training set, encompassing novel and evolving fraud scenarios. To ensure the robustness of the proposed model, rigorous testing on diverse and evolving fraud scenarios is imperative. Here are some key aspects to consider for assessing the model's generalization capabilities:

- Diverse Testing Datasets: Apart from the publicly available dataset used during model development, it is crucial to evaluate the model on multiple datasets, including those collected from different sources and time periods. Diverse datasets can represent a broader range of fraud patterns and help uncover potential weaknesses in the model's detection capabilities.

- Cross-Domain Evaluation: Fraud patterns may differ across various industries and regions. Evaluating the model's performance on datasets from different domains, such as e-commerce, banking, insurance, etc., helps assess its ability to handle variations in fraud characteristics and attack vectors.

- Time-based Evaluation: Fraud patterns evolve over time, necessitating the model's ability to adapt to emerging fraud tactics. Testing the model on data from different time periods can reveal its responsiveness to temporal changes in fraud behavior.

- Transfer Learning: Applying transfer learning techniques allows leveraging knowledge gained from one dataset to improve performance on another. Pre-trained models can serve as a starting point for fine-tuning on specific fraud detection tasks, potentially enhancing the model's generalization capacity.

- Data Augmentation: To expose the model to a wider array of fraud patterns, data augmentation techniques can be employed. Synthetic fraud scenarios can be generated by perturbing existing data or by using generative models, thus enriching the training data and improving generalization.

- Continuous Monitoring and Feedback: Real-world deployment of the model demands continuous monitoring of its performance and feedback from analysts and fraud experts. This feedback loop helps identify potential misclassifications and enables timely updates to the model to account for evolving fraud patterns.

- Adversarial attacks pose a significant challenge to fraud detection systems, as they can lead to severe financial losses and reputational damage. Malicious actors exploit vulnerabilities in the model's decision boundaries, making subtle changes to input data that are imperceptible to humans but can mislead the model into producing incorrect outputs. For instance, attackers may modify features in a transaction or manipulate user behavior to hide fraudulent activities. To ensure the reliability and effectiveness of the proposed deep reinforcement learning model in real-world scenarios, it is essential to assess its robustness against various types of adversarial attacks. There are several approaches to evaluate the model's susceptibility to such attacks:

- Adversarial Testing: Conducting rigorous adversarial testing involves generating adversarial samples and evaluating how the model responds to them. Adversarial samples can be crafted using techniques like Fast Gradient Sign Method (FGSM), Projected Gradient Descent (PGD), or Genetic Algorithms. By testing the model's performance on these samples, researchers can identify vulnerabilities and areas of improvement.

- Robustness Metrics: Various robustness metrics have been proposed to quantify a model's resilience against adversarial attacks. Examples include robust accuracy, fooling rate, and adversarial training loss. These metrics help in comparing the model's performance under normal and adversarial conditions, providing insights into its vulnerability.

- Adversarial Training: Adversarial training is a popular technique to enhance a model's robustness. It involves augmenting the training dataset with adversarial samples, forcing the model to learn from both clean and adversarial data. This process can improve the model's ability to detect fraudulent activities in the presence of adversarial examples.

- Transferability Analysis: It is crucial to examine whether adversarial attacks generated for one model can also fool other models. Transferability analysis helps in understanding the generalizability of adversarial attacks across different fraud detection models. If attacks transfer across models, it indicates a common vulnerability that needs to be addressed.

- Use of Certified Defenses: Certified defenses, such as certified robustness and provable security techniques, provide mathematical guarantees against adversarial attacks. By incorporating such defenses into the model, the system can offer formal guarantees of security and robustness.

- Real-world Adversarial Testing: It is essential to conduct adversarial testing using real-world data and attack scenarios. This involves simulating how actual attackers might attempt to evade the model's detection mechanisms. This testing should include both known and novel adversarial strategies to ensure comprehensive evaluation.

VI. Conclusion

The suggested model offers a hopeful solution to the issue of identifying fraud in e-commerce transactions, a significant apprehension for companies and customers. The use of multilayer perceptron, RL, and ABC allows for a more robust and accurate fraud detection system. Pre-training the network weights with the evolutionary ABC algorithm is a crucial measure to prevent being trapped in local optima. By using this initialization method, the model is better able to converge to a global optimum, leading to improved accuracy and reliability. The utilization of RL to address dataset imbalance is another notable aspect of the proposed model. Imbalanced datasets are a common challenge in machine learning, and traditional approaches often fail to provide satisfactory results. RL offers a new way to address this issue, allowing the model to learn how to handle imbalanced data on its own, leading to improved performance. Based on the results obtained from the experiments conducted on the utilized dataset, it can be inferred that the proposed model outperforms other existing machine learning models in terms of common metrics. The superior performance of the ABC algorithm and RL over other metaheuristic initialization algorithms and loss functions demonstrates the effectiveness of the suggested approach.

Potential future work includes testing the proposed model on a broader and more varied dataset of e-commerce transactions to assess its ability to generalize. This would allow assessing whether the model is robust enough to identify fraud patterns in different scenarios and datasets, which is crucial for its practical applicability. Additionally, it would be interesting to explore the interpretability of the model, as understanding how it identifies fraudulent transactions can provide valuable insights for fraud detection in e-commerce. Finally, further research could investigate the scalability of the proposed approach, as it may become computationally expensive when dealing with large datasets.

***Abstract*—Fog computing can be considered a decentralized computing approach that essentially extends the capabilities offered by cloud computing to the periphery of the network. In addition, due to its proximity to the user, fog computing proves to be highly efficient in minimizing the volume of data that needs to be transmitted, reducing overall network traffic, and shortening the distance that data must travel. But this technology, like other new technologies, has challenges, and scheduling and optimal allocation of resources is one of the most important of these challenges. Accordingly, this research aims to propose an optimal solution for efficient scheduling within the fog computing environment through the application of the advanced cat swarm optimization algorithm. In this solution, the two main behaviors of cats are implemented in the form of seek and tracking states. Accordingly, processing nodes are periodically examined and categorized based on the number of available resources; servers with highly available resources are prioritized in the scheduling process for efficient scheduling. Subsequently, the congested servers, which may be experiencing various issues, are migrated to alternative servers with ample resources using the virtual machine live migration technique. Ultimately, the effectiveness of the proposed solution is assessed using the iFogSim simulator, demonstrating notable reductions in execution time and energy consumption. So, the proposed solution has led to a 20% reduction in execution time while also improving energy efficiency by more than 15% on average. This optimization represents a trade-off between improving performance and reducing resource consumption.**

Keywords—Scheduling; fog computing; optimal balancing; cat swarm optimization algorithm

I. Introduction

In order to overcome the challenges arising from resource limitations in IoT devices, the prevalent approach has been to rely on large-scale cloud data centers for interactions between IoT devices and supporting end servers [1]. However, as the number of IoT devices and their generated data continue to escalate, reliance on cloud-based infrastructure has become costly, inefficient, and often unfeasible [2]. In response to this issue, fog computing has emerged as a solution by offering networking, storage, and computing resources in proximity to IoT devices and users [3, 4]. One notable advantage of fog computing is its ability to reduce service latency for end-user applications, unlike the cloud, which typically exhibits higher latency due to its more extensive computing capacity and remote storage [5]. The exponential growth of the Internet of Things has posed significant challenges for cloud computing, including network failures and increased latency. To tackle these challenges, cloud computing has sought to bring cloud capabilities closer to IoT devices. Fog computing entails the utilization of heterogeneous and distributed processing nodes, presenting challenges for fog-based services in accommodating the diverse aspects of a constrained environment [23]. By examining the structural and service-oriented characteristics of fog computing, various challenges become apparent, with optimal scheduling being particularly significant. Scheduling holds great importance in the realm of the Internet of Things as it has the potential to decrease execution time and minimize energy consumption [6, 24]. However, scheduling problems become increasingly complex with the growing number of services and requests, leading to a rapid increase in the number of possible solutions. Due to the exponential growth of feasible states, it becomes impractical to evaluate all possibilities to determine the best scheduling exhaustively, resulting in these problems falling under the NP-Hard category that deterministic methods cannot be used in solving this category of problems due to their time-consuming nature, and meta-heuristic methods should be developed to solve these problems properly [2, 25]. Meta-heuristic methods have been the attention of researchers due to their simplicity, flexibility, no need for derivation, and escape from local optima. The No Free Lunch (NFL) theorem establishes that no meta-heuristic algorithm can solve all optimization problems perfectly. In other words, an algorithm that performs well on a set of problems may not yield favorable outcomes for another set of problems [3, 26]. Taking this into account, this study introduces an advanced strategy based on the cat swarm optimization (CSO) algorithm to achieve optimal scheduling in cloud infrastructure. The primary objective is to significantly reduce energy consumption in cloud data centers by effectively allocating tasks to processing servers, thereby preventing server overload or underload. The following section presents a literature review on scheduling and load balancing, followed by an examination of the proposed technique in section 3. Finally, in section 4, the proposed technique is implemented in the iFogSim simulator, and the results are evaluated.

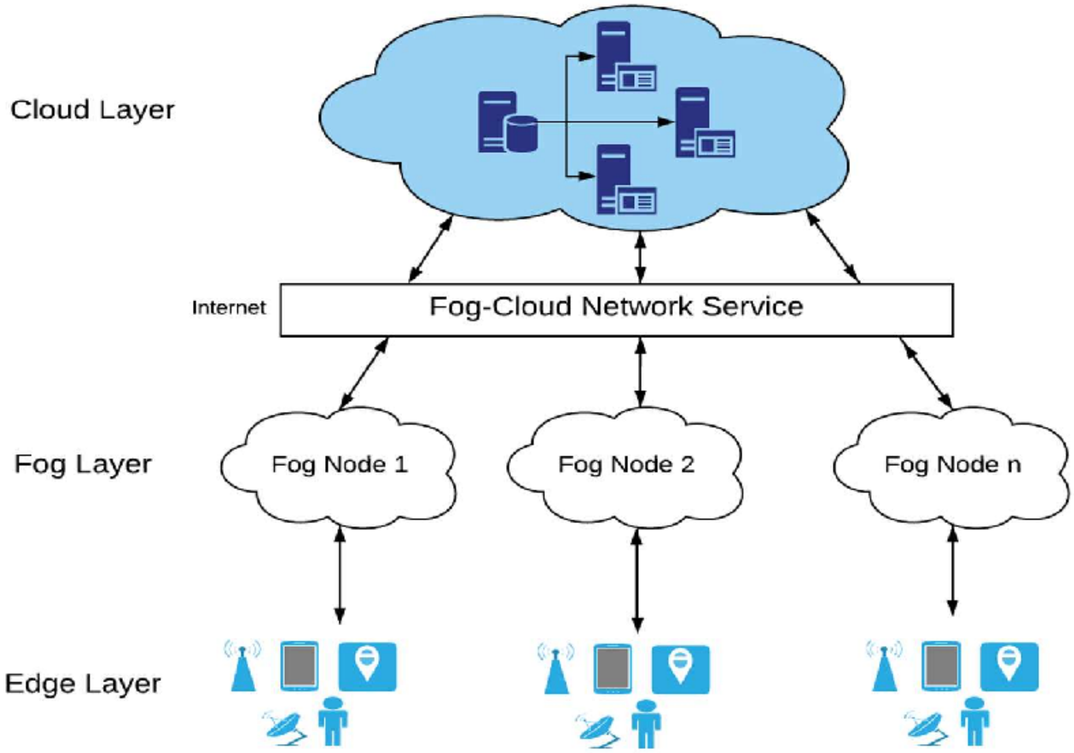

Fig. 1. Fog computing architecture.

A. *Fog Computing*

As illustrated in Fig. 1, fog computing operates by conducting local processing and storage of IoT data on IoT devices rather than transmitting the data to the cloud. In contrast to the cloud, fog computing offers faster response times and improved quality, making it an optimal choice for enabling the Internet of Things. It is known for providing efficient and secure services to a wide range of users [4, 27]. While the cloud serves as an intermediary between endpoint clients and cloud computing, fog computing occurs closer to the edge of the cloud and end devices, resulting in significantly lower latency. Cloud computing services are located on the Internet, whereas fog computing operates at the edge of the local network. Real-time interactions are supported by both cloud and fog computing, but processing data and applications in the cloud can be time-consuming, particularly for large-scale data. Fog computing facilitates centralized resource management, including the allocation of computing, networking, and storage resources. The primary objective of fog computing is to equip network edges and network devices with virtual services for processing, storage, and network provisioning [5, 28]. Table I provides a comparison of the similarities and differences between fog computing and cloud computing.

TABLE I. DIFFERENCES BETWEEN CLOUD AND FOG INFRASTRUCTURE

Ability	Fog Computing	Cloud Computing
Delay	Low	Up (depending on the user's path to DC)
Response time	milliseconds	several minutes
Service location	Network edge	In cloud data centers
Data storage period	transitory	months or years (according to the contract)
Steps between user and server	one step	Several steps
Aware of location	Very local	no
architecture	Distributed	concentrated
Type of communication	wireless	Broadband, MPLS
Possibility of data recording	Low	High
End-to-end security	can be defined	It cannot be defined or controlled
Data collection nodes	unlimited	Very low
Mobility support	supports	Limited support

Fog computing offers significant advantages by reducing data transfer, traffic, and distance traveled. It involves decentralizing computations to the edge of the network, where downstream data processing occurs in cloud services and upstream data processing occurs in Internet of Things (IoT) services [6, 29]. In cloud computing, information storage and processing are directed towards the network edge and closer to the source of information generation. Instead of transmitting IoT-generated data to distant data centers or remote servers for storage and processing, this data is stored on local servers and storage devices through a local gateway. This approach enhances the speed of information analysis and alleviates network congestion [7, 30]. The concept behind fog computing is that computation should be performed in close proximity to data sources. It has the potential to impact society as significantly as cloud computing. Fog computing offers numerous advantages over traditional architectures, particularly optimizing resource utilization within a cloud computing system. By conducting computations at the network edge, fog computing reduces network traffic. Essentially, edge computing operates within the cloud but in proximity to objects interacting with IoT data. As depicted in Fig. 1, fog computing acts as an intermediary between the cloud and end devices, bringing processing, storage, and network services closer to the end devices. These devices, known as edge nodes, can be deployed anywhere with a network connection. In essence, fog computing extends cloud infrastructure to the network edge. While fog and cloud computing share network, computing, and storage resources, they utilize similar mechanisms and features such as virtualization and multi-tenancy [8, 31].

II. Related Work

The study in [9] focuses on addressing concerns related to scheduling and resource allocation within fog computing for various types of applications. In this research, it has been stated that different programs composed of a collection of interrelated services are mapped to cloud computing for processing, but the placement of services has its challenges. Accordingly, this article presents a distributed placement strategy, the main goal of which is to reduce energy consumption and the cost of communication. The proposed method is based on game theory, which uses iterative combinatorial auction (ICA). The proposed solution through game theory makes significant changes in the ICA method. Based on this, the proposed solution is decentralized and is able to interact between fog nodes and applications so that decisions related to placement are made in each round. The results of the evaluations show the optimality of the solution in reducing the cost of communication and increasing the productivity of the fog node processor, which is an important advantage considering the limited resources in the fog nodes. In [10], a solution for autonomous scheduling of services on devices on the edge of the network is presented. In this solution, the dynamic capability of programs based on microservices is used in order to provide an adaptive solution for placement. The main objective of this solution is to minimize the response time of services, ultimately enhancing the quality of user experience, particularly in critical services. In this method, the decision about the placement of the service is made based on the response time of the applications. Various functions have been used for this purpose. Then, through the use of a meta-heuristic algorithm based on PSO, a decision is made regarding the placement of the service. The first input parameter for the algorithm is the graph call related to the application service.

In the end, through a series of evaluations, it was shown that the proposed solution was able to perform the placement of services and microservices in such a way that the response time is minimized. The authors in [11, 32] have presented a lightweight framework for providing fog computing services to be used by IoT devices that are sensitive to delay, and their needs must be answered in real-time. The FogPlan solution is a QoS-aware proposal, and the placement of services in it is done according to the network status. This framework works with minimal assumptions and information about IoT nodes. Then a probabilistic formula for the optimization problem, along with two heuristic algorithms, has been presented to answer the QoS needs. By using this solution, in addition to more accurate positioning, the amount of delay and network cost can also be reduced. In the evaluations, it has been concluded that the solution has reduced the average delay and the scheduling costs through the optimal scheduling of services.

Research [12] introduces a task scheduling policy in fog computing that is based on graph partitions. The main objective of this solution is to enhance accessibility. By employing this method, the quality-of-service delivery is enhanced through program prioritization across all cloud devices and transferring services to these devices. The main idea is based on the premise that the more necessary services are provided near the user, the quality and delay of service delivery can be reduced. Based on this, with the help of graphic partitions, the desired services and related tasks are determined and based on the number of available resources, the best possible placement is done. In the end, the proposed solution has been evaluated with a linear programming approach, and the results indicate an improvement in accessibility and service delivery. The work described in [13] focuses on scheduling application components within hybrid cloud and fog systems based on network function virtualization (NFV) principles. This study investigates the main challenges of deploying components related to cloud and fog applications in NFV. In fact, these challenges are mostly expressed due to the heterogeneity between the components. To solve this problem in this research, a model based on four hierarchies 1) sequence, 2) parallel, 3) selection and 4) compliance loop was used. In this solution, it is assumed that the program components are implemented as VFSs, and the structural diagrams represent an application program that follows the proposed hierarchical structure. In this structure, each VFN becomes a tree, where the leaf nodes represent the program components, and the costs of the model are calculated by gathering the information of the nodes from bottom to top. The main goal of this method is to minimize the processing costs, which are modeled using an ILP integer programmer. The authors of [14] propose a concept to address the challenge of deploying Internet of Things (IoT) services within the fog computing environment. They model the deployment problem of IoT applications on resources as an optimization problem. The concept of a "fog colony" is introduced, and the coordinated fog cell colony and deployment approach are presented as a solution for deploying services on virtual resources within the fog domain. The optimization problem primarily focuses on the deployment and execution time of the application, aiming to maximize resource utilization in the fog through a greedy heuristic method based on the genetic algorithm. In this model, the communication and subscription of fog cell services are done by the control node. Also, the communication between the cells and the control node with the cloud is made possible by the fog computing management system.

In the end, the results of this research have been compared with the classical approach that executes all tasks in the cloud. The intended evaluations have been carried out in the iFogSim simulator environment, and the results indicate that the optimization method has a favorable effect on the use of fog resources, and the genetic algorithm has a lower delay for execution compared to the cloud. In [15], a service placement algorithm is presented for efficient use of the network and improvement of energy consumption. This algorithm sequentially allocates application modules with the highest needs to the nodes with the highest capacities. To test the proposed algorithms, the program has been implemented on network topologies named JSON. The scenario has been implemented with more than three different network topologies and workloads. The proposed cloud-fog placement and deployment method were evaluated by comparing it with the traditional cloud-based deployment approach. The evaluation considered program delay (response time), network usage, and energy consumption as the primary metrics. Data was collected from the iFoSim simulator using the proposed placement and resource deployment methods. The results demonstrate the favorable impact of the proposed placement approach across all three topologies, showcasing improvements in network utilization, program delay (response time), and energy consumption compared to the traditional cloud-based approach. The authors in [16] presented a tool called FogTorch. Accordingly, the first part of the article presents a model for the use of service quality systems in multi-sector applications of the Internet of Things for fog architecture. In the second part, the results of using Monte Carlo simulations for the FogTroch tool are stated, and the application of this tool is examined in terms of service quality and resource consumption.

FogTroch is a tool that enables the simulation and comparison of different fog scenarios in the design phase, as well as the resource and quality-of-service (QoS) aware deployment of IoT applications through cloud-fog architecture. It takes into account various processing resources such as CPU, RAM, storage, and software, along with QoS constraints like latency and bandwidth, which are essential for real-time fog applications. Notably, FogTroch is the first tool capable of estimating the quality of service resulting from fog-based application deployments based on probability distribution models of bandwidth and delay provided by communication links. Additionally, it provides estimates of resource consumption within the fog layer, allowing for the optimization of resource utilization among different fog nodes. In [17], a dynamic module is presented to schedule the tasks of Internet of Things applications in edge and cloud computing. Through this solution, the problem related to IoT requests in a heterogeneous network environment based on edge cloud has been solved. As a result, a mapping between the application module and the main resources of the devices can be created. In this way, problems related to the delay of tasks and energy consumption can be overcome. To achieve this objective, the application employs a dynamic discovery algorithm that enables the step-by-step execution of operations in the fog computing environment. This algorithm helps to reduce the delay in task execution by efficiently discovering and allocating resources. Through simulations conducted in the iFogSim environment, the results demonstrate the remarkable service quality of the applications, accompanied by a significant reduction in energy consumption compared to other scheduling strategies. The combination of the dynamic discovery algorithm and the fog computing environment contributes to improved application performance and energy efficiency.

After conducting a thorough examination of the aforementioned studies, we have identified their strengths and limitations in several aspects:

- Studies, such as [9], [13], [14] have provided comprehensive introductions to the theoretical concepts and platforms of fog computing. They have significantly contributed to the research on optimization strategies in this field.
- Several existing studies, like [10]-[12] and [15]-[17] have focused on optimizing the trade-off between time and energy consumption in fog computing scenarios. However, one critical aspect they often overlook is the consideration of task characteristics and resource types concerning the problem of balancing delay and device load. This omission can lead to inefficient resource allocation and potential wastage of resources.

Our research falls within the category of optimizing Quality of Service (QoS) and energy consumption simultaneously. It complements and extends existing works in several ways. For instance, unlike the study in [10] where multiple user devices share one Multi-access Edge Computing (MEC) server, or [11] where a single device generates a task, our approach considers a more complex system involving multiple users and multiple fog nodes. Additionally, our focus is on reducing the energy consumption of the fog nodes themselves, which sets us apart from the majority of existing approaches that primarily aim to minimize energy consumption on the mobile devices [9,11,12,16,17]. Furthermore, we present a novel approach that jointly minimizes the overall energy consumption and the execution time while taking into account the computation resource constraints of fog devices. This approach offers a comprehensive optimization strategy for the system.

III. Proposed Method

The primary objective of the scheduling solution is to efficiently allocate n tasks to m machines, where n > m, with the aim of minimizing both the execution time and energy consumption. To achieve this objective, it is crucial to compute the resource availability of all machines. An upper bound is established for the minimization function, which is defined as $m \times L_{max}$. Here, L_{max} represents the maximum execution time for each node. Thus, for any task scheduling completion time G, it should satisfy the condition m × L_{max} > G. In other words, the execution of the assigned tasks will take at least as long as L_{max} for each container. Let's consider S = (S1, S2, ..., Sn) as the set of user tasks given to the system. During the scheduling process, these user tasks are assigned to available fog nodes. Each node is equipped with {PE_1, PE_2, ..., PE_m} processing elements to handle service tasks. Each processing element has a distinct processing speed characteristic denoted as PE_S and the CSO (Cat Swarm Optimization) algorithm [18, 33] is used to allocate resources and schedule tasks in a fog infrastructure effectively.

The CSO algorithm models the two primary behaviors of cats, known as tracking and searching modes, using sub-models. By combining these modes in a defined ratio, the cat crowding optimization algorithm exhibits strong performance. Similar to particle swarm optimization, the positions of the cats serve as solutions, and the algorithm utilizes the cats' behavior to solve optimization problems. In the cat swarm optimization, the number of cats to be used is determined, and each cat possesses a position with M dimensions. Additionally, each cat has a speed for each dimension and a fitness value indicating its level of fitness. This fitness value is obtained using a fitness function. Furthermore, each cat is assigned a flag to identify whether it is in tracking or seeking mode [19, 34].

The aim of this research is to minimize energy consumption and reduce the execution time of user requests in the cloud infrastructure. To achieve this, the cat swarm optimization algorithm is modified to enable the effective allocation of resources to tasks. The modified algorithm optimizes the resource allocation process, leading to improved energy efficiency and reduced request execution time. By leveraging this modified cat swarm optimization algorithm, the cloud infrastructure can allocate resources more effectively, resulting in enhanced performance and reduced energy consumption. In the proposed solution, a set of cats will be used; some of which are in search mode and at the same time, some others are in tracking mode. In this method, each cat represents a specific task-resource mapping. The cats are updated based on their current state, and the goal is to minimize the cost of mapping. The fitness value is assigned to each cat, reflecting the quality of its mapping solution. In each iteration of the algorithm, a new set of cats is selected to be in the search state, where they explore different mappings. Ultimately, the cat with the best fitness value represents the best mapping solution, which results in the lowest cost among all the possible mappings. By iteratively updating the cats and selecting the best solutions, the algorithm aims to find an optimal task-resource mapping that minimizes cost and improves overall efficiency. Accordingly, in the following, the search and tracking modes are examined as a sub-model to model the cat's search behavior to find the desired target: processing servers in this research.

A. Seeking Mode

During the search process in the SM (Seeking Mode) of the algorithm, the exploration of different regions in the search space is conducted. However, the search is limited to the local vicinity of the current position of the seeking cat. This approach focuses on refining existing solutions rather than exploring distant areas of the search space. Fig. 2 illustrates this local search behavior. There are four main factors considered in the seeking mode of each cat:

1) Search Memory Source (SMP): This factor determines the size of the search memory for each cat, representing the positions previously searched by the cat. Based on the fitness functions, the cat chooses one position from its memory as a potential candidate for movement.

2) Number of Dimensions that Change (CDC): This factor determines the number of dimensions in the current position of the cat that will be modified during the search process.

3) Search in the Defined Range of Dimensions (SRD): This factor indicates the rate of change for the selected dimensions. If a dimension is chosen for modification, the difference between the new and old values will be within the range defined by SRD.

4) Attention to the Current Position (SPC): This factor is a Boolean variable that determines whether the current position of the cat is considered a candidate for movement or not. It ensures that the current position, which has already been explored, is not included in the search memory (SMP).

By considering these factors, the seeking mode of the cat swarm optimization algorithm focuses on local search, efficiently exploring and refining solutions within the vicinity of the current positions of the cats.

The seeking mode algorithm, as depicted in Fig. 3, outlines the steps followed when a cat is in seeking mode [35]. The algorithm proceeds as follows:

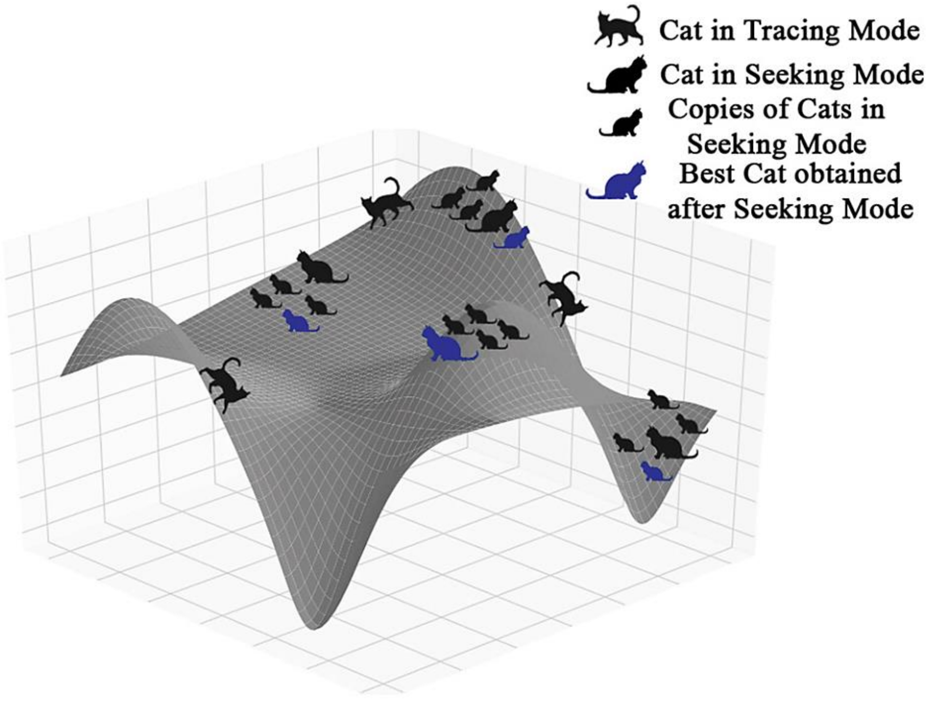
1) Create j copies of the current position of cat k (Cat_k), where j is equal to SMP (Search Memory Source). If the value of SPC (Attention to the position) is true, then j is adjusted to (SMP-1), allowing the current position to be considered one of the candidates.

2) For each copy, based on the CDC (Number of Dimensions that Change), increase the SRD (Search in the defined range of dimensions) by a percentage of the current values and add it to the previous values. This step determines the range within which the selected dimensions can change during the search.

3) Calculate the fitness function (FS) for each candidate point generated in the previous step.

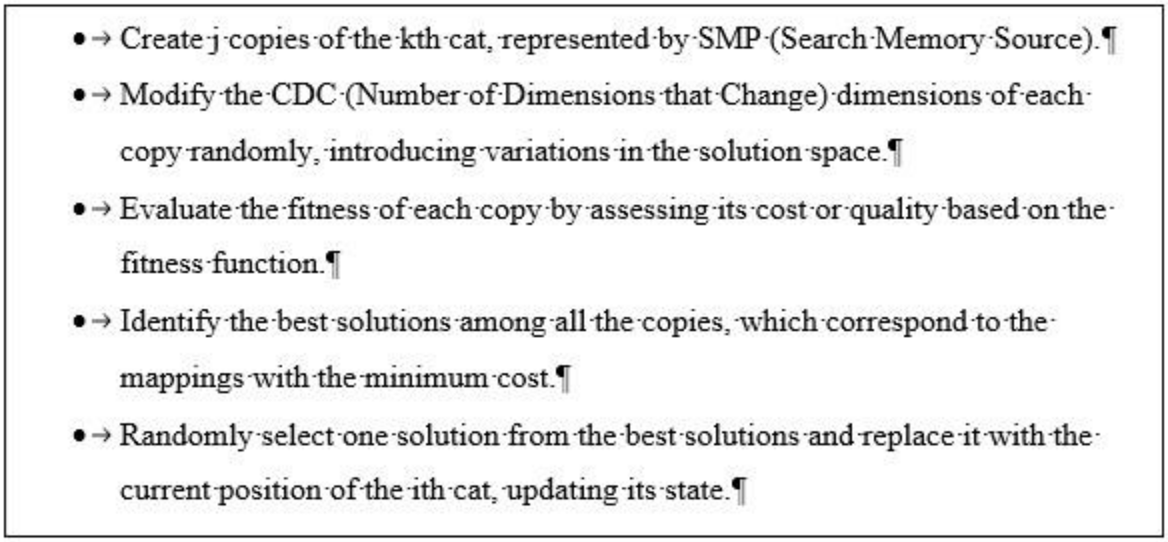
4) If not, all FS values are exactly equal, proceed to calculate the probability of selecting each candidate position based on the normalized fitness (fit) of that position. If all FS values are equal, set the probability of selecting all candidate positions to be equal.

By following this algorithm, the seeking mode effectively explores the search space by creating multiple copies of the current position, determining the range of changes in dimensions, evaluating the fitness for each candidate point, and selecting the next position based on the calculated probabilities.



Cat in Tracing Mode
Cat in Seeking Mode
Copies of Cats in Seeking Mode
Best Cat obtained after Seeking Mode

Fig. 2. Seeking mode.



- Create j copies of the kth cat, represented by SMP (Search Memory Source).
- Modify the CDC (Number of Dimensions that Change) dimensions of each copy randomly, introducing variations in the solution space.
- Evaluate the fitness of each copy by assessing its cost or quality based on the fitness function.
- Identify the best solutions among all the copies, which correspond to the mappings with the minimum cost.
- Randomly select one solution from the best solutions and replace it with the current position of the ith cat, updating its state.

Fig. 3. Seeking mode algorithm.

B. *Tracing State*

The tracking mode algorithm, which describes the behavior of the cat when tracking the target, can be outlined in the following three steps:

1) Calculate the new position of the cat based on its current position and speed in each dimension. The cat moves in the search space according to its velocity, exploring different locations.

2) Evaluate the fitness of the new position using the fitness function. This assesses the quality or cost associated with the new mapping.

3) Update the cat's position to the best position found during the tracking process. The cat moves towards the position that yields the minimum cost or maximum quality, improving its mapping.

By following these steps, the cat in tracking mode continuously adjusts its position based on its velocity, evaluates the fitness of the new position, and updates its location to the best position encountered during the tracking process. This allows the cat to gradually converge towards an optimal solution by iteratively exploring and refining its mappings.

In the first step, the speed synchronization for each dimension (vk, d) is calculated according to the following relationship:

$$v_{k,d} = v_{k,d} + r_1 \times c_1 \times (x_{best\,,d} - x_{k,d}) \qquad , \quad d = 1,2, \ldots , M$$

$x_{best,d}$ shows the position of the cat that has the highest value of fitness and $x_{k,d}$ is the position of the kth cat. c_1 is a fixed number, and r1 is a random number in the interval [0,1]. In the second step, it is checked that the speeds are within the defined range. If there were a higher speed, it would be replaced with the maximum possible value in the desired range, and finally, in the third step, the position of the cat will update according to the following relationship:

$$x_{k,d} = x_{k,d} + k_{k,d}$$

In fact, TS is for Teaching-Learning-Based Optimization. During this phase, the cats aim to exploit the information about the best position found so far to reach the optimal solution. Even though a cat's position change may be large during this phase, the search is still focused on the best solution found so far. Please refer to Fig. 4 for an illustration.

In other words, at this stage, the set of answers obtained from the best location of the cat in the current iteration is updated. As seen, cat swarm optimization uses two sub-models of seek and tracking mode; the way to combine these two sub-models to perform scheduling operations is described in the next section.

C. Scheduling

The optimal utilization of available resources is the main goal of task scheduling that provides a basis for load balancing. In order to reduce the cost of services provided to users, fog service providers adopt different policies depending on the type of user and the desired services. However, the aim of this study is to reduce the resource consumption cost. Thus, parameters such as energy consumption and traffic consumption are considered. These parameters are formulated based on the following equations to be used in the CSO-based approach.

D. Modelling Energy Consumption

In order to model the amount of energy consumed, the proposed approach in [20, 36, 40] is used. The idea of this model is based on the fact that there is a linear relationship between processor efficiency and power consumption. In other words, if we know the processing time of a task and the efficiency of the processor, we can calculate the energy consumed by that task. This means that by understanding how long a task takes to complete and how efficiently the processor performs it, we can determine the energy usage associated with that task.

The efficiency of a given resource r_j in a given time is calculated as follows.

$$U_j = \sum_{j=1}^{n} u_{i,j} \qquad (1)$$

Here, n represents the number of tasks currently in progress, and u_{ij} represents the amount of resources consumed by task t_j. Accordingly, the energy consumption (E_j) of resource r_j in a given time can be calculated using the following formula:

$$E_j = (P_{max} - P_{min}) \times U_j + P_{min} \qquad (2)$$

E. Traffic Consumption

This section aims to model the network's bandwidth usage and the volume of traffic produced by individual physical machines.

$$D_j = \sum_{\forall m \epsilon v_j} \lambda(j,m) \sum_{i=1}^{\rho(j,m)} C_i \qquad (3)$$

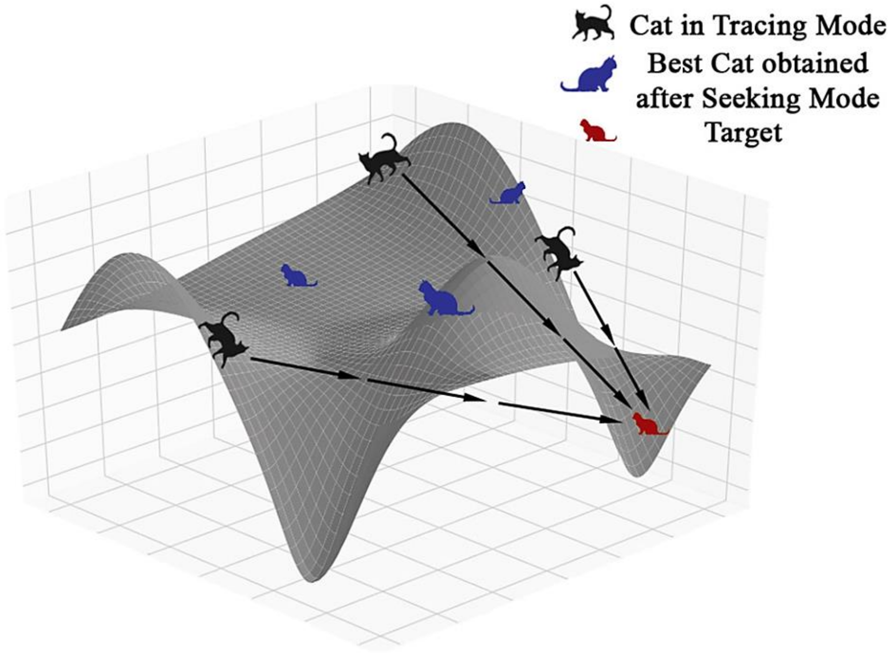


Fig. 4. Tracing state.

D_j represents the communication between physical machine j and other physical machines. λ(j, m) denotes the traffic load between physical machines j and m. V_j indicates a set of physical machines connected to physical machine j. C_i represents the weight of the communication link between two physical machines at level i. ρ(m, j) represents the communication level between physical machines m and j.

The multi-objective cost function for modeling the fog computing environment is formulated based on these two parameters as follows:

$$\text{Minimize} \quad \sum_{j=1}^{m} E_j \tag{4}$$

$$\text{Minimize} \quad \sum_{j=1}^{m} D_j \tag{5}$$

The minimum cost for task scheduling is obtained using the above functions. In the following, it is described how to combine two states tracking and seeking:

1) The initial population consists n cats.

2) The cats in this scenario are distributed randomly within a d-dimensional search space by assigning each cat a random speed for each dimension within a given range.

3) A number of cats are randomly selected. According to the Mixture Ratio (MR), some cats are put in the searching state, and the remaining ones are considered for the tracking state.

4) The movement of cats is based on their flag value which shows the tracking or seeking states.

5) The fitness value of each cat is evaluated, and the position of the best cat (Xbest) is recorded and stored.

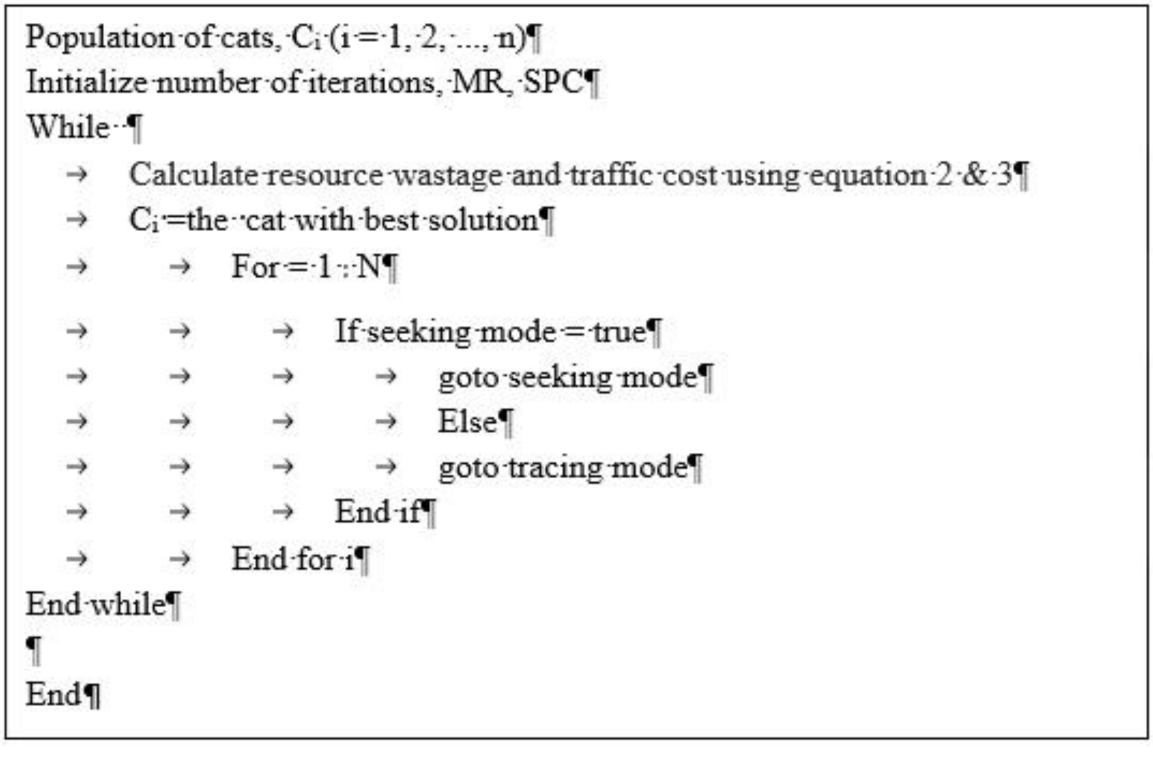
6) The situation of cats is updated according to their position. Then, step 3 is repeated.

7) Steps 5 and 6 are repeated iteratively until the termination criterion is met. i.e. a complete task scheduling is reached.

The pseudo-code for scheduling based on CSO is depicted in Fig. 5.

It is important to note that while executing scheduled commands on processing servers using cat swarm optimization, it is possible for some servers to fail to execute the commands or experience additional traffic and load due to delays in processing previous commands or hardware and software errors. Meanwhile, some servers may remain idle after completing their assigned commands. To address this, the resources of processing servers are periodically monitored, and the following three conditions are used to determine the status of their resources:

- If the resource consumption of a server has exceeded 95% of its maximum efficiency, it is categorized as an overloaded machine.
- If the resource consumption of a server is lower than the average efficiency determined (usually in the range of 10%), it is categorized as a server with a low load.
- Servers that do not meet the above conditions are considered normal servers.



```
Population of cats, Ci (i = 1, 2, ..., n)
Initialize number of iterations, MR, SPC
While
    Calculate resource wastage and traffic cost using equation 2 & 3
    Ci=the cat with best solution
        For = 1 : N
            If seeking mode = true
                goto seeking mode
                Else
                goto tracing mode
            End if
        End for i
End while

End
```

Fig. 5. Pseudo-code of algorithm.

Now to balance the load, the following load-balancing strategies can be applied:

- Servers in overloaded mode: Loads of these servers can be migrated to other servers in the P_{under} (low load) or normal mode. This can be achieved through the virtual machine migration technique, where the tasks and loads are transferred to another server that has sufficient resources to accommodate them.
- Servers with an efficiency below 10%: These servers can be considered candidates for task migration and subsequent shutdown. By migrating their tasks to other servers, the load on the underutilized servers can be increased, and energy consumption can be reduced by shutting down the inefficient servers.

By applying these load-balancing strategies, the goal is to optimize resource utilization, minimize overload conditions, and reduce energy consumption in the system.

IV. Evaluation

The implementation and evaluation of the proposed approach require a set of programming tools. These tools are necessary and useful for implementing different scenarios and evaluating the results. The comparison of the proposed approach with other existing techniques can also be made using these tools. For this purpose, the iFogSim2 simulator is used in this study [21, 37]. In order to evaluate the performance of the proposed approach, it is compared with metaheuristic algorithms such as PSO, ACO, Genetic (GA) and Random (RND) scheduling algorithms. In this study, the workload of simulations in the real traced data of the CoMon project is used, which is a monitoring infrastructure for PlanetLab [22, 38]. The main attributes of the cat swarm optimization algorithm are illustrated in Table II.

A. Evaluation Results

The outcomes of the assessment are depicted in Fig. 6 to 10. The initial evaluation encompassed three distinct experiments involving varying numbers of virtual machines. The objective was to explore how algorithms operate with diverse virtual resources and examine the correlation between resource quantity, execution time, and energy consumption. The subsequent results are presented below. Fig. 6 illustrates the energy consumption for all three solutions corresponding to the number of available virtual resources.

TABLE II. Main Characteristics of the CSO Algorithm

Decision-making variables	The position of cats in each dimension
Solution	The position of cats
The previous solution	Previous position of cats
New solution	The new position of cats
Better answer	Any cats exhibit the highest level of fitness.
Initialization of answers	Random location of cats
How to create a new answer	Use tracking and seeking modes.

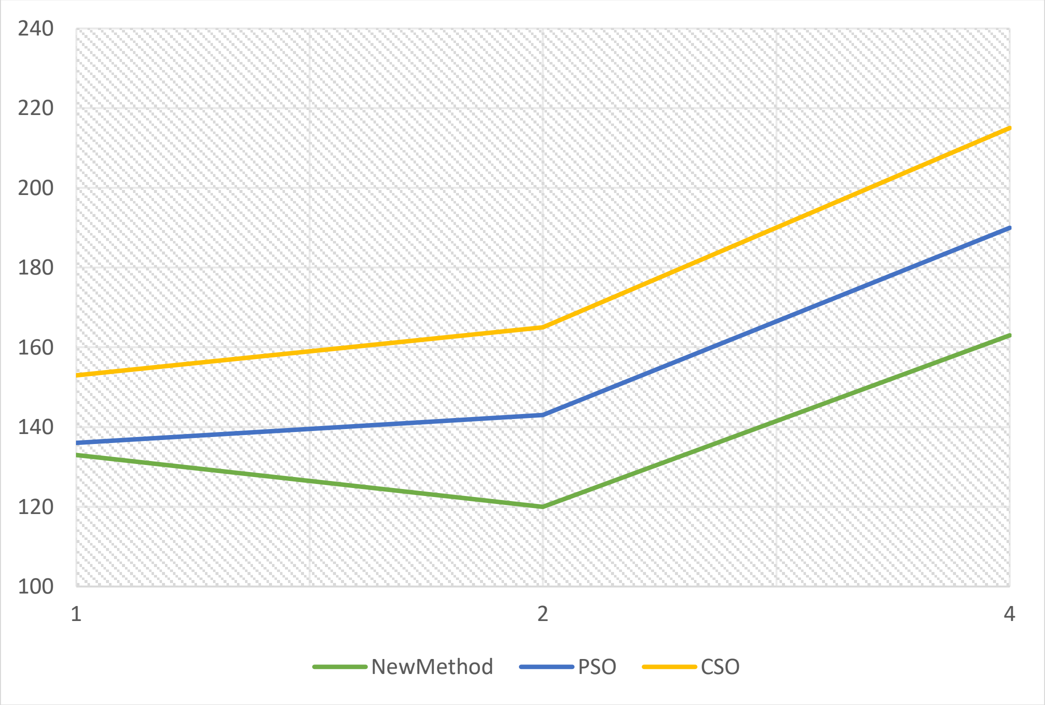


Fig. 6. Energy consumption in different tests.

As depicted in Fig. 6, an increase in the number of virtual machines leads to a rise in energy consumption across all three solutions. However, the proposed method consistently exhibits lower energy consumption at each stage. Although the optimality rate was initially low in the first test, it improved in subsequent evaluations as the number of available resources increased. This improvement was facilitated by the optimal arrangement of virtual machines achieved through CSO scheduling. Consequently, the proposed solution outperforms other methods with a significantly higher optimality rate. Moving forward, Fig. 7 evaluates the implementation time of the solutions in three distinct modes.

As depicted in Fig. 7, the execution time of the solutions increases with the growth in the number of virtual machines. However, the proposed method effectively addresses this issue through optimal resource allocation, the precise arrangement of virtual machines, and achieving load balancing. Consequently, the proposed solution outperforms the others by completing tasks in a shorter period in all three tests. The optimization carried out with the assistance of the CSO algorithm enables the identification of the best available nodes, resulting in the allocation of resources to the most suitable machines. As a result, both the execution time and energy consumption are reduced.

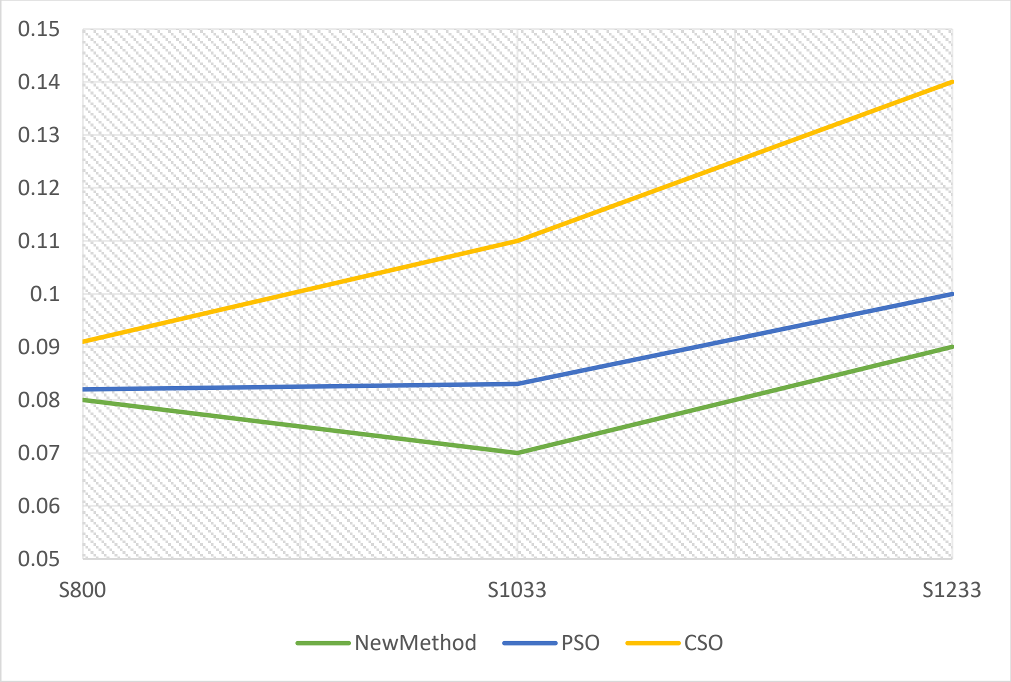

Fig. 7. Execution time of solutions in different experiments.

	NewMethod	GA	PSO	ACO	RND
Series1	163	215	185	177	234

Fig. 8. Energy consumption (KW/hr).

The next test was done with a constant amount of virtual and available resources, as well as applying a workload based on the CoMon project [38, 39]. The results of the evaluation of all algorithms are shown below. First, in Fig. 8, the amount of energy consumption of the proposed solution is shown in comparison with the other solutions.

Fig. 8 clearly illustrates a significant reduction in energy consumption within the proposed solution compared to other algorithms. This achievement can be attributed to the allocation and optimal arrangement of resources facilitated by the enhanced cat swarm optimization algorithm. In the proposed solution, the process of identifying available nodes has been optimized using the algorithm, and resource allocation is performed based on the status of these available resources. Consequently, energy consumption is minimized through the creation of optimal scheduling, alongside a reduction in execution time.

By adopting the proposed approach, notable improvements can be observed. For instance, in comparison to the RND-based solution, energy consumption has been reduced by approximately 24%. Similarly, compared to the PSO algorithm, the proposed solution demonstrates a reduction of approximately 10% in energy consumption. These results highlight the effectiveness and efficiency of the proposed method in optimizing energy consumption. Due to the fact that the amount of available resources is checked in every resource allocation operation, this energy reduction was predictable. In the following Fig. 9, the implementation time of the solutions is shown.

Indeed, in fog computing, minimizing the execution time of requests is crucial alongside reducing energy consumption. As depicted in the diagram in Fig. 9, the proposed solution exhibits a remarkable reduction in execution time compared to alternative approaches. Specifically, compared to schedules based on the PSO and ACO algorithms, the proposed solution achieves a reduction of approximately 21%. Furthermore, in comparison to the RND-based schedule, the execution time is reduced by approximately 33%. These results highlight the significant gains in efficiency and speed achieved through the proposed solution, further enhancing the benefits of fog computing.

This significant reduction in execution time can be attributed to the scheduling and optimal resource arrangement, as well as the establishment of load balancing through the proposed solution based on the cat swarm optimization algorithm. The solution efficiently utilizes the processing servers' resources by considering their status and allocating resources accordingly. Additionally, Fig. 10 presents the level of violation of the service level agreement (SLA).

The service level agreement (SLA) serves as the framework for establishing the expected level of service. It defines the formal conditions for the provided service, including aspects such as performance and availability. Fig. 10 illustrates that the proposed solution, through effective load balancing, enhances the reliability and availability of servers within the fog computing infrastructure compared to alternative solutions. In other words, the proposed solution exhibits a lower percentage of SLA violations, indicating its superior ability to meet the agreed-upon service level requirements.

V. CONCLUSION

This research introduces an approach based on the CSO algorithm to achieve optimal scheduling and load balancing. The proposed technique aims to prevent server overload or underload by efficiently allocating tasks to physical servers. To enhance the performance further, the CSO algorithm is extended by incorporating new parameters, including the amount of available resources and network traffic. By considering these factors, the proposed approach minimizes the execution time of requests by appropriately distributing tasks among candidate servers. Finally, the proposed approach is implemented and simulated in iFogSim, allowing for a comparison with other algorithms such as PSO, ACO, GA, and Random. The results obtained from the simulation demonstrate that the proposed approach successfully achieves its objectives and surpasses the other methods in terms of execution time and energy consumption. This highlights the effectiveness and superiority of the proposed approach in optimizing these important performance metrics. It could improve the energy consumption compared to ACO and PSO by the values of 24% and 10%, respectively.

Additionally, the execution time is significantly reduced, and in compared to ACO and PSO, the proposed approach could improve the execution time by 21% and 22%, respectively. The observed improvement can be attributed to the load balancing achieved in the fog environment through the combined utilization of the CSO-based scheduling method and virtual machine migration technique. This combination effectively distributes tasks and resources across the fog network, ensuring optimal utilization and minimizing resource imbalances. As a result, the proposed approach enhances load balancing, leading to improved performance in terms of execution time and energy consumption. The results also show that the proposed approach has less violations in SLA when compared to the other algorithms and consequently provides more reliable servers with higher availability in the fog infrastructure.

VI. FUTURE WORK

The proposed approach can be applied to Content Delivery Networks (CDNs). Therefore, the CSO-based approach enables the identification and replication of the best content within alternative servers. By leveraging the capabilities of the CSO algorithm, the proposed approach effectively identifies the optimal servers to store and replicate content. This ensures that content is efficiently distributed across multiple servers, enhancing availability, fault tolerance, and overall system performance. In fact, by generalizing this approach and using the tracking mode of cats, the best contents can be obtained to be cached and replicated in servers found in the seeking mode. As a result, the performance of such cloud servers can greatly improve.

A Hybrid Cryptography Method using Extended Letters in Arabic and Persian Language

Ke Wang*
School of Software Engineering, Jilin Technology College of Electronic Information, Jilin 132000, Jilin, China

***Abstract*—Cryptography is widely used in information security systems. In encryption, the goal is to hide information in such a way that only the sender and receiver are aware of the existence of communication and information. Encryption takes place in various media, such as image, sound and text. Today, the rapid growth of network technologies and digital tools has made digital delivery fast and easy. However, the distribution of digital data in public networks such as the Internet has various challenges due to copyright infringement, forgery, coding and fraud. Therefore, methods of protecting digital data, especially sensitive data, are very necessary. Accordingly, in this article, a combined solution is used based on the technique of stretching the letters and making minor changes in the letters that have closed spaces so that the bits related to the hidden text can be inserted into a Persian or Arabic language. For this purpose, a new solution has been designed, in which the cover text is similar to the normal text, with the difference that, in addition to the extended letters that are longer due to the status of the secret message, it also has some prepositions, which have spaces. They are empty and closed. Of course, this difference in the closed space between the original letters and the changed letters will be very slight, and as a result, there will not be much difference between them that the normal user can feel the change. Finally, the proposed solution has been evaluated with the help of the MATLAB program, and according to the rate parameter of encryption capacity, the results show that the proposed method has an average encryption capacity of more than 50% compared to other common solutions.**

Keywords—Cryptography; extended letters; Persian language; Arabic language

I. Introduction

Text-in-text encryption is used for the purpose that the host data does not have any visible signs of the presence of encrypted data in it, and thus it enables the secure transmission of information [1]. Therefore, the way to hide the data is important according to the changes that are made in the external details of the text. But what is of secondary importance is to protect the transmission against widespread attacks on the data sent and, of course, to make the original data unreachable in case the attackers discover the existence of a password in the host data. In fact, the advantage of using text as a cover media is that the text file consumes less storage space and less bandwidth is required for its transmission [2, 29, 30]. In order to encrypt a text, watermarking methods can be used in the text image, shifting the words in the middle space between them or shifting the background line to hide the data of the desired series in the background text, but this method which is considered in this research is the use of making changes in details. The majority of steganography research employs various types of cover media, such as images [3, 31], video clips [4, 32], and audio [5, 33]. Nevertheless, text steganography is not commonly favored due to the challenges associated with identifying redundant bits in text files [6, 7, 34]. Text documents typically exhibit a structure similar to what is visible, while other types of cover media have different structures, making it easier to hide information without noticeable alterations. However, text steganography offers advantages like lower memory usage and simpler communication.

The main goal of this project is to provide a new method for hiding information in Persian and Arabic texts. The choice of steganographic system often depends on the language and its structures. One technique cannot be universally applied to all languages. In the proposed method, it has been tried to avoid making changes in the appearance and format of the font as much as possible so that while increasing the capacity, the level of transparency and readability of the text does not change significantly compared to the state before hiding. So in this method, the technique of stretching Persian and Arabic letters is used in addition to creating changes in the letters that have closed empty space, which includes the letters: "ص،ض،ط،ظ،ع،غ،ف،ق،م،و،ه" covert writing of information in Persian and Arabic texts is discussed. Of course, for the letters "ع, غ" only when these letters are used in the middle of the word, they have a closed space. Therefore, in this method, only one position of the letters "ع, غ" (in the middle of the word) can be used to hide the information in the letters "ع, غ".

This paper is organized as follows. Section I provides an overview for text steganography. Section II discusses the related works. Section III presents our new text steganography technique that utilizing character extension. The evaluation and results are discussed in Sections IV and V, respectively and finally, conclusion and future work are outlined in Sections VI and VII.

A. Cryptography Basics

According to the type of application, several characteristics are considered to express the efficiency of cryptographic methods, which are different in different applications. The important things considered in the design of this method are as follows [3]:

- Transparency: In the encryption operation, it is necessary to hide the information in the desired text in such a way that the inserted information is not visually clear and understandable. This amount of similarity, before and after inserting information, is called transparency.

- Resistance: In a cryptography solution, resistance means against unwanted and unintentional changes that are created due to the presence of noise in the transmission channel or other changes that are intentionally made by an attacker, and it is done in the direction of changing the message so that it has the necessary resistance to a large extent.
- Capacity: The amount of information that can be included in the cover text is called capacity. The methods that are presented for the purpose of encryption should be designed in such a way that they are able to hide a significant amount of information in the cover text.

Considering that in order to encrypt texts, letters and characters need to be converted into a set of numbers 0 and 1 so that they are easy to manage [8, 9, 35]. Therefore, there must be a single standard to determine what characters each of these numbers and letters should display and how they should be stored. This standard is called Unicode.

Converting data so that the system can read and use it is called encoding. In fact, encoding is the process of converting data into a format required for a number of information processing needs, including:

- Data encryption
- Formulation of the program and its implementation
- Data transfer, storage and compression/decompression
- Application data processing, such as file conversion

For the coding standard mentioned above, the American Standards Association introduced a 7-bit coding method called ASCII in 1960. At that time, the ASCII character set, including 128 characters (7 bits), was defined, mostly for Latin languages. ASCII encoding is important because many communication tools and protocols only accept ASCII characters. In fact, this is the accepted minimum standard for the text. Some Unicode encodings, due to the universal acceptance of ASCII, convert their code points into a series of ASCII characters so that they can be moved without any problems. In the 1980s, it was decided to use a full byte (i.e., 8 bits) for encoding in the ASCII character set instead of 7 bits [10, 36]. Therefore, the number of characters reaches 256. Based on this, the characters after 127 to 255 were also considered reserved codes, and other languages, including Persian and Arabic, were generally included in this range. But in this range between different languages, there was no single standard, and each language showed its alphabet code. In other words, code 200 in one language returns a different letter in another language. As a result, there was a need for a single standard to consider unique codes for each character while being compatible with all languages. Based on this, the Unicode unit standard has been presented. Unicode is a set of characters with unique numbers, which is called a code point. Each code point represents a single character. Accordingly, the Unicode standard specifies three encoding methods, allowing a character to be encoded within one or more bytes (i.e., in 8, 16, or 32 bits). These coding methods are as follows [11, 37]:

- UTF-16
- UTF-8
- UTF-32

The difference between these coding methods is in the way letters, numbers and symbols are presented between the languages of different countries. So that the way characters are presented in one country is different from another country [12, 38]. Table I shows the Unicode standard for Persian and Arabic letters, along with the code of each letter in this standard. In cryptography, this table is used to convert each letter to its corresponding value of 0 or 1.

TABLE I. UNICODE STANDARD FOR A NUMBER OF PERSIAN LETTERS, ALONG WITH THE CODE OF EACH LETTER

Form	letter name	Code	Form	letter name	Code
ت	letterت	062A	ء	letterحمزه	0621

II. RELATED WORK

Numerous research studies have explored concealing one text within another, employing diverse linguistic techniques. These studies classify linguistic steganography into two primary categories: syntax-based and semantic-based approaches [13][14] [39].

For instance, [15] and [16] proposed a method based on synonyms, aimed at data concealment. The method consists of two phases: in phase one converting the hidden message into binary codes. In phase two, with the help of a synonyms file, both sender and recipient must possess the same word list for encryption and decryption. If the sender inserts a Zero, no word replacement is necessary. However, if another value is inserted, the synonym file serves as the basis for word replacement. This process continues until the end of the secret message, and the receiver can decrypt the message using an inverse strategy.

In [17] proposed method that takes three input sources (secret message, natural language, and the key) and produces one output known as the Stego-text. The system identifies each word and its corresponding group, generating lexical replacement groups and variant forms of similar words. To ensure proper embedding of the correct word in the carrier file while considering the context, a lexical analyzer for the Chinese language was utilized in the proposed system. The steganography algorithm, based on three inputs representing the source natural language text, the information to hide, and the key, generates one output displaying the stego-text with embedded data. The steps of the steganography algorithm include:

- Embedding data: Encrypting the information into a binary bit sequence using the key (embedded data).
- Text preprocessing: Segmentation of sentences using the Chinese lexical analyzer ICTCLAS, where English characters, Chinese and English punctuation, blank spaces, and new line characters are considered inter-sentence symbols.

In [18], a novel method was proposed to hide information not only in specific pointed letters but in any letters. The researchers utilized pointed letters with an extension to represent the secret bit 'one,' and un-pointed letters with an extension to hold the secret bit 'zero.' It was emphasized that letter extensions do not affect the writing content and are considered redundant characters for formatting purposes in Arabic electronic typing. However, not all letters can be extended due to their positions in words and the nature of Arabic writing. Extensions can only be added between connected letters, not at the end of words or before the beginning letter. Thus, letters without extensions or intentionally without extensions are considered not to hold any secret bits.

In [19], authors introduced a new approach for hiding information by manipulating white spaces between words and paragraphs. The method offered greater capacity to conceal more bits of data within a cover-text. While the previous embedding scheme used the space between words, it required a significant amount of space to encode a few bits. However, combining inter-word and inter-paragraph spacing allowed effective utilization of most white spaces in a text document, increasing the data-hiding capacity.

In [20], the authors built upon a previous Arabic text steganography method using letter points and extensions to address the low-capacity aspect. They proposed a technique to hide information within suitable positions inside words, not limited to pointed letters only. These positions were carefully determined to preserve the beauty of Arabic text if justified, ensuring that the message could be hidden without affecting the cover text. Extensions were inserted at the specified positions to represent the secret bit 'one,' while leaving the positions empty represented the secret bit 'zero.'

Another study [21] introduced the Line Shifting method, which involved shifting lines vertically to pass data via the carrier. However, this method had weaknesses, including the potential detection of line shifting when using character recognition programs and the risk of hidden data destruction when retyping the carrier file.

In [22], researchers adopted a syntactic method based on punctuation to convey the secret message. They added punctuation in suitable locations to hide the data without impacting the carrier message's meaning or affecting the embedded data within it. The study highlighted the importance of finding optimal trade-offs between bit rates, robustness, and perceivability through experimental definitions.

In [23], the researchers used emoticon-based steganography to facilitate secret chatting. They classified emoticons semantically and controlled the symbol order using a secret key to pass the secret message among parties. Different groups of emoticons were created to hide data, and the order of passing a symbol represented specific bit values. This method proved to be robust and beneficial for chat systems, with some systems allowing users to generate their customized symbols.

III. Proposed Method

In this research, a method of hiding in the text is presented so that by using it, confidential texts can be hidden inside the text. For this purpose, a combined solution is used based on the technique of stretching the letters and making minor changes in the letters with a closed, empty space so that the bits related to the hidden text can be hidden inside a normal hidden text. He made a drawing. For this purpose, a new solution has been designed, in which the cover text is similar to the normal text, with the difference that, in addition to the letters that are longer due to the status of the secret message, it also has some prepositions, which have spaces. They are empty and closed. Of course, this difference in the closed space between the original letters and the changed letters will be very slight, and as a result, there will not be much difference between them that the normal user can feel the change [24].

As shown in Fig. 1, the proposed encryption solution will have two inputs. One of its entries will be related to the cover text used for encryption, and the other entry will be the secret message that must be hidden inside the cover text. The proposed solution in the form of a new font acts as a converter and embedder, which can be used to change the cover text in such a way that the secret text can be hidden inside it. This solution will have the following features:

- High capacity to encrypt confidential text.
- High security due to very minor changes.
- High power in encryption.
- High transparency due to minor changes in font.

In fact, through the use of this combined solution, the capacity of confidential messages that must be encrypted can be increased because many Persian and Arabic letters are stretchable and have closed spaces. On the other hand, due to the fact that the changes in the letters are minor, normal users will not be able to recognize the desired changes, and as a result, security is established. Also, this solution is able to be resistant to the factors that can change the data and, as a result, damage the comprehensiveness because the encryption operation is carried out bit by bit according to the state of the letter. The original data is encrypted. On the receiver's side, there is a need to perform an operation in the direction of the photo, and for this purpose, a special tool is provided to detect the changed letters and, as a result, the hidden secret message. As a result, in this case, according to the status of each letter and its length, the main message can be extracted from the cover text, and there is no need for a private key for data exchange. Because in encryption algorithms, the encryption key must also be transmitted, and if for any reason this key is intercepted or discovered, all the encrypted data can be accessed, and as a result, the security and integrity of the data will be compromised [25].

A. How the Method Works

In Arabic and Persian languages, each character can have a different state according to its position. In fact, in this category of languages, a number of letters have the ability to change their shape according to the type of connection that they are at the beginning, end, or middle of a word, which is an important ability for encryption. For example, the letter "ع" at the beginning of the word is written as "عـ " in the middle as "معا " and at the end of the word as "تع " while in English words, each letter is written separately and does not have this feature. Fig. 2 shows a section of different states of Persian letters.

According to the Unicode standard, each letter can have a unique code according to its position. On the other hand, in some cases, in order to make a letter more beautiful, it can also be written with a stroke. For example, the word "خانه", which consists of four letters "خ", "ا", "ن" and "ه" can be written as "خانه" without changing its meaning or the number of letters. In fact, stretching the letters is one of the advantages of Persian and Arabic languages; this ability does not have the slightest effect on the readability or changing the meaning of the text [26]. The only problem is that not all letters have this ability, and it is limited to the position in which that letter is placed; that is, in general, the ability to stretch can be applied to the connecting letters of a word, and this feature cannot be applied to a number of letters that are at the end or beginning of a word [12]. Accordingly, in this research, a combined solution has been used, which solves this limitation to a large extent. In the following, the method of using the ability to stretch the letter is shown with an example. At first, let's assume that we intend to perform the encryption process with the help of dragging on the text of Table II. First, we select the secret bits that should be hidden, which in this example is equal to the value (110010). The encryption operation is performed from the least valuable bits to the most valuable ones. Also, considering that the texts are Persian and Arabic and start from right to left; as a result, encryption is done from right to left. Accordingly, the first secret bit is equal to "0", and considering its value is zero, the letter to be hidden in it is extended once, but if it were one, it would be extended twice. Now, in this example, encryption should be done by stretching the letter "م" once. The value of the next secret bit is equal to "1", and the second letter of this word is "ن" considering that this letter is at the end of the word, so it cannot be extended in this position. The next point from which the operation can be continued is at the beginning of the word Turkey, and considering that the secret bit is equal to "1", as a result, the letter "ت" is doubled and changed to "تـــ ". Find this operation is carried out confidentially until the end of data encryption.

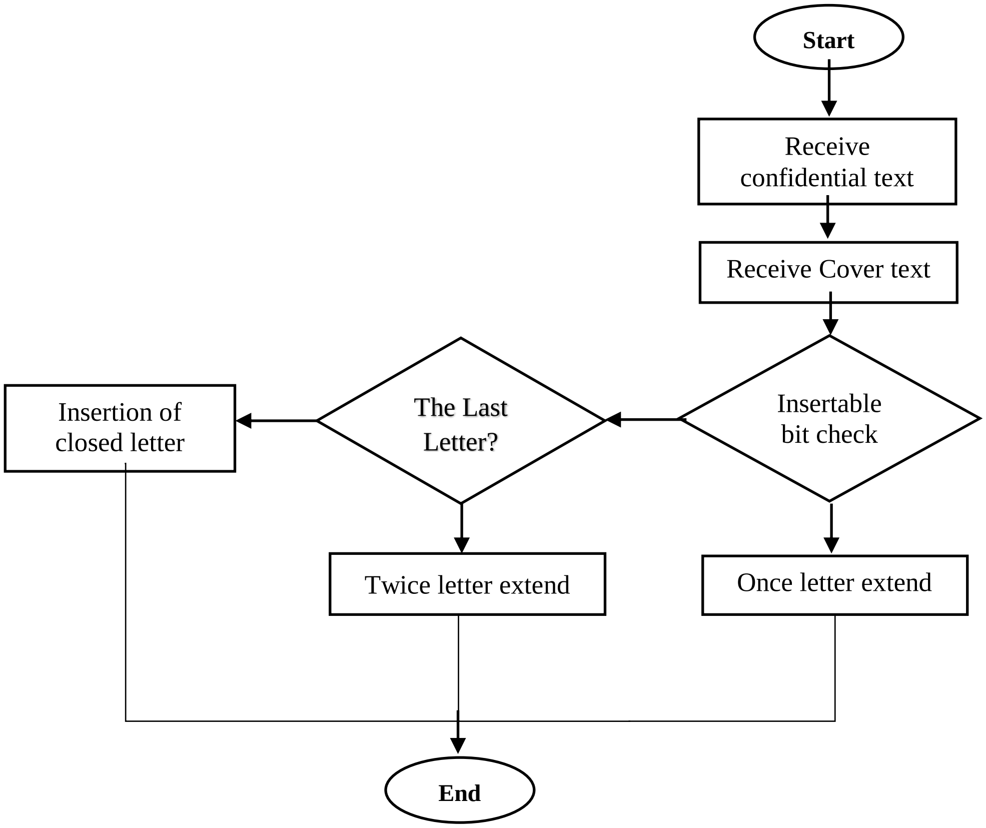

Fig. 3. Proposed method flowchart.

Now, in order to increase the efficiency of the solution, changes can be made in the letters with closed spaces so that the capability of this solution increases. The letters with closed space include the characters "ص،ض،ط،ظ،ع،غ،ف،ق،م،و،ه ". Of course, for the letters "ع،غ" only when these letters are used in the middle of the word will they have a closed space; therefore, in this method, only one position of the letters "ع،غ" (in the middle of the word) can be used to hide the information in the letters "ع،غ". Accordingly, in order to hide these letters, the amount of empty space is slightly smaller so that it has the least effect on changing the font of the desired letters and through this change if the last letter of a word cannot be it is drawn, it is part of the letters with closed space, it is used. As a result, if the insertable bit is zero, the character will remain unchanged. But if the insertable bit was 1, the character is inserted with a smaller enclosed space. In this case, the complete flowchart of the proposed solution is shown in Fig. 3.

IV. EVALUATION

MATLAB 2018 program was used to implement the solution. MATLAB has considered two environments, GUIDE and App Designer, for designing graphic interfaces. The GUIDE environment has been used since the old versions of MATLAB, but the App Designer environment has recently been presented in the new versions of MATLAB and is being developed. Based on this, the user interface related to the proposed solution has been designed with the help of the advanced App Designer tool so that by using it, it is possible to receive cover text and secret text and carry out operations related to encryption or secret text extraction. Fig. 4 shows a view of the program environment implemented in MATLAB.

Based on this and as seen in Fig. 4, the user enters the cover text in the relevant box and then, in the next box, the confidential text that he intends to hide. Then, by clicking the hide button, the confidential text will be hidden inside the cover text according to the proposed solution. An example of the implementation of the solution is shown in Fig. 2 to 4.

The part related to the recovery of encrypted text is also shown in Fig. 5. For this purpose, it is sufficient for the user to click on the button to copy the encrypted text after performing the encryption operation. In this case, the page corresponding to Fig. 6 will open. Now the user clicks on the "decode" button so that the encrypted text will be shown along with the original cover text.

A. Evaluation Parameters

In order to measure the proposed solution, a series of parameters are needed for review and evaluation. According to the studies that have been done on the articles written in the field of cryptography of Arabic and Persian texts, the proposed solution has been examined according to the parameter of cryptography capacity. The following relationship is used to calculate the hiding capacity:

$$CapacityRatio = \frac{\text{hidden text size}}{\text{covered text size}}$$

1) The solutions to be evaluated: In order to check the effectiveness of the solution, it is necessary to compare it with other common methods in the field of text encryption. Accordingly, in this research, the proposed solution is compared and evaluated with the following solutions, which were also examined in the research conducted in [27, 40]:

- Enhanced Kashida [3]
- ZWC and space [8]
- Enhanced capacity [9]
- Pseudo-space [10]
- Method 2 [11]
- Alhusban's method [12]
- Moon and Sun letters [24].

V. Results

Considering that only Arabic texts were used in the evaluation of the solutions mentioned in the previous section, as a result, in order to have the same data in the proposed solution, the same Arabic texts with the same size determined in the evaluated solutions were used. It has been done so that the checks and comparisons are done in a standard and uniform way. First, in order to compare the output of the solutions in Tables III and IV, an example of the output of the solutions has been implemented according to the number of different words. The purpose of this evaluation is to check the output of text encryption in each of the solutions.

Also, in Table IV, another example of the application of encryption solutions is shown on a cover text with a length of 155.

As can be seen in the output of Tables III and IV, the proposed solution is able to perform the encryption operation by applying the least noticeable change in the letters. Now, according to the ratio of encryption capacity, solutions with different lengths have been examined. The purpose of this evaluation is to check the percentage of optimality in hiding the message in envelopes of different sizes. The results of this evaluation are shown in Tables V to VIII. Also, the summarization of the overall performance of the proposed method is shown in Table IX.

As can be seen in Table VI, in the case where in the proposed solution only the encryption technique based on closed letters is used, the encryption capacity has decreased to a great extent. Based on this, the results of this evaluation indicate that the use of the extended technique (keshida) along with closed letters can effectively increase the capacity of cryptography.

As seen in the output of Tables III to VIII, in all three evaluations, the proposed solution has a higher encryption capacity compared to other methods, and with the increase in the length of the cover text, this amount has become more than optimal. The reason for this is the use of two techniques in the proposed solution. So that at first, using the technique of stretching the letters, the encryption operation was done, and as can be seen, this feature did not have the slightest effect on the readability or changing the meaning of the text. In addition, the utilization of the closed space available in Persian and Arabic letters has made the ability of the solution for encryption higher and the more the number of these letters, the higher the encryption capacity. Also, as it is clear from the results of these evaluations, in the case where the proposed solution, only the encryption technique based on the closed letter space is used, the encryption capacity has decreased to a great extent. Based on this, the results of this evaluation indicate that the use of the extended technique along with closed letters can increase the cryptography capacity in a more effective way.

A. *Coverage Capacity*

To assess the capability of the suggested approach, the formula for determining the number of secret message encodings based on letter is presented in [28]. The results are illustrated in Fig. 7, representing the coverage capacity (CC) values computed through the application of Eq. (1).

$$CC(M) = \frac{1}{M}\sum_{i=1}^{M}\frac{(L_i).k}{D(S_i)} \times 100$$

In the given context, "M" denotes the count of covered secret messages, representing the number of matched segments at the maximum length of "N" bits. "Li" refers to the length of each matched segment, measured in the number of letters within it. The average number of embedded bits in each letter of the segment is denoted by "K," and the number of bits in a segment is represented by "D(Si)." For the Arabic letter, the standard encoding system utilizes 8 bits; therefore, D(Si) = 8 * Li.

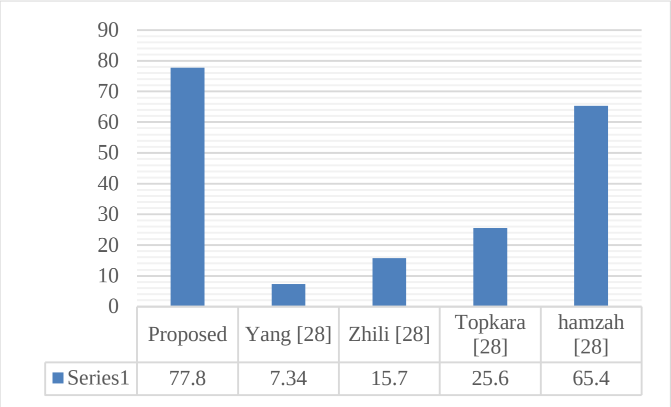

Fig. 7. Coverage capacity compared to other approaches.

Fig. 7 shows the coverage capacity between proposed method and other methods [28]. The coverage rate of the proposed method, which utilizes multiple shapes of letters, significantly surpasses the capacity rate of other methods. These CC values are derived from the proposed and other methods are based on a dataset sample. Furthermore, a comparison is made between these CC values and those obtained from previous works and similar studies to gauge the efficacy and efficiency of the proposed methodology. Upon applying this equation, the coverage capacity of our proposed method, which employs multiple shapes of letters, reached average at level of 77.8%. As can be seen, in this case, the proposed method has performed better than all the other four solutions. It has performed more than 70% better than Yang method [28], and more than 60% better than Zhili method [28], and more than 25% better than Hamzah [28] method. The findings demonstrate that the proposed solution, with employing both stretching and altering closed letters, has achieved a favorable capacity for concealing text.

VI. Conclusion

In Persian and Arabic languages, each letter can have a unique code according to its position. On the other hand, in some cases, in order to make a letter more beautiful, it can also be written with a stroke. In fact, stretching letters is one of the advantages of Persian and Arabic languages; this feature does not have the slightest effect on the readability or changing the meaning of the text. The only problem is that not all letters have this ability, and it is limited to the position in which that letter is placed. Accordingly, this feature has been used in Persian and Arabic languages in this research, and a hybrid encryption solution has been presented. Based on this, minor changes were made in the letters with closed spaces in addition to stretching the letters. The letters with closed space include the characters "ص،ض،ط،ظ،ع،غ،ف،ق،م،و،ه ”. Of course, for the letters "ع،غ " only when these letters are used in the middle of the word will they have a closed space; therefore, in this method, only one position of the letters "ع،غ " (in the middle of the word) can be used to hide the information in the letters "ع،غ ". Accordingly, in order to hide these letters, the amount of empty space is slightly smaller so that it has the least effect on changing the font of the desired letters and through this change, if the last letter of a word that cannot be if is drawn, it is part of the letters with closed space, it is used. As a result, if the insertable bit is zero, the character will remain unchanged. But if the insertable bit was 1, the character is inserted with a smaller enclosed space. In the end, the proposed solution was implemented in the MATLAB program environment and was evaluated by the rate parameter of the encryption capacity compared to other solutions. The evaluations were carried out according to the sentences with different lengths, and the relevant results indicated that in this case, the proposed solution through the use of two techniques of stretching and changing closed letters has been able to have a suitable capacity of hiding to get writing. So in all the evaluations, it has a noticeable superiority compared to other methods.

VII. Future Works

In the future work, we can focus on the development a mobile application. Also, more improvements can be made by using the available space in Arabic and Persian letters. As a result, in this way, the coverage rate can be increased to a greater extent in the proposed solution.

VIII. Funding

This work was supported by the Education Department of Jilin Province 2022 Annual vocational education and adult education teaching reform research project. Project name: Design and Research of Thin Client Online Training System Based on 5G and Cloud Computing Virtualization Technology. Project number: 2022ZCZ011.

A Comprehensive Review of Fault-Tolerant Routing Mechanisms for the Internet of Things

Zhengxin Lan*
College of Power Technology, Liuzhou Railway Vocational and Technical College, Liuzhou 545616, Guangxi, China

***Abstract*—The Internet of Things (IoT) facilitates intelligent communication and real-time data collection through dynamic networks. The IoT technology is ideally suited to meet intelligent city requirements and enable remote access. Several cloud-based approaches have been proposed for constrained IoT systems, including scalable data storage and effective routing. In real-world scenarios, the effectiveness of many methods for wireless networks and communication links can be challenged due to their unpredictable characteristics. These challenges can result in path failures and increased resource utilization. To enhance the reliability and resilience of IoT networks in the face of failures, fault tolerance mechanisms are crucial. Network failures can occur for various reasons, including the breakdown of the wireless nodes' communication module, node failures caused by battery drain, and changes in the network topology. Addressing these issues is essential to ensure the continuous and reliable operation of IoT networks. Fault-tolerant routing plays a critical role in IoT-based networks, but no systematic and comprehensive research has been conducted in this area. Therefore, this paper aims to fill this gap by reviewing state-of-the-art mechanisms. An analysis of the practical techniques leads to recommendations for further research.**

Keywords—Internet of things; routing; data transmission; fault-tolerant; review

I. Introduction

The Internet of Things (IoT) has witnessed rapid growth due to advancements in software and hardware platforms, the expansion of communication networks, and the progress in data analysis tools [1]. IoT refers to a network of interconnected devices that generate and collect data using technologies like RFID, sensors, actuators, and mobile phones [2, 3]. The International Telecommunication Union (ITU) defines IoT as a global infrastructure that connects physical and virtual objects through integrated information and communication technologies. Another definition in [4] describes IoT as a network that connects people and things, allowing them to be connected anytime, anywhere, with anyone and anything, utilizing various networks, paths, and services. Moreover, IoT technology enables communication-related services such as information exchange for collaborative IoT services, user connectivity for global networking, and data offloading to edge cloud servers for enhanced computation [5].

There has been a growing interest in the IoT in academia and industry over the last few years. As the IoT becomes increasingly ubiquitous, it provides comprehensive representations of physical environments and offers a high level of engagement with them [6]. Some examples of potential applications for this innovative paradigm include e-health, business management, Intelligent Transportation Systems (ITS), and logistics. The realization of IoT is greatly influenced by several factors, such as the system's architecture, the network and communication infrastructure, the processing of data, and ubiquitous computing technologies, which enable effective, reliable, physical, and cyber connectivity. As part of IoT, networking, and primarily routing in the network, is an integral component that facilitates the interconnection of devices. It entails the creation of traffic routes and routing packets from the source to the final destination in a network.

In the realm of the Internet of Things (IoT), the convergence of big data, cloud computing, artificial intelligence (AI), machine learning (ML), deep learning, feature and channel selection, meta-heuristic algorithms, game theory, and association rule mining holds paramount significance, shaping the potential and efficacy of IoT applications. The massive influx of data generated by interconnected devices in IoT necessitates the utilization of big data techniques to handle, store, and process this vast volume of information [7]. Cloud computing plays a pivotal role by providing the scalable infrastructure and computational power required for efficient data management and analysis in IoT environments [8]. The integration of AI and ML in IoT applications unlocks the capability of devices to learn from data patterns, enabling them to make intelligent decisions, adapt to changing circumstances, and optimize their performance [9-11]. Deep learning, a subset of ML, further empowers IoT devices to process complex and unstructured data like images, audio, and text, enabling advanced applications in computer vision, speech recognition, and natural language processing [12-15]. Feature and channel selection play a critical role in optimizing IoT data processing by identifying the most relevant data attributes and sources, streamlining data analysis and reducing computational overhead [16]. Meta-heuristic algorithms find applicability in IoT systems for optimization tasks, such as routing and resource allocation, ensuring efficient utilization of resources and enhancing IoT network performance [17, 18]. Moreover, game theory principles are instrumental in designing cooperative or competitive strategies among IoT devices, optimizing resource allocation and energy usage in dynamic IoT environments [19]. Association rule mining brings valuable insights by discovering patterns and correlations within IoT data, aiding in decision-making processes and providing recommendations for improving IoT system performance [20].

Despite the promise of IoT, ensuring network reliability remains a significant challenge. Broken links and faulty nodes can severely impact the reliability of IoT-enabled networks, hindering seamless communication and data exchange. To address this challenge and enhance the resilience of IoT networks, fault-tolerant routing mechanisms are indispensable. These mechanisms are designed to maintain network performance and data delivery even in the presence of failures, disruptions, or changes in the network topology. In light of the growing importance of fault tolerance in IoT networks, this review paper aims to explore state-of-the-art fault-tolerant routing mechanisms comprehensively. By analyzing critical factors such as packet delivery ratio, network lifetime, energy consumption, delay, scalability, availability, and reliability, we seek to identify effective techniques and recommend further research in this crucial area. Our goal is to contribute to the advancement of reliable and resilient IoT networks, unlocking their full potential in various applications and domains.

II. Background

A. IoT Definitions

The IoT has been defined as a communication network where all our daily devices can connect to other devices by identifying, sensing, and processing functions. The International Telecommunication Union (ITU) has defined these devices as innovative items of the information world (virtual objects) or the physical world (physical objects), which may connect and exchange information with each other [21]. As a dynamic global network infrastructure based on standard and adaptive communication protocols, the IoT enables smart and virtual objects to be autonomous, have a physical identity, and have virtual personalities [22]. The IoT is regarded as the most influential among emerging technologies, ranking higher than artificial intelligence and robotics. The IoT is currently the most significant technology trend in the world, as stated by Burrus [23]; it is expected to cause the most disruption and provide the most opportunities over the next five years. According to a study published in Forbes Insights by over 500 executives from countries with a minimum of 500 employees, IoT has acquired global traction [24]. Forecasts encompass all aspects of the IoT ecosystem, including professional services, analytics, security, infrastructure purpose-built IoT platforms, connectivity services, and intelligent and embedded systems. All predictions indicate that IoT adoption and usage will grow regardless of the number of forecasts [5].

The IoT is defined in some ways only from a physical perspective. Real-world or virtual objects can be regarded as things. For example, Al-Fuqaha, et al. [25] defined IoT as the ability of tangible objects to perceive, listen, reason, communicate, collaborate on decisions, and fulfill tasks. As explained in a special IEEE report, the IoT is a network of connected devices, each equipped with sensors. IoT is also described by the Organization for the Advancement of Structured Information Standards (OASIS) as a system where ubiquitous sensors are used to connect the Internet to the physical world. This perspective is often called Machine to Machine (M2M) in definitions. As defined by ETSI, M2M communications are communications between two or more entities without direct human involvement. IoT covers many application fields today, including transport, utilities, healthcare, smart cities, and monitoring. It can apply to a variety of situations effectively. For instance, IoT can collect valuable data through sensor devices. In addition, IoT devices can serve as an efficient means of transmitting data. However, IoT devices have some limitations regarding transmission, processing, battery life, and memory capabilities.

B. IoT Architecture

All nodes in the IoT environment can communicate and cooperate to accomplish predefined goals. Therefore, the IoT must have a layering architecture that is flexible enough to support a wide range of heterogeneous elements over the Internet. Despite the growing number of IoT architectures, none can be adopted as a reference model. A typical IoT architecture comprises three layers: application, network, and perception. In the meantime, researchers have proposed updated models by incorporating additional abstractions into the architecture of the IoT. Fig. 1 illustrates two common IoT architectures. Several research studies like [26, 27] used a 5-layer model similar to TCP/IP. A 5-layer architecture model starts with the perception or objects layer, which comprises physical sensors that collect, process, and analyze information. Several crucial technologies facilitate the transfer of the produced data from the perception layer to the next layer, including Wireless Fidelity (Wi-Fi), Third Generation (3G), Radio Frequency Identification (RFID), Global System for Mobile Communications (GSM), and infrared. The object abstraction layer securely transfers data from the preceding layer (objects) to the upper layer (management of services). This layer serves as a standard interface to handle a variety of things. Known as the pairing (middleware) layer, the service management layer pairs services with requesters based on their names and addresses. IoT programmers can work independently with heterogeneous objects platforms through this layer. The application layer provides the requested services to users. The business layer creates a business representation, flowcharts, diagrams, etc., according to the data provided by the application layer.

Connectivity is a necessary and sufficient condition for IoT, which integrates different technologies. It is, therefore, essential to enhance communication protocols as part of the technology. IoT communication protocols are generally classified into three categories, Server to Server (S2S), Device to Device (D2D), and Device to Server (D2S). S2S communications involve the exchange of data between servers, which is mainly used in cellular networks. Mobile phones can communicate with each other through D2D communication, referred to as the next generation of cellular networks. In D2S, all data is transmitted to servers, regardless of location. These communications require the processing and preparation of data. This challenge calls for various data processing methods, such as analytics at the edge, stream analysis, and IoT analysis at the database. Each process should be customized based on the specific application and its requirements. Cloud and fog processing are two analytics tools used to prepare and process data before transferring it to another application. In a nutshell, sensors and IoT devices collect environmental data. The next step is to extract knowledge from the unprocessed data. Afterward, data can be transferred to other elements, devices, or servers over the Internet [8].

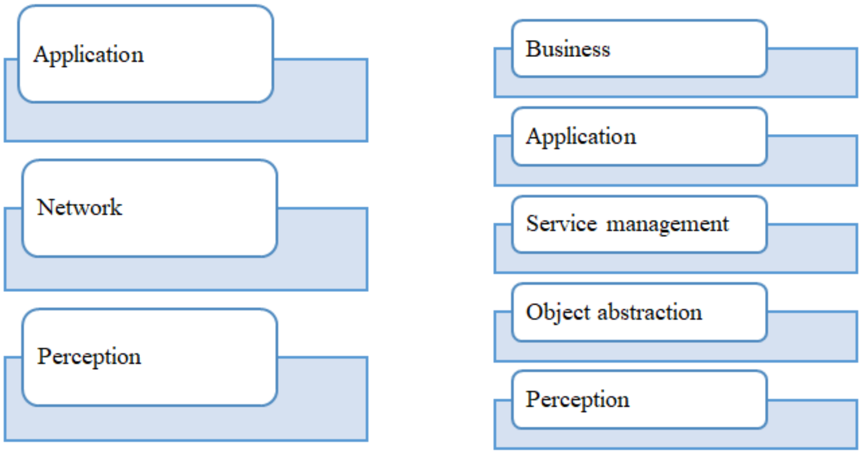

Fig. 1. Two common IoT architectures.

C. IoT Key Elements

As shown in Fig. 2, the IoT environment involves some critical elements defined below.

- Identification: The IoT requires identification to establish its services and match them with the demands of its users. Identifying objects paves the way for query, management, and control of object information. Currently, several identification methods exist, each with its characteristics in terms of coding schemes and analysis systems, such as Ubiquitous Codes (uCode) and Electronic Product Codes (EPC) [28].

- Sensing: IoT sensing involves capturing data from connected sensor nodes and delivering it to a database or data warehouse. Based on the recorded data, specific actions are taken according to the required services. IoT sensors can be intelligent actuators or wearable sensing devices [29].

- Communication: Connecting heterogeneous objects with IoT communication technologies enables customized intelligent services. Generally, IoT nodes should operate at low power when communication links are lossy and noisy. The IoT uses a variety of communication protocols, such as RFID, Near Field Communication (NFC), Wi-Fi, ultra-wide bandwidth (UWB), LTE-Advanced, IEEE 802.15.4, Z-wave, and Bluetooth [30].

- Computation: The IoT is powered by microcontrollers, microprocessors, SOCs, FPGAs, and software applications. IoT applications can be run on various hardware platforms, including T-Mote Sky, Z1, Cubieboard, Gadgeteer, Raspberry PI, and Arduino [31].

- Semantics: The concept of semantics focuses on the capability of machines to intelligently extract knowledge to facilitate the provision of services necessary for the IoT. Extraction of knowledge involves discovering and utilizing resources and incorporating information into models. In addition, it consists of the recognition and analysis of data to determine the most appropriate service. Semantics are integral to the IoT by sending requests to the appropriate resources. Semantic Web technologies, such as the Resource Description Framework (RDF) and Web Ontology Language (OWL), support this requirement [32].

- IoT service: Aiming to facilitate human life, the IoT provides a wide range of services typically delivered as physically isolated vertical solutions. Discovering suitable IoT services faces various challenges and requirements, such as the heterogeneity of accessible services, vast distribution of services, and a highly dynamic environment [33]. Some essential services that IoT provides include healthcare systems [34], remote control [35], transportation [36], education [37], environment monitoring [38], disaster recovery [39], and anomaly detection [40].

- IoT resource: As the IoT entails diverse heterogeneous components, it requires substantial storage and processing to meet users' requests and provide valuable services. Some applications may require complex processing, such as time series analysis, while others may be latency-sensitive. Since the resources of IoT objects are limited in terms of energy, network bandwidth, CPU, and memory, it isn't easy to obtain an ultra-scale and real-world IoT network without taking advantage of cloud platforms or some powerful devices, such as edge or fog nodes and smart gateways [41].

- IoT task: In an IoT-based network, users' requests are organized into two main types of tasks: independent tasks and dependent tasks. The separate tasks, also called atomic tasks, refer to the tasks in which no dependency exists among them. In contrast, the dependent tasks require a specific execution order due to their relationship [42].

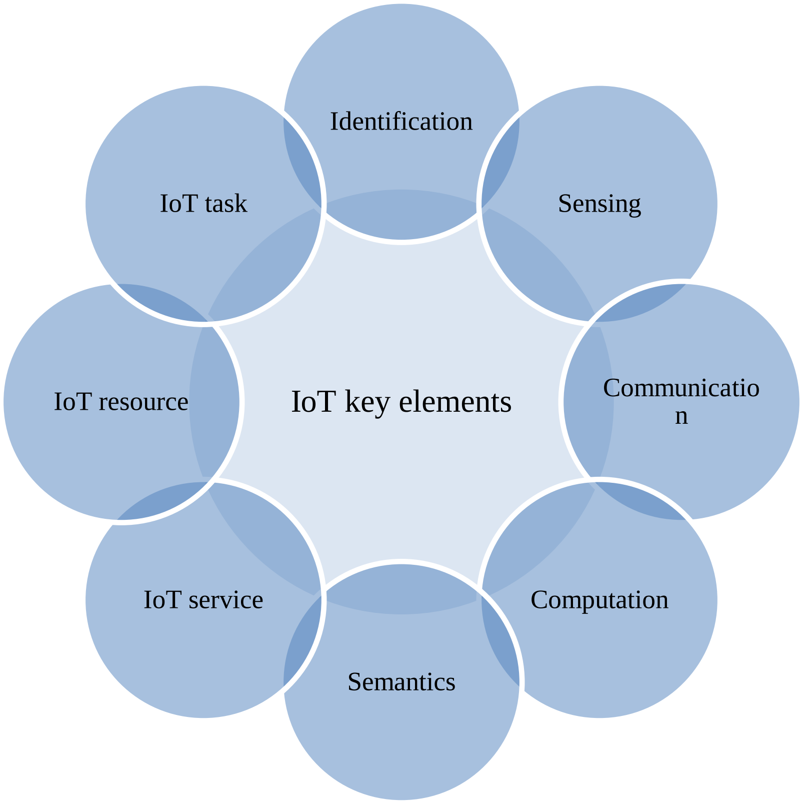

Fig. 2. IoT key elements.

D. *Basic Optimization Parameters*

- Optimization problem definition: Optimization in the computational domain refers to selecting the most optimal solution, among others, based on various factors [43].

- Search space: In a given problem, the search space refers to a collection of potential or candidate solutions. Each point within the search space represents a specific solution that can be evaluated based on its value or suitability for the problem. The search space encompasses all feasible solutions that can be explored and considered during problem-solving. Analyzing and assessing different points within the search space can identify the most optimal or desirable solution for the problem. [44].

- Objective function: An objective function quantifies the solution to an optimization problem. It refers to an optimization objective, such as minimizing or maximizing metrics (e.g., performance, energy consumption). Optimization variables are transformed into real numbers by the objective function, which can be a single-objective (minimizing response time) or a multi-objective (e.g., minimizing energy consumption and maximizing throughput) [45].

- Population and individual encoding: In meta-heuristic algorithms, individuals within a population represent potential solutions to a specific problem. These individuals are encoded using various data structures, such as Boolean values, strings, or trees. The choice of encoding depends on the nature of the problem being solved and the information required to represent the solutions accurately. In many cases, fixed-length and fixed-order bit strings encode candidate solutions in meta-heuristic approaches. This allows for a consistent and standardized representation of solutions across the population. Fig. 3 illustrates the common encoding methods employed in meta-heuristic algorithms. The encoding can involve binary, discrete, or real values, depending on the specific problem requirements and constraints [46].

- Initialization: Initialization is the process of assigning initial values to the search space in order to create the initial population for a meta-heuristic algorithm. The selection of initial solutions can be made using various methods, one of which is random initialization. In random initialization, individuals are randomly chosen from the search space to form the initial population. This means that the values of the individuals are selected without any specific pattern or bias, providing a diverse starting point for the algorithm. Random initialization helps to explore different regions of the search space and avoids getting stuck in local optima. By introducing randomness in the selection of initial solutions, the algorithm has the potential to discover better solutions throughout the optimization process [47].

Needs modification to the optimization algorithms provided for continuous

Fig. 3. Encoding techniques adopted in IoT routing.

- Termination criteria: Optimization algorithms are typically executed multiple times in order to obtain the best possible results. The way in which these algorithms are executed can be classified as either dynamic or static. In dynamic mode, the iterations of the algorithm continue until the fitness function, which measures the quality of the solutions, fails to improve after a certain number of repetitions. This approach allows the algorithm to adapt and continue searching for better solutions as long as progress is made. If the fitness function stops improving, it suggests that the algorithm has reached a point where further iterations are unlikely to yield significant improvements. In static mode, a fixed number of iterations is predetermined before the optimization algorithm begins. The algorithm will iterate for the specified number of iterations, regardless of whether the fitness function continues to improve or not. Once the predetermined number of iterations is completed, the algorithm terminates. Both dynamic and static termination criteria have their advantages and use cases. Dynamic termination criteria provide flexibility and allow the algorithm to adapt its stopping point based on progress. On the other hand, static termination criteria provide a predetermined stopping point, which can be useful in scenarios where a fixed number of computational resources or time is allocated for the optimization process. The choice of termination criteria depends on the specific problem, available resources, and desired optimization objectives [48].

III. Review of Fault-Tolerant Routing Protocols

This section reviews recent fault-tolerant IoT routing protocols based on important factors such as network lifetime, energy consumption, packet delivery ratio, delay, scalability, availability, and reliability. The strengths and weaknesses of existing works are briefly outlined. Table I provides a side-by-side comparison of the protocols using qualitative parameters for analysis and evaluation. This comparison helps identify efficient methods based on specific requirements.

Agarwal, et al. [49] introduced a multi-objective Deep Reinforcement Learning (DRL)-based approach to fault tolerance in IoT-enabled WSNs. They proposed a double-layer DRL-based approach that incorporates a low-level DRL agent to identify and isolate faulty nodes and a high-level DRL agent to select optimal fault-tolerant routing paths. Their approach was tested on a real-world WSN dataset and showed promising results. The proposed double-layer DRL-based approach enables the WSNs to identify and isolate faulty nodes in a timely manner and select optimal fault-tolerant routing paths with the optimal deployment of resources. The results of the study suggest that the proposed approach is able to detect faulty nodes with high accuracy and minimal overhead, which is essential for the robust and reliable operation of IoT-based WSNs. In addition, it emphasizes the need to transmit data in a reliable manner after fault detection. This is because faulty nodes can cause significant delays in data transmission and lead to data loss. The proposed approach is able to identify such faulty nodes quickly, allowing them to be removed from the network and data transmission to be resumed in a timely manner. The last step is to use a mobile sink to gather data in an energy-efficient manner, which in turn significantly increases the lifetime of the network. The proposed algorithm outperformed the state-of-the-art algorithms in terms of throughput, network lifetime, and fault detection accuracy.

Moreover, it demonstrated superior scalability, allowing it to be implemented in larger networks without compromising performance. However, there are some potential drawbacks to this algorithm as well. One such drawback is that it requires more computational resources than some of the other algorithms. Additionally, it is unclear how well this algorithm will perform in more complex networks.

Cluster-based routing is an effective way to reduce transmission overhead and conserve energy as well as improve transmission quality. It also allows nodes to form clusters which are then used to route data between nodes. By forming clusters, the number of messages that need to be transmitted across the network is reduced, which leads to improved energy efficiency. The Cluster Heads (CHs) are responsible for aggregating and filtering the sensed data before forwarding it to the base station, which further reduces the transmission overhead. Additionally, cluster-based routing allows for better scalability, as nodes can be added or removed from clusters without disrupting the overall network. When one or more CHs fail, the faulty CHs cannot forward data from their serving sensor nodes. This results in insufficient sensed data of the IoT application field being available to the sink node. The IoT applications will be adversely affected by this change. Lin, et al. [50] developed virtual CH formation and flow graph models to tolerate CH failures effectively. By using the virtual CH formation and flow graph models, the resources of all failure-free CHs can be effectively utilized. This allows the CHs to serve as a backup for any faulty CHs, ensuring that packets are still able to be routed properly even in the event of a failure. The experiments conducted show that the approach is successful in providing fault-tolerant routing for IoT WSNs. However, there are also potential drawbacks to this approach. For example, if there are too many CH failures, the system may become overloaded and unable to function properly. Additionally, if the CHs are not properly distributed, this could lead to areas of the network being underserved or not having any CHs at all.

WSNs are vulnerable to physical and environmental factors, such as node failure, interference, and signal attenuation, which can lead to significant delays and packet losses. This can cause disruption to applications that rely on the network for communication, such as smart home applications and automated industrial systems. Topology changes, battery drain, or failure of the wireless node communication module pose the greatest threat to network failure. These factors can cause a decrease in the Quality of Service (QoS) of the network, which can lead to increased latency, data loss, increased energy consumption, and, finally, failure of the application. WSNs can be configured with fault tolerance mechanisms to ensure reliable data acquisition and transmission in IoT applications. Jaiswal and Anand [51] proposed a fault-tolerant cluster-based routing scheme for WSNs combining Grey Wolf Optimization (GWO) and Firefly Optimization (FO) algorithms. An optimal clustering algorithm is implemented using FO, and a routing algorithm is implemented using GWO. To improve network performance and meet quality of service criteria, the algorithm takes into account the energy efficiency and fault tolerance of sensor nodes and CHs. The FO and GWO algorithms were simulated in WSN scenarios in order to compare the results to those from existing techniques. The results showed that the algorithms were able to achieve optimal clustering, improved network performance, and higher energy efficiency while also providing greater fault tolerance and meeting quality of service requirements. However, it should be noted that the FO and GWO algorithms have not been tested in large-scale or real-world scenarios. As such, it is unclear how well they would perform in these types of environments.

The routing strategy proposed by Muhammed, et al. [52] uses multiple clusters and a hierarchical routing structure, which allows it to detect faults and dynamically reroute messages quickly. This reduces the amount of energy consumed and increases the reliability of the network. The simulations show that the proposed method is more reliable and efficient than LEACH and DFTR protocols, as it can detect and reroute traffic more quickly and with less energy consumption. This makes it a better option for networks with large numbers of nodes and dynamic traffic patterns. According to the results, the proposed method performs better than LEACH and DFTR in terms of the network's total energy, the number of nodes left active after a given period, and the network bandwidth. The proposed method is able to balance the energy load more efficiently by selecting the appropriate nodes for activation. It also provides a more balanced traffic pattern across the entire network, which leads to improved energy efficiency and better performance overall. However, there are some potential drawbacks to the proposed method. First, it is more complex than LEACH and DFTR and thus requires more processing power and time to execute. Second, it may be less effective in very large networks with a large number of nodes due to the increased complexity.

WSN-based IoT networks are deployed to collect and transmit data from various sources. IoT sensor nodes within these networks possess diverse properties and characteristics. To efficiently manage data transmission, cluster-based routing is commonly employed. This approach involves dividing the network into clusters, with each cluster being managed by a CH node responsible for aggregating and forwarding the data. However, in the event of one or more CH failures, the sensor nodes within the affected clusters are unable to forward their sensed data to the CHs.

Consequently, the sink node or gateway, which receives and processes the collected data, may not be able to effectively receive the data from the IoT application due to the disrupted data transmission caused by the faulty CHs. This will have a significant impact on the processing of information in this field. To avoid this problem, a more reliable routing protocol is needed that can detect and recover from faults quickly. Such a protocol should be able to detect the failure of CHs and re-assign the sensed data of sensor nodes to other CHs so that the sink node (gateway) can still collect the sensed data of the IoT application in a timely manner. Sivakumar and Vivekanandan [53] present a paired cluster of fault-tolerant disjoint path routing in a path graph and a novel method for solving this dilemma in polynomial time. By providing disjoint paths, the proposed routing model increases the reliability of the system since even if one path fails, the data packets can be rerouted over the other path.

Additionally, the polynomial time solution ensures fast and efficient routing in terms of latency and throughput. The benchmark network simulators measure the latency, throughput, packet delivery ratio, and packet drop ratio in order to accurately evaluate the proposed routing model's performance. In addition to the reliability and efficiency of the system, the simulators also measure the scalability of the model in order to ensure that it can handle large numbers of nodes in a network. However, there are some potential drawbacks to this approach. For example, if the network topology changes, the routing table will need to be recalculated, which could cause delays in communication. Additionally, this approach may not be well suited for highly dynamic networks.

IoT routing problems can be most effectively addressed by swarm intelligence algorithms. Swarm intelligence algorithms are highly adaptive and flexible, allowing them to adjust to changes in the environment and traffic conditions. They also have the ability to make decisions based on real-time data and to quickly update routing paths in response to changes in the network. This makes them an ideal tool for addressing the ever-changing challenges of IoT routing. IoT devices should be fault free in order to improve their efficiency and reliability. To ensure that the devices are error free, many approaches and mathematical models are used. Sharma, et al. [54] proposed the Improved Efficient and Intelligent Fault-Tolerance Algorithm (IEIFTA). IEIFTA can fix any fault at a fast rate, improve efficiency, and prevent data loss if any fault occurs. IEIFTA is a highly reliable and efficient algorithm that can identify the source of any fault and fix it before it can affect the entire system. It also uses a predictive model to anticipate potential faults and take preventive measures to ensure that the system remains error free.

Additionally, it can identify any potential threats and take preventive measures to ensure that the system does not suffer from any data loss. However, there are some potential disadvantages to using IEIFTA. First, it is possible that the algorithm may identify a false positive, which would result in the unnecessary shutdown of a system. Additionally, IEIFTA requires a significant amount of data to be effective, which may not be available in all cases. Finally, the algorithm may be computationally intensive, which could impact its performance in real-time applications.

The proposed routing protocol Bounceur, et al. [55] addresses the need for a leader node in ad hoc networks, particularly in WSNs and IoT networks. The leader node serves various purposes, such as key generation for encryption or decryption and identifying nodes with minimum energy. In their protocol, the process of identifying boundary nodes begins by placing a leader node on the far left of the network. These nodes typically monitor sensitive, dangerous, or inaccessible areas. Since it can be challenging or impossible to intervene if a node fails, the algorithm must be robust and fault-tolerant. In case the leader node fails, it can have catastrophic consequences. To overcome these challenges, the authors propose a new algorithm called DoTRo, which is based on a tree routing protocol. The algorithm involves initiating a flooding process by the local leaders to determine a spanning tree. During this process, the values of the local leaders are routed. If two spanning trees meet, the tree with the best value continues while the other tree stops. The dominant tree that remains becomes the leading tree, and its root becomes the new leader. The DoTRo algorithm has demonstrated high energy efficiency, achieving reduction rates exceeding 85%. It operates effectively even in scenarios where any node can fail or when the network becomes disconnected. The algorithm is designed to be efficient and fault-tolerant in such situations.

Increasingly sophisticated applications, such as fire sprinkler systems, employ multiple sources and sinks, referred to as many-many IoT networks. The development of a fault-tolerant routing protocol is necessary for these critical applications to ensure that messages can be routed around failed nodes without causing significant overhead. Focusing on many-many IoT networks, Grosso and Jhumka [56] propose an efficient distributed fault-tolerance IoT routing scheme based on the Ant Colony Optimization (ACO) algorithm, capable of routing data from multiple sources to multiple sinks. Based on the simulation results, the protocol achieves a delivery rate of more than 80% with a failure rate of only 5%. In comparison with a number of approaches that require periodic maintenance of the topology, this approach is more scalable.

Hasan and Al-Turjman [57] introduce a biologically inspired particle swarm optimization (PMSO) routing approach for constructing, recovering, and selecting k-disjoint paths that can tolerate failure while maintaining the quality-of-service requirements. Using a multi-swarm strategy, the optimal direction for selecting the multipath routing can be determined while all segments of the network exchange message at the same time. Compared with canonical particle swarm optimization (CPSO), the proposed algorithm has demonstrated high-quality solutions. The results indicate that multi-swarm and full PMSO with constriction coefficients are superior to CPSO in terms of sensor count and 89.15% and 86.51% under the ring and mesh topologies, respectively.

Misra, et al. [58] suggest an integrated multi-layer and learning automata-based fault-tolerant routing approach for IoT networks, ensuring packet delivery despite failures affecting both source and destination nodes. As this work involves IoT, the algorithm designed should be highly scalable and should deliver high levels of performance in heterogeneous environments. The learning automata and multi-layer strategies incorporated into the proposed method provide a flexible structure to the algorithm so that a consensus can be achieved across the network using the same standard. As a result, it chooses the optimal action based on the changing environment. In order to conserve energy, all nodes located on unused paths are put to sleep. Simulated results show that the proposed strategy improves the overall energy efficiency of the network and reduces overhead compared to the existing protocols we have used as benchmarks.

In order to address the constraints of IoT systems, numerous cloud-based solutions with effective routing and scalable data storage have been presented. These solutions allow for the efficient handling of large amounts of data and reliable communication between connected devices. They also provide a secure and reliable platform for various applications and services, such as analytics and machine learning. However, as mobile networks and communication links are unpredictable, most of the solutions may not be suitable for realistic applications and will result in path failure and an increase in resource consumption. Thus, data forwarding can only be reliable and valuable when the algorithms proposed are trusted and aware, have low overheads, and consume a balanced amount of energy across the nodes. Haseeb, et al. [59] suggested a fault-tolerant supervised routing scheme in the context of IoT trust management in order to enhance trustworthiness and collaboration within smart cities. A reliable and optimized network structure is established by each node evaluating its neighbors' behavior.

Furthermore, a fault-tolerant relaying system is provided by employing supervised machine learning without imposing additional overhead. In addition, it eliminates the additional workload associated with determining the optimal decision and training the IoT system to balance network costs. Finally, a secure algorithm with secured keys is proposed to ensure the privacy and authentication of the relaying system. Compared with previous work, the proposed model has shown significant improvements in performance. However, the proposed model has not been proven to be secure against all possible attacks. Furthermore, the algorithm has not been tested on a large scale.

Chanak, et al. [60] present a fault-tolerant routing protocol for IoT-driven WSNs, which significantly enhances the QoS of these networks. They develop a new multi-population z-test-based fault detection method to identify faulty devices in the network. This method is based on the analysis of the data collected from the network and uses a combination of the z-test and the chi-square test to detect faulty nodes. The protocol also utilizes a novel routing algorithm to reroute the data around faulty nodes in order to ensure that the data is delivered to its destination in a timely manner with minimal disruption. The proposed routing protocol has been designed to provide fault tolerance and flexibility, allowing the reuse of faulty nodes in the network. The experiments conducted to test the protocol demonstrate its efficiency and effectiveness in various areas, including fault detection accuracy, energy consumption, and network lifetime. The results of these experiments are then compared with the state-of-the-art algorithms to show the effectiveness of the proposed scheme. However, there are some potential drawbacks to this scheme that should be considered. First, the reliance on faulty nodes could lead to increased network instability. Second, the additional overhead required to maintain the fault tolerance could lead to higher energy consumption and shorter network lifetimes.

In Industrial 4.0, safety is one of the main concerns, where various physical parameters are monitored to prevent uncertain events. A natural disaster, such as a fire or the leakage of harmful gases, can cause tremendous damage to both life and property in the industrial sector. Industrial IoT (IIoT) is employed to monitor such natural calamities and take appropriate action in a timely fashion. The IIoT, however, is susceptible to sensor failures as a result of energy depletion and hardware malfunctions. This results in a significant reduction in the network's reliability. Kaur and Chanak [61] propose a fault-tolerant framework in which faults in the WSN-assisted IIoT in the form of node failures and link failures are identified and handled efficiently. The proposed framework uses a distributed consensus-based approach to identify and detect faults in the WSN-assisted IIoT. It also uses a fault-tolerant routing protocol to route traffic around the faulty nodes, thus ensuring that the IIoT remains reliable even in the case of a node or link failure. The proposed scheme has been extensively simulated and has been found to outperform other schemes as measured by recovery speed, communication delay, network lifetime, throughput, and energy consumption. Although the proposed scheme has been found to have many benefits, there are also some drawbacks to consider. For example, the scheme requires more energy to operate than other schemes, which may not be feasible for some IIoT applications. Additionally, the scheme may not be able to handle all types of node and link failures, which could lead to network outages.

The implementation of various technologies for industrial information delivery and process control has been hindered by the challenges of increased complexity and associated faults. These factors have posed obstacles to achieving reliable and timely network activation. This is because industrial systems are usually comprised of multiple components that can be affected by different environmental conditions, as well as by the transmission of inaccurate or incomplete data. As a result, the transmission of reliable data to activate the timely network is challenging. In order to transfer this data from one node to another, there must be no faults or delays between the nodes. As a solution to this problem, Vishal Sharad, et al. [62] developed a new algorithm to communicate messages between different services without any delays. Their algorithm, based on the MoO4RPL objective, simulates IoT with mobile sink nodes in the network. The strategy consists of several phases, including topology generation, route discovery, communication, and route maintenance. In the multi-objective route discovery phase, the algorithm constructs the network topology and calculates a rank based on factors, such as energy, trust, delay, fault tolerance, and link quality. The proposed method with fitness function factors is used to select the optimal route during the communication phase. The fitness function factors are used to evaluate each route based on metrics, such as distance, energy, link quality, and trust. The route with the best metrics is determined to be the optimal route and is then maintained during the route maintenance phase. However, the proposed method may not be feasible in real-world scenarios due to the computational overhead required to calculate the fitness function factors for each route. In addition, the proposed method does not consider dynamic changes in the network, which can lead to suboptimal routing decisions.

Pankajavalli and Karthick [63] introduced a novel approach known as the Free Poisson Law method. This technique addresses the challenge of paired fault-tolerant cluster routing in a data flow graph by establishing disjoint routes. The technique utilizes the idea of assigning probabilistically independent Poisson-distributed weights to the edges of the graph. This allows for a simple and efficient algorithm that can find a pair of disjoint routes between two nodes using a single pass through the graph. The Free Poisson Law technique takes advantage of the fact that Poisson-distributed weights can be used to represent the probability of a given edge being selected. This allows the algorithm to select a pair of disjoint routes that are both likely to be successful. In addition, the algorithm only needs to take one pass through the graph, making it highly efficient. The primary objective of the algorithm is to minimize latency, energy consumption, dissipated energy, and functional complexity, thereby enhancing the packet delivery ratio, throughput, and fault detection rate. However, the proposed algorithm does not guarantee that the selected pair of routes will be successful. In addition, the algorithm may not be able to consider all the factors that can affect packet delivery, such as network congestion.

IV. DISCUSSION

The reviewed protocols encompass diverse approaches, each offering unique advantages and addressing specific challenges. Throughout our analysis, we observed that fault tolerance plays a pivotal role in ensuring the reliability and resilience of IoT networks, particularly in the face of various failures, topology changes, and node malfunctions. One promising approach we encountered is the use of Deep Reinforcement Learning (DRL)-based methods for fault tolerance in IoT-enabled Wireless Sensor Networks (WSNs) [36]. These approaches leverage a double-layer DRL agent to identify and isolate faulty nodes and select optimal fault-tolerant routing paths. The results indicate high accuracy in fault detection with minimal overhead, enabling robust and reliable operation of IoT-based WSNs. However, some of these algorithms may require more computational resources and might not perform optimally in highly complex networks.

Cluster-based routing emerged as an effective method for conserving energy and improved transmission quality by forming clusters and aggregating data before forwarding it to the base station. To handle potential CH failures, virtual CH formation and flow graph models are proposed to effectively utilize resources from failure-free CHs, ensuring continuity in data routing. However, the proper distribution of CHs and excessive CH failures could still pose challenges to the overall system's stability and efficiency. Multi-cluster and hierarchical routing structures provide a rapid fault detection and dynamic rerouting mechanism, reducing energy consumption and increasing network reliability. While such protocols demonstrate superiority in terms of network performance, they may require more processing power and might be less effective in very large networks.

Swarm intelligence algorithms, known for their adaptability to changing environments, have shown the potential to address IoT routing problems effectively. Such algorithms can anticipate faults, fix them promptly, and make decisions based on real-time data, making them suitable for the dynamic challenges in IoT routing. However, their effectiveness in large-scale or real-world scenarios remains to be validated.

Cloud-based fault-tolerant routing solutions have been proposed to address the constraints of IoT systems. These solutions aim to handle large data volumes and offer reliable communication between devices. Supervised routing schemes based on trust management enhances trustworthiness and collaboration in smart cities. However, ensuring security against all possible attacks and real-world testing in large-scale environments are still areas of concern. In the Industrial IoT (IIoT) context, a distributed consensus-based approach coupled with fault-tolerant routing protocols has been introduced to handle sensor failures and link disruptions. While the proposed framework demonstrates improved efficiency and effectiveness, it may require additional energy, and its ability to handle all types of node and link failures requires further scrutiny.

Finally, the Free Poisson Law method presents a novel technique for establishing disjoint routes in paired fault-tolerant cluster routing in data flow graphs. This technique provides an efficient algorithm for finding probabilistically independent Poisson-distributed weights on graph edges, minimizing latency and enhancing packet delivery ratio. However, ensuring successful routing and considering all factors affecting packet delivery requires further investigation. In conclusion, our review of fault-tolerant routing mechanisms in IoT-based networks has revealed a rich landscape of innovative approaches that tackle the challenge of ensuring reliable and resilient communication. Each approach offers unique strengths and limitations, making it crucial to select the most appropriate method based on the specific application requirements and network characteristics. We recommend further research to explore hybrid approaches, combining the strengths of different techniques and conducting extensive real-world testing to validate the performance and scalability of these methods. Additionally, addressing security concerns and investigating the potential trade-offs between energy efficiency and fault tolerance is vital for optimizing network performance in IoT environments. By building upon these findings and pursuing further research in fault tolerance, we envision the development of more robust and efficient IoT networks, unlocking their full potential in diverse applications and domains.

V. Conclusion

The IoT is revolutionizing various facets of our lives and leading us towards enhanced societies in the future. WSNs play a crucial role in the IoT landscape. Energy conservation, resilience, and reliability are three essential requirements for WSNs. The ability of WSNs to tolerate faults ensures their reliability and resilience in the event of failure. The most frequent causes of network failure are typically attributed to changes in network topology, node failure caused by battery depletion, and the malfunctioning of wireless communication modules within nodes. These factors have been identified as the primary culprits responsible for disrupting the seamless operation of networks. It is essential to address these challenges to ensure the reliability and stability of network connectivity in various environments. This paper reviewed state-of-the-art fault-tolerant IoT routing protocols concerning critical factors such as packet delivery ratio, network lifetime, energy consumption, delay, scalability, availability, and reliability. Based on the analysis of the effective techniques, recommendations are made for further research. One promising direction lies in exploring machine learning-based approaches, leveraging real-time data to dynamically adapt network routing decisions. Additionally, investigating the integration of blockchain technology could enhance the security and reliability of fault-tolerant routing in IoT systems. Efforts towards developing lightweight fault-tolerant routing algorithms, mindful of the resource constraints and energy limitations of IoT devices, will greatly benefit the scalability and practicality of fault-tolerant IoT networks. Moreover, tailored fault-tolerant solutions catering to specific IoT applications, such as smart cities, industrial automation, or healthcare systems, can better address unique challenges and requirements in those domains.

DeepShield: A Hybrid Deep Learning Approach for Effective Network Intrusion Detection

Hongjie Lin*
School of Economics and Management, Xiamen University of Technology, Xiamen, 361024, China

Abstract—**In today's rapidly evolving digital landscape, ensuring the security of networks and systems has become more crucial than ever before. The ever-present threat of hackers and intruders attempting to disrupt networks and compromise online services highlights the pressing need for robust security measures. With the continuous advancement of security systems, new dangers arise, but so do innovative solutions. One such solution is the implementation of Network Intrusion Detection Systems (NIDSs), which play a pivotal role in identifying potential threats to computer systems by categorizing network traffic. However, the effectiveness of an intrusion detection system lies in its ability to prepare network data and identify critical attributes necessary for constructing robust classifiers. In light of this, this paper proposes, DeepShield, a cutting-edge NIDS that harnesses the power of deep learning and leverages a hybrid feature selection approach for optimal performance. DeepShield consists of three essential steps: hybrid feature selection, rule assessment, and detection. By combining the strengths of machine learning and deep learning technologies, a new solution is developed that excels in detecting network intrusions. The process begins by capturing packets from the network, which are then carefully preprocessed to reduce their size while retaining essential information. These refined data packets are then fed into a deep learning algorithm, which employs machine learning characteristics to learn and test potential intrusion patterns. Simulation results demonstrate the superiority of DeepShield over previous approaches. NIDS achieves an exceptional level of accuracy in detecting malicious attacks, as evidenced by its outstanding performance on the widely recognized CSE-CIC-DS2018 dataset.**

Keywords—Network intrusion detection system; IDS; cyber security; machine learning; deep learning

I. Introduction

The Internet has evolved into a necessary tool and one of the most reliable sources of knowledge about the modern world. It can be considered a crucial component of education and business. Therefore, preserving data across the Internet becomes challenging [1]. Nowadays, internet security is a serious problem [2]. Over the last decade, computer networks have grown in complexity, usage, and size. Cloud computing and the Internet of Things (IoT) have evolved into entirely new types of devices and networks [3]. These networks and systems have grown in size and complexity, so their security has become a critical concern [4]. According to CyberEdge group statistics, the number of attacks on large enterprise networks worldwide has increased significantly in recent years [5]. Advanced Persistent Threats (APT), malware, and denial of service attacks are examples of these attacks [6]. APTs are particularly hazardous and expensive since they are long-term, targeted operations carried out by sophisticated perpetrators targeting the public sector and business enterprises in order to exfiltrate data and cause infrastructure damage [7]. According to cybersecurity studies, these attacks were active for an average of 184 days in 2018 (the duration of attack effectiveness before it is detected) [8].

As a primary layer of defense against computer system vulnerabilities and attacks, a robust security model implements industry-standard security standards such as authorization, access control, confidentiality, and other security requirements [9]. Nevertheless, attacks are likely to continue to present a threat due to vulnerabilities in the system, operational errors, and other issues [10]. Intrusion Detection Systems (IDSs) are critical in identifying and alerting system administrators to intrusions into computers and networks [11]. The IDS can be installed on individual servers within a network, at a centralized location, or distributed around the network [12]. A Network Intrusion Detection System (NIDS) is a kind of IDS intended to track attacks across multiple hosts instead of a single host. These systems monitor network operations using network telemetries, such as network traffic, network flow metadata, and host event logs, to identify attack events [13].

In the realm of NIDS, the convergence of machine learning, artificial intelligence, meta-heuristic algorithms, deep learning, feature selection, association rule mining, and fault diagnosis plays a pivotal role in fortifying cybersecurity defenses and safeguarding critical network infrastructures against evolving cyber threats. Machine learning and artificial intelligence techniques enable IDSs to continually learn and adapt to new attack patterns, enhancing their accuracy in distinguishing between normal and malicious network activities [14-17]. The integration of meta-heuristic algorithms optimizes the performance of intrusion detection models, fine-tuning parameters and reducing false positives [18]. Deep learning empowers systems to automatically extract intricate features from raw network data, enabling the identification of sophisticated and novel attack signatures [19, 20]. Feature selection techniques help to identify the most relevant network attributes, streamlining the detection process and reducing computational overhead [21]. Additionally, fault diagnosis capabilities enable swift identification and response to potential anomalies, further strengthening the overall resilience of intrusion detection systems [16, 22]. Association rule mining holds paramount importance in NIDS as it enables the discovery of hidden patterns and correlations in network data, facilitating the identification of suspicious and anomalous activities that might go undetected using traditional IDSs [23]. This amalgamation of cutting-edge technologies empowers organizations to proactively detect, mitigate, and thwart cyber threats, ensuring the confidentiality, integrity, and availability of critical data and establishing robust and future-proofed NIDs.

To identify intrusions and anomalies, a NIDS continuously monitors network traffic. In the case of high network throughput, using a single NIDS on a network can cause congestion. Deep packet inspection may include significant similarities to complicated signatures of attack rules [24, 25]. Pattern matching is a time-consuming procedure that requires substantially more computing power than a firewall, which might cause a NIDS to become overloaded [26]. When a NIDS becomes overburdened and begins dropping or ignoring packet content, network security may be compromised. Finally, some vulnerabilities may remain unnoticed since some packets associated with the same attack may escape the NIDS's inspection, leading to an insufficient match between packets [27]. NIDS employ several strategies to handle high levels of network traffic, including:

- Hardware upgrades, including the addition of dedicated packet capture cards and more computing resources, as well as modifying the NIDS software to increase its capacity.
- Utilizing a cluster of NIDSs and distributing signature rules and network traffic among the NIDS hosts.

The first strategy, which involves optimizing the NIDS application and upgrading hardware, is prohibitively expensive and unscalable. Every four years, network bandwidth rates grow by a factor of 10; therefore, maintaining a NIDS requires ongoing hardware upgrades. Adjusting a NIDS to cope with greater traffic is a difficult procedure that includes various trade-offs, resulting in the NIDS being more complex than anticipated. The second strategy, which relies on NIDS clusters, is cost-effective and scalable. When network traffic is low, the solution can be adjusted to accommodate it, and resources can be released and utilized for other reasons. Numerous studies have demonstrated the benefit of low-cost clustering computers equipped with NIDS to manage high network traffic loads. Additionally, the cluster can be expanded by adding additional NIDS instances. However, both the distribution of traffic among NIDS instances and the distribution of signature rules are critical to the effectiveness of the solution [28].

The use of machine learning algorithms in the context of NIDS has received considerable attention. Training machine learning algorithms on normal and attack traffic enables them to detect novel differences in network traffic. Traditionally, the NIDS is designed by an expert human analyst who codifies rules defining normal behavior and intrusions [29]. Due to the numerous failures of this method to identify novel intrusions and the aim to reduce the analyst's effort, machine learning algorithms have been incorporated into NIDS to automate the process and supplement the human effort. This study proposes a new method comprised of machine learning and deep learning algorithms for feature selection and intrusion detection.

The key contributions of this research paper include the development of a cutting-edge NIDS that leverages deep learning and a hybrid feature selection approach. The three-step architecture, consisting of hybrid feature selection, rule assessment, and detection, enhances the effectiveness of the intrusion detection system. By combining the strengths of machine learning and deep learning technologies, the proposed NIDS demonstrates superior performance in detecting network intrusions. The careful preprocessing of network data, followed by the application of a deep learning algorithm, allows for the identification and testing of potential intrusion patterns. Simulation results showcase the exceptional accuracy of the proposed method, surpassing previous approaches, as demonstrated by its outstanding performance on the widely recognized CSE-CIC-DS2018 dataset.

II. Importance of the NIDS

As the Internet is vulnerable to various threats, it is critical to develop a system that protects the data and the individuals using it [30]. For years, the scientific community has focused on identifying cyber-attacks that target information and communication networks. Developing a comprehensive and efficient NIDS is one of the primary challenges in network security. These systems are critical for network administrators to detect different security vulnerabilities within an organization's network. The NIDS monitors and analyses network traffic incoming and departing an organization's network devices and triggers alerts if an intrusion is detected.

An IDS takes its name from the conjunction of two concepts, intrusion and detection systems. Generally, an intrusion is defined as gaining access without authorization to a network or computer system with the intent of compromising its functionality, privacy, or reliability. The IDS detects such illegal activities. Therefore, the IDS serves as a security component responsible for monitoring network traffic to identify suspicious activities that violate security policies and endanger the network's availability, reliability, and stability. It notifies hosts or network administrators of detected malicious activities. As shown in Fig. 1, NIDS is deployed passively by connecting to a network switch equipped with mirror ports. In order to monitor traffic and detect intrusions, all inbound and outbound network traffic should be mirrored to NIDS. By installing NIDS in the middle of the network switch and firewall, all traffic can be routed through it.

Modern NIDS are divided into two categories: rule-based misuse detection and statistical anomaly detection. In the first method, a database is used to store the characteristics of a wide variety of known attacks and the network traffic is classified as an "attack" if the retrieved characteristics match those stored in the database. Although this kind of NIDS can rapidly and accurately detect known attacks, it is weak at detecting future attacks. As a result, anomaly detection-based NIDS has gained popularity recently. According to its basic assumptions, the system detects and identifies abnormalities in network traffic properties or distributions [31].

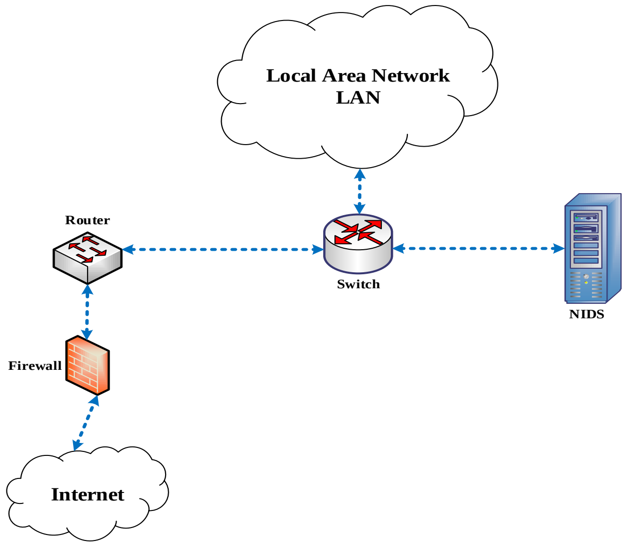

Fig. 1. Passive deployment of NIDS.

A wide range of machine learning algorithms have been implemented in NIDS to detect anomalies. Different machine learning algorithms have been used to discriminate normal from abnormal network activity, including Random Forest (RF), Support Vector Machine (SVM), and Decision Tree (DT). Nevertheless, as attack categories diversify and network traffic grows, shallow learning approaches cannot be applied effectively to large-scale NIDS. Recently, deep learning has been the subject of extensive research owing to its ability to generate features automatically. Convolutional Neural Networks (CNNs), Recurrent Neural Networks (RNNs), and Multi-Layer Perceptron (MLP) have also been incorporated into NIDS.

According to [32], When dealing with large datasets, deep learning-based NIDS perform better. Nevertheless, these NIDS approaches are limited in certain respects. First, the majority of them fail to indicate the nature of the attack in their categorization results. Since various attacks demand distinct defense mechanisms in actual systems, detecting "normal" or "abnormal" is inadequate. Second, most of these approaches are evaluated using NSL KDD, or KDD99 datasets gathered around 20 years ago. New attacks emerge practically daily; thus, relying on historical traffic statistics does not accurately represent the effectiveness of NIDS in modern networks. Experiments are conducted on a subset of the dataset without considering the system's performance as a whole. Lastly, they ignore the effects of class imbalances on classification performance, which results in a large reduction in detection rates, particularly for minority classes.

III. Related Work

Generally, NIDSs are categorized into three main classes: anomaly-based, misuse-based, and hybrid. Misuse-based techniques detect intrusions using a pattern-matching model. Due to the fixed model, this approach is capable of detecting the most common types of attacks with a high degree of accuracy. Nevertheless, this characteristic also presents an inherent disadvantage since a dynamic environment may give rise to novel attacks or variations at any time. A second kind of IDS strategy is anomaly-based, which relies solely on normal data in order to identify abnormal samples. The NIDS raises alarms in the event of a real-world attack using the misuse-based technique, but it does not offer any additional information about the type of attack. The drawback of this technique is that it performs poorly in terms of accuracy because some attacks resemble normal data, or the extracted properties are difficult to distinguish between attack and normal data.

Over the last decade, machine learning algorithms have gained much attention from researchers in developing IDSs. Anwer, et al. [33] have proposed a method for selecting features that consider irrelevant and redundant features. The method applies different strategies based on the selection of filter and wrapper features. It achieves a high level of accuracy by selecting the minimum number of features. Experimental results are presented using the UNSW-NB15 dataset. Tian, et al. [34] have suggested a robust and sparse technique based on a one-class support vector machine (OSVM) to find samples that vary from the majority of data. The Ramp loss function has been used to enhance the performance of this model, making the approach more robust and sparser.

The NSL-KDD dataset is used in the study presented in [35]. The dataset in this research is normalized and discretized using the k-means technique. Feature selection is made using the Information gain algorithm and then submitted to the Naive Bayes machine learning algorithm. They discovered that the k-means clustering approach outperforms the mean and standard deviation discretization methodology. The data is sent to the information-gain technique after it has been labeled using the k-means approach, which employs scoring methods for nominal or weighting continuous qualities that are discredited by applying the maximum entropy. The k-means technique cannot handle nonlinear or incomplete data, one of its key shortcomings. The system's accuracy and false-positive rate may be enhanced further.

Kan, et al. [36] have introduced a novel approach for intrusion detection in IoT networks called Adaptive Particle Swarm Optimization Convolutional Neural Network (APSO-CNN). The approach utilizes the PSO algorithm with a change of inertia weight to dynamically optimize the structure parameters of a one-dimensional CNN. To achieve this, the cross-entropy loss function value of the validation set, obtained from the initial training of the CNN, is utilized as the fitness value for PSO. This adaptive optimization process ensures efficient parameter tuning for improved performance. A new evaluation method is defined that considers both the prediction probability assigned to each category and the prediction label. This evaluation method enables a comprehensive comparison between the proposed APSO-CNN algorithm and manually set parameters for CNN (R-CNN). Furthermore, a comparison is conducted between the proposed APSO-CNN and three other well-known algorithms using five traditional evaluation indicators and accuracy statistical characteristics from ten independent experiments. The simulation results reveal that the APSO-CNN algorithm proves to be effective and reliable for multi-type IoT network intrusion attack detection tasks.

Andresini, et al. [37] have proposed an innovative intrusion detection method that focuses on analyzing the flow-based characteristics of network traffic data. Their approach leverages deep metric learning, which combines autoencoders and Triplet networks to create an effective intrusion detection model. During the training stage, two separate autoencoders are trained using historical normal network flows and attack data, respectively. The autoencoders are designed to reconstruct the original network flow data. Subsequently, a Triplet network is trained to learn an embedding of the feature vector representation of the network flows. This embedding ensures that each flow is positioned close to its reconstruction by the autoencoder associated with the same class (normal or attack) and far away from its reconstruction by the autoencoder of the opposite class. In the predictive stage, when presented with a new network flow, the method assigns it to the class associated with the autoencoder that provides the closest reconstruction of the flow in the embedding space. This process capitalizes on the learned embedding from the training stage and effectively detects potential signs of malicious activities in the network traffic. The results of their proposed methodology demonstrate superior predictive accuracy compared to competitive intrusion detection architectures when evaluated on benchmark datasets. The combination of deep metric learning, autoencoders, and Triplet networks empowers their intrusion detection approach to achieve impressive performance in detecting new instances of malicious behavior within network traffic.

Ravi, et al. [38] have presented an end-to-end model for network attack detection and classification, leveraging deep learning-based recurrent models. Their proposed approach involves extracting features from the hidden layers of recurrent models and utilizing a kernel-based principal component analysis (KPCA) feature selection method to identify optimal features. These optimal features from recurrent models are then combined and used for classification through an ensemble meta-classifier. Extensive experimental analysis and evaluation of the proposed method were conducted on multiple benchmark network intrusion datasets. The results demonstrated that the proposed approach outperformed existing methods as well as commonly used machine learning and deep learning models. In particular, the proposed method achieved a remarkable maximum accuracy of 99% for network attack detection and 97% for network attack classification when applied to the SDN-IoT dataset. Similarly impressive performances were obtained on other network intrusion datasets, including KDD-Cup-1999, UNSW-NB15, WSN-DS, and CICIDS-2017.

Talukder, et al. [39] have introduced a novel hybrid model that combines machine learning and deep learning techniques to achieve higher detection rates while ensuring dependable results. The proposed method focuses on efficient pre-processing by utilizing SMOTE for data balancing and XGBoost for feature selection. To evaluate the effectiveness of their developed method, they conducted a comparison with various machine learning and deep learning algorithms. The goal was to identify the most efficient algorithm to incorporate into the detection pipeline. Through benchmarked performance analysis criteria, they selected the most effective model for network intrusion detection. Their method was tested on two datasets, KDDCUP'99 and CIC-MalMem-2022, and produced remarkable results. The accuracy achieved was 99.99% for KDDCUP'99 and 100% for CIC-MalMem-2022, showcasing the superior performance of the proposed hybrid model. Additionally, their method exhibited no signs of overfitting or issues related to Type-1 and Type-2 errors.

Mohamed and Ejbali [40] have introduced a novel deep reinforcement learning model that effectively combines a SARSA-based reinforcement learning algorithm with a deep neural network for intrusion detection systems. The primary objective of their proposed deep SARSA model is to enhance the detection accuracy of modern and complex attacks in network environments. To validate the performance of their method, they conducted experiments using two well-known benchmark datasets, NSL-KDD and UNSW-NB15. By comparing their approach with various classic machine learning and deep learning models, as well as other published results in the field, they demonstrated that their proposed approach outperforms the other models across multiple evaluation metrics, including accuracy, recall, precision, and F1-score. The integration of deep reinforcement learning, SARSA-based algorithm, and deep neural networks has proven to be a successful strategy for achieving superior intrusion detection accuracy. The proposed approach addresses the challenges posed by modern and complex attacks in network environments, making it a valuable contribution to the field of network security.

IV. PROBLEM STATEMENT

The rapid pace of technological advancements in network and hardware devices presents significant challenges for the implementation and enhancement of intrusion detection systems (IDSs). To fully understand these challenges, it is important to delve into their specific details and implications. Firstly, the challenge of diversity arises from the continuous development of network protocols. As these protocols evolve, it becomes increasingly difficult to differentiate between normal and abnormal data traffic. This poses a significant hurdle for IDSs, as they need to accurately identify potential threats amidst a wide range of network activities. Another challenge is related to low-frequency attacks. The distribution of attack types is often imbalanced, with some occurring less frequently than others. This imbalance negatively impacts the detection precision of IDSs, particularly those utilizing data-driven approaches. It becomes more challenging to identify and accurately detect these low-frequency attacks, which can potentially evade detection and compromise the security of the network.

The adaptability of IDSs is also a key challenge. The dynamic and flexible nature of networks necessitates regular updates and modifications to IDS models. As the network environment changes, the IDS must adapt to the evolving landscape to maintain its effectiveness. Failure to do so, results in outdated detection models that are ineffective against new and emerging threats. Choosing the appropriate placement strategy for an IDS is another consideration. Organizations must carefully evaluate and select between centralized, distributed, and hybrid deployment strategies based on factors such as financial constraints, computational capabilities, and time costs. Each strategy comes with its advantages and trade-offs, making the decision a critical one. As a final consideration, accuracy poses a significant challenge. Traditional IDS methods often fall short of providing a high degree of precision in detecting intrusions. To address this, a comprehensive and in-depth understanding of intrusion behavior becomes crucial. A complete knowledge of how intrusions manifest and evolve can significantly enhance IDS performance and ensure more accurate threat detection.

In summary, the implementation and improvement of intrusion detection systems face various challenges in today's technological landscape. These challenges include dealing with the diversity of network protocols, addressing low-frequency attacks, ensuring adaptability to changing network environments, making informed placement decisions, and improving accuracy through a deeper understanding of intrusion behavior. Overcoming these challenges requires innovative approaches and continuous research to develop robust and effective IDS solutions.

V. Proposed Method

This section discusses the suggested approach for detecting network intrusions. This section is divided into two subsections, where we explore the requirements and the proposed technique. As depicted in Fig. 2, the suggested NIDS system is divided into three major components.

- The infrastructure layer is composed of two distinct elements: software and hardware. Software elements can communicate with hardware, for example, OpenFlow switches. Hardware elements include switches and routers.
- The control layer regulates activities and data management in the network by creating or refusing each network flow.
- The application layer is responsible for all network management operations. These activities may be accomplished with the aid of a NIDS controller.

As illustrated in Fig. 3, the NIDS generated utilizing machine learning and deep learning algorithms typically entails three key processes, namely data preprocessing, training, and testing. For each of the potential approaches, the dataset is preprocessed and transformed into an algorithm-compatible format. Encoding and normalization are generally included in this step. Frequently, the dataset needs cleaning, which includes eliminating items with duplicate records and incomplete data. The preprocessed data is randomly separated into two parts: the training and testing datasets. Generally, the training dataset accounts for around 80% of the entire dataset, leaving 20% for testing. In the training stage, the deep learning algorithm is trained using the training dataset. The learning time of the method is affected by the complexity of the proposed model and the amount of the dataset. Deep Learning models often need additional training time owing to their deep and complicated underlying structures. After training the model, its performance is evaluated using the testing dataset and its predictions. NIDS models classify network traffic instances as benign (normal) or malicious (attack). The flowchart of the suggested approach is illustrated in Fig. 4. The steps of the proposed technique are described in the following.

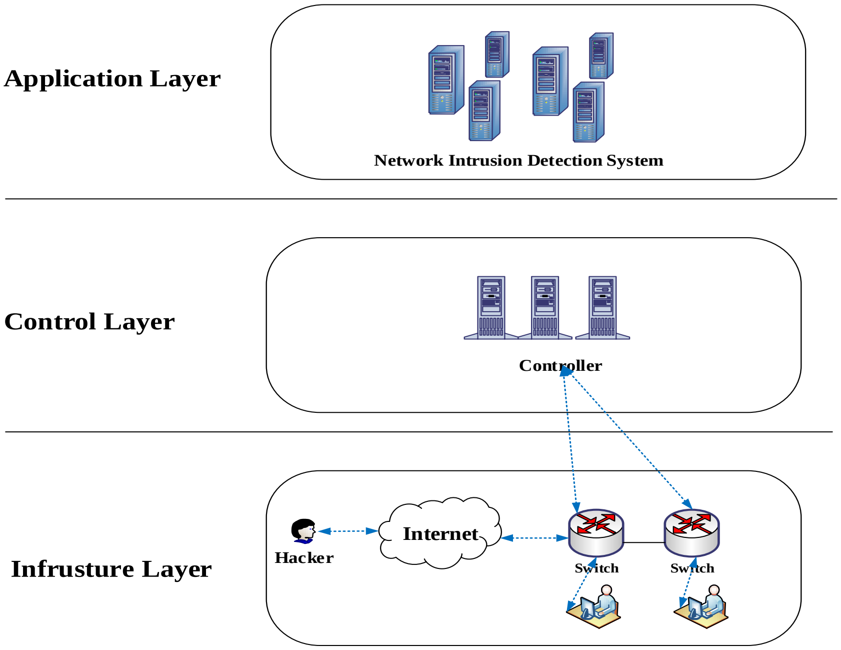

Fig. 2. System model.

Training Dataset
Machine Learning Or Deep Learning
Prediction Attack or Normal Traffic

Fig. 3. Machine learning and deep learning-based intrusion detection system.

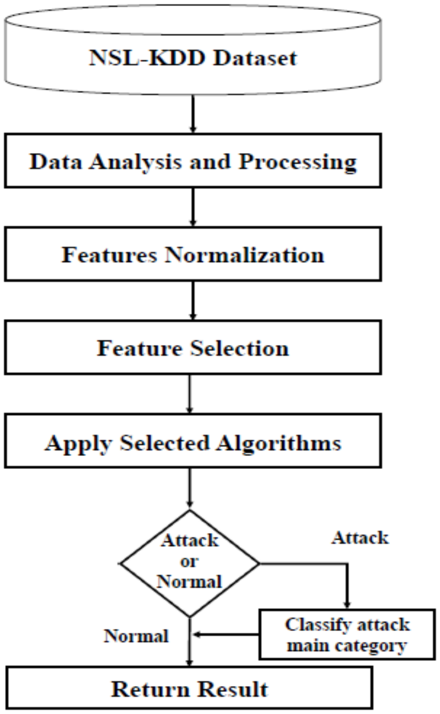

Fig. 4. Flowchart of the proposed NIDS.

A. First Phase: Load Dataset and Export it into Resilient Distributed Datasets (RDDs)

Numerous researchers have developed and evaluated the NIDS issue using the NSL-KDD or other datasets detailed in the assessment part of this proposal. A wide variety of attacks are included in the dataset. It includes 41 features classified into three major categories (traffic-based, content-based, and basic) and distinguished as normal or malicious.

B. Second Phase: Data Preprocessing

The features dataset includes values with varying scale ranges to mitigate the loss function during learning. These scales influence the gradient optimization process, thereby affecting learning rate optimization, as the model should rapidly reach a global or local minimum as a result. Min-Max normalization provides some benefits in comparison to conventional scaling. Min-Max scaling can deal with non-Gaussian feature distributions since anomaly detection applications do not need a certain distribution to follow, in contrast to the signature-based technique in NIDS. The Min-Max normalization strategy is presented to avoid the gradient from the un-smoothing route toward the global minimum, thereby improving the loss function. As illustrated in the following equation, it retrieves the column's lowest and maximum values, with output values ranging from 0 to 1.

$$Normalised\ Parametr\ (X) = \frac{X - X_{min}}{X_{max} - X_{min}} \quad (1)$$

Where X_{min} is the column's lowest value, X_{max} is the column's highest value, and X represents the initial data sample value. Also, we employed the Apache Spark system during this phase. Spark is a high-performance, general-purpose cluster computing system optimized for large-scale in-memory data processing. Spark follows the MapReduce programming paradigm but adds a data-sharing concept called Resilient Distributed Datasets, or RDD. A Spark was developed to be quick for iterative algorithms, enable in-memory storage, and perform well under load.

C. Third phase: Feature Selection

Feature selection forms an integral part of data preprocessing in intrusion detection. A network intrusion detection system is characterized by diverse features and a large amount of data. There are different attribute values for features in different categories, including duplicate features that complicate classification. The proliferation of redundant features reduces the efficiency of detection algorithms and increases the likelihood of false positives in intrusion detection. IDS accuracy and detection speed are increased by an efficient feature selection algorithm, which reduces the dimensionality of network data. This paper uses Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM) algorithms for feature selection and training models. CNN is a deep neural network that is composed of three main layers.

- Convolutional layer: In this layer, the input data is processed with a set of filters known as convolutional kernels. A feature map is produced as each filter is applied to the input data. The final output of the convolution layer can be obtained by stacking all the produced feature maps together.
- Pooling layer: It performs subsampling on the feature maps, resulting in reduced dimensionality. The most common methods of pooling are average pooling and maximum pooling.
- Fully connected layer: The output of the previous layers is transformed into a vector that can be used as an input for the next layer.

Recurrent Neural Network (RNN) is a deep learning model driven by supervised learning. Using a traditional RNN, it was possible to predict the temporal training data; however, it encountered difficulties when dealing with gradient explosions. LSTM was proposed as a solution to this problem. An LSTM model replaces the hidden RNN units with a memory function. The LSTM model consisted of three important gates: forget, input, and output gates.

D. *Fourth Phase: Train with the Training Dataset*

Two causal convolution layers, two dense layers, and a softmax layer are used in the training and optimization phase for the multi-class classification task. In order to avoid overfitting, we employ maximum global pooling, batch normalization, and dropout layers. Adam optimizer is used to update weights and optimize the cross-entropy loss function. It is a combination of two stochastic gradient descent approaches, including Root Mean Square Propagation (RMSProp) and Adaptive Gradient Algorithm (AdaGrad). In particular, the training and optimization phase comprises the following layers:

- First causal convolution layer: The input vectors are convolved with 64 filters of three sizes across the input vectors.
- Second 1D causal convolution layer: A total of 128 filters are used, each with a size of 3. Prior to pooling, this layer enables the model to learn more complex features.
- 1D global maximum pooling layer: The maximum value of the filter is replaced with the data covered by the filter. The maximum value prevents the learned features from overfitting.
- Batch normalization layer: The data are normalized before they are sent to the next layer.
- Fully connected dense layer: It utilizes 128 hidden units with a dropout rate of 30%.
- Fully connected dense layer with softmax activation function: multi-class classification is achieved by producing five units for each of the five traffic categories.

VI. Results and Discussion

As choosing the appropriate NIDS data to assess the system is critically important, the data was chosen prior to simulation. While there are a number of publicly available datasets, some of them comprise out-of-date, illogical, inadequately validated, and potentially unrecoverable intrusions. Amazon Web Services (AWS) developed the CSE-CIC-DS2018 [41] dataset to address these limitations and generate modern traffic patterns. It includes a variety of datasets that are suitable for evaluating anomaly-based approaches. CSE-CIC-DS2018 highlights real-time network activities and includes a variety of intrusion detection modes. The data packet payload is calculated by encapsulating the inner network traces as a whole network. Several intrusion profiles are contained in this dataset, which can be applied to a variety of network protocols and topologies. IDS2017 criteria were applied to enhance this dataset. There are currently seven intrusion strategies and two profiles included in IDS2018, a publicly available dataset. IDS2018 contains 80 statistical variables, such as the number of bytes, volume, and packet length. It is accessible via the Internet, which contains approximately 5 million records, and is available in two formats: PCAP and CSV. PCAP is commonly employed to obtain new functions, while the CSV format is typically used in artificial intelligence applications. This dataset represents seven types of attacks: Botnet, Web attacks, Heartbleed, Infiltration, Brute-force SSH, DDOS attacks, and Brute-force DOS attacks.

The creation of the CIC-IDS-2017 and CSE-CIC-IDS-2018 datasets has garnered significant interest among researchers, leading to the implementation of various classifiers using these datasets. The datasets' specifications are detailed in Table I. The files within the dataset are utilized for both binary and multi-class classification tasks. An ideal Intrusion Detection System (IDS) is one that can precisely detect each type of attack. To achieve this, building an efficient IDS requires merging the files in the dataset to cover a wide range of attack categories [42]. The CIC-IDS-2017 and CSE-CIC-IDS-2018 datasets exhibit certain limitations related to the data samples and files generated through network flow analysis, which can be listed as follows:

- Tedious data processing: The data samples generated by network flow analysis are stored in files, and processing these files can be a time-consuming and tedious task, especially since each file contains a large number of data instances.
- Dataset size and computing time: Merging the files in the dataset to include all attack labels can lead to an increase in the dataset's size. This, in turn, results in more computing and processing time, making it challenging to handle large datasets efficiently.
- Missing and redundant data: The dataset contains some missing and redundant data records, which can affect the quality and accuracy of the analysis performed on the data.
- High-class imbalance: Both CIC-IDS-2017 and CSE-CIC-IDS-2018 datasets suffer from the issue of high-class imbalance. This means that some attack types may

have significantly fewer instances compared to others, leading to lower accuracy and higher False Positive Rate (FPR) for the system.

There are 50 computers involved in the dataset-attacking infrastructure, while 30 servers and 420 terminals are utilized by the attackers. CSE-CIC-DS2018 data represent a system log with 80 attributes extracted from CICFlowMeter-V3 and network traffic captured from AWS. There is approximately 400 GB of data in CSE-CIC-DS2018, which is larger than CIC-DS2017 in terms of size. Table II compares the CSE-CIC-DS2018 and CIC-DS2017 datasets with respect to sample size. The number of CSE-CIC-DS2018 samples has increased significantly compared to CIC-DS2017, especially in the Infiltration and Botnet attacks, where the number of samples increased respectively by 4497 and 143.

Using the CSE-CIC-DS2018 ID dataset, the effectiveness of our mechanism was evaluated by examining error rate, accuracy, true negative, false negative, true positive, and false positive. The confusion matrix is used to determine the difference between the actual and predicted classifications. Categorization results can be divided into two groups: normal and abnormal. Table III provides an overview of the confusion matrix. It is necessary to measure four levels of criticality in the confusion matrix.

- True negative: In this case, the model correctly predicts the negative outcome.
- False positive: In this case, the classifier considers normal traffic as abnormal.
- False negative: When an IDS fails to detect an actual attack.
- True positive: It is an actual intrusion successfully discovered by the IDS.

Based on the specifications given above for the confusion matrix, we can calculate the output of the system. An IDS is analyzed based on FAR and DR as key and common metrics. FAR represents the sum of misclassified regular incidents, whereas DR signifies the number of intrusions identified by the model. As DR rises and FAR decreases, we claim our approach is superior to traditional approaches.

$$FAR = {}^{FP}/_{(TN + FP)} \qquad (2)$$

$$DR = {}^{TP}/_{(TP + FN)} \qquad (3)$$

The performance of the classifier on CSE-CIC-DS2018 is summarized in Table IV. A random search hyperparameter optimization technique was used to generate the results. The ensemble classifier XGB significantly enhances classification effectiveness, achieving an accuracy rate of 85%. The tree-based classifier provides a higher level of accuracy than ensemble-based classifiers.

TABLE I. SPECIFICATIONS OF CIC-IDS-2017 AND CSE-CIC-IDS-2018 DATASETS

Dataset	Type	Number of classes	Features	Victim Infrastructure	Attack Infrastructure	Duration of Capture
CSE-CIC-DS2018	Multi-class	18	80	420 PCs, 30 servers	50 PCs	Ten days
CIC-DS2017	Multi-class	15	80	Three server, one firewall, two switches, 10 PCs	Four PCs, one router, one switch	Five days

TABLE II. COMPARISON OF THE CSE-CIC-DS2018 ID DATASET WITH CIC-DS2017

Dataset	Web attacks	Infiltration	Brute force	Botnet	DoS	DDoS	Normal
CSE-CIC-DS2018	929	161,936	380,950	286,195	954,311	687,740	6,112,149
CIC-DS2017	2182	37	13,840	1968	252,665	128,024	1,743,181

TABLE III. OVERVIEW OF THE CONFUSION MATRIX

	Predicted outcome		
Actual value	Abnormal	True negative	False positive
	Normal	False negative	True positive

TABLE IV. CLASSIFIER RESULTS WITH CSE-CIC-DS2018

Classifier	FAR	DR	F-score	Recall	Precision
DT	7.81	0.89	0.87	0.88	0.87
XGB	9.1	0.84	0.83	0.83	0.84
LR	11.5	0.80	0.79	0.80	0.78
Proposed classifier	2.6	0.96	0.981	0.976	0.968

TABLE V. COMPARISON OF IDS METHODS

References	False alarm rate	Accuracy
[43]	1.1	96%
[44]	1.3	96%
[45]	8.5	96%
[46]	5	95%
[41]	0.93	90.2%
[47]	0.97	94%
Our method	1.5	98.2%

In order to use the proposed mechanism to capture both temporal and spatial features efficiently, recurrent layers were introduced following the CNN layers in order to capture both features. In this manner, we attempted to avoid the vanishing gradient and explosion problem, resulting in an improved ability to capture temporal and spatial dependencies and learn efficiently from sequences of variable extent. The number of variables in large-scale data (imbalances), while exceeding the sample size, is not well suited to traditional machine-learning classifiers. This model is suitable for high-dimensional datasets due to its scale invariance. Nevertheless, the most significant improvement was achieved with advanced deep learning approaches such as CNNRNN, which detected misuse with 97% accuracy. This performance improvement can be attributed to the long-term dependencies between the nonlinear features, and details on their implementation can be found in supplementary materials.

A summary of the results obtained using existing methods for the CSE-CIC-DS2018 dataset is provided in Table V. Several preliminary results are available since these datasets are generated following the KDD and DARPA datasets. Considering current simulation results, optimal values for accuracy and FAR was calculated for each phase. The accuracy and FAR of our method are superior to those of conventional methods. The reason for this is the execution of the deep learning algorithm. Due to the differences in the quantity of data distributions, preprocessing procedures, and sampling methods, the similarities should only be used as a source of reference. Therefore, measuring a simple metric, such as the amount of time spent on testing or training is rarely appropriate. Although the suggested method demonstrated superior performance in some respects, it remains questionable whether it can perform better in all respects than other approaches. The proposed solution enables exceptional network protection as well as easy identification of malicious threats.

In comparison to previous approaches, the proposed method demonstrates superiority based on simulation results. It achieves an exceptional level of accuracy in detecting malicious attacks, as evidenced by its outstanding performance on the widely recognized CSE-CIC-DS2018 dataset. This indicates that the proposed NIDS has surpassed the capabilities of existing methods in terms of accuracy and effectiveness. By capturing packets from the network and performing careful preprocessing to reduce their size while retaining crucial information, the proposed method optimizes the input data for the deep learning algorithm. The utilization of machine learning characteristics enhances the NIDS's ability to learn and test potential intrusion patterns, further contributing to its superior performance.

The hybrid feature selection approach introduced in the proposed method addresses the challenge of identifying critical attributes necessary for constructing robust classifiers. This feature selection process, combined with rule assessment and detection steps, provides a comprehensive and effective framework for intrusion detection. In summary, the proposed method stands out among previous approaches by leveraging deep learning, hybrid feature selection, and a carefully designed process flow. Its exceptional accuracy in detecting malicious attacks on the CSE-CIC-DS2018 dataset indicates its superiority over existing methods. The proposed method offers significant advancements in network intrusion detection and presents a promising solution to bolster the security of networks and systems in today's digital landscape.

VII. Conclusion

Cyber security has become a paramount area of research in modern society, given the indispensable role of networks. Within this domain, Intrusion Detection Systems (IDSs) play a pivotal role in monitoring the status of software and hardware on a network. However, IDSs continue to face challenges in accurately identifying potential threats, minimizing false alarms, and enhancing detection accuracy. To address these challenges, extensive research has been dedicated to developing IDSs that harness the power of machine learning. In our study, we have devised a cutting-edge IDS methodology based on a layered Recurrent Neural Network (RNN). This approach leverages the strengths of deep learning to adeptly predict and classify unauthorized intrusions. The layered RNN effectively captures local features, while the recurrent RNN seamlessly incorporates temporal characteristics, substantially elevating the performance of our IDS system. Through comprehensive evaluations on the esteemed CSE-CIC-DS2018 dataset, our proposed method has demonstrated superior performance over previous approaches. The simulation results unequivocally establish the exceptional accuracy of our IDS in detecting malicious attacks. The integration of deep learning techniques and hybrid feature selection enables our IDS, named DeepShield, to outperform traditional machine learning-based methods, providing a reliable defense against network intrusions. The significance of DeepShield extends beyond the system itself. The higher accuracy achieved by our NIDS translates to more robust network security, helping organizations proactively safeguard their critical data and online services. As cyber threats continue to evolve, the effectiveness of intrusion detection becomes increasingly crucial, and our approach contributes to a safer digital environment. Moreover, the versatility of our methodology allows for scalability and adaptability to various network infrastructures and environments. This adaptability ensures that DeepShield can be applied in diverse security scenarios, making it a valuable tool for network administrators and cyber security professionals.

Deep-Learning-based Analysis of the Patterns Associated with the Changes in the Grit Scores and Understanding Levels of Students

Ayako OHSHIRO
Department of Economics and Environmental Policy
Okinawa International University
Ginowan City, Okinawa 901-2701, Japan

Abstract—**The purpose of this study is to classify the pattern of the understanding level changes for university students during class term, and analyze the relation between them and the changes in the Grid score before and after the class term. Dynamic time warping was applied for classification of the understanding level, and the decision tree was applied to analyze the relation between the changes in the understanding level and that in the Grid score. As a result, it was shown that a large variety of the patterns of changes in the understanding level, and the relations between the understanding level and Grid score cover a wide variety, too. It is necessary to take these results for conducting effective lectures.**

Keywords*—*Time series; dynamic time warping; decision tree; Grit

I. Introduction

With the spread of information, communication equipment, the online management of student learning data for learning analysis has become popular. Furthermore, with the advent of machine learning and time series analysis, research on learning analysis and education data mining[1] has been actively conducting for improving education quality. Studies that predict students' careers and probability of dropping out of school analyze educational data as time series data using the state transition model and machine learning algorithms [2] [3]. In the knowledge accumulation approach to learning, learners reflect on their understanding levels before undertaking a task, and the teacher visualizes the students' understanding levels from the results. Accordingly, learners can improve their comprehension, and the teacher can make improvement to the contents of their lecture accordingly [4]. Regarding knowledge accumulation, it not only focuses on cognitive factors, which are measured by academic assessments such as examinations, but it also highlights the importance of non-cognitive factors such as self-adjustment capability.

Many reports have confirmed that non-cognitive factors influence not only social behavior but also academic performance [5] [6]. Additionally, they can potentially strongly impact cognitive capabilities such as academic ability and intelligence quotient [7]. The Grit score [8], which measures a learner's self-control in pursuing goals and enthusiasm in overcoming difficulties, is a particularly strong predictor of their educational achievements. This score has attracted wide attention globally in the field of education, with many reports investigating its impact on academic grades in higher educational institutions [9] and colleges [10][11]. Specifically, it has been reported that the level of perseverance measured by the Grit score is related to both a learner's English acquisition time and proficiency [12]. In the field of information technology in education, the relation between information and communication technology and students' self-efficacy and information literacy has been studied [13]. In a study for medicine Residents, higher Grit scores are reported associated with less burnout [14]. For these reasons, the Grit score has attracted widespread attention. It is also known that Grid score changes in the case of situation, and Grid score at the school base has large variance, and it is higher in the sports area than in school and life [15]. In my previous study [16], data on students' understanding levels were treated as time series data, and the effect of the understanding levels in a previous lecture on the understanding levels in a new lecture was reported using time series analysis. The study discussed the relation between maintaining the understanding level and decrease in retention of learned information over time. Furthermore, it revealed that correspondence with the levels of learning retention in the learning pyramid could improve the quality of education. Moreover, the differences in learners' grades had a significant effect on their cumulative understanding levels. Additionally, a study on students' Grit scores during clinical practice in a physical therapy training course showed improvements in the Grit score improvement and variations in their understanding levels [17]. Regarding a university-lecture setting, which involves many students, there are various factors that affect students' understanding levels. As previously mentioned, Grit scores can change, and the variations in students' motivation and understanding levels can potentially affect such changes.

It can be difficult to assess students' understanding levels in a lecture-type setting where there are more than a hundred registered students, compared to hands-on practice or seminar-type settings that offer more scope for one-on-one interactions. Therefore, it is important that lecturers are acquainted with patterns in students' understanding levels or changes in their Grit scores to conduct their lectures more effectively. Furthermore, by clarifying the relation between the understanding level and Grit score , lecturers can identify students who may need additional support or interventions and assist them accordingly. This study aims to classify the patterns found in the changes between students' understanding levels and Grit scores in both traditional lecture-type classroom and practical hands-on settings. Dynamic time warping (DTW) [18], a time-series analysis algorithm, was used for classification. Furthermore, the decision tree algorithm was used to analyze the relation between the changes in students' understanding levels and Grit scores.

The remainder of this paper is organized as follows. Section II provides a succinct background of Grid score and DTW, and introduces the proposal analysis for students' understanding level and Grid score. Section III introduces the experimental data and discusses the results. Finally, Section IV concludes the paper and future work.

II. Method

This section provides a brief overview of certain time-series analytics and evaluation indices that are frequently used in this study, and proposed procedure for analysis of the patterns associated with the changes in the Grit scores and understanding levels of students.

A. Grit Score

The Grit score consists of the subscales "consistency in interest", which represents passion, and "perseverance in effort", which represents persistence; the average value of these scores is used as the Grit score. A high passion score corresponds to carefully working toward a single goal for a long time, and a high persistence score corresponds to displaying determination in the face of difficulties and not being satisfied till a specified result is achieved. In this study, the relation between students' understanding levels and passion and persistence scores was also analyzed.

B. Dynamic Time Warping (DTW) Model

The DTW model finds the optimal alignment between two-time sequences by the brute force approach. This technique is often used to analyze human behavior data, such as voice data or walking data. In the field of education, clustering methods such as DTW have been used to study the detection of students' Grit scores[19]. The distance between two time-series data points (x_t, y_t) is defined as follows:

$$DTW(x,y) = min \sum_{i=1}^{p} |x_t - y_t|, \tag{1}$$

Moreover, it is possible to classify multiple time-series data by applying the k-means method in DTW[20]. In the current study, DTW has been applied to determine the patterns in the changes in the understanding levels of students.

C. Proposal Analysis based Deep-Learning Regarding Students'Understanding Levels and Grid Score

In this study, the changes in students' understanding levels in different types of lecture settings were observed. Students were asked to rate their understanding levels for a day's lecture using one of these five options: 100%, 80%, 60%, 40%, or less than 20%, 0% denoted a student's absence. Next, the students' Grit score data over more than 10 lectures were collected as time series data, and DTW was applied to determine any patterns in the changes in the students' understanding levels. Furthermore, the decision tree algorithm was applied to obtain the rules that explained the changes in both the understanding level and those in the Grit score before and after the classes to visualize the relation between these changes. The process of data generation for the Grit score or the students' understanding levels are described in steps 1–4 (Fig. 1), and the process of data analysis is described in steps 5–8.

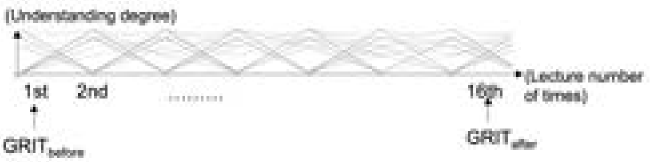

Fig. 1. Procedure of investigation (steps 1–4):The horizontal axis indicates the number of lectures, and the vertical axis indicates the understanding level. $Grit_{before}$ will be collected before the start of lecture term, and $Grit_{after}$ will be collected after the end of lecture term.

Step1 Measure the students' $Grit_{before}$ scores on the day of the first lecture for each subject.

Step2 Ask each student to select the option (out of five) corresponding to their understanding level after each lecture.

Step3 Implement step 2 in all the classes and save the data on the understanding level scores as time series data.

Step4 Measure the students' $Grit_{after}$ scores on the day of the final lecture for each subject.

Step5 Apply DTW to the time series data obtained in step 3 and predict the patterns in the changes in the students' understanding levels.

Step6 Classify the Grit scores obtained in steps 1 and 4 as either a "passion score" or "persistence score," compare the $Grit_{before}$ and $Grit_{after}$, and convert the increase or decrease in the scores to "up" or "down," respectively.

Step7 Generate learning data using the students' understanding levels in each lecture as the explanatory variable and the changes (increases/decreases) in the Grit scores comprising the passion score and persistence score as the objective variable.

Step8 Apply the decision tree algorithm to the learning data obtained in step 7 and extract the rules for the relationships between the changes in the Grit scores and understanding levels.

Based on the properties and components of the Grit score, three hypotheses regarding the patterns in the relation between the changes in the understanding levels and Grit scores are proposed.

H_1 The Grit (especially passion) scores increase when the understanding levels are high.

H_2 Maintaining diligent class participation results in high Grit (especially persistence) scores even if the understanding levels are low.

H_3 The Grit (especially passion) scores decrease when the understanding levels are low.

In this study, these hypotheses were tested through analyses performed through DTW and the decision tree algorithm.

III. Results and Discussion

This section provides the detail of experimental data and discuss the results. First, the results of applying DTW to each data regarding students' understanding levels are reported as described in Step 5 of the proposed procedure. Second, the relation between changes in the understanding level and those in the Grit scores are by use of decision tree reported as explained in Step 6.

A. Experimental Data

The collected experimental data are described in this section. To obtain data for this research, a survey for six classes was conducted in 2021. In this investigation, 328 time-series data were collected, wherein participants 1, 2, and 3 were in a lecture-type setting, and participants 4, 5, and 6 were in a practical-type setting. Details of the collected data include the type of class setting and the number of students in each class, as shown in Table I.

TABLE I. Details of Each Class

	Lecture or practical	Number of students
Participant 1	Lecture	103
Participant 2	Lecture	69
Participant 3	Lecture	70
Participant 4	Practical	30
Participant 5	Practical	31
Participant 6	Practical	17

B. The Results of Applying DTW to Data of Students' Understanding Levels

The analysis results of the acquired data and the discussion are presented. First, the results of applying DTW to each data regarding students' understanding levels with different numbers of clusters (2, 3, and 4) are shown. Fig. 2 to Fig. 4 show the results of the practical-type classes, and Fig. 5 to Fig. 7 show the results of the lecture-type classes. In these figures, the horizontal axis indicates the number of the lectures, and the vertical axis indicates the understanding levels.

Considering that an understanding level of 0 indicates the absence of a student for a class, only cases wherein the understanding level was 0.2 or more have been discussed. In the case of practical-type classes, when the cluster number was two, the data were classified into groups with either red lines or blue lines. In both the group with the red lines and that with the blue lines, the understanding levels were only 1.0 in the mid and later periods, with them transitioning between 0.4 and 1.0. When the cluster number was three, the data were classified into groups with either red lines, blue lines, or green lines. In the group with the red lines, all kinds of understanding levels were included. The group with the blue lines included understanding levels between 0.6 and 1.0 while that with the green lines included understanding levels of all kinds and noticeably included absenteeism. When the cluster number was four, the data were classified into groups with red, blue, green, or yellow lines. The groups with red or blue lines resembled the groups for the cluster number of three. The group with the green lines included understanding levels between 0.2 and 0.6 and high understanding levels in the starting and later periods

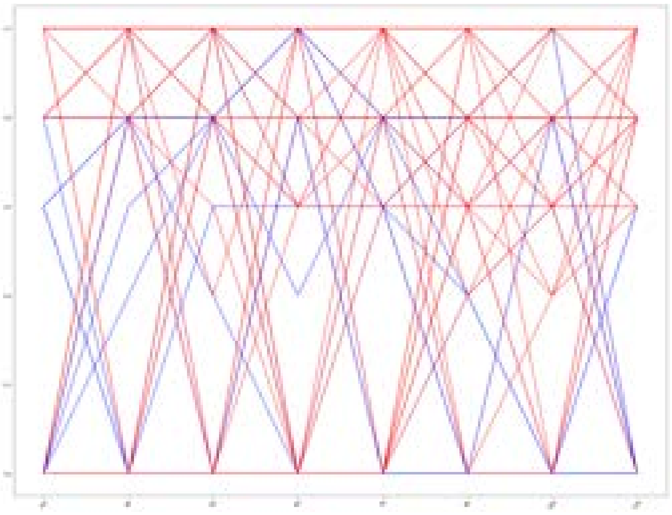

Fig. 2. Practical-type classes (number of clusters =2).

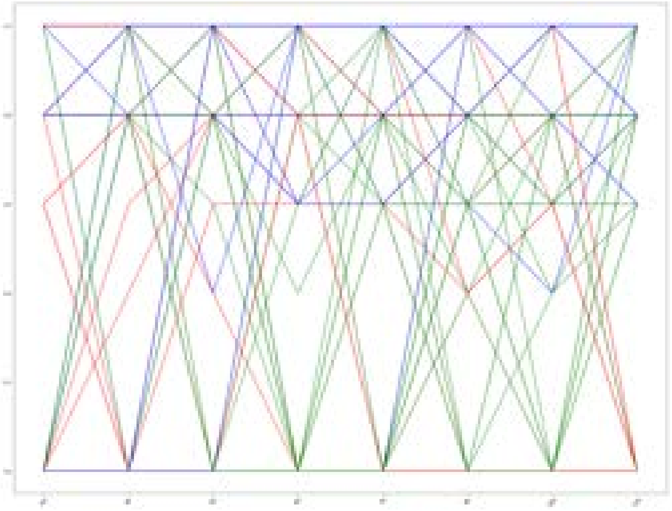

Fig. 3. Practical-type classes (number of clusters =3).

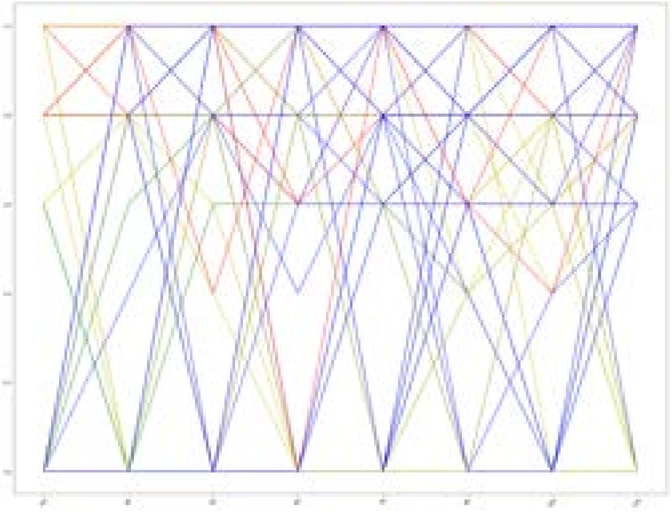

Fig. 4. Practical-type classes (number of clusters =4).

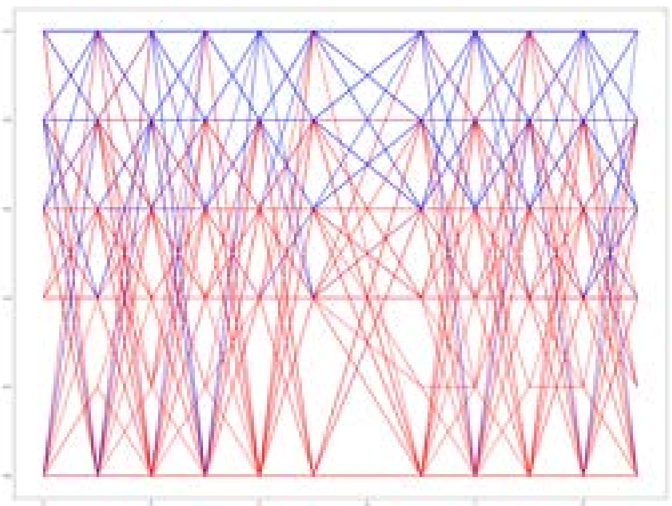

Fig. 5. Lecture-type classes (number of clusters =2).

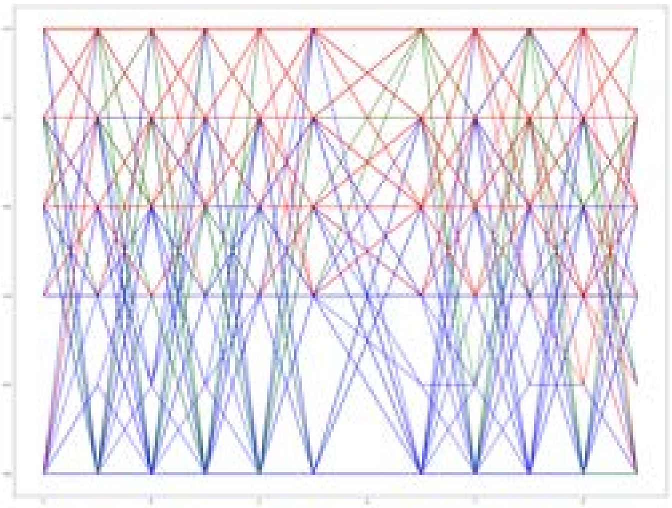

Fig. 6. Lecture-type classes (number of clusters =3).

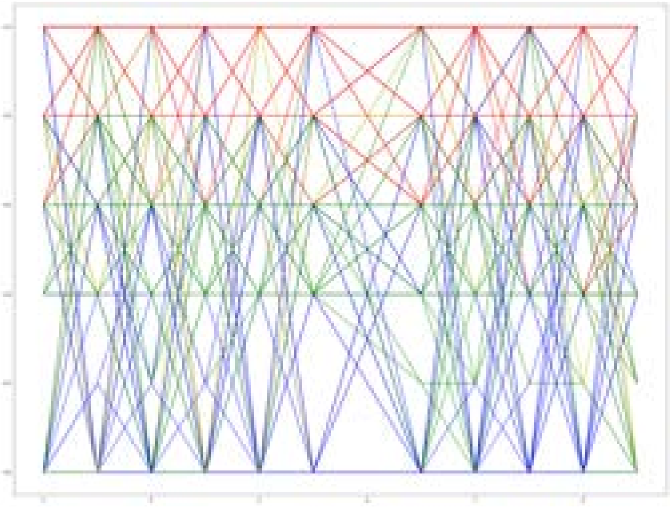

Fig. 7. Lecture-type classes (number of clusters =4).

while the group with yellow lines included low understanding levels.

Regarding lecture-type classes, when the cluster number was two, the data were classified into groups with either red or blue lines. Most of the blue lines were positioned at the upper side while most of the red lines were positioned at the lower side. Each group either contained high understanding levels or low understanding levels.

When the cluster number was three, the data were classified into groups with either red, blue, or green lines. The group with red lines included high understanding levels (more than 0.4), and the group with blue lines included various understanding levels of either other degrees or 0, indicating the presence of frequent absenteeism. The group with the green lines included understanding degrees that were both high and low. When the cluster number was four, the data were classified into groups with red, blue, green, or yellow lines. The groups with red or blue lines resembled the groups for the cluster number of three. The group with the green lines included understanding levels between 0.2 and 0.6 and high understanding levels in the starting and later periods while the group with yellow lines included low understanding levels.

C. The Relation between Changes in the Understanding Level and Those in the Grit Scores

Under the application of DTW, many trends were observed in the changes in the understanding levels. Here, the relation between more specific changes in the understanding level and those in the Grit scores will be discussed. Table II to Table V presents the rules obtained by applying the decision tree algorithm to analyze the relation between changes in Grit scores and those in the understanding level. Table II to Table III presents the results of practical type, and Table IV to Table V presents the results of lecture type.

TABLE II. PRACTICAL TYPE:RELATIONS AND SUMMARY BETWEEN THE CHANGES IN THE GRIT SCORES AND UNDERSTANDING LEVELS

Practical type:Grit
Rule 1: 10th<0.7, up (0.16)
Rule 2: 6th $\geq$ 0.9, 10th $\geq$ 0.7, 11th <0.9, up (0.13)
Rule 3: 6th $\geq$ 0.9, 10th $\geq$ 0.7, 11th $\geq$ 0.9, down (0.07)
Rule 4: 6th <0.9, 10th $\geq$ 0.7, down (0.04)

Rule 1: The Grit scores of 16% of the students increased even though their understanding levels in the tenth lecture were less than 70%.
Rule 2: The Grit scores of 13% of the students increased when their understanding levels were more than 90% in the sixth lecture and less than 90% in the eleventh lecture.
Rule 3: The Grit scores of 7% of the students decreased when their understanding levels were more than 90%, 70%, and 90% in the sixth, tenth, and eleventh lectures, respectively.
Rule 4: The Grit scores of 4% of the students decreased when their understanding levels were less than 90% in the sixth lecture and more than 70% in the tenth lecture.

First, the data classification results for the practical-type setting will be discussed. Regarding the Grit score, the following patterns were observed: 1) the Grit scores increased even when the understanding levels were low in the latter period; 2) the Grit scores increased even when the understanding levels were high in the middle period and low in the later period; and 3) the Grit scores decreased even though the understanding levels were high in the middle and latter periods. Concerning the persistence score component of the Grit score,

TABLE III. PRACTICAL TYPE:RELATIONS AND SUMMARY BETWEEN THE CHANGES IN THE GRIT SCORES (PERSISTENCE AND PASSION) AND UNDERSTANDING LEVELS

Practical type: Grit(Persistence)
Rule 1: 4th $<$0.2, up (0.16)
Rule 2: 2nd $\geq$ 0.7, 4th $\geq$ 0.2, 6th $>$0.9, up (0.15)
Rule 3: 2nd $\geq$ 0.7, 4th $\geq$ 0.2, 6th $<$0.9, down (0.11)
Rule 4: 2nd $<$0.7, 4th $\geq$ 0.2, down (0.09)

Rule 1: The Grit (Persistence) scores of 16% of the students increased even though their understanding levels were less than 20% in the fourth lecture.
Rule 2: The Grit (Persistence) scores of 15% of the students increased when their understanding levels were more than 70, 20, and 90% in the second, fourth, and sixth lectures, respectively.
Rule 3: The Grit (Persistence) scores of 11% of the students decreased when their understanding levels were more than 70% in the second lecture, more than 20% in the fourth lecture, and less than 90% in the sixth lecture.
Rule 4: The Grit (Persistence) scores of 9% of the students decreased when their understanding levels were less than 70% in the second lecture and more than 20% in the fourth lecture.

Practical type: Grit(Passion)
Rule 1: 4th $\geq$ 0.2, 7th $\geq$ 0.7, 9th $\geq$ 0.7, down (0.13)
Rule 2: 4th $\geq$ 0.2, 7th $<$0.7, 9th $\geq$ 0.7, up (0.09)
Rule 3: 4th $\geq$ 0.2, 9th $<$0.7 down (0.04)
Rule 4: 4th $<$0.2, down (0.02)
Rule 1: The Grit (Passion) scores of 13% of the students decreased even though their understanding levels were more than 20% in the fourth lecture and more than 70% in both the seventh and ninth lectures.
Rule 2: The Grit (Passion) scores of 9% of the students increased when their understanding levels were more than 20% in the fourth lecture, less than 70% in the seventh lecture, and more than 70% in the ninth lecture.
Rule 3: The Grit (Passion) scores of 4% of the students decreased when their understanding levels were more than 20% in the fourth lecture and less than 70% in the ninth lecture.
Rule 4: The Grit (Passion) scores of 2% of the students decreased when their understanding levels were less than 20% in the fourth lecture.

TABLE IV. LECTURE TYPE:RELATIONS AND SUMMARY BETWEEN THE CHANGES IN THE GRIT SCORES AND UNDERSTANDING LEVELS

Lecture type: Grit
Rule 1: 3rd $<$0.2, down (0.02)
Rule 2: 3rd $\geq$ 0.2, 10th $<$0.7, 13th $\geq$ 0.5, down (0.07)
Rule 3: 3rd $\geq$ 0.2, 9th $<$0.9, 10th $\geq$ 0.7, 13th $\geq$ 0.5, 13th $\geq$ 0.9 down (0.01)
Rule 4: 3rd $\geq$ 0.2, 9th $<$0.9, 10th $\geq$ 0.7, 12th $<$0.7, 13th $\geq$ 0.5, 13th $<$0.9 down (0.03)
Rule 5: 3rd $\geq$ 0.2, 9th $<$0.9, 10th $\geq$ 0.7, 12th $\geq$ 0.7, 13th $\geq$ 0.5, 13th $<$0.9, down (0.12)
Rule 6: 3rd $\geq$ 0.2, 9th $\geq$ 0.9, 10th $\geq$ 0.7, 13th $\geq$ 0.5, up (0.12)
Rule 7: 3rd $\geq$ 0.2, 13th $<$0.5, up (0.07)

Rule 1: The Grit scores of 2% of the students decreased when their understanding levels were less than 20% in the third lecture.
Rule 2: The Grit scores of 7% of the students decreased when their understanding levels were more than 20% in the third lecture, less than 70% in the tenth lecture, and more than 50% in the thirteenth lecture.
Rule 3: The Grit scores of 1% of the students decreased when their understanding levels were more than 20, 90, 70, and 50% in the third, ninth, tenth, and thirteenth lectures, respectively.
Rule 4: The Grit scores of 3% of the students decreased when their understanding levels were more than 20% in the third lecture, less than 90% in the ninth lecture, more than 70% in the tenth lecture, less than 70% in the twelfth lecture, and between 50 and 90% in the thirteenth lecture.
Rule 5: The Grit scores of 12% of the students decreased when their understanding levels were more than 20% in the third lecture, less than 90% in the ninth lecture, more than 70% in the tenth and twelfth lectures, and between 50 and 90% in the thirteenth lecture.
Rule 6: The Grit scores of 12% of the students increased when their understanding levels were more than 20, 90, 70, and 50% in the third, ninth, tenth, and thirteenth lectures, respectively.
Rule 7: The Grit scores of 7% of the students increased when their understanding levels were more than 20% in the third lecture and less than 50% in the thirteenth lecture.

the following patterns were noted: 1) the persistence scores increased when the understanding levels were low in the former period and increased in the latter period; 2) owing to the diligent student participation, the persistence scores ultimately increased when the understanding levels decreased and increased; and 3) the persistence scores increased even though the understanding levels were less than 20% in the former period; 4) the persistence scores ultimately decreased when the understanding levels decreased in the former period; and 5) the persistence scores ultimately increased even when there were increases and decreases in the understanding level, owing to the diligent student participation. Regarding the passion score component of the Grit score, the following patterns were noted: 1) the passion scores decreased even though the understanding levels gradually increased; 2) the passion scores increased when the understanding levels gradually increased; and 3) the passion scores decreased when the understanding levels were low in the former period.

Now , the data classification results for lecture-type settings will be discussed. Regarding the Grit score, the following patterns were observed: 1) the Grit scores decreased when the understanding levels were low in the former period; 2) the Grit scores decreased even though the understanding levels were low in the former period and high in the latter period; 3) the Grit scores ultimately increased when the understanding levels were low in the former period and high in the latter period, owing to the diligent student participation; 4) the understanding levels were low throughout, but there was diligent participation, resulting in the Grit scores ultimately. Concerning the persistence score component of the Grit score, the following patterns were observed: 1) the persistence scores increased even though the understanding levels were low in the latter period; 2) the understanding levels were low in the former period and average in the latter period, and the persistence scores finally decreased; 3) the persistence scores finally decreased, even though the understanding levels were high in both the former and latter periods; and 4) the persistence scores ultimately increased, when the understanding levels were high throughout the entire period. Regarding the passion score component of the Grit score, the following patterns were observed: 1) the passion scores decreased when the understanding levels were less than average in the middle period; 2) the passion scores ultimately decreased when the understanding levels were low in the former period and high in the latter period; and 3) the passion scores ultimately increased when the understanding levels were average in the former period and even when they were low in the latter period. The above observations revealed that changes in the understanding levels and Grit scores varied depending on the students and type of class setting. Moreover, the hypotheses described in chapter 2 were verified from the data analysis; and additionally, there were some students whose Grit score decreased even when their understanding level was high.

IV. CONCLUSION

This research has made contributions to the viewpoint of comparative study for time series data. The changes in students 'understanding levels over more than ten lectures were considered as time series data, and both lecture-type and practical-type class settings in a university were analyzed. First, changes in the patterns of students' understanding levels were analyzed through DTW. The change patterns were quite diverse; thus, subdividing them was necessary. Next, rules

TABLE V. LECTURE TYPE:RELATIONS AND SUMMARY BETWEEN THE CHANGES IN THE GRIT SCORES (PERSISTENCE AND PASSION) AND UNDERSTANDING LEVELS

Lecture type: Grit(Persistence)
Rule 1: 13th <0.5, up (0.08) Rule 2: 3rd <0.7, 13th ≥ 0.5 down (0.08) Rule 3: 3rd ≥ 0.7, 4th <0.7, 13th ≥ 0.5, down (0.05) Rule 4: 3rd ≥ 0.7, 4th ≥ 0.7, 13th ≥ 0.5, 13th <0.7 up (0.06) Rule 5: 3rd ≥ 0.7, 4th ≥ 0.7, 6th ≥ 0.9, 13th ≥ 0.7, 13th <0.9 down (0.01) Rule 6: 3rd ≥ 0.7, 4th ≥ 0.7, 6th <0.9, 13th ≥ 0.7, 13th <0.9 up (0.1) Rule 7: 3rd ≥ 0.7, 4th ≥ 0.7, 13th ≥ 0.9, up (0.08)
Rule 1: The Grit (Persistence) scores of 8% of the students increased when their understanding levels were less than 50% in the thirteenth lecture. Rule 2: The Grit (Persistence) scores of 8% of the students decreased when their understanding levels were less than 70% in the third lecture and more than 50% in the thirteenth lecture. Rule 3: The Grit (Persistence) scores of 5% of the students decreased when their understanding levels were more than 70 and 50% in the third and thirteenth lectures, respectively. Rule 4: The Grit (Persistence) scores of 6% of the students increased when their understanding levels were more than 70% in the third and fourth lectures and between 50 and 70% in the thirteenth lecture. Rule 5: The Grit (Persistence) scores of 1% of the students decreased when their understanding levels were more than 70% in the third and fourth lectures, more than 90% in the sixth lecture, and between 70 and 90% in the thirteenth lecture. Rule 6: The Grit (Persistence) scores of 10% of the students increased when their understanding levels were more than 70% in the third and fourth lectures, less than 90% in the sixth lecture, and between 70 and 90% in the thirteenth lecture. Rule 7: The Grit (Persistence) scores of 8% of the students increased when their understanding levels were more than 70% in the third and fourth lectures and more than 90% in the thirteenth lecture.
Lecture type: Grit(Passion)
Rule 1: 9th <0.5, down (0.01) Rule 2: 3rd <0.2, 9th ≥ 0.5,13th ≥ 0.7, down (0.01) Rule 3: 3rd ≥ 0.2, 9th ≥ 0.5, 9th <0.7, 12th ≥ 0.7, 13th ≥ 0.7 down (0.01) Rule 4: 2nd <0.9, 3rd ≥ 0.2, 9th ≥ 0.7, 12th ≥ 0.7, 13th ≥ 0.7, down (0.07) Rule 5: 2nd ≥ 0.9, 3rd ≥ 0.2, 9th ≥ 0.7, 12th ≥ 0.7, 13th ≥ 0.7 up (0.09) Rule 6: 3rd ≥ 0.2, 9th ≥ 0.5, 12th <0.7, 13th ≥ 0.7 up (0.07) Rule 7: 2nd <0.7, 5th <0.7, 9th ≥ 0.5,13th <0.7 down (0.02) Rule 8: 2nd ≥ 0.7, 5th <0.7, 9th ≥ 0.5,13th <0.7 up (0.08) Rule 9: 5th ≥ 0.7, 9th ≥ 0.5,13th <0.7 up (0.11)
Rule 1: The Grit (Passion) scores of 1% of the students decreased when their understanding levels were less than 50% in the ninth lecture. Rule 2: The Grit (Passion) scores of 1% of the students decreased when their understanding levels were less than 20% in the third lecture and more than 50 and 70% in the ninth and thirteenth lectures, respectively. Rule 3: The Grit (Passion) scores of 1% of the students decreased when their understanding levels were more than 20% in the third lecture, between 50 and 70% in the ninth lecture, and more than 70% in both the twelfth and thirteenth lectures. Rule 4: The Grit (Passion) scores of 7% of the students decreased when their understanding levels were less than 90% in the second lecture, more than 20% in the third lecture, and more than 70% in the ninth, thirteenth, and, respectively. Rule 5: The Grit (Passion) scores of 9% of the students increased when their understanding levels were more than 90% in the second lecture; more than 20% in the third lecture; and more than 70% in the ninth, twelfth, and thirteenth lectures. Rule 6: The Grit (Passion) scores of 7% of the students increased when their understanding levels were more than 20% in the third lecture, more than 50% in the ninth lecture, less than 70% in the twelfth lecture, and more than 70% in the thirteenth lecture. Rule 7: The Grit (Passion) scores of 2% of the students increased when their understanding levels were less than 70% in the third, fifth, and thirteenth lectures and more than 50% in the ninth lecture. Rule 8: The Grit (Passion) scores of 8% of the students increased when their understanding levels were more than 70% in the second lecture, less than 70% in the fifth lecture, more than 50% in the ninth lecture, and less than 70% in the thirteenth lecture. Rule 9: The Grit (Passion) scores of 11% of the students increased when their understanding levels were more than 70% in the fifth lecture, more than 50% in the ninth lecture, and less than 70% in the thirteenth lecture.

reflecting the relation between changes in the Grit score before and after students participated in classes and changes in their understanding level were acquired through the decision tree algorithm. The proposed hypotheses were verified through data analysis, and noteworthily, unexpected patterns were extracted. The analysis results clearly showed that when conducting classes, the various relations between the changes in understanding levels and Grit scores of students should be considered.

The limitations of this study are two points. The first point is about the experimental data. Since students' data used in this study limited to the one university, it is necessary to try analyzing the case of the other university. The second point is the evaluation index. Since the understanding level is subjective scale that is students evaluate themselves, objective scale has to be applied. In addition, DTW was used for clustering of time series data and other statistical methods are necessary, as the future work.
