Ebel et al. [27]	Emoji-only communication	Explored how young people use emoji-only messages, finding that most users increase their understanding of emojis over time.	Focused only on young participants and emoji-only use.
Kelly et al. [19]	Emojis in computer-mediated communication	Emojis help maintain conversations, express feelings, and create an enjoyable interaction environment.	General findings without specific cultural focus.
Gomes et al. [28]	Sentic LDA and sentiment analysis	Enhanced corpus clustering using Sentic LDA, manually tagged based on aspect lexicons; no focus on emojis.	Excluded emojis and emoticons from the analysis.
Khattak et al. [30]	Aspect-based sentiment analysis with LSTM	Used LSTM and hierarchical attention for aspect-based sentiment analysis; excluded emojis and emoticons.	Text-focused, omitted emojis and emoticons.
Rodrigues et al. [31]	Concept-based feature extraction with FCA	Extracted features using FCA for concept-ontology relations; did not consider emojis in data analysis.	Ignored emojis in concept-based analysis.
Koroteey [32]	Co-LSTM for large text sequential analysis	Combined CNN and LSTM for scalable sequential text analysis; excluded emoji data.	Did not include emojis in analysis.
Consoli et al. [33]	Commonsense-based sentiment analysis	Employed ConceptNet and bidirectional LSTM for sentiment analysis, focusing on textual data only.	Did not address the role of emojis.
Ben Ayed et al. [34]	Latent Dirichlet Allocation (LDA) for sentiment	Applied LDA and PLSA for aspect-based sentiment analysis, calculated scores using SimRank algorithm; excluded emojis.	Focused solely on text, excluding emojis.
Liao et al. [35]	Fine-grained aspect-based sentiment (FiGAS)	Focused on sentiment analysis in financial and economic domains, using polarity scores without considering emojis.	Lexicon-based, did not incorporate emojis.

III. PROPOSED SENTIMENT ANALYSIS MODEL

The main problem addressed in this study was to propose an accurate system for reliably sentiment analyzing a message combining text with a string of emojis. The proposed system, illustrated in Fig. 1, comprises two phases: (1) the translation phase and (2) the classification phase.

In the translation phase, the sentiment of the text is analyzed using the Bidirectional Encoder Representations from Transformers (BERT) model, a transformer-based architecture renowned for its ability to capture the contextual meaning of text [36]. BERT processes the input text by considering the entire sentence, allowing it to understand how each word contributes to the overall sentiment. The output from BERT is a contextualized embedding—a vector representation that encapsulates the sentiment conveyed by the text. The vector includes mainly sentiment strength, sentiment polarity, and contextual dependencies. This embedding is then passed through a Long Short-Term Memory (LSTM) network. The LSTM further refines this representation by capturing any sequential dependencies in the sentiment, which is particularly advantageous in understanding how the sentiment might evolve over a longer text. The use of BERT ensures that the model comprehends the nuanced and context-dependent nature of language, while the LSTM helps in maintaining coherence in sentiment analysis over extended sequences.

Simultaneously, the sentiment conveyed by the emojis in the message is interpreted using a different yet complementary approach. Each emoji is first converted into a dense vector representation through an embedding layer using Emoji2Vec [37], which maps emojis into a vector space that reflects their semantic similarities. The word2vec tool transforms words into vectors for computation. This tool defines context based on words that are semantically similar. The skip-gram model in word2vec is preferred over Continuous Bag-of-Words (CBOW) because it predicts context based on current words used. This step is crucial because it translates the often-subtle emotional nuances of emojis into a format that the model can process. The embedded emojis are then processed by an LSTM network, which is particularly effective at capturing the sentiment in sequences of emojis, recognizing how their order and combination might alter the conveyed emotion. The LSTM's

ability to understand sequences makes it particularly well-suited for interpreting the sentiment from emoji sequences, as it can capture changes or continuities in emotional expression across multiple emojis.

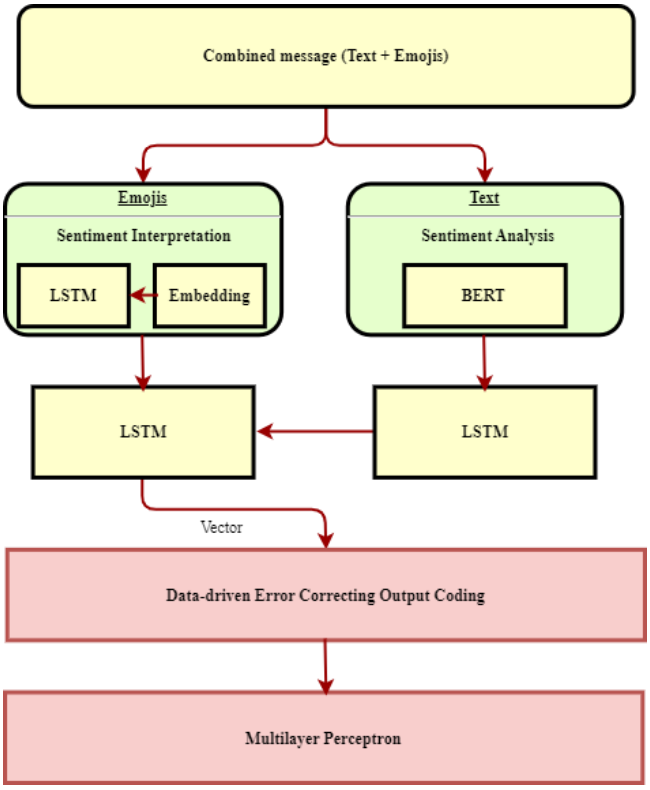

Fig. 1. Sentiment analysis model.

Once the text and emoji sentiments have been individually processed, the outputs from the respective LSTM networks are combined into a single vector that encapsulates the overall sentiment of the message. This combination of text and emoji sentiment ensures that the model considers the full spectrum of emotional expression, leveraging both the explicit and implicit cues provided by the user.

In the classification phase, this combined sentiment vector undergoes further refinement through a data-driven error-correcting output coding layer (DECOC) [38]. The DECOC constructs a coding matrix where each row corresponds to a class and each column to a binary classifier. The classes are encoded as binary strings, allowing the system to decode the output into one of the multiple classes. This approach is particularly effective in handling the variability and complexity of emoji sequences. This layer helps in reducing any noise or errors that may have been introduced during the Translation Phase, thereby enhancing the model's ability to generalize across different types of messages. It ensures that the sentiment analysis remains robust, even in complex scenarios where text and emojis might convey conflicting emotions.

The refined vector is then passed into a Multilayer Perceptron (MLP) which is tasked with classifying the overall sentiment of the message. The MLP's architecture, with its multiple layers of neurons, allows it to perform complex transformations on the input data, gradually refining it until it reaches the final sentiment classification. The use of MLP ensures that the model can accurately classify the sentiment into categories such as positive, negative, or neutral, providing a comprehensive analysis of the emotional content of the message.

Overall, the design leverages advanced NLP techniques, combining the strengths of BERT, LSTM networks, DECOC, and MLPs to offer a robust and accurate sentiment analysis system. The translation phase ensures that the nuanced sentiments in both text and emojis are captured, while the classification phase refines and classifies these sentiments, resulting in a system that can accurately interpret the emotional tone of a combined text and emoji message.

IV. Results and Discussion

The DECOC-MLP classifiers achieved outstanding predictive accuracy across all identified emotional undertones, whether derived from text or emojis, with a high degree of confidence. During the data processing phase, emotional cues are extracted from both the textual and emoji components. The emoji data is processed using a pre-trained model based on the EmojiNet and EmojiString datasets [39], where 80% of the data is randomly assigned for training and 20% for testing. The DECOC classifier generates an output vector populated with potential emotional meanings, while the spaCy library in Python is used to analyze the emotional content of the text.

In the classification phase, the DECOC-MLP model processes keywords and sentences, utilizing a dataset from the Twitter Developer's API [40], which contains 1,440,438 sentences categorized by sentiment. Following training, the model is capable of accurately categorizing words according to

their respective categories. The DECOC-MLP model was trained over 25, 50, 75, and 100 epochs, with batch sizes ranging from 200 to 400. After thorough analysis, an epoch size of 50 and a batch size of 300 were identified as the optimal parameters. Tenfold cross-validation was performed during training, resulting in a mean accuracy of 94.76%, indicating the model's high effectiveness. Accuracy is calculated as the ratio of correctly predicted instances to the total number of instances in the dataset as shown in Eq. (1).

$$Accuracy = \frac{True\ classification}{Total\ of\ samples} \quad (1)$$

The model also demonstrated a low variance value of 2.05×10^{-6}, see Eq. (2), confirming that the predictions are not only accurate but also stable and consistent with expected outcomes.

$$Variance = \frac{\sum(M_i - \overline{M})}{n-1} \quad (2)$$

Where M_i is the value of a specific message, $\overline{M}$ is the mean value, and n is the total number of messages.

The model was validated using the testing set from the Twitter Developer's API dataset and achieved an accuracy of approximately 94%, and a created one based on local survey accomplishing an accuracy of 92.8%, as depicted in Fig. 2.

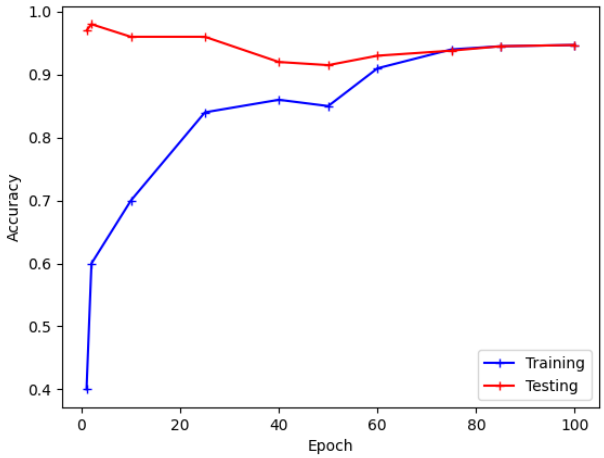

Fig. 2. DECOC-MLP trained-test accuracy.

The Fig. 2 indicates that the model performs well on both the training and testing datasets, but there is a small indication of overfitting. The testing accuracy remains high, which is a positive sign.

To assess the accurate recognition of the emotional undertones of an emoji string in a real case, we designed a survey for Saudis using WhatsApp, consisting of 100 common messages including text and emojis. Table II presents some of these messages.

TABLE II. SAMPLES OF MESSAGES

Message (Text + Emojis)	Translation (Arabic)	Sentiment
"I'm so happy today! ☺️☼ "	"أنا سعيد جدًا اليوم! ☺️☼"	Positive
"I can't believe this happened... 😒💔"	"لا أستطيع تصديق ما حدث... 😒💔"	Negative
"This is just okay. 😐"	"هذا فقط جيد. 😐"	Neutral
"What a wonderful surprise! 🎉"	"يا لها من مفاجأة رائعة! 🎉"	Positive
"I'm really frustrated right now. 😩"	"أنا محبط حقًا الآن. 😩"	Negative
"Feeling a bit down today... ☹️"	"أشعر بالحزن قليلاً اليوم... ☹️"	Negative
"Wow, that was unexpected! 😲"	"واو، لم أتوقع ذلك! 😲"	Neutral to Positive
"Best day ever! 🎉☺️"	"أفضل يوم على الإطلاق! 🎉☺️"	Positive

Therefore, Table III shows a comparison with previous works. The table compares different sentiment analysis approaches over the years, focusing on the data types, classifiers used, datasets, and achieved accuracy. Behera et al. (2021) achieved a high accuracy of 98% using CNN and LSTM on airline reviews based solely on text data. Gupta et al. (2023) incorporated both text and emojis, using multiple classifiers on a large Twitter dataset, reaching an accuracy of 91%. The proposed approach for 2024 also integrates text and emojis, employing advanced techniques like LSTM, DECOC, and MLP, resulting in a strong accuracy of 94% on diverse datasets.

TABLE III. COMPARISON BETWEEN MODELS

Approach	Year	Message	Classifier Used	Dataset	Accuracy
Behera et al. [41]	2021	Text	LSTM CNN	Airline review	98%
Gupta et al. [42]	2023	Emoji + Text	Decision Tree SVM Naïve Bayes	168548 tweets	91%
Proposed approach	2024	Emoji + Text	LSTM DECOC MLP	EmojiString Twitter Developer's API dataset	94%

To sum up, emojis are becoming increasingly important in sentiment analysis as they play a crucial role in conveying emotions in digital communication. This rise in emoji usage does not replace traditional text-based language but rather enhances it as part of the natural evolution of language. As technology continues to influence daily communication, the integration of emojis into sentiment analysis models becomes increasingly significant. The proposed model in this paper focuses on accurately interpreting the emotional undertones conveyed by emoji sequences using DECOC machine learning models. The results demonstrate that the DECOC classifier effectively predicts the sentiment expressed through both textual and emoji inputs with high accuracy.

V. CONCLUSION

This paper highlights the increasing use of emojis on social media platforms among Saudis and presents a machine learning-based model specifically designed for sentiment analysis of messages that combine text and emojis, providing highly accurate emotional assessments. The proposed DECOC-MLP model excels at thoroughly analyzing the emotional content of message components, including both text and emoji sequences, using "EmojiString" and Twitter Developer's API datasets. This dataset allows the model to precisely detect the emotional nuances conveyed by emoji sequences, thereby significantly improving the accuracy of sentiment analysis.

The importance of this approach lies in its potential for future advancements, where the EmojiString dataset can be expanded to include more complex emoji combinations, offering deeper insights into the role of emojis in conveying emotions. This will not only refine the model's accuracy but also contribute to understanding how emojis complement or even replace text in digital communication. Future research should explore the cultural implications of this model, particularly its impact on the evolution of language and communication in various user groups. Recognizing emojis as a fundamental part of language development is essential as they continue to shape the landscape of sentiment analysis.

***Abstract*—School districts globally implement comprehensive and expensive strategies to offer safe bus transportation to and from school. However, these technologies are unfeasible to schools with limited financial resources, thereby leaving students at risk of serious injury. This study focuses on five major obstacles to safe school transportation: 1) forgetting students on the bus unattended; 2) students' abnormal behavior; 3) overcrowding; 4) abnormal driver behavior; and 5) the risk of a bus running over children after they have disembarked. This paper developed an intelligent system using the Internet of Things, including rule-based and mathematical solutions to overcome the five transportation safety issues in student buses mentioned above, and to enhance student safety, using a bracelet system, short- and long-RFID sensors, and a processing unit to monitor the bus and its surrounding area. Therefore, in this paper, the proposed solution is superior to previous works in the same field. It is distinguished by its comprehensiveness and reasonable cost, making it affordable and easy to both install and maintain.**

***Keywords*—IoT; safety; RFID; school bus; transportation**

I. INTRODUCTION

Keeping students safe on their journey to and from school is of great importance not only to parents, school officials, and administration, but to the entire local community. School buses play a crucial role in transporting students to and from school, serving as a prevalent and cost-effective mode of transportation in many educational communities and countries. Public institutions, communities, and nations aim to expand and improve their school bus services to lower transportation costs, alleviate traffic congestion, and decrease carbon emissions.

Despite these benefits, ensuring safe transportation for students can be difficult due to five safety issues that might harm their safety. The first is when children are forgotten and left on the bus. It is difficult to keep track of all the children to make sure everyone gets off the bus. Left unattended for long periods of time, these forgotten children can harm their health or even cause death [1, 2]. Second, student fights on school transport can hinder their and others' safety, as can other abnormal behavior on the school bus [3, 4]. Some parents complain about fights on the school bus as their children exhibit signs of aggression. It is challenging for the transportation supervisor or driver to monitor the children throughout the entire trip, particularly on a crowded bus.

The third issue is that overcrowded buses where that pose significant risks to students' safety and well-being, as it can lead to discomfort, accidents, delays, and difficulties in emergency evacuations, all of which put students at risk [5]. The fourth impediment to student safety is the unruly behavior of drivers [6]. Such behavior can create a negative environment on the bus, leading to distractions, discomfort, and potentially unsafe conditions for the children. Finally, the fifth obstacle to student safety is accidents that occur when the children disembark. As they cross the road or move away from the bus, they may unknowingly position themselves in the bus's blind spots, outside of the driver's view. If the bus starts moving, there is a risk of the child being injured or killed [7, 8].

Recent technological advancements, especially within the Internet of Things (IoT), play a crucial and effective role in providing safe and effective solutions to various problems [9]. IoT refers to the network of physical objects, or "things," embedded with technologies, software, and sensors, which exchange data with other devices and systems over the internet [10]. This paper applies IoT solutions to handle the five safety issues and enhance security in school transportation. To prevent children from being forgotten on the bus, this paper suggests the use of a bracelet system, which is scanned when the student enters the bus and again when they exit. This solution tracks the boarding and disembarking times and locations, as well as the duration of the time on the bus.

The bracelets, which would be equipped with location-tracking capabilities, should transmit location data to a central system capable of receiving and processing this data. This location data could solve multiple safety issues. In addition to monitoring students who are forgotten on the bus, it could also be used to identify abnormal student behavior via a special algorithm (criteria for a fight could be included frequent position changes, the simultaneous swapping of places by multiple students, or a large gathering of students in one area); location data could also trigger automated alerts when buses surpass safe occupancy levels. In addition, the bracelet could also generate alerts for abnormal driver behavior using the location data. Finally, location data could be used to notify drivers if a student or students are in the bus's blind spot; the driver would then be restricted from moving until all students are a safe distance from the bus.

The contribution of our proposed system is to provide a comprehensive set of safety functionalities at a very minimal cost and with low computational power requirements. This makes our proposed system accessible and applicable to a wide

range of users. The remaining sections of the paper are organized as follows: Section II discusses recent and updated related works. Section III describes the mathematical model used to develop this smart IoT system. Section IV contains a detailed explanation of the system's implementation. Section V presents a validation of the proposed IoT system. Finally, the discussion and conclusion are presented in Section VI.

II. Related Work

This section discusses related research on IoT systems and safety. The timeframe was limited to the period from 2019 to 2024, as technology has been evolving rapidly, and any work published before this period could be considered outdated. Two factors served as inclusion criteria. Firstly, the work must address one or more of the problems outlined in the introduction (Section I). Secondly, the work should offer practical, and implementable, solutions. All theoretical works were excluded, as well as any redundant ideas.

Abbas et al., [11] addressed the issue of students being inadvertently left on school buses by introducing a system that enabled parents to monitor their children's daily commute using GPS technology. This system alerted parents before the bus reached their home, ensuring the safety of their children. In study [12], Liu and Peng, addressed safety incidents where young children were left unattended on school buses during the summer by implementing a Force Sensing Resistor (FSR) sensor array. This system detected the movement of a forgotten child based on the resistance of the FSR module. Krishnan and Vasuki, in study [13], created an intelligent system employing Global System for Mobile applications (GSM) and Radio Frequency Identification (RFID) technologies. RFID was utilized to recognize students and link them to their parent's contact information, with GSM serving as the medium to notify parents of their child's whereabouts via text message. Paul and Sasirekha, in the study [14], developed a smart system by utilizing three technologies—global positioning system (GPS), RFID and GSM—to ensure a safe school bus journey. RFID oversaw children entering and exiting the bus and sent SMS notifications to parents. If the child didn't reach school or home on time, parents could activate the registered number on the GPS tracker. The tracker then monitored the child's position, providing the latitude and longitude coordinates to the parent's mobile device.

Mott and Kotla, in [15], addressed the issue of children being run over after disembarking from the school bus by developing a detection system based on a LiDAR unit and a dashcam, both controlled by a Raspberry Pi computer. Kumari et al., in [16], created an IoT- and Android-based system that allowed parents and schools to monitor the comfort and safety conditions on the bus in real-time. Gadekar et al., in [17], developed a smart school bus tracking system using QR codes to monitor student boarding and disembarking. To track bus movement, they created a mobile application utilizing the Django framework and GPS integrated with the Google Maps API, enabling parents to stay informed about the real-time location of the bus. In Naik et al.'s research [18], a school bus monitoring system was developed to share details on the bus's location, speed, estimated arrival time, and the students' whereabouts. This functionality was facilitated by IoT technology. The tracking of the school bus was carried out using GPS technology. Parents are alerted through GSM. Everyone is identified by a unique ID through RFID. The bus tracking system allowed for real-time tracking on smartphones. Additionally, the researchers incorporated an algorithm to track the bus and estimate its arrival time.

Sakphrom et al., in [19], developed a smart system for monitoring children inside a school bus by utilizing Bluetooth Low Energy (BLE), which is compatible with a signal strength indicator (RSSI) algorithm. The system monitored children entering and exiting the bus and notified the driver to help them ascertain whether any child was left on-board. The system assessed the distance between devices to determine the current position of the children. To achieve this, this study employed a simplified and highly accurate machine learning approach known as the least mean square (LMS) algorithm, combined with model-based RSSI localization techniques. Malathy et al., in [20], introduced a smart module that relied on GPS to transmit data to a remote server via Wi-Fi. The data uploaded was subsequently accessible to the client through a mobile application, which retrieved the information and mapped the vehicle's location. An alert system activated the microcontroller to generate a push notification from the server script upon scanning the student's RFID tag with the RFID reader, signaling to the relevant authorities and parents that the student has boarded the bus.

Wang et al., [21], developed an abnormal behavior prediction method by integrating multiple indices of student behavior and text information within a big data environment. They utilized an optimized K-means algorithm for clustering student behavior data and combined it with long-short-term memory (LSTM) networks and neural factorization machines for predictive analysis. This study enhanced the field's ability to identify and manage potentially dangerous behaviors in educational settings. Ding et al., [22], developed an intelligent system to detect abnormal behavior in students using human skeleton analysis and deep learning. They utilized the OpenPose deep learning network to extract spatiotemporal features of the human skeleton and classified these features with a graph convolutional neural network to reduce computational complexity. The system demonstrated high accuracy, with a recognition rate exceeding 99.50%. These results underscore the system's potential for real-time monitoring of student behavior on school buses, enhancing safety measures through effective detection and classification of abnormal behavior. Murawski et al., [23], deployed an intelligent system for overseeing school bus drivers using a "stability" index, which contrasts with the 11 risky driving behaviors determined by the digital tachograph (DTG) and GPS integrated with the Google Maps API.

Etaati et al., [24], evaluated the effectiveness of promoting active transportation to school by utilizing the Safe Routes to School (SRTS) program to estimate the likelihood of students choosing to walk to school. They employed SHapley Additive exPlanations to identify significant variables that influenced active transportation behavior in their models. The findings highlighted factors such as home-to-school distance and safety concerns, including crime rates and traffic speed along the route. In this solution, however, they replaced the bus transportation system with a safe road, which may not be applicable in all locations.

TABLE I. SUMMARY OF RELATED WORKS

No	Work	Techniques/ Algorithms	Limitation
1	Krishnan and Vasuki, in [13]	SMS and GSM	The speed and cost are affected by the use of GSM technology.
2	Abbas et al., in [11]	GPS and Mobile application	There is no monitoring system in place for the students themselves; instead, manual checks are required to ensure students board the bus.
3	Liu and Peng, in [12]	Force Sensing Resistor and android application	The accuracy could be affected by the movements of students.
4	Paul and Sasirekha, in [14]	GPS, RFID and GSM	It is very difficult to provide real-time data.
5	Mott and Kotla, in [15]	LiDAR unit a dashcam, both, and Raspberry Pi	High processing cost.
6	Kumari et al., in [16]	Dashcam, Android	High-cost devices are challenging to provide.
7	Gadekar et al., in [17]	QR Code, Google Maps API, Django	Scanning the QR code of every student when boarding and disembarking slows the system and makes it impractical.
8	Naik et al., in [18]	GPS, GSM, RFID, and Android application	High-cost devices are challenging to provide to everyone.

14	Etaati et al., in [24]	random forest, logistic regression, and support vector machines	The researchers replaced the bus transportation system with a safe road, which may not be applicable in all locations.
15	LR et al., in [25]	RFID and GPS	Does not provide complete solutions.
16	Gadade et al., in [26]	ESP32 microcontroller, GPS module, RFID reader, RTC module, LCD	High-cost devices are challenging to provide to everyone.
17	Kumari et al., in [27]	Python-configured PC with a camera and OpenCV	High processing cost.

LR et al., in [25], developed a system that addressed safety standards by ensuring continuous student monitoring through RFID and GPS technologies. This system recorded the boarding and disembarking times of students passing through two checkpoints, tracked the real-time location of the bus, and monitored its speed to comply with regulations. In Gadade et al.'s research [26], a smart school bus and student tracking system based on IoT was developed utilizing an ESP32 microcontroller, GPS module, RFID reader, RTC module, LCD display, and integration with Google Sheets. The ESP32 microcontroller functioned as the central processing unit. The GPS module facilitated the tracking of the school bus's location, enabling real-time monitoring for parents, school staff, and authorities.

Furthermore, RFID technology was employed to monitor students during boarding and disembarking. For accurate timekeeping, a Real-Time Clock (RTC) module was integrated to synchronize system time and ensure precise event logging. Additionally, an LCD display served as a local interface, offering real-time updates on bus location, current time, and important announcements. Kumari et al., in [27], created a smart system utilizing a Python-configured PC with a camera and OpenCV for instant facial recognition of students during school bus boarding and exiting. Upon identifying a student, the system automatically sent an email notification to inform parents, providing reassurance to caregivers. Alongside student recognition, the system included alcohol detection features for the driver. In cases where the driver was deemed intoxicated, the bus's ignition system would lock, preventing unsafe driving.

Table I, illustrates this analysis of the related works, defining the techniques or algorithms that each utilized and detailing their limitations. The related works have been analyzed by defining the strengths and weaknesses of each work. The datasets are associated with their related work. Similar works have discussed safety in school transportation systems. The database used in the work is specific to each study, and currently, there is no general-use database available.

III. MODELING

This section presents a mathematical model that serves as the foundation for implementing this paper's five solutions. There are three assumptions, which are:

Assumption 1: Each student should wear a bracelet.

Assumption 2: The bus driver should wear a bracelet.

Assumption 3: Each bracelet has a unique integer number.

Fig. 1 displays the variables utilized in these proposed solutions, which are incorporated into the mathematical model.

1. s → student
2. b → bracelet
3. seat → bus seat
4. r1 → first reader
5. r2 → second reader
6. r3 → inside reader
7. r4 → inside reader
8. r5 → inside reader
9. bdrv → driver bracelet
10. driver_set → driver seat

Fig. 1. Variables of the proposed solutions.

In the following formulas, the mathematical model has been described in form on First Order Logic (FOL), which is suitable for describing real life problems [28].

$$\forall b: bracelet\ (b) \wedge integer(number) \implies unique(b, number) \quad (1)$$

Rule 1 denotes that there is a unique integer number assigned to each bracelet, which functions as the primary key or identifier for a bracelet.

$$\exists s\ \exists b: student(si) \wedge bracelet\ (bj) \wedge wear\ (si\ , bj) \implies assign(si, bj) \quad (2)$$

Rule 2 denotes that each student has their own unique bracelet, which means the reading of a specific bracelet number identifies the associated specific student.

$$\forall s\ \forall r1\ \forall r2\ \forall ti\ \forall b: reader(r1) \wedge reader(r2) \wedge time(t) \wedge bracelet\ (bj) \wedge assign(si, bj) \wedge read(r1, bi, t1) \wedge read(r2, bi, t2) \wedge (t2 > t1) \implies si\ boarding\ the\ bus \quad (3)$$

Rule 3 denotes that if the bracelet of student (i) was read by reader 1 first and then read by reader 2 later, this means that student (i) has boarded the bus.

$$\forall s\ \forall r1\ \forall r2\ \forall ti\ \ \forall b: reader(r1) \wedge reader(r2) \wedge time(t) \wedge bracelet\ (bj) \wedge assign(si, bj) \wedge read(r1, bi, t1) \wedge read(r2, bi, t2) \wedge (t1 > t2) \implies si\ gets\ off\ the\ bus \quad (4)$$

Rule 4 denotes that if student (i)'s bracelet was read by reader 2 first and then reader 1 later, then the student (i) has gotten off the bus.

$$\forall s: true\ (rule\ 3) \wedge true(rule\ 4) \implies time(si, boarding\ and\ alighting) \wedge location(si) \quad (5)$$

Rule 5 indicates that once rules 3 and 4 are met, the boarding and disembarking of a student have been established, along with their location during the bus ride. Rules 3, 4, and 5 present the mathematical formulation for the first solution, which confirms that no students were forgotten on the bus.

$$\forall bn\ \forall ri\ \forall seatj\ \forall sx: ((ri == reader\ 3) \wedge (ri == reader\ 4) \wedge (ri == reader\ 5)) \wedge student(sx) \wedge seat(seatj) \wedge set(setj, sx) \wedge wear\ (si\ , bn) \wedge read(ri, bn) \implies assign(sx\ , seat\ j) \wedge location(seatj) \quad (6)$$

Rule 6 specifies that the three readers, r1, r2, and r3, are used to determine the student's seat. After the student takes a seat in a specific location, the three readers employ the triangulation method to identify the student's seat and exact location.

$$\forall ri\ \forall bx\ \forall setj\ \forall sx: ((ri == reader\ 3) \wedge (ri == reader\ 4) \wedge (ri == reader\ 5)) \wedge seat\ (setj) \wedge bracelet\ (bx) \wedge assign(setj, sx) \wedge ((distance(ri, bx) == n) \wedge ((distance(ri, setj) == m) \wedge (n \neq m) \implies sx\ in\ incorrect\ seat \implies send(alarm) \quad (7)$$

Rule 7 states that if the distance between a particular reader i and a specific seat j (predefined distance) assigned to student x is not equal to the distance between bracelet x assigned to student x and the particular reader i, this indicates that student x is seated in the incorrect seat; an alarm will be sent to administrators.

$$\forall ri\ \forall b\ \forall setj\ \forall s: ((ri == reader\ 3) \wedge (ri == reader\ 4) \wedge (ri == reader\ 5)) \wedge bracelet\ (bx) \wedge bracelet(by) \wedge (distance(ri, bx) == n) \wedge (distance(ri, by) == m) \wedge (m \wedge n) < safe\_distance \implies student\_gathering \implies send(alarm) \quad (8)$$

Rule 8 states that if the distance between two or more students is less than the predefined safe distance that should be maintained, indicating a group gathering, an alarm will be triggered and sent to the administrators as an alert. Rules 6, 7, and 8 illustrate the mathematical representation for the second solution, which seeks to prevent student fights and other erratic behavior.

$$\forall r1\ \forall r2\ \forall bi: reader(r1) \wedge reader(r2) \wedge bracelet\ (bi) \wedge read(r1, bi) \wedge \neg read(r2, bi) \wedge count(bi, n) \wedge (n > bus\_capacity) \implies send(alarm) \quad (9)$$

Rule 9 states that if the number of students who have been scanned by the first reader but not by the second reader exceeds the bus capacity, the system will send an alert to the administrators to indicate overcrowding. Rule 9 illustrates the mathematical representation for the third solution.

$$\exists bdrv\ \exists r1\ \exists driver\_set: reader(r3) \wedge reader(r4) \wedge reader(r5) \wedge bracelet\_driver\ (bdrv) \wedge (distance(ri, driver\_set) == x) \wedge$$

$$distance(r1, bdrv) > x \implies driver\ misplaced \wedge send(alarm) \quad (10)$$

Rule 10 denotes that if the distance between the driver's bracelet and the readers is greater than the distance between the first reader and the driver's seat, it indicates that the driver is not in the correct position and triggers an alarm to administrators. Rule 10 presents the mathematical formulation for the fourth solution, which seeks to prevent erratic driver behavior.

$$\forall ri\ \forall b\ \forall s: ((ri == reader\ 1) \wedge (ri == reader\ 2) \wedge (ri == reader\ 3) \wedge (ri == reader\ 4) \wedge (ri == reader\ 5)) \wedge bracelet(bx) \wedge assign(sx, bx) \wedge out\_range(ri, bx) \implies bus\ save\ to\ move \quad (11)$$

Rule 11 mandates that the bus will only move when all students are out of the reader's range, ensuring that the bus does not depart while students are still within proximity. This rule introduces the mathematical formulation for the fifth solution, which addresses student safety after they've disembarked from the bus. Table II, displays the rules and their corresponding solutions.

TABLE II. THE RULES AND THEIR CORRESPONDING SOLUTIONS

Rule	Solution
3, 4, and 5	First solution, which prevents students being forgotten on the bus: track the boarding and disembarking times, locations, and the duration of the student's time inside the bus.
6, 7, and 8	Second solution, which prevents erratic student behavior: set thresholds for the frequency of place changes, the number of students swapping places simultaneously, and instances of groups of students gathering in one place.
9	Third solution, which prevents bus overcrowding: trigger automated alerts for administrators when buses surpass safe occupancy levels.
10	Fourth solution, which prevents erratic driver behavior: track driver movement and generate alerts for abnormal driving behavior, such as frequent changes in location
11	Fifth solution, which prevents students from being injured or killed when in the bus's blind spot: prevent the bus from moving if students are still in the bus area. The driver is restricted from moving until all students are safely outside the bus area.

IV. IMPLEMENTATION

This section explains the implementation of the aforementioned rules in order to achieve increased bus safety. The implementation system has been developed based on different components. The main concept of the developed smart IoT system for enhancing safety in school bus transportation is presented in Fig. 2.

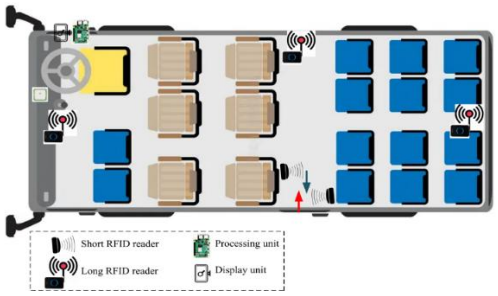

Fig. 2. The main components of the developed smart IoT system.

The entrance of the bus employs two short-range RFID readers, as presented in Fig. 2. There are two main reasons for utilizing these readers: the first is to identify students as they enter or leave the bus, and the second is to determine the direction of the student (entering or leaving). For instance, if reader A detects the RFID signal of the student before reader B does, then the student is entering the bus; whereas if reader B detects the RFID signal of the student first, then the student is leaving the bus. Algorithm 1 presents the method for determining the student's direction (entering or exiting the bus). This ensures that students are not forgotten on the bus.

Algorithm 1: Determine the status of the student (enter / exit the bus)

```
let sb_i is the student's bracelet of student i
let rf_e is the first short-range RFID reader
let rf_x is the second short-range RFID reader
let status is the current status of the student (1: enter and 2: exit)
if rf_e detects sb_i then
    if rf_x detects sb_i then
        return 1
else if rf_x detects sb_i then
    if rf_e detects sb_i then
        return 2
```

One of the main benefits offered by the developed IoT system is its continuous monitoring of children's positioning on the bus. Three long-range RFID readers are employed to triangulate the children's locations. When a child enters the bus, the system records the location for each child and stores these locations in a local database. Subsequently, the system continuously estimates the location of each child to keep track of their initial location. The code used to estimate the continuous locations of the students and check for changes in position is shown in Algorithm 2.

Algorithm 2: Check for students change-position in the bus

```
let sb_i is the student's bracelet of student i
let student[] is the array of students in the bus
let init_pos[] is the array of 2D positions for students in the bus
let new_pos[] is the array of the new estimated 2D positions for students in the bus
let change-position = False
while (every 20 seconds):
    for each student in new_pos[]:
        if dist(init_pos[], new_pos[]) >= 100 cm then
            change-position = True
            show alarm in driver display
            send alarm to administrators
End
```

When one or more students have changed their initial locations (seats), the driver will be informed by displaying an alarm on the screen, and an alarm will also be sent to the administrators. Furthermore, the developed IoT system can detect crowds, such as more than two students in the same position on the bus. In such cases, the driver will be informed by

displaying an alarm on the screen, and an alert will be sent to the administrators. Algorithm 3 is utilized to check for any gatherings (crowds) inside the bus. Algorithms 2 and 3 are utilized to implement the second solution, which involves detecting abnormal behavior inside the bus.

Algorithm 3: Check for students gathering inside the bus

0: let sb_i is the student's bracelet of student *i*
1: let *student[]* is the array of students in the bus
2: let *init_pos[]* is the array of 2D positions for students in the bus
3: let *new_pos[]* is the array of the new estimated 2D positions for students in the bus
4: let *gathering* = False
5: **while** (every 20 seconds):
6: **for each** *position* in *new_pos[]*:
7: **if any dist**(*position*, *position*+1, *position*+2) <= 50 cm **then**
9: *gathering* = True
10: show alarm in driver display
11: send alarm to administrators
12: **End**

The long-range RFID readers are utilized to perform a significant localization task. For example, when the system detects a person leaving the bus, the long-range RFID readers begin tracking the location of that student. If the RFID readers no longer receive signals from the student's bracelet, the driver is alerted to safely depart from the drop-off point. However, if the student remains within range of one or more long-range RFID readers, the driver is instructed to wait until the student moves away from the bus. Algorithm 4 outlines the method used to estimate the distance between the child and the bus, to ensure that children standing in the bus's blind spot are not injured or killed.

Algorithm 4: Check for student's distance to bus

0: let sb_i is the student's bracelet of student *i*
1: let lRF_1 is the first long-range RFID reader
2: let lRF_2 is the second long-range RFID reader
3: let lRF_3 is the third long-range RFID reader
4: let *must_stop* = True
4: **if** status == 2: (Algorithm 1)
5: **if** sb_i in the range of (lRF_1 or lRF_2 or lRF_3) **then**
6: *must_stop* = True
7: display alarm
8: **else if** sb_i **not** in the range of (lRF_1 or lRF_2 or lRF_3) **then**
9: *must_stop* = False
10: **End**

Moreover, the developed system can monitor the driver's behavior by continuously tracking the driver's position. Each driver possesses a unique bracelet for identification purposes. Consequently, when the driver relocates from their initial position, the coordinator is promptly notified to prevent accidents and increase safety. Algorithm 5 demonstrates this method.

Algorithm 5: Determine the location of the driver

0: let db_i is the student's bracelet of student *j*
1: let $init\_loc_{dj}$ is the initial location of the driver *j*
2: let lRF_1 is the first long-range RFID reader
3: let lRF_2 is the second long-range RFID reader
4: let lRF_3 is the third long-range RFID reader
5: estimate_driver_loc(lRF_1, lRF_2, lRF_3)
6: let cur_loc_{dj} is the current location of the driver *j*
7: **while** (True):
8: **if** ($init\_loc_{dj}$!= cur_loc_{dj}) **then**
9: emergency_call()
10: send alarm
11: **else:** cur_loc_{dj} = estimate_driver_loc(lRF_1, lRF_2, lRF_3)
12: **End**

Furthermore, the system has the capability to calculate the total students aboard the bus to prevent overcrowding issues. This count is determined by the short-range RFID readers located at the bus entrance. If the number of students onboard exceeds the bus capacity, the coordinator is promptly alerted. Algorithm 6 demonstrates this, below.

Algorithm 6: Count the total number of students inside a bus

0: let sb_i is the student's bracelet of student *i*
1: let rf_e is the first short-range RFID reader
2: let rf_x is the second short-range RFID reader
3: let cap_k is the capacity of the bus *k*
4: let $count_k$ is the total number of students inside the bus *k*
5: **if** ($count_k$< cap_k) **then**
6: emergency_call()
7: send alarm
8: **End**

The developed system was implemented using different components (processing, RFID readers, and communication), as follows:

1) Processing unit: Raspberry Pi 4 processes the data received from short- and long-range RFID readers, and takes suitable action accordingly.

2) Long-range RFID readers: These are required to obtain the precise position of the student on the bus. Three long-range RFID readers were deployed in the bus area in order to obtain accurate localization information from each child.

3) Short-range RFID readers: Two short-range RFID readers were employed at the bus door to identify the direction of the student (entering or leaving the bus).

4) Communication unit: For reliable communication between the above units, processed data, and short- and long-range RFID readers, this paper utilized WiFi (IEEE 802.11) network. Fig. 3 presents the communication process between the above components; it also shows the proposed IoT system architecture. Fig. 4 shows the communication process between the main components.

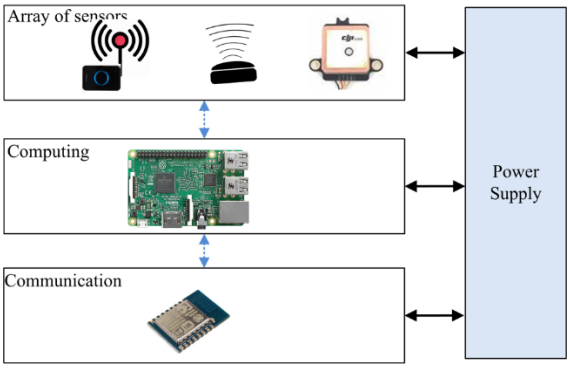

Fig. 3. The proposed IoT system architecture.

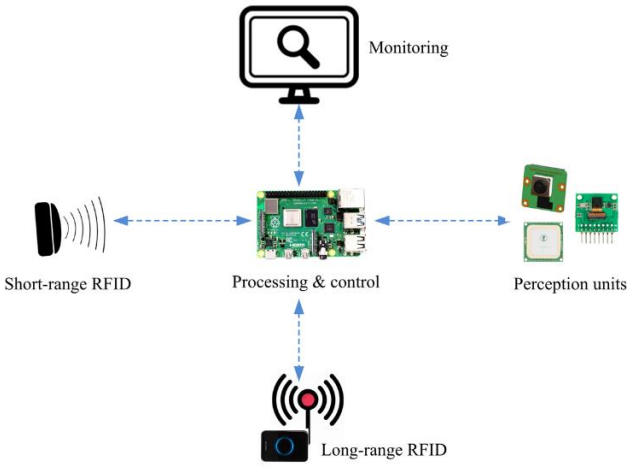

Fig. 4. The communication process between the main components.

V. VALIDATION

This paper's solutions were tested using simulation software designed by implementing the aforementioned algorithms to replicate various threats to students' safety. In an IoT environment, it is an acceptable practice to use simulated scenarios to test and demonstrate the accuracy and scalability of the proposed solutions [29, 30].

A. First Scenario

A bus with 30 seats (s1, s2, …, s30) has 30 students (st1, st2, …, st30) entering the bus and sitting randomly in the seats. The bus has been simulated as an array, and the students are represented as variables occupying the array positions. Additionally, the researchers entered an excess number of students to exceed the bus capacity in order to test rule 9.

To verify the accuracy of the IoT system, this paper compared the data from the readers' database with the array content, achieving a consistent 100% accuracy. The experiment was replicated with buses having 45 seats and 45 students, 60 seats and 60 students, 75 seats and 75 students, and 90 seats and 90 students. Assuming a one-hour bus journey, readings were recorded every 30 seconds, totaling 120 intervals. Accuracy remained at 100% throughout.

B. Second Scenario

In the same simulation environment as before, a bus with 31 seats (s1, s2, …, s30) and 30 students (st1, st2, …, st30) was considered, with the first seat reserved for the driver. Therefore, the first position of the array is occupied by a special variable 'd' representing the driver. Randomly, the driver variable 'd' changed position five times during a 30-minute period. Additionally, four random students changed their seats after five minutes and again after 10 minutes. Subsequently, three contents were compared—the readers' database, array content, and alarms file. The proposed system achieved an accuracy of 100%.

C. Third Scenario

In this scenario, a different simulation environment was implemented. The school bus safety domain model was represented as a box with four points (x,y), (x1,y1), (x2,y2), (x3,y3), as shown in Fig. 5.

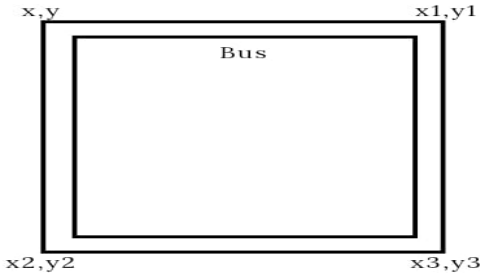

Fig. 5. Bus safety domain as simulated environment.

The student is considered inside the bus if their location (n, m) satisfies this following equation:

$$a = b\ \forall x \forall y \forall n \forall m: (x < n) \wedge (x2 < n) \wedge (x1 > n) \wedge (x3 > n) \wedge (y < m) \wedge (y2 < m) \wedge (y1 > m) \wedge (y3 > m) \Longrightarrow student\ inside\ the\ bus\ safety\ domain \Longrightarrow \neg\ move\ (bus) \quad (12)$$

The above rule indicates that if the student is in the bus safety domain, then the student is too close to the bus, and the bus cannot move. The following rules indicate that there are no students in the bus safety domain; hence, the bus can move.

$$\forall x \forall y \forall n \forall m: (x < n) \wedge (x2 < n) \wedge (x1 > n) \wedge (x3 > n) \wedge (y < m) \wedge (y2 < m) \wedge (y1 > m) \wedge (y3 > m) \Longrightarrow false \Longrightarrow move\ (bus) \quad (13)$$

Using a full school bus, the researchers randomly redistributed students to test the model's ability to identify students within and outside the bus safety domain. This scenario also tested for the system's detection of student gatherings. A safety space of 24 cm was defined between student locations; thus, any distance less than 24 cm between two or more students indicated a gathering. Student locations were randomly distributed to test the gathering detection rules in our IoT smart system. The experiments were repeated five times with an accuracy of 100%.

First scenario proved the scalability and accuracy of rule 3 to rule 9. The second scenario proved the scalability and

accuracy of rules 10. Finally, the third scenario proved the scalability and accuracy of rules 8 and 11.

VI. Discussion and Conclusion

In this paper, a smart IoT system for enhancing safety in school bus transportation was introduced. The main aim of this smart IoT system was to address five issues in school bus transportation that are well-documented in the literature and frequently reported in the news. These problems include: 1) forgetting children on the bus; 2) students' abnormal behavior; 3) overcrowding; 4) unruly driver behavior; and 5) the risk of a school bus running over children after they have disembarked from the bus.

This paper's aim was to provide easy and accessible solutions for everyone, making them applicable across all segments of society by leveraging available technology at an affordable cost. To achieve this, this paper used a rule-based system to avoid the complexity and cost of deep learning solutions. The authors in study [31], conducted a comprehensive survey on deep learning-based anomaly detection in video surveillance. They examined various techniques, including Autoencoders, Generative Adversarial Networks (GANs), and Long Short-Term Memory (LSTM) networks, to identify effective methods for detecting abnormal behaviors. Their survey highlighted the strengths and limitations of these approaches and discussed common challenges such as occlusion, complex backgrounds, and low illumination. Additionally, the authors provided insights into future research directions, emphasizing the need for improved accuracy and robustness in anomaly detection systems. Their results proved the difficulties of using video surveillance in school bus transportation. These results motivate these researchers to provide alternative solutions for detecting students' abnormal behavior in school bus transportation. The proposed IoT system proves a complete solution in terms of providing solutions for all the mentioned problems. Table III, shows a comparison between the proposed smart IoT system and related works, Future work in this domain should include the addition of a GPS device for monitoring bus location and speed, further enhancing the safety of school bus transportation. In addition to GPS, we are planning to extend our model to provide additional safety functionality within school classrooms and facilities.

VII. Data and Method

The scenario code available at https://drive.google.com/file/d/1xv94YNfcG5b5L-bHVbHYfSGbVdpNjsWg/view?usp=share_link (TBA)

Abstract*—Machine learning techniques in smart agriculture for yield prediction involve using algorithms to analyze historical and real-time data to forecast crop yields. These approaches aim to optimize agricultural practices, improve resource efficiency and enhance productivity, this paper reviews the application of machine learning techniques in smart agriculture for predicting agricultural yields. With the advent of data-driven technologies, machine learning algorithms have become instrumental in analyzing vast amounts of agricultural data to forecast crop yields accurately. Various machine learning models such as regression, classification, and ensemble methods have been employed to process historical and real-time data on weather patterns, soil conditions, crop types, and farming practices. These models enable farmers and stakeholders to make informed decisions, optimize resource allocation, and mitigate risks associated with agricultural production. Furthermore, the integration of Internet of Things devices and remote sensing technologies has facilitated data collection and improved the precision of yield predictions, this paper discusses the key machine learning approaches, challenges, and future directions in leveraging data analytics for enhancing agricultural productivity and sustainability in smart farming systems. to ensure stability and tracking. Simulations is carried out to verify the theoretical results, The study found that different machine learning techniques had varying accuracy for predicting agricultural yields. ViT-B16 achieved the highest F1-SCORE (99.40%), followed by ResNet-50 (99.54%) and CNN (97.70%), while RPN algorithms had lower accuracy (91.83%). Correlation analysis showed a strong positive relationship between humidity and soil moisture, favoring crop growth, while production had minimal correlation with temperature and area. The AdaBoost Regressor was the best performer, with the lowest MAE (0.22), MSE (0.1), and RMSE (0.31), and Random Forest showed strong predictive power with an R2 score of 0.89, Seasonal data indicated that autumn had the highest agricultural production, followed by spring, while summer and winter had much lower yields due to weather conditions. Seasonal temperature variations from 1997 to 2014 showed autumn was the warmest (34.43°C), boosting crop production, and winter the coldest (34.31°C), reducing yields. These temperature shifts significantly impacted agricultural productivity, with warm seasons enhancing growth and extreme temperatures in summer and winter limiting it, machine learning techniques in smart agriculture are pivotal for predicting crop yields by leveraging historical and real-time data, thus optimizing practices and resource use while boosting productivity. This involves deploying diverse machine learning models like regression, classification, and ensembles to analyze extensive data on weather, soil, crops, and farming methods. Such models empower stakeholders with insights for informed decisions, efficient resource allocation, and risk mitigation in agricultural operations. The integration of Internet of Things and remote sensing further refines data accuracy, aiding precise yield predictions. Despite advancements, challenges persist, including data quality assurance, model complexity, scalability, and interoperability, driving ongoing research and simulations to validate and improve ML applications for sustainable and productive smart farming systems.

Keywords*—Machine learning; IOT; artificial intelligence; agricultural yields; smart agriculture; CNN; ViT-B16

I. INTRODUCTION

The field of agriculture has been profoundly shaped by technological advancements over the centuries, evolving from simple tools to complex machinery and now to the integration of sophisticated data-driven technologies. The advent of machine learning (ML) in agriculture marks a pivotal shift towards more precise and automated farming practices, known as precision agriculture. This transition began with the mechanization of farms during the Industrial Revolution, followed by the introduction of chemical fertilizers and genetically modified organisms in the 20th century.

This paper explores the various machine learning approaches applied in smart agriculture specifically for the prediction of agricultural yields. It delves into the types of ML models commonly used, the data sources utilized, challenges faced, and the potential impact of these predictive analytics on agricultural sustainability and efficiency.

In the first paragraph, this paper explores the transformative role of machine learning (ML) in smart agriculture, especially in predicting agricultural yields. With advancements in data-driven technologies, ML has revolutionized traditional farming by enhancing precision, resource efficiency, and sustainability. Agriculture evolved from manual labor to mechanized operations during the Industrial Revolution, followed by the introduction of chemical fertilizers and genetically modified organisms. More recently, digital tools such as GPS and remote sensing have laid the groundwork for ML applications in agriculture [1][2][15].

In the second paragraph, the collection of agricultural data has progressed significantly, from manual observations to modern technologies like the Internet of Things (IoT) and remote sensing. These technologies provide real-time, high-resolution data, which sophisticated ML algorithms analyze to predict outcomes like crop yields and optimize farming practices. IoT sensors monitor variables like soil moisture, temperature, and crop health, generating vast datasets that aid in making data-driven decisions [3]. These insights help farmers

manage resources efficiently and mitigate risks associated with agricultural production [4].

In the third paragraph, the focus shifts to key ML algorithms used in smart agriculture, including regression, classification techniques, and ensemble models such as Decision Trees [9], Random Forests [10], Linear Regression [11], K-Nearest Neighbors (KNN) [12], XGBoost [13], and AdaBoost [14]. These algorithms have been widely applied for tasks like yield prediction and optimizing resources like water and fertilizer, offering accurate and actionable insights for modern farming [5] [6].

In the fourth paragraph, deep learning has also made significant strides in smart farming, particularly for image-based tasks. Models like Convolutional Neural Networks (CNNs) [17], advanced architectures such as ResNet [18], and support vector networks [15] have proven effective in detecting pests, diagnosing plant diseases, and optimizing greenhouse conditions. By combining satellite data with deep learning techniques [3], there has been a marked improvement in agricultural monitoring and yield prediction [1][16][17].

In the fifth paragraph, despite the advancements, challenges remain. Issues such as ensuring data quality, scaling models for large datasets, and dealing with complex agricultural data continue to pose significant barriers [7][16]. Ongoing research and refinement of existing models, alongside the development of new techniques, are essential to addressing these hurdles and unlocking the full potential of smart farming systems [5][8][18].

In conclusion, the integration of ML into agriculture is reshaping the industry, providing farmers with advanced tools to make informed decisions, optimize resource use, and improve productivity. Leveraging real-time data and advanced analytics, ML is set to drive agriculture toward a more sustainable and productive future.

II. Machine Learning Algorithms

Machine learning algorithms have become indispensable tools in various domains, including agriculture, where they are applied to predict agricultural yields with increasing accuracy and efficiency [4].

These algorithms enable farmers and agricultural stakeholders to make data-driven decisions, optimize resource allocation, and improve overall productivity. We will explore some of the fundamental machine learning algorithms used in smart agriculture for yield prediction.

Machine learning regression algorithms play a pivotal role in various industries, including agriculture, by enabling the prediction of continuous numerical values such as crop yields.

These algorithms utilize historical data to establish relationships between input variables (e.g., weather conditions, soil quality) and the target output (e.g., crop yield), allowing for accurate forecasting and decision-making.

A. Decision Tree Regressor

Decision Tree Regressor is a type of machine learning algorithm used for regression tasks, including predicting continuous numerical values such as crop yields in smart agriculture. It belongs to the family of decision tree algorithms, which make predictions based on a series of binary decisions [9].

B. Random Forest Regressor

Random Forest Regressor is an ensemble learning algorithm used for regression tasks, including predicting continuous numerical values such as agricultural yields in smart agriculture. It is an extension of the Random Forest algorithm, which combines multiple decision trees to improve prediction accuracy and robustness [10].

C. Linear Regression

Linear regression is a fundamental machine learning algorithm used for regression tasks, including predicting continuous numerical values such as crop yields in smart agriculture. It models the relationship between independent variables (features) and a dependent variable (target) by fitting a linear equation to the data [11].

D. KNN Regressor

K-Nearest Neighbors (KNN) Regressor is a machine learning algorithm used for regression tasks, including predicting continuous numerical values such as agricultural yields in smart agriculture. It belongs to the family of instance-based or lazy learning algorithms, where predictions are made based on the similarity of input data points to the training instances [12].

E. XGB Regressor

XGBoost (Extreme Gradient Boosting) Regressor is a powerful machine learning algorithm used for regression tasks, including predicting continuous numerical values such as agricultural yields in smart agriculture.

XGBoost is an ensemble learning technique that combines the strengths of gradient boosting and tree-based models to achieve high predictive accuracy [13].

Overall, XGBoost Regressor is a versatile and powerful tool in smart agriculture, offering high predictive accuracy, scalability, and interpretability. Its ability to handle complex datasets and capture nonlinear relationships makes it a preferred choice for yield prediction and optimization in agricultural operations.

F. Adaboost Regressor

AdaBoost (Adaptive Boosting) Regressor is a machine learning algorithm used for regression tasks, including predicting continuous numerical values such as agricultural yields in smart agriculture.

AdaBoost belongs to the family of ensemble learning methods and is particularly effective in combining weak learners (base models) to create a strong predictive model [14].

Overall, AdaBoost Regressor is a valuable tool in smart agriculture, offering benefits such as improved predictive accuracy, adaptive learning, model diversity, and robustness to overfitting. Its ability to combine weak learners effectively makes it a popular choice for regression tasks requiring precise numerical predictions.

III. ALGORITHMS USED

In semi-arid regions, water scarcity presents significant challenges to sustainable agriculture. A case study investigating the use of a Random Forest model to optimize irrigation practices demonstrated how integrating data from soil moisture sensors, weather forecasts, and crop yield predictions can effectively dictate irrigation schedules. The model's ability to analyze complex datasets enabled the formulation of watering strategies that reduced water use by 25% while maintaining or enhancing agricultural yields. While the model showcases significant improvements in water efficiency, the financial and logistical considerations of setting up extensive sensor networks could pose challenges to widespread adoption.

A. Predicting Pest Infestations in Large-Scale Farms Using AdaBoost

Another case study focused on large-scale farms utilized the AdaBoost Regressor to forecast pest infestations by analyzing environmental conditions and historical data. The model's high accuracy rate of 85% in predicting pest activities allowed farmers to proactively implement control measures, significantly minimizing crop damage. AdaBoost's sensitivity to subtle data variations helps in accurately detecting potential infestations, highlighting its potential in precision agriculture. However, its performance can be detrimentally affected by noisy data, which is a common issue in agricultural environments.

B. Enhancing Yield Predictions in Organic Farms with XGBoost

Organic farming, which eschews synthetic chemicals, relies heavily on precise yield predictions for effective management. Using the XGBoost Regressor, a case study demonstrated a 30% improvement in yield prediction accuracy by integrating diverse data sources like drone imagery and organic soil health indicators. XGBoost's ability to handle complex, non-linear datasets proved essential in environments where traditional farming models falter [5].

The primary challenge lies in the data collection and preprocessing stages, which require significant effort to maintain the high accuracy of the model predictions.

C. Linear Regression Models for Smallholder Farms in Developing Countries

Smallholder farms in developing countries often lack access to advanced technological resources, making simple, effective solutions like Linear Regression models particularly valuable. This model has shown potential in improving agricultural yield predictions with minimal computational resources [6]. Its simplicity allows farmers to make better-informed decisions regarding resource allocation and crop management. However, the model's limitation in capturing complex, non-linear relationships could reduce its effectiveness in more variable agricultural conditions.

D. KNN for Real-Time Crop Health Monitoring

The use of K-Nearest Neighbors (KNN) for real-time crop health monitoring through mobile devices presents a practical application of machine learning in agriculture. Farmers can capture images of their crops using smartphones, and the KNN model processes this data to provide immediate health diagnostics. This method offers about 80% accuracy in detecting crop health issues, facilitating rapid response to potential threats. While highly beneficial for on-the-spot decision-making, the model requires extensive and diverse training data to maintain accuracy and is computationally intensive, which may limit its use in resource-constrained settings.

E. Random forest Models for Smallholder Farms in Developing Countries

Random Forest models are highly beneficial for smallholder farms in developing countries due to their ability to handle complex and noisy data, which is common in agricultural contexts. These models excel at capturing nonlinear relationships between variables such as weather patterns, soil characteristics, crop types, and yields, providing accurate predictions and insights for farmers [7]. The ensemble learning approach of Random Forests mitigates overfitting and improves generalization, making them suitable for situations with limited data availability. Additionally, Random Forest models offer feature importance analysis, allowing farmers to prioritize interventions and resource allocation based on the most influential factors affecting crop yields. Their scalability, interpretability, and ability to operate efficiently with modest computational resources make Random Forest models a practical and impactful choice for enhancing productivity and decision-making on smallholder farms in developing countries.

F. Decision Tree Regressor Models for Smallholder Farms in Developing Countries

Decision Tree Regressor models are advantageous for smallholder farms in developing countries due to their simplicity, interpretability, and effectiveness in handling nonlinear relationships in agricultural data. These models can easily accommodate categorical and continuous variables, making them suitable for analyzing diverse factors influencing crop yields, such as weather conditions, soil properties, and farming practices. Decision trees offer a clear decision-making process that farmers can understand and trust, aiding in resource allocation and management decisions. Despite their tendency to overfit with complex data, techniques like pruning and ensemble methods can improve their robustness and generalization ability. Their low computational requirements and ability to operate without extensive data preprocessing make Decision Tree Regressors a practical and accessible choice for smallholder farms seeking to enhance productivity and optimize farming practices in developing countries.

IV. PERFORMANCE MEASURES

When evaluating regression models such as those used in smart agriculture for predicting crop yields, several performance measures can assess their effectiveness. Here are some commonly used metrics:

A. Mean Absolute Error (MAE)

The Mean Absolute Error (MAE) holds paramount importance in smart agriculture for predicting agricultural yields as it quantifies the average magnitude of errors between predicted and actual yield values. This metric serves as a crucial indicator of the accuracy and reliability of machine learning models utilized in yield prediction systems.

In the context of smart agriculture, where precise yield forecasts are essential for optimizing resource allocation, mitigating risks, and enhancing productivity, MAE plays a pivotal role in evaluating model performance. Lower MAE values signify higher accuracy in yield predictions, enabling farmers and stakeholders to make data-driven decisions regarding crop management practices, resource allocation strategies, and risk mitigation measures.

Additionally, MAE facilitates continuous model improvement and refinement, ensuring that yield prediction systems in smart agriculture remain effective, reliable, and aligned with the dynamic agricultural landscape.

MAE measures the average absolute difference between the predicted values and the actual values. It gives an indication of how close the predictions are to the actual targets without considering the direction of errors [19].

$$mae = \frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i| \quad (1)$$

B. Mean Squared Error (MSE)

Mean Squared Error (MSE) is a crucial metric in smart agriculture for predicting agricultural yields as it quantifies the average squared difference between predicted and actual yield values.

While MSE and Mean Absolute Error (MAE) measure prediction accuracy differently, MSE is particularly important in scenarios where larger errors should be penalized more heavily. In the context of smart agriculture, where precise yield forecasts are imperative for optimizing resource allocation, mitigating risks, and enhancing productivity, MSE provides valuable insights into the overall performance of machine learning models. Lower MSE values indicate higher accuracy and consistency in yield predictions, enabling farmers and stakeholders to make informed decisions regarding crop management practices, resource allocation strategies, and risk mitigation measures.

Additionally, MSE aids in identifying areas for model improvement and refinement, ensuring that yield prediction systems in smart agriculture remain robust, reliable, and effective in addressing the dynamic challenges of agricultural production.

MSE calculates the average of the squared differences between predicted and actual values. Squaring the errors gives higher weight to large errors, making MSE more sensitive to outliers [20].

$$mse = \frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2 \quad (2)$$

C. Root Mean Squared Error (RMSE)

Root Mean Squared Error (RMSE) is a critical metric in smart agriculture for predicting agricultural yields as it provides a measure of the average magnitude of errors between predicted and actual yield values, while also considering the variability of these errors. RMSE is particularly important in scenarios where both the magnitude and spread of errors are essential considerations. In smart agriculture, precise yield forecasts are fundamental for optimizing resource allocation, mitigating risks, and enhancing productivity.

RMSE offers valuable insights into the overall accuracy and consistency of machine learning models used for yield prediction. Lower RMSE values indicate higher precision in yield predictions, enabling farmers and stakeholders to make informed decisions regarding crop management practices, resource allocation strategies, and risk mitigation measures. Furthermore, RMSE helps identify areas for model improvement and refinement, ensuring that yield prediction systems in smart agriculture remain reliable, effective, and aligned with the evolving needs of agricultural production.

RMSE is the square root of MSE and provides a measure of the standard deviation of the errors. It is in the same units as the target variable, making it more interpretable [21].

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(y_i - \hat{y}_i)^2} \quad (3)$$

D. R2 Scores

R2 Score, or the coefficient of determination, is a critical metric in smart agriculture for assessing the goodness-of-fit of regression models used in predicting agricultural yields. It measures the proportion of the variance in the dependent variable (yields) that is predictable from the independent variables (e.g. weather data, soil conditions). In the context of smart agriculture, where accurate yield forecasts are crucial for optimizing resource allocation, mitigating risks, and improving productivity, R2 Score plays a pivotal role in evaluating the overall performance and predictive power of regression models. A higher R2 Score indicates that the model can explain a larger portion of the variance in yields, providing farmers and stakeholders with confidence in the model's ability to make informed decisions regarding crop management practices, resource allocation strategies, and risk mitigation measures. Additionally, R2 Score helps in comparing different models and selecting the most suitable one for yield prediction, ensuring that smart agriculture systems are equipped with reliable and effective tools for addressing the challenges of agricultural production.

R2 measures the proportion of variance in the target variable that is explained by the regression model. It ranges from 0 to 1, where 1 indicates a perfect fit and 0 indicates no improvement over a baseline model [22].

$$R^2 = 1 - \frac{\sum_{i=1}^{n}(y_i - \hat{y}_i)^2}{\sum_{i=1}^{n}(y_i - \bar{y})^2} \quad (4)$$

V. Related Work

The global agricultural landscape faces numerous challenges, including climate change, resource scarcity, and the need for increased food production to meet growing population demands. In this context, the application of machine learning techniques offers promising solutions by leveraging data-driven insights to enhance agricultural practices.

The global agricultural landscape confronts multifaceted challenges, from climate change impacts to the imperative of increasing food production sustainably. In response, machine learning techniques are proving pivotal, leveraging data-driven insights to revolutionize agricultural practices. These models delve into extensive datasets encompassing climate patterns, soil

attributes, crop genetics, and historical yield data, crafting predictive models that enhance decision-making and resource allocation in farming.

The evaluation of strengths and limitations inherent in each method is pivotal for identifying the most effective techniques in yield prediction. Such insights are instrumental in advancing precision agriculture, where optimized resource utilization and informed decision-making are paramount.

This comparative study aims to analyze and compare different machine learning approaches applied in smart agriculture for the prediction of agricultural yields. By evaluating the strengths and limitations of each approach, this study seeks to provide insights into the most effective methods for yield prediction, contributing to advancements in precision agriculture and sustainable food production.

The dataset was created to train and test prediction models using the different attributes. The data was obtained from previous studies, the data was extracted from charts using ORIGIN software or collected from tables in recently published works. The dataset included various biomass characteristics, such as Crop year, Crop, Soil moisture, state name, district name, season, temperature, humidity, area, production.

In the related work presented in Table I of the research paper, various machine learning and deep learning techniques were evaluated for their performance in agricultural applications, highlighting the broad spectrum of methodologies and their respective efficiencies. The table encapsulates results from different studies that have applied models like CNN, ViT-B32, ViT-B16, RPN algorithms, and ResNet-50 to agriculture-related datasets. Notably, the CNN model [17] achieved an accuracy of 97.70%, while the ViT-B16 model excelled with an F1-SCORE of 99.40%, indicating its superior capability in handling plant classification tasks. The RPN algorithms showed a relatively lower accuracy of 91.83%, and the ResNet-50 model demonstrated a high accuracy of 99.54%, underscoring its robustness in image-based agricultural applications. Additionally, the table included comparisons involving semantic image segmentation techniques such as UNet with different configurations, which achieved MeanIoU scores ranging from 0.58 to 0.75, showing the potential for detailed phenotyping of vine leaves. This diverse array of techniques and results emphasize the importance of selecting the appropriate model based on the specific needs and characteristics of the agricultural data, as well as the performance metrics crucial to the success of the application [18].

VI. ENGINEERING CASE STUDIES

In this section, we will talk about the dataset and the different results obtained.

A. About Database

Our dataset contains 50000 rows and 10 columns, the dataset named data1, its Size is 4306 ko, for the attributes it contains 10 attributes are the following:

- State name: typically refers to the name of a state within a country or a region. It is a term used to identify and refer to a specific political subdivision or administrative region within a larger geopolitical entity.
- District name: refers to the name of a district, which is an administrative division or geographic area within a larger political or administrative region. Districts are often used for purposes such as local governance, electoral representation, statistical reporting, and resource allocation.
- Crop year: refers to a specific period of time during which crops are grown, harvested, and typically marketed. The duration of a crop year can vary depending on the type of crop, geographical location,

and agricultural practices. It is an important concept in agriculture and is used for planning, record-keeping, and analyzing crop production and market trends.

- Season: refers to a period of time characterized by distinct weather conditions, environmental changes, or cultural activities. Seasons are typically associated with variations in temperature, precipitation, daylight hours, and natural phenomena such as plant growth, animal behavior, and climate patterns. The concept of seasons is observed in different contexts, including meteorology, agriculture, astronomy, and cultural traditions.
- Crop: refers to any cultivated plant or agricultural produce that is grown and harvested for human consumption, animal feed, industrial use, or other purposes. Crops are a fundamental component of agriculture and play a crucial role in providing food, fiber, and raw materials for various industries.
- Temperature: In agriculture, temperature refers to the measurement of thermal conditions in the environment that directly influence the growth, development, and productivity of crops, livestock, and other agricultural activities. Temperature plays a critical role in shaping agricultural practices, determining suitable crop types, planting schedules, and livestock management strategies.
- Humidity: Humidity in agriculture refers to the amount of moisture or water vapor present in the air within a farming or growing environment. It is a critical environmental factor that influences plant growth, crop health, pest and disease dynamics, as well as various agricultural operations. Humidity levels are typically measured as relative humidity (RH), expressed as a percentage, which indicates the moisture content of the air relative to its maximum capacity at a given temperature.
- Soil-moisture: Soil moisture refers to the amount of water held in the soil, which is crucial for supporting plant growth, nutrient uptake, and overall soil health. It is a key factor in agriculture, influencing crop development, irrigation scheduling, soil fertility, and water conservation practices.
- Area: refers to a specific piece of land or a defined region where agricultural activities take place. This could include farmland, cropland, pasture, orchards, vineyards, or any other area used for cultivating crops, raising livestock, or conducting agricultural operations.
- Production: refers to the branch of agriculture focused on the large-scale cultivation of crops and the raising of livestock for commercial purposes. It encompasses the systematic and organized management of agricultural activities to produce food, fiber, fuel, and other agricultural products on a significant scale. Production agriculture plays a vital role in meeting global food demand, supporting rural economies, and contributing to the agricultural sector's overall productivity.

B. *Number of Productions by Season*

The number of agricultural productions can vary significantly by season due to factors such as climate, crop cycles, and farming practices. Here's a general of agricultural productions that occur during different seasons:

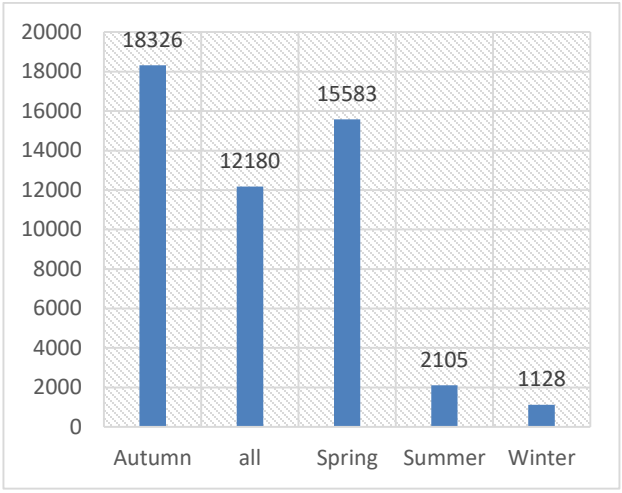

Fig. 1. Number of productions by season.

Fig. 1 provides a visual representation of the number of agricultural productions categorized by season between 1997 and 2014 in India, illustrating the seasonal impact on agricultural output. This graph is pivotal for understanding how different times of the year affect crop yields, potentially guiding farmers in planning planting and harvesting activities.

The data visualized here can assist in determining which seasons are most productive and which ones may require additional resource allocation such as irrigation during drier months or more robust pest management during warmer periods.

Such seasonal insights are crucial for optimizing agricultural strategies and ensuring sustainable production levels throughout the year.

The graph delineates the average production of various plants across the seasons in India, offering a comprehensive snapshot of the country's agricultural output throughout the year. Notably, autumn emerges as the most prolific season, with an average production of 18,326 tones, showcasing the peak productivity experienced during this period. This heightened production likely correlates with favorable weather conditions, such as moderate temperatures and adequate rainfall, conducive to robust plant growth.

Spring follows closely behind, boasting an average production of 15,583 tones, indicating another significant period for plant cultivation and yield.

Spring is typically characterized by increasing daylight hours and rising temperatures, triggering plant growth after the winter dormancy period.

However, as the graph transitions to summer, there is a noticeable decline in average production, plummeting to 2,105 tones. The summer season in India is marked by soaring temperatures and often dry conditions, which can adversely

affect plant health and productivity, leading to this stark drop in average production. Winter, similarly, exhibits lower production levels compared to autumn and spring, with an average of 1,128 tones.

C. Temperature by Season

Seasonal temperature variations significantly impact agricultural activities and crop yields.

In spring, moderate temperatures foster optimal conditions for seed germination, root development, and vigorous plant growth, promoting higher yields.

Summer brings challenges with heat stress, water scarcity, and potential yield reductions if crops are not adequately managed. Autumn's cooler temperatures slow plant growth but also mark the harvest season for many crops, contributing to overall yield.

Winter's cold temperatures can lead to frost damage and shorter growing periods, necessitating protective measures for maintaining productivity. Managing these temperature fluctuations is crucial for agricultural success, requiring careful planning, resource allocation, and the use of adaptive practices to optimize yields across seasons.

Seasonal temperature variations profoundly influence agricultural activities and crop outcomes. In India, autumn typically experiences the highest average temperature, signaling the transition from monsoon rains to drier conditions. This warmth in autumn fosters favorable environments for certain crops, aiding in their growth and yield.

Spring follows closely with slightly lower temperatures, marking the beginning of warmer weather suitable for planting and cultivation.

Summer, characterized by higher heat levels, can pose challenges such as water stress and heat damage to crops if not managed effectively.

Winter, with cooler temperatures, impacts crop selection and growth rates, favoring cool-season crops while requiring protective measures against frost or cold damage. These temperature dynamics shape agricultural calendars, impacting planting schedules, harvest times, and overall crop productivity throughout the year.

The temperature dynamics during winter are crucial in determining agricultural calendars. The onset of cooler weather signals the need to adjust planting schedules to ensure that crops can mature and be harvested before the most severe conditions set in. Additionally, the timing of these schedules can affect the overall yield and quality of the crops, making it essential for farmers to carefully plan their activities throughout the year.

In conclusion, the temperature dynamics of winter are a crucial determinant of agricultural calendars, requiring careful planning and adaptation by farmers. These adjustments ensure that crops can thrive despite the challenges posed by cooler weather, optimizing yield and quality while maintaining the health of the farm ecosystem. By aligning their practices with seasonal changes, farmers can achieve sustainable productivity throughout the year.

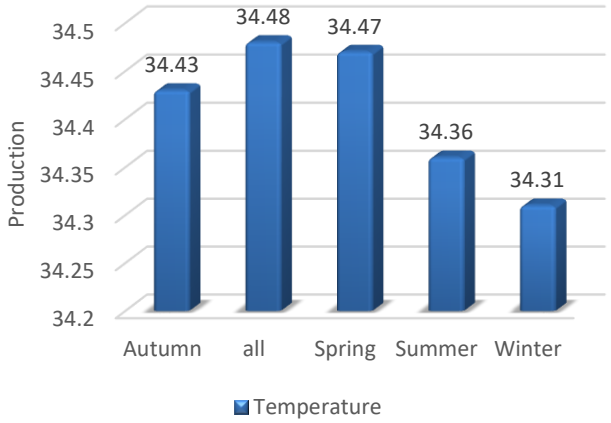

Fig. 2. Temperature by season.

By processing data from our database and data visualization for the temperature attribute, the graph in the Fig. 2 detailing the average temperature according to the seasons in India from 1997 to 2014 reveals a nuanced understanding of how temperature variations impact agricultural production. With autumn exhibiting the highest average temperature at 34.43 degrees Celsius, this season's warmth likely correlates with the transition from the monsoon season to drier conditions, fostering conducive environments for certain crops' growth. The overall average temperature across all seasons, standing at 34.48 degrees Celsius, underscores India's generally warm climate, which plays a crucial role in determining suitable crops and agricultural practices throughout the year. Spring, with an average temperature of 34.47 degrees Celsius, signals the beginning of warmer weather, prompting the planting and growth of various crops. However, the slight increase in temperature from autumn to spring could also indicate shifts in weather patterns affecting crop cycles and yields. Summer, characterized by an average temperature of 34.36 degrees Celsius, experiences higher heat levels, which can both benefit and challenge agriculture. While warm-season crops may thrive, excessive heat can lead to water stress, heat stress in plants, and reduced yields if not managed effectively. Winter, with the lowest average temperature at 34.31 degrees Celsius, introduces cooler conditions, impacting crop selection and growth rates. Certain crops like winter wheat and leafy greens may perform better during this period, while others may require protective measures against frost or cold damage.

The impact of these temperature variations on agriculture production is multifaceted. Warmer temperatures in autumn and spring can extend growing seasons, allowing for multiple crop cycles and increased yields for heat-tolerant crops. However, they may also accelerate pest and disease pressures, necessitating robust pest management strategies. Summer's heat can lead to water evaporation, soil moisture depletion, and stress on crops, requiring efficient irrigation systems and drought-resistant crop varieties. Conversely, cooler temperatures in winter can limit crop options but may also provide relief from heat stress, benefitting cool-season crops and contributing to overall crop diversity.

Moreover, temperature fluctuations influence the timing of planting, harvesting, and crop management practices, impacting agricultural calendars and strategies. Farmers must adapt to these temperature dynamics by employing climate-smart agricultural techniques, leveraging technology for weather monitoring and forecasting, and diversifying crop portfolios to mitigate risks associated with temperature extremes. Overall, the graph's depiction of average temperatures across seasons underscores the intricate relationship between climate patterns and agricultural production in India, highlighting the need for resilient and adaptive agricultural systems to ensure food security and sustainability in a changing climate.

D. Correlation Processing

Correlation processing refers to the analysis and calculation of correlation coefficients between variables or data sets. Correlation is a statistical measure that quantifies the strength and direction of the relationship between two or more variables.

Correlation processing is a powerful tool for exploring data relationships, identifying predictive factors, and making informed decisions.

We used this treatment to keep just the most correlated attributes.

Correlation processing plays a vital role in smart agriculture for predicting agricultural yields by identifying and quantifying the relationships between various factors influencing crop production.

This process involves analyzing correlations between factors such as weather patterns, soil characteristics, crop genetics, and historical yields. By understanding the degree and direction of these correlations, machine learning models can effectively capture and utilize this information to make accurate predictions.

For example, strong positive correlations between certain weather conditions and crop yields may indicate favorable conditions for crop growth, while negative correlations could highlight potential risks or challenges.

Correlation processing enables smart agriculture systems to prioritize relevant factors, optimize resource allocation, and implement targeted interventions to enhance yield prediction accuracy and promote sustainable food production practice.

In terms of yield prediction, correlation processing enhances accuracy by integrating data from various sources, such as remote sensing, weather forecasts, and historical crop performance. By understanding how different variables interact and influence crop growth, smart agriculture systems can predict yields more reliably, allowing farmers to make better-informed decisions regarding harvest timing, storage, and market planning.

TABLE II. CORRELATION BETWEEN ATTRIBUTES

	Crop_Year	Temperature	Humidity	Soil moinsture	Area	Production
Crop_Year	1	0	0	0	0	0.01
Temperature	0	1	-0.7	-0.29	0	0.01
Humidity	0	-0.7	1	0.81	0	0
Soil moinsture	0	-0.29	0.81	1	0	0
Area	0	0	0	0	1	0.03
Production	0.01	0.01	0	0	0.03	1

Using a correlation treatment, Table II explores the correlation between the different agricultural attributes using a correlation matrix that summarizes the different correlations existing between the attributes in our database., offering valuable insights into how different variables interact with each other. This matrix helps identify which factors most significantly affect crop yields, such as the relationships between soil moisture, temperature, and crop health. Understanding these correlations is essential for developing more accurate predictive models and for making informed decisions regarding soil management, crop selection, and resource allocation. By highlighting the strongest correlations, this figure directs research and practice towards the most impactful factors, facilitating more targeted and effective agricultural interventions [23].

This correlation matrix offers a comprehensive view of the relationships between key attributes related to crop production, including Crop_Year, Temperature, Humidity, Soil Moisture, Area, and Production [24]. Starting with Crop_Year, it shows a negligible correlation with all other variables except for a minimal positive correlation of 0.01 with Production, implying a very weak association between the years and production levels. Moving to Temperature, it exhibits a perfect positive correlation with itself (1.0), as expected, and a minor positive correlation of 0.01 with Production, indicating a slight influence of temperature on crop yield. Humidity and Soil Moisture, on the other hand, demonstrate a strong positive correlation of 0.81, highlighting a significant relationship between these two factors crucial for plant growth and development. This correlation suggests that higher humidity levels are generally associated with increased soil moisture content, which is favorable for crop growth. In contrast, both Humidity and Temperature show negative correlations with Soil Moisture (-0.7 and -0.29, respectively), albeit not as strong as the positive correlation between Humidity and Soil Moisture, indicating that higher humidity or temperature may slightly decrease soil moisture levels. The correlation between Area and other variables is notably minimal, except for a minor positive correlation of 0.03 with Production, suggesting that while cultivation area may have a minor impact on production levels, it is not strongly correlated with other attributes. Lastly, Production displays weak positive correlations with Temperature (0.01), Humidity (0.01), and Area (0.03), implying minor influences of these factors on crop production. Overall, this analysis elucidates the interplay

between temperature, humidity, soil moisture, cultivation area, and production levels, providing valuable insights into the factors influencing crop yield and agricultural outcomes [25].

E. Evaluation of Machine Learning Models

Machine learning models play a pivotal role in evaluating and enhancing agriculture yield by providing valuable insights and predictive capabilities. These models enable the analysis of vast amounts of data, including climate patterns, soil conditions, crop types, and management practices, to identify key factors influencing yield. By leveraging algorithms such as regression, decision trees, and neural networks, machine learning can uncover complex relationships between variables and predict future outcomes with a high degree of accuracy. This predictive power is especially crucial in agriculture, where optimizing crop production, minimizing resource use, and mitigating risks are paramount. Machine learning models can help farmers make data-driven decisions regarding planting schedules, irrigation strategies, pest management, and crop selection based on historical data and real-time inputs. Moreover, these models facilitate precision agriculture techniques, such as satellite imaging, drone technology, and sensor data analysis, to monitor crop health, detect anomalies, and optimize resource allocation at a granular level. Overall, the importance of machine learning in agriculture yield lies in its ability to harness data-driven insights, enhance decision-making processes, and ultimately drive sustainable and efficient farming practices for improved productivity and food security.

Before evaluating the performance of machine learning models, it is important to establish the metrics that best capture the accuracy and reliability of these models. Common evaluation metrics such as Mean Absolute Error (MAE), Mean Squared Error (MSE), Root Mean Squared Error (RMSE), and the R^2 score are widely used to quantify the prediction errors and variance explained by the models. These metrics provide insights into how well the model's predictions align with actual outcomes, helping to identify areas for optimization and improvement. Additionally, these measures allow for a direct comparison between models, highlighting their strengths and weaknesses. By analyzing the errors and the proportion of explained variance, researchers can make data-driven decisions on model selection and refinement. Below are the different results obtained based on these metrics:

TABLE III. EVALUATION OF MACHINE LEARNING MODELS

Performance Measures	Rf regressor	DT regressor	LR	Knn regressor	XGBR	ADR
MAE	0,28	0,32	0,3	0,35	0,4	0,22
MSE	0,16	0,18	0,31	0,36	0,16	0,1
RMSE	0,39	0,42	0,56	0,6	0,41	0,31
R2 SCORE	0.89	0.87	0.13	0.13	0,62	0,6

In the Table III, this predictive power is especially crucial in agriculture, where optimizing crop production, minimizing resource use, and mitigating risks are paramount. Machine learning models can help farmers make data-driven decisions regarding planting schedules, irrigation strategies, pest management, and crop selection based on historical data and real-time inputs [8].

F. Discussion

By applying the various machine learning models shows in the Table III to our database, the choice of the best model depends on the specific requirements of your application, the importance of different evaluation metrics, and the trade-offs between model complexity and interpretability.

The comparative analysis of various machine learning models employed in the research document for predicting agricultural yields underscores distinct characteristics and performance outcomes for each model. The Random Forest Regressor emerged as the top performer with an R^2 Score of 0.89, indicating excellent predictive accuracy and robustness.

This model is particularly adept at managing the balance between bias and variance, thanks to its ensemble learning approach which combines multiple decision trees to enhance performance and guard against overfitting. However, despite its effectiveness, the model's computational demands and the slower training times due to its complex nature pose practical limitations.

However, practical considerations such as computational demands and slower training times due to its complexity present challenges for widespread adoption, highlighting the need for further optimization and exploration of alternative models in smart agriculture applications.

The performance measures for various regression models including Random Forest (Rf), Decision Tree (DT), Linear Regression (LR), K-Nearest Neighbors (Knn), Extreme Gradient Boosting (XGBR), and AdaBoostRegressor (ADR) are evaluated based on several metrics: Mean Absolute Error (MAE), Mean Squared Error (MSE), Root Mean Squared Error (RMSE), and R2 Score. The MAE metric measures the average magnitude of errors between predicted and actual values, with lower values indicating better model performance. Among the models, ADR stands out with the lowest MAE of 0.22, followed by Rf with 0.28, LR with 0.3, DT with 0.32, Knn with 0.35, and XGBR with 0.4. Moving to MSE, which penalizes larger errors more heavily, ADR again performs the best with the lowest MSE of 0.1, while Rf also shows strong performance with an MSE of 0.16. However, LR and Knn exhibit higher MSE values of 0.31 and 0.36, respectively, indicating comparatively poorer performance in terms of squared errors. RMSE, which is the square root of MSE, further emphasizes ADR and Rf's superiority, as they have the lowest RMSE values of 0.31 and 0.39, respectively. Conversely, DT and Knn have higher RMSE values of 0.42 and 0.6, respectively, highlighting their tendency to produce larger errors.

Lastly, the R2 Score measures the proportion of variance in the dependent variable that is predictable from the independent variables, with values closer to 1 indicating a better fit. Here, Rf and ADR demonstrate excellent performance with R2 scores of 0.89 and 0.6, respectively, showcasing their ability to explain a significant portion of the variance in the data. Conversely, LR, DT, and Knn exhibit lower R2 scores of 0.13, indicating weaker predictive capabilities. Overall, these performance measures provide a comprehensive evaluation of the regression models, highlighting ADR and Rf as top performers based on their MAE, MSE, RMSE, and R2 Score metrics.

Comparing the performance measures of various regression models for predicting farm yields in India, we can deduce the best-performing model based on the provided metrics. Among the models evaluated – Random Forest (Rf), Decision Tree (DT), Linear Regression (LR), K-Nearest Neighbors (Knn), Extreme Gradient Boosting (XGBR), and AdaBoostRegressor (ADR) – the model with the most consistently superior performance across multiple metrics appears to be AdaBoostRegressor (ADR).

Firstly, looking at the Mean Absolute Error (MAE), ADR has the lowest MAE of 0.22, indicating that, on average, its predictions are closest to the actual farm yields. This suggests a higher level of accuracy compared to other models like Rf (MAE of 0.28), LR (MAE of 0.3), DT (MAE of 0.32), Knn (MAE of 0.35), and XGBR (MAE of 0.4).

Moving on to Mean Squared Error (MSE), ADR again performs exceptionally well with the lowest MSE of 0.1, indicating that its predictions have the smallest squared errors on average.

Rf also shows strong performance with an MSE of 0.16, but ADR outperforms it in this metric. LR and Knn exhibit higher MSE values of 0.31 and 0.36, respectively, indicating comparatively poorer performance in terms of squared errors.

Root Mean Squared Error (RMSE), which is the square root of MSE, further emphasizes ADR's superiority with the lowest RMSE of 0.31, followed by Rf with an RMSE of 0.39. This indicates that ADR's predictions have the smallest overall errors among the models.

Lastly, the R2 Score measures the proportion of variance in the dependent variable that is predictable from the independent variables. Here, Rf and ADR demonstrate excellent performance with R2 scores of 0.89 and 0.6, respectively. While Rf has a higher R2 score, indicating a better fit, ADR's R2 score of 0.6 is still respectable and combined with its superior performance in other metrics, it showcases ADR's ability to predict farm yields effectively.

Based on these comparisons, AdaBoostRegressor (ADR) emerges as the best-performing model for predicting farm yields in India due to its consistently low MAE, MSE, and RMSE values, indicating higher accuracy and smaller errors in predictions compared to other models.

Its respectable R2 score further supports its effectiveness in capturing variance and predicting farm yields reliably, demonstrating its potential to enhance decision-making in agricultural practices. This capability allows farmers to optimize their operations and improve overall productivity. Moreover, it fosters a data-driven approach that can lead to more sustainable farming practices.

VII. CONCLUSION

The use of these semantic segmentation approaches based on deep learning enables farmers to obtain detailed information about their crops, such as the state of health of the plants, the presence of diseases or pests, estimated yields, and so on. This enables them to make more informed decisions about crop management, resource use and optimizing farming practices.

The application of machine learning approaches in smart agriculture for predicting agricultural yields offers significant benefits, including improved accuracy, optimized resource management, enhanced decision-making, early risk detection, precision agriculture implementation, and integration with IoT and big data technologies. These advancements contribute to sustainable and efficient agricultural practices, addressing the challenges of food security, climate change, and resource scarcity in modern agriculture.

The integration of machine learning approaches in smart agriculture for predicting agricultural yields marks a transformative leap in agricultural innovation. This comprehensive application of advanced technologies leverages data-driven insights to revolutionize traditional farming practices and address the complex challenges faced by the global agricultural landscape. Through the analysis of vast and diverse datasets encompassing climate patterns, soil characteristics, crop genetics, and historical yields, machine learning models emerge as powerful tools capable of generating precise and actionable predictions. The comparative analysis of various machine learning techniques further underscores the importance of selecting the most suitable models for specific agricultural contexts, considering factors such as accuracy, robustness, computational efficiency, and scalability.

Among the diverse range of machine learning models explored, the Random Forest Regressor has shown remarkable performance, demonstrating excellent predictive accuracy and robustness with an R^2 Score of 0.89 in our analysis. Its ensemble learning approach, which combines multiple decision trees, effectively manages the trade-off between bias and variance, guarding against overfitting and ensuring generalization to new data. However, practical constraints such as computational demands and slower training times due to its complexity highlight the ongoing need for optimization and exploration of alternative models tailored to the unique requirements of smart agriculture applications.

Machine learning approaches in smart agriculture improve yield prediction accuracy and promote precision agriculture, sustainable food production, and resource optimization. By providing data-driven insights, these technologies enhance decision-making, resource allocation, and productivity while supporting global efforts to tackle food security, climate change, and sustainable agricultural development. Comparing the performance measures of various regression models for predicting farm yields in India, we can deduce the best-performing model based on the provided metrics. Among the models evaluated – Random Forest (Rf), Decision Tree (DT),

Linear Regression (LR), K-Nearest Neighbors (Knn), Extreme Gradient Boosting (XGBR), and AdaBoostRegressor (ADR) – the model with the most consistently superior performance across multiple metrics appears to be AdaBoostRegressor (ADR).

Firstly, looking at the Mean Absolute Error (MAE), ADR has the lowest MAE of 0.22, indicating that, on average, its predictions are closest to the actual farm yields. This suggests a higher level of accuracy compared to other models like Rf (MAE of 0.28), LR (MAE of 0.3), DT (MAE of 0.32), Knn (MAE of 0.35), and XGBR (MAE of 0.4).

Moving on to Mean Squared Error (MSE), ADR again performs exceptionally well with the lowest MSE of 0.1, indicating that its predictions have the smallest squared errors on average.

Rf also shows strong performance with an MSE of 0.16, but ADR outperforms it in this metric. LR and Knn exhibit higher MSE values of 0.31 and 0.36, respectively, indicating comparatively poorer performance in terms of squared errors.

Root Mean Squared Error (RMSE), which is the square root of MSE, further emphasizes ADR's superiority with the lowest RMSE of 0.31, followed by Rf with an RMSE of 0.39. This indicates that ADR's predictions have the smallest overall errors among the models.

Lastly, the R2 Score measures the proportion of variance in the dependent variable that is predictable from the independent variables. Here, Rf and ADR demonstrate excellent performance with R2 scores of 0.89 and 0.6, respectively. While Rf has a higher R2 score, indicating a better fit, ADR's R2 score of 0.6 is still respectable and combined with its superior performance in other metrics, it showcases ADR's ability to predict farm yields effectively.

Based on these comparisons, AdaBoostRegressor (ADR) emerges as the best-performing model for predicting farm yields in India due to its consistently low MAE, MSE, and RMSE values, indicating higher accuracy and smaller errors in predictions compared to other models. Its respectable R2 score further supports its effectiveness in capturing variance and predicting farm yields reliably.

In conclusion, machine learning is crucial for the future of smart agriculture, promoting innovation and sustainability in production systems. Ongoing research and widespread adoption of these technologies are vital for unlocking their full potential and enhancing agricultural productivity globally.

NOMENCLATURES

ML	Machine learning
DL	Deep learning
Rf regressor	Random forest regressor
DT regressor	Decision Tree regressor
LR	Linear Regression
KNN Regressor	K-Nearest Neighbors Regressor
XGBR	XGBoost Regressor
ADR	AdaBoost Regressor
IOT	Internet of Things

Appendix 5. Temperature by season

Fig. 2 illustrates the temperature variations by season, showing that autumn has the highest average temperature, while winter exhibits the lowest.

K-Means and Morphology Based Feature Element Extraction Technique for Clothing Patterns and Lines

Xiaojia Ding[1]
Zhengzhou Academy of Fine Arts, Zhengzhou, 451450, China[1]

***Abstract*—In the process of clothing design and production, the traditional artificial feature element extraction method has the problems of low efficiency and insufficient precision, which is difficult to meet the automation and intelligent needs of modern clothing industry. In order to solve this problem, this paper proposes a technology that combines K-means clustering algorithm and morphology method to extract clothing pattern and line feature elements. This technology uses K-means clustering algorithm to preprocess clothing images to realize feature extraction of clothing pattern elements, and then introduces morphology method to realize feature extraction of image line elements. This technology not only improves the accuracy and efficiency of feature element extraction, but also retains the details of clothing images, which provides a strong support for automatic and intelligent processing in clothing design and production.**

Keywords*—K-means; morphological algorithm; feature extraction

I. Introduction

In the digital age, the field of clothing design and manufacturing is undergoing unprecedented changes. With the rapid development of computer vision, machine learning and image processing technology, automatic extraction and recognition of clothing pattern and line feature elements has become one of the key technologies to improve design efficiency and optimize production process. In 2017, Zhang Peng [1] compared and analyzed the applications of K-Dimensional tree's two nearest neighbor matching algorithm and random sampling agreement algorithm (RANSAC) in the field of image matching retrieval based on scale invariant feature transform (SIFT) algorithm. The results show that although K-Dimensional tree's NNN algorithm is superior in applicability and better in retrieval, RANSAC algorithm is superior in matching accuracy. In 2020, Jia Xiaojun [2] and his team successfully extracted feature elements from blue printed cloth through a series of image processing techniques, including gray level processing, corrosion, expansion, binarization and contour extraction, and built a database containing 12 elements accordingly, with an accuracy rate of 98.66%. At the same time, Chen Kaiqing [3] et al. deeply explored human preference feature extraction methods by using evolutionary matrix functions based on evolutionary strategies, and further studied how to combine deep learning with evolutionary strategies.

However, despite the remarkable progress in this field, there are still many problems. Traditional extraction methods are often inefficient and difficult to accurately capture the complex features of clothing patterns and lines, so it is particularly important to explore more efficient and accurate extraction techniques. K-means clustering algorithm and morphological analysis, as two powerful tools, have shown great potential and application value in the extraction of clothing feature elements. As a classical unsupervised learning method, K-means clustering algorithm has been widely used in many fields such as data analysis and image processing because of its simplicity and high efficiency. The algorithm divides the data into K clusters iteratively, so that the similarity of data points within the same cluster is high and the similarity of data points between different clusters is low [4]. In the feature extraction of clothing patterns, K-means algorithm can effectively group pixels or feature points in images according to their similarity, so as to identify the basic units of patterns and the direction of lines, providing strong support for subsequent design analysis and optimization. Morphological analysis is a shape-based image processing technology, which extracts the key features of the image by describing and analyzing the shape and structure in the image. In line feature extraction, morphological analysis can optimize and enhance the extracted feature elements through morphological operations, such as corrosion, expansion, open operation, close operation, etc., so that it is more in line with the design requirements and production requirements. This paper aims to explore the extraction technology of clothing pattern and line feature elements based on K-means clustering algorithm and morphological analysis, and demonstrate the application potential and practical effects of this technology in the field of clothing design and manufacturing through theoretical analysis and experimental verification [5].

Firstly, this paper gives a brief overview of K-means clustering algorithm and morphology algorithm, and then deeply discusses the extraction technology of clothing pattern and line feature elements based on these two algorithms. Specifically, the technical framework covers the K-means algorithm to extract pattern features from clothing images and the morphological algorithm to extract line feature elements in images. In order to verify the effectiveness and superiority of this comprehensive technology, a set of targeted experiments were designed and implemented in the end, and image data including clothing patterns were selected for testing.

II. K-means Algorithm and Morphology Algorithm

A. K-means Algorithm

K-means algorithm, also known as K-means clustering algorithm, is a widely used partitioning based clustering technology. Its core lies in the pre-set k value, which directly determines the number of initial cluster centers and thus

affects the partitioning of the whole data set. The K-means algorithm iteratively optimizes a cluster objective function, aiming to minimize the similarity between different clusters, while the data points within the same cluster show the greatest similarity [6]. The flexibility and effectiveness of K-means algorithm make it widely used in many fields. In the field of market segmentation, the algorithm can automatically divide the customer base into multiple market segments with different characteristics according to the customer's purchasing behavior or preference pattern, helping enterprises to develop more accurate marketing strategies. In the field of image processing, K-means algorithm is used in image segmentation tasks, which can realize automatic analysis and understanding of images by dividing pixels in images into different regions according to color, texture and other features, providing strong support for image recognition, image compression and other applications. In addition, K-means algorithm also plays an important role in text clustering, data mining, bioinformatics and other fields [7].

B. Morphology Algorithm

Mathematical Morphology is an algorithm system pioneered by French scholars J. Serra and Marceron in 1964, and has been deeply applied to many frontier fields such as computer vision, pattern recognition, image analysis and processing. As a powerful tool, it is widely used to analyze all kinds of complex images, such as the accurate identification of ground buildings in high-resolution satellite images from a high altitude, and the in-depth exploration of the structural mysteries of cells, bacteria, viruses and even lizard red blood cells in the biological microscopic world. Morphology has a series of basic operations, including expansion, corrosion, open operation and close operation. These operations not only play a significant role independently, but also can be skillfully combined and derived into a variety of practical algorithms such as top cap and bottom cap transformation, hit and miss transformation, watershed transformation, morphological gradient and particle analysis, which greatly enrich the means of image processing. Make image analysis more accurate and efficient [8]. As a core concept in morphology, the design and application of Structure Element directly determine the effect and efficiency of morphological processing. When applying mathematical morphology algorithm to process images, selecting the appropriate structural element is a crucial step, which determines how the algorithm "senses" and "transforms" the morphological structure in the image. With the continuous progress of technology and in-depth research, the application prospect of mathematical morphology will be broader, bringing more innovations and breakthroughs to the field of image analysis and processing [9].

III. Extraction of Clothing Pattern and Line Feature Elements Based on K-Means and Morphology

A. Clothing Pattern Extraction Based on K-means Algorithm

1) Cluster analysis: Cluster analysis aims to divide a large data set into multiple categories, ensuring that similar objects are highly similar and different categories are significantly different. This analysis technology has been widely used in many fields such as data compression, image segmentation, text retrieval and bioinformatics. Over the years, the research of cluster analysis has spawned many classical theories and algorithms, including hierarchical clustering, model clustering, grid clustering and partition clustering, etc. Each algorithm has its own characteristics and limitations. Hierarchical clustering can realize data grouping by building a tree structure, and the hierarchy is clear but difficult to trace back [10]. Model clustering depends on the strong robustness of the model set by the researcher; Grid clustering is efficient in spatial data processing and suitable for incremental implementation and high dimensional processing. Partitioning clustering is based on the distance between classes and is often limited to finding round or spherical clusters [11].

Clustering is significantly different from classification in that classification requires predictive training sets to extract classification rules and then apply them to unknown data, which is supervised pattern recognition. Cluster analysis, however, does not have such prior knowledge and automatically divides data into various categories by function or statistical method, which belongs to unsupervised pattern recognition.

The basic flow of cluster analysis covers the following key steps:

a) Data preprocessing: The core of this stage lies in the standardized data processing and feature dimension reduction. Standardization aims to eliminate the influence of different dimensions on the clustering results and ensure that each feature has the same weight in the clustering process. Feature dimensionality reduction reduces the dimensionality of the data set through methods such as principal component analysis (PCA) [12], while retaining key information in the original data as much as possible to improve the clustering efficiency and effect.

b) Feature screening: The process of identifying and selecting the most critical features in the original feature set helps reduce noise and redundant information, and makes the clustering process more focused on the essential characteristics of the data. The filtered features are converted into vector form, which is convenient for subsequent processing [13].

c) Feature refining: The selected features are further processed and extracted to obtain a more refined and effective feature representation for cluster analysis [14]. This step may involve advanced techniques such as feature transformation and feature fusion to improve the accuracy and stability of clustering.

d) Formulation of clustering strategies: According to prior knowledge, actual demand and data characteristics, the appropriate clustering criterion function is selected, which will guide the whole clustering process and ensure that the clustering results meet the expectations[15]. Under the guidance of criterion function, combined with mathematical tools and statistical theory, we perform clustering algorithm to divide data into different categories.

e) Evaluation of clustering results: After the clustering is completed, the quality of the clustering results needs to be evaluated, and the evaluation criteria mainly include intra-class validity evaluation, inter-class validity evaluation and correlation test [16]. Through comprehensive evaluation, we can judge the advantages and disadvantages of clustering results, and provide support for subsequent data analysis and decision making.

2) K-means clustering algorithm analysis: In this study, the K-means clustering algorithm is used to extract pattern feature elements from clothing images [17]. The algorithm aims to effectively divide n pixels in the image into K clusters, where k represents the number of preset color clusters. According to its RGB color value, each pixel is assigned to the cluster with the cluster center with the smallest Euclidean distance. The Euclidean distance is calculated as shown in Eq. (1).

$$d(X,C_i)=\sqrt{\sum_{j=1}^{m}(X_j-C_{ij})^2} \tag{1}$$

In formula 1, X is the data object; C_i is the i th cluster center. m is the dimension of the data object; X_j, C_{ij} is the JTH attribute value of X and C_i.

In the execution process, the distance between each pixel in the image and all clustering centers is first calculated, and each pixel is classified to the nearest clustering center based on this distance [18], and then the clustering center of each color cluster is iteratively updated by calculating the average value of RGB values of all pixels in the cluster as the new clustering center. This process is repeated until the convergence condition is met, that is, the location of the cluster center remains basically unchanged in successive iterations, which marks the completion of the clustering process. The algorithm flow chart is shown in Fig. 1.

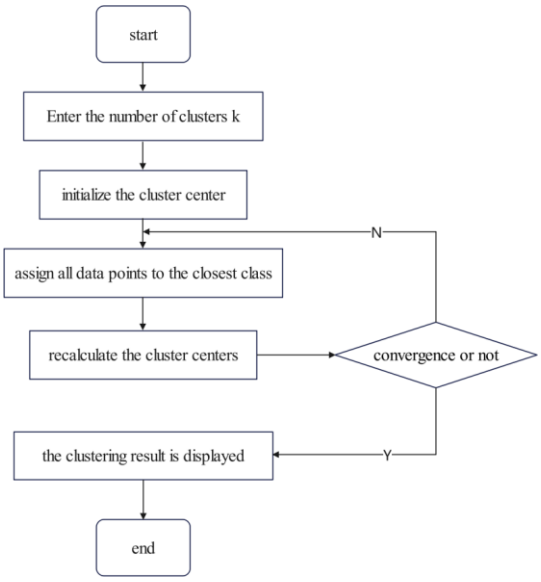

Fig. 1. K-means algorithm implementation flow.

The specific implementation steps of K-means clustering algorithm are as follows:

a) Initialization phase: Determine the number of clusters k and prepare a dataset with n data points $X=\{x_1, x_2, x_3,... x_n\}$. These data points can be pixels in an image, whose properties are RGB color values.

b) Select the initial clustering center: k data points are randomly selected from data set X as the initial clustering center, denoted as $m_1, m_2,... , m_k$ [19]. Each data point is then assigned to the nearest cluster center based on its distance to these cluster centers, resulting in k initial clusters $C=\{c_1, c_2,... , c_k\}$.

c) Calculate and update the cluster center: For each cluster c_i (i=1,2,... ,k), calculates the mean of the RGB color values of all data points in the cluster and uses this mean as the new cluster center m_i. The purpose of this step is to allow the cluster center to more accurately reflect the characteristics of the data points within its cluster.

d) Reassign data points to clustering: Iterate over each data point in the dataset again, calculating their distance to each new cluster center and reassigning each data point to the cluster to which the nearest cluster center belongs.

e) Iterative optimization: Repeat steps 3 and 4, that is, continuously compute new clustering centers and redistribute data points until a stop condition is met [20]. The commonly used stopping condition is that the change of cluster center is very small or the Sum of Squared Errors SSE (Sum of Squared Errors) no longer changes significantly, which indicates that the clustering results have become stable.

f) Output clustering results: The algorithm ends when the stop condition is reached, at which time k clusters are obtained, and each cluster contains a series of data points with high similarity in color features. The final output of this k subset is as clustering results, which can be used for subsequent pattern analysis, recognition, or other related applications.

The calculation formula of the squared error and SSE of the whole data set is Eq. (2).

$$SSE=\sum_{i=1}^{k}\sum_{X\in C_i}\left|d(X,C_i)\right|^2 \tag{2}$$

In Eq. (2), SSE represents the quality of clustering results; k is the number of clusters.

B. Garment Line Feature Element Extraction Based on Morphological Algorithm

In this study, morphological algorithm is used to accurately extract line feature elements in clothing. In the specific implementation process, corrosion and expansion operations in morphological processing are used to realize efficient identification and extraction of clothing line features [21].

Erosion is an image processing technique that removes pixels from the edges of the image so that the edges of the

image shrink inward. This process can not only fine-tune the edge shape of the image, but also effectively eliminate those objects in the original image whose size is smaller than a specific structural element, so as to remove noise and smooth the image edge. Corrosion operations are represented by a specific operator, denoted Θ. When A corrosion operation is applied to an image A to be processed, the selected structural element is S, and the operation can be expressed as $A \Theta S$, meaning that S is used to corrode A. The concrete implementation of corrosion operation is shown in Eq. (3).

$$A \Theta S = \{x : S + x \subset A\} \tag{3}$$

The main purpose of image processing by etching operation is to make the image boundary to be processed to shrink inward evenly, this shrinkage effect is usually manifested as the overall image shrinking a circle, and the specific size of this circle, that is, the degree of image shrinking inward, is directly affected by the shape and size of the selected structural elements [22]. As a key parameter in the corrosion operation, the structure element determines which boundary pixels will be removed, thus affecting the image shape after corrosion. Fig. 2 below shows the simulation effect of the corrosion operation, which intuitively shows the phenomenon of the inward contraction of the boundary after the image has been corroded.

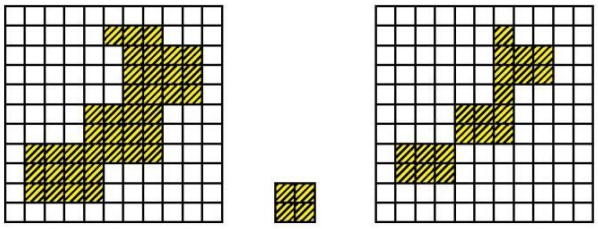

Fig. 2. Corrosion operation simulation diagram.

The principle of Dilation is the opposite of corrosion, it is an operation to expand the boundary of the target image by increasing the pixel points of the image boundary. The main function of the expansion operation is to connect the original discontinuous and breakpoint boundaries in the image, so as to restore or form a complete and smooth image boundary [23]. This is because the breakpoint on the image boundary may interfere or affect the subsequent computational statistical operations on the complete area of the image, and the expansion operation can effectively solve this problem. In expansion operations, the operator used is usually expressed as $\oplus$. When the expansion operation is performed on an image A to be processed, the selected structural element is S, and the operation can be expressed as $A \oplus S$, that is, S is used to expand A. The concrete implementation of the expansion operation is shown in Formula 4, which defines how to extend the boundary of image A based on the shape and size of the structural element S.

$$A \oplus S = \{a | A + S \cup A \neq \phi\} \tag{4}$$

In the dilation operation, an important property is that it satisfies the exchange rate of the operation, which means that the result of inflating image A with the structural element S (denoted as $A \oplus S$) is the same as that of "inflating" image A with the structural element S, as shown in Equation 5. After expansion processing, the boundary of the image to be processed will expand outward evenly for a circle, and the specific size of this circle is also affected by the shape and size of the selected structural elements [24]. Dilation operation can not only help to connect the original discontinuous boundaries in the image, but also fill the small holes or missing parts in the image to a certain extent, making the overall shape of the image more complete and coherent. Fig. 3 below shows the simulation effect of the expansion operation, and intuitively shows the phenomenon of the image boundary expanding outward after the expansion processing.

$$A \oplus S = S \oplus A \tag{5}$$

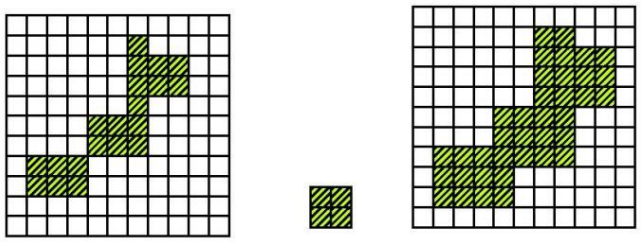

Fig. 3. Simulation diagram of expansion operation.

The corrosion operation effectively reduces the area of the target region by making the image boundary shrink inward, the essence of which lies in the removal of image edge pixels. On the contrary, the expansion operation increases the coverage of the target region by extending the image boundary outwards, making the object in the image look more expanded [25]. It is worth noting that whether it is corrosion or expansion, their changes to the image are mainly concentrated in the edge area, and the impact on the interior of the image is relatively small. Based on this property, when we subtract the corroded image from the original image, we can highlight the edge pixels that disappear due to corrosion and recover due to expansion, so as to effectively extract the edge outline of the object in the image.

The algorithms for edge detection using morphology generally include the following:

1) BM edge detection optimization technology: The core of BM edge detection technology is to reduce the noise effect by preprocessing. The strategy applies fuzzy filtering technology to reduce the noise in the image, and then performs the basic operation of morphology. In this process, the width of the carefully designed structural element B matches the size of the local average processing window, aiming to capture the edge information more accurately and reduce the noise interference at the same time, which is expressed as Eq. (6).

$$BM(f) = \min\{f_{av} - (f_{av} \Theta B), (f_{av} \oplus B) - f_{av}\} \tag{6}$$

In Formula 6, B represents the structural element to be used, and f_{av} represents the gray value of the image after fuzzy processing.

2) ATM edge detection strategy: ATM edge detection method introduces α-adjustment mechanism, the core of which is to optimize the input image by adjusting parameter α, so as to effectively suppress the noise in the image. This α-adjustment strategy provides a clearer and less noisy input environment for image edge detection, thus improving the accuracy and reliability of edge detection. The expression of α-adjustment is Eq. (7).

$$f = \sum_{l=\alpha+1}^{k-\alpha} \frac{f(l)}{k-2\alpha} \tag{7}$$

The formula expression of edge detection is shown in equation 8.

$$ATM(f) = \min\{(f \bullet B)-(f\Theta B),(f \oplus B)-(f \circ B)\} \tag{8}$$

3) ASF multi-directional edge detection: ASF edge detection method is a multi-dimensional analysis method. It adopts the structural elements in the four directions of 0°, 45°, 90° and 135° with the X-axis, and performs the combination of open γ_l operation and close φ_l operation on the image to capture the edge features in different directions, and then implements corrosion operations on the processed image to further refine and strengthen the edge information. The formula is shown in Eq. (9).

$$f = (\gamma_l \varphi_l \Theta B) - \gamma_l \varphi_l \tag{9}$$

In the field of morphological edge detection, the size and shape of structural elements are directly related to the detection effect. Larger structural elements can effectively suppress noise, but may be at the expense of edge details, while smaller structural elements can capture edge features more finely, but may not completely eliminate noise. Therefore, the ideal structural element should be able to remove noise while retaining the edge details. The directivity of the edge is also significantly affected by the shape of the structural element, with different shapes having higher sensitivity to edges of a particular shape. In order to overcome this limitation and improve the anti-noise ability of edge detection, an effective strategy is to use multi-structural elements combined with multi-scale morphological edge detection operators. By combining structural elements of different sizes and shapes, this method can capture edge information in images more comprehensively and enhance the robustness to noise, so as to achieve high-precision image edge detection. In practical applications, in order to obtain detailed elements such as clothing line outline more accurately, the image will be preprocessed first, including noise elimination to reduce interference, binary processing to simplify image information and possibly reverse the light and dark areas in the image by taking the inverse operation, and then combined with expansion and corrosion operations to further emphasize and extract the clothing line outline elements.

IV. EXPERIMENT

This experiment aims to extract key pattern and line feature elements from a set of image data containing clothing patterns by K-means clustering algorithm. The main objective of the experiment is to verify the practicability and effectiveness of K-means algorithm in image processing and feature extraction tasks, and to explore its potential value in practical application scenarios such as clothing design and automatic image classification and recognition.

The experiment first imports the image dataset into a Python environment, and performs a series of pre-processing steps on these images, including but not limited to conversion to grayscale, resizing the image to ensure consistency, and normalization of pixel values. After feature processing, the image data is converted into a format suitable for K-means algorithm. The K-means clustering algorithm is applied to perform cluster analysis on these feature vectors, and similar pattern and line elements are grouped into different clusters through the iterative process. After the clustering is completed, visualization technology is used to visually present the clustering results, as shown in Table I.

TABLE I. RESULTS OF PATTERN LINE EXTRACTION

Master drawing	
Pattern extraction	
Line extraction	

After the experimental application of K-means clustering algorithm to cluster the feature vectors of image data, the experiment successfully groups similar pattern and line elements into different clusters, which shows that K-means algorithm has strong effectiveness and accuracy in image feature extraction and grouping. At the same time,

visualization technology is used to visually present the clustering results, and the differences and similarities between different clusters can be clearly seen from Table I, which further verifies the effectiveness of K-means clustering algorithm in image feature extraction and grouping.

Experiments show that in the complex and changeable background environment, K-means algorithm not only has remarkable clustering effect, but also has strong anti-noise property, ensuring the accuracy of segmentation results. However, the automation degree of this algorithm is still insufficient, and its performance is highly dependent on the setting of key parameters by experienced operators. Meanwhile, the long operation time also limits its application potential in the pursuit of efficient processing scenarios. In contrast, morphology algorithm stands out for its short operation time and high processing efficiency, but its effect is easily affected when processing images containing noise, especially when processing color images, complexity and timeliness become challenges. Nevertheless, the advantages of morphology algorithm in spatial and frequency domain image recognition cannot be ignored. It can effectively retain the original information of the image while filtering the noise, which lays a solid foundation for the subsequent image processing. The limitations of a single algorithm in extraction accuracy, efficiency or specific target recognition are obvious, so exploring a new path of algorithm fusion has become the key to improve the ability of image feature extraction. By organically combining and optimizing different algorithms to build a multi-level recognition and extraction system, more accurate and efficient image feature extraction can be achieved. This fusion strategy can not only make full use of the advantages of each algorithm, but also make up for each other's shortcomings, so as to improve the overall performance. In addition, with the rapid development of deep learning technology, its application in the field of pattern segmentation and extraction undoubtedly opens up a new way to improve the extraction accuracy and automation level. Deep learning algorithms have strong feature extraction and pattern recognition capabilities, and can automatically learn and adapt to complex image features, which also puts higher requirements on the technical requirements of computing equipment. More computing power is needed to support the operation of complex algorithms and programs. Nevertheless, I think this challenge is worthwhile, because the introduction of deep learning technology will greatly promote the development of clothing pattern and line feature element extraction technology, and bring more intelligent and efficient solutions to the field of clothing design and manufacturing.

V. Conclusion

This paper deeply discusses the extraction technology of clothing pattern and line feature elements based on K-means clustering algorithm and morphology method, expounds the basic principle of K-means algorithm and morphology algorithm in detail, and focuses on how to use K-means algorithm to perform pixel-level clustering analysis of clothing images. The morphology algorithm is introduced to achieve fine extraction of line feature elements. This paper describes the implementation process of the whole feature extraction technology in detail, and finally verifies the effectiveness and superiority of K-means and morphology algorithm in the extraction of clothing pattern and line feature elements through experiments. The experimental results show that this technology can accurately and efficiently identify and extract key patterns and line features in clothing images. It provides powerful technical support for clothing design, analysis, retrieval and other fields. Looking forward to the future, with the continuous development of artificial intelligence technology and the continuous optimization of algorithms, the extraction technology of clothing pattern and line feature elements based on K-means and morphology will have a broader application prospect. It can help fashion designers quickly capture trends, innovative design ideas, but also to provide strong support for the automation and intelligence of the clothing production process, while the technology is also expected to play an important role in personalized customization, virtual reality fitting, intelligent collocation recommendation and other fields, to promote the entire fashion industry to more efficient, intelligent, personalized direction.

Simulation Analysis of Obstacle Crossing Stability for Transmission Line Inspection Robot

Qianli Wang
School of Mathematics and Computer Science, Yichun University, Yichun, 336000, China

***Abstract*—As an indispensable energy source in production and daily life, electricity has important implications in the operation of society and economic development. As the hub of power transmission, the safety of transmission lines is related to the stability of the power grid. Regular inspection of transmission lines is an effective measure to ensure the stability of the power system. Patrol robots are used for regular inspection of transmission lines due to their advantages such as low cost and long running time. To achieve collision free, the study proposes an obstacle path planning algorithm based on an improved bidirectional fast expanding random tree through kinematic analysis of the robot. According to the experimental results, when overtaking the damper, the rotation ranges of the 1st claw/arm and the 2nd bracket/arm/claw were (0°~22°), (-50°, 10°), (0°, 25°), (-50°, 10°), and (0°, 22°), respectively. The corresponding rotational speeds were (-1.5~1.5) deg/s, (-3, 2.5) deg/s, (-3.5~3.5) deg/s, (-2.5, 3) deg/s, and (-27, 2) deg/s, respectively. The expansion and contraction ranges of the upper, middle, lower, and horizontal push rods were (0, 100) mm, (0, 110) mm, (-60, 10) mm, and (0, 20) mm, respectively. From the above results, when crossing obstacles, the motion acceleration of the inspection robot is not significant. The speed changes smoothly. The obstacle crossing path planning algorithm proposed in the study can achieve stable motion of the inspection robot.**

Keywords*—Transmission line; inspection robot; obstacle crossing path; kinematic analysis; bidirectional fast expanding random tree

I. INTRODUCTION

To meet daily production and living needs, power plants transmit electricity to various regions through high-voltage transmission lines. Due to long-term exposure of high-voltage transmission lines to the wild, various faults continue to occur, posing a threat to the safety of the power grid. Meanwhile, with the continuous growth of electricity demand, the mileage of high-voltage transmission lines has also rapidly increased. A large number of high-voltage transmission lines penetrate into areas that are rarely visited, posing great difficulties for circuit inspection work. This makes it difficult to detect transmission line faults in a timely manner, increasing the probability of safety accidents occurring [1-2]. Compared with manual inspections and drone inspections, inspection robots have high inspection quality, low cost, and long working hours, making them suitable for various environments. In addition to cables, there are also various metal fittings on the transmission line, which are obstacles for inspection robots. Therefore, to ensure the inspection range, the inspection robot needs to cross these obstacles [3-4]. In recent years, with the vigorous development of various technologies such as machine vision, deep learning, intelligent sensors, and intelligent Internet of Things, overhead transmission line inspection robots have also ushered in new development opportunities. For example, combining machine vision, deep learning, and multi-sensor information fusion technologies can achieve online obstacle recognition, localization, and model construction. Based on obstacle models, online obstacle crossing path planning can be performed to ensure that the patrol robot has obstacle crossing capabilities in different obstacle and attitude environments. It can also be combined with intelligent IoT technology to achieve real-time feedback monitoring and adjustment of the entire obstacle crossing process. Therefore, the research on obstacle crossing path planning for overhead transmission line patrol robots in this article has great practical application significance. In the current field of 110kV overhead transmission line inspection robots, the main obstacle crossing technology solutions include linear guide rail and linkage robotic arm. However, each has its own advantages and disadvantages. The former is stable and reliable when crossing obstacles, but the overall weight is too large, the load capacity is low, and the obstacle crossing distance is short. The latter has lower overall weight and improved obstacle crossing distance, but requires higher requirements for rotary joint motors and lower reliability in obstacle crossing. Meanwhile, due to the complexity of obstacle crossing actions, it is difficult to ensure that the relative position and posture of the line patrol robot and obstacles are fixed during each obstacle crossing operation. Pre-planning and fixing the obstacle crossing action sequence for each obstacle can easily lead to collisions with obstacles, wires, etc. during the obstacle crossing process, resulting in failure. Therefore, to improve the work efficiency of Transmission Line Inspection Robot (TLIR) and achieve collision free motion of inspection robots, a cost-effective obstacle crossing path planning method for inspection robots based on the improved Rapidly Expanding Random Tree-Connect (RRT-Connect) is proposed. By improving joint motion and search step size, and setting an intermediate random tree, the RRT-Connect algorithm being prone to local search is improved, simplifying the search process.

Rest of the study is divided into five sections. Section II will briefly describe the research status of transmission line inspection robots and RRT algorithms. Section III will conduct dynamic analysis on the optional robot and designs the obstacle crossing path planning algorithm. Section IV will simulate and analyze the obstacle crossing performance of the inspection robot. Section V will discuss the research results to further analyze them. Section VI will summarize the research of the entire article.

II. Related Works

With the increasing demand for transmission lines in the power system, it has become a current trend for inspection robots to conduct line inspections. Wang et al. [5] proposed a new four arm inspection robot to address the low obstacle crossing efficiency and poor safety of inspection robots. This new inspection robot had a rectangular frame on its walking arm to improve obstacle crossing efficiency. In addition, the robot could also use two different sets of arms to cross the tension tower together. The experimental results showed that the new four arm inspection robot could cross common obstacles on transmission lines. Wei et al. [6] proposed a lateral friction recognition method based on fuzzy control to address the limited movement of inspection robots. This method monitored the friction between the walking wheel line and the wheel flange, effectively avoiding "wheel line" jamming caused by external uncertain factors. This method could effectively improve the automation and intelligence level of the operation and transmission system of the inspection robot. Huang et al. [7] proposed a detection method based on visual sensors for rapid detection of wire looseness issues. This method collected wire images through an image acquisition system. The GEG algorithm was used for foreground highlighting and hierarchical enhancement. The implementation results showed that this method could quickly detect loose wires. Qingkai et al. [8] proposed a fault detection method based on lightweight semantic segmentation network to address the accuracy in line fault detection. A two branch network was designed to locate instances and refine contours. This method improved the accuracy of line fault detection. Xiong et al. [9] proposed an object recognition model based on human concept learning to address the automatic fault detection for inspection robots. The model was preliminarily identified through Mask R-CNN. Bayesian contextual network was used for result correction. Compared with other methods, the accuracy of this method was increased by 9.7%.

As a tree-based algorithm, RRT is suitable for multi-dimensional space, with simple principles and strong applicability. It is a typical path planning algorithm. Hu B et al. [10] proposed a path planning algorithm based on RRT to find accessible paths for wheeled robots. This algorithm used a motion control law guided by a posture-based steering function to reach its destination. From the experimental results, the trajectory generated by this method was smoother and shorter in length. Sun et al. [11] proposed a motion planning method based on the SC-RRT algorithm for autonomous navigation of mobile robots. This method improved the branch growth mode of the RRT-Connect algorithm, reduced the sampling space, and quickly obtained a path away from obstacles. Jhang et al. [12] proposed a motion planning method based on bidirectional fast exploration random trees and Reeds-Shepp curves for the path planning problem of autonomous parking. This method could be independently proposed in complex parking lots. Zammit and Kampen [13] proposed a path planning algorithm based on RRT for real-time safe navigation of unmanned aerial vehicles. From the experimental results, in simple location environments, the RRT algorithm had a success rate of over 95%. Compared with other algorithms, the path was shorter. Wang et al. [14] proposed a hybrid bidirectional fast exploration random tree based on reinforcement learning to address the randomness and slow convergence speed in path generation. This method improved search efficiency and shortened the generation path.

In summary, the research on TLIR has been quite effective. However, most studies overlook the stability of the obstacle crossing process. The RRT algorithm, as a typical path planning algorithm, although suitable for multi-dimensional spaces, is prone to falling into local search. Therefore, to ensure the motion stability of the inspection robot, an obstacle crossing path planning algorithm based on the improved RRT-Connect algorithm is proposed. By improving joint motion and search step size, and setting an intermediate random tree, the traditional RRT-Connect is improved.

III. Obstacle Crossing Stability Analysis of TLIR

In transmission lines, in addition to equipment such as tension towers and cables, it also includes hardware such as insulator strings and spacer rods. These hardware tools that exist in transmission lines are obstacles for TLIR. During the inspection process, whether the robot can stably cross various obstacles is the key to complete the inspection work.

A. Dynamic Analysis of Obstacle Crossing Motion of TLIR

During the obstacle crossing process of the TLIR, one claw of the robot grasps the line and the other claw disengages. The motion of the detachment claw is similar to the reverse motion of the gripping claw. To analyze the obstacle crossing engineering of robots, a kinematic analysis is conducted on the obstacle crossing process of the inspection robot using the D-H parameter method with a horizontal plane as the reference plane. The joint change matrix of the inspection robot is shown in Eq. (1).

$$ {}_{i}^{i-1}T = \begin{bmatrix} \cos\theta_i & -\sin\theta_i\cos\alpha_i & \sin\theta_i\sin\alpha_i & a_i\cos\theta_i \\ \sin\theta & \cos\theta_i\cos\alpha_i & -\cos\theta_i\sin\alpha_i & a_i\sin\theta_i \\ 0 & \sin\alpha_i & \cos\alpha_i & d_i \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad (1) $$

In Eq. (1), θ_i represents the amount of rotation of the rotating joint, (rad). d_i represents the extension and retraction of the arm, (mm). α_i and a_i are constants. In the link model of the TLIR, the angle relationship between the upper push rod, middle push rod, and wheel claw is shown in Fig. 1.

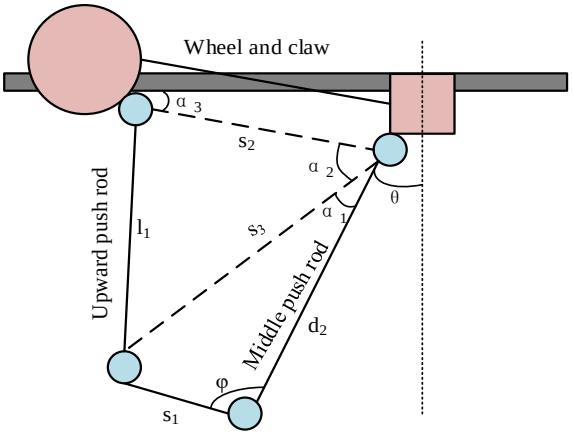

Fig. 1. Upper bar / middle bar and wheel claw angle relationship.

In Fig. 1, the upper push rod is responsible for adjusting the angle between the middle push rod and the wheel claw. According to the relationship shown in the above figure, the geometric relationship among the three is shown in Eq. (2).

$$\begin{cases} s_3 = \sqrt{s_1^2 + d_2^2 - 2s_1 d_2 c\cos\varphi} \\ \alpha_1 = \arccos\left(\dfrac{s_3^2 + d_2^2 - s_1^2}{2s_3 d_2}\right) \\ \alpha_2 = \arccos\left(\dfrac{s_3^2 + s_2^2 - l_1^2}{2s_3 s_2}\right) \\ \theta = \pi - \left(\dfrac{\pi}{2} - \alpha_3\right) - (\alpha_1 + \alpha_2) \end{cases} \quad (2)$$

In Eq. (2), s_3 represents the distance between joint 1 and joint 2. s_1 stands for the length of the connector. d_2 stands for the length of the middle push rod. φ stands for the angle between the middle push rod and the connecting piece. α_1 signifies the angle between s_3 and the middle push rod. α_2 stands for the angle between the wheel claw and s_3. l_1 represents the length of the upper push rod. θ refers to the angle between the middle push rod and the vertical line. α_3 represents the angle between the wheel claw and the horizontal line. According to the length of the middle push rod, the range of the angle between the upper push rod and the wheel claw can be determined. The angle relationship between the lower/middle push rod and the center turntable is illustrated in Fig. 2.

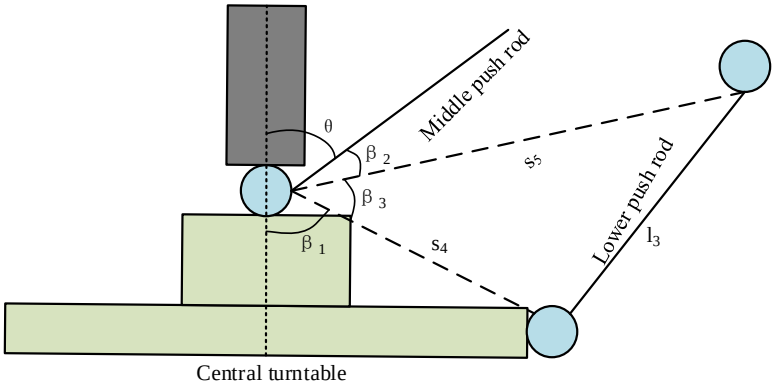

Fig. 2. Angle relationship between lower / middle push rod and center turntable.

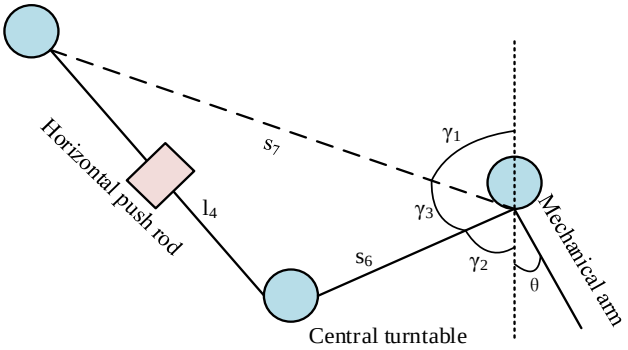

Fig. 3. Angle relationship between horizontal lever / robotic arm and center turntable.

In Fig. 2, the angle between the middle push rod and the center turntable is adjusted by the lower push rod. According to the relationship shown in Fig. 2, the geometric relationship among the three is shown in Eq. (3).

$$\begin{cases} \beta_2 = \arccos\left(\dfrac{s_4^2 + s_5^2 - l_3^2}{2s_4 s_5}\right) \\ \theta = \beta_1 + \beta_2 + \beta_3 - \pi \end{cases} \quad (3)$$

In Eq. (3), β_3 represents the angle between the center turntable and s_5. s_4 represents the length of the central turntable. s_5 represents the distance between joint 5 and the upper endpoint of the central turntable. l_3 refers to the length of the lower push rod. β_1 refers to the angle between the center turntable and the vertical line. β_2 is the angle between the middle push rod and s_5. The relationship between the horizontal push rod/robotic arm and the center turntable angle is shown in Fig. 3.

In Fig. 3, the angle between the robotic arm and the central turntable is adjusted by a horizontal push rod. According to the relationship shown in the above figure, the geometric relationship expression among the three is shown in Eq. (4).

$$\begin{cases} \gamma_3 = \arccos\left(\dfrac{s_6^2 + s_7^2 - l_4^2}{2 s_6 s_7}\right) \\ \theta' = \gamma_1 + \gamma_2 + \gamma_3 - \pi \end{cases} \tag{4}$$

In Eq. (4), γ_3 represents the angle between s_7 and the central turntable. s_6 represents the length of the central turntable. l_4 refers to the length of the horizontal push rod. θ' refers to the angle between the robotic arm and the vertical line. γ_1 refers to the angle between s_7 and the vertical line. γ_2 refers to the angle between the center turntable and the vertical line. The D-H parameters of each connecting rod can be combined with Eq. (1) to obtain the homogeneous transformation matrix of each joint. Directly below the transmission line is the origin of the global coordinate system. The homogeneous transformation matrix of the inspection robot end in the global coordinate system can be obtained by multiplying the Homogeneous Transformation Matrices (HTM) between different coordinate systems, as displayed in Eq. (5).

$${}_7^G T = {}_0^G T \cdot {}_1^0 T \cdot {}_2^1 T \cdot {}_3^2 T \cdot {}_4^3 T \cdot {}_5^4 T \cdot {}_6^5 T \cdot {}_7^6 T = \begin{bmatrix} n_x & o_x & a_x & p_x \\ n_y & o_y & a_y & p_y \\ n_z & o_z & a_z & p_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{5}$$

In Eq. (5), ${}_7^G T$ stands for the HTM of coordinate system 7 relative to the global coordinate system. ${}_0^G T$ stands for the HTM of coordinate system 0 relative to the global coordinate system. ${}_1^0 T$, ${}_2^1 T$, ${}_3^2 T$, ${}_4^3 T$, ${}_5^4 T$, ${}_6^5 T$ and ${}_7^6 T$ represent the HTM of coordinate system 1/2/3/4/5/6/7 relative to coordinate system 0/1/2/3/4/5/6, respectively. To obtain the desired joint angle, the inverse kinematics analysis on the robot is performed. The inspection robot has seven joints and many variables, which are difficult to solve. The special structure of the inspection robot allows it to obtain the inverse kinematics expression without considering the last joint variable. At this time, the HTM of the global coordinate system at the end of the robot is shown in Eq. (6).

$${}_6^G T = {}_0^G T \cdot {}_1^0 T \cdot {}_2^1 T \cdot {}_3^2 T \cdot {}_4^3 T \cdot {}_5^4 T \cdot {}_6^5 T = \begin{bmatrix} n'_x & o'_x & a'_x & p'_x \\ n'_y & o'_y & a'_y & p'_y \\ n'_z & o'_z & a'_z & p'_z \\ 0 & 0 & 0 & 1 \end{bmatrix} \tag{6}$$

When the rotation of the second robotic arm is not 0, the analytical expressions for the first six joint variables are shown in Eq. (7).

$$\begin{cases} \theta_1 = \arctan\left(d_2 \sin\theta_1 / d_2 \cos\theta_1\right) \\ d_2 = d_2 \cos\theta_1 / \cos\theta_1 \\ \theta_3 = \left(\theta_1 + \theta_3\right) - \theta_1 \end{cases} \tag{7}$$

In Eq. (7), θ_1 represents the rotational amount of the claw 1. d_2 represents the extension and retraction amount of arm 1. θ_3 represents the rotation amount of arm 1. When the rotation of the arm 2 is 0, the analytical expressions for the first six joint variables are shown in equation (8).

$$\begin{cases} \theta_1 = \arcsin o_x \\ d_2 = \dfrac{\dfrac{p_x - 266}{\sin\theta_1} + \left(\dfrac{p_z}{-\cos\theta_1}\right)}{2} \\ d_6 = \dfrac{\dfrac{p_x - 266}{\sin\theta_1} - \left(\dfrac{p_z}{-\cos\theta_1}\right)}{2} \end{cases} \tag{8}$$

In Eq. (8), d_6 represents the telescopic amount of arm 2. The length of each push rod is shown in Eq. (9).

$$\begin{cases} l_1 = \sqrt{s_2^2 + s_3^2 - 2 s_2 s_3 \cos\left(\dfrac{\pi}{2} - \alpha_1 + \alpha_3 - \theta_1\right)} \\ l_3 = \sqrt{s_4^2 + s_5^2 - 2 s_4 s_5 \cos\left(\pi - \beta_1 - \beta_2 + \theta_3\right)} \\ l_4 = \sqrt{s_6^2 + s_7^2 - 2 s_6 s_7 \cos\left(\pi - \gamma_1 - \gamma_2 + \theta_4\right)} \\ l_5 = \sqrt{s_4^2 + s_5^2 - 2 s_4 s_5 \cos\left(\pi - \beta_1 - \beta_2 + \theta_5\right)} \\ l_1 = \sqrt{s_2^2 + s_3^2 - 2 s_2 s_3 \cos\left(\dfrac{\pi}{2} - \alpha_1 + \alpha_3 - \theta_7\right)} \end{cases} \tag{9}$$

In Eq. (9), l_1 - l_7 respectively represent the length of the push rod that adjusts the corresponding joint variable.

B. Obstacle Crossing Path Planning Algorithm for TLIR

To ensure the collision free motion of the TLIR during the operation, an obstacle crossing path planning algorithm based on the improved RRT-Connect algorithm is proposed by combining its kinematic analysis model. RRT is a path planning algorithm based on random sampling, which can effectively overcome the high dimensionality caused by motion. The search tree extension diagram of the RRT is displayed in Fig. 4.

In Fig. 4, when using the initial point as the extended root node and conducting search expansion in space, each search randomly generates sampling points. If the distance between the random sampling point and its nearest point is greater than the set extension step, the nearest point will be extended to the random sampling point at the set step size, generating a new node. Otherwise, the random sampling points are used as new nodes [15-17]. If the connection between the new node and the nearest node collides with an obstacle, the new node will be abandoned. Otherwise, the new node is added to the random tree. The distance between nodes is shown in Eq. (10).

$$\rho\left(x_1, x_2\right) = \left\| x_2 - x_1 \right\| \tag{10}$$

In Eq. (10), x_1 and x_2 represent different nodes. The new node is shown in Eq. (11).

$$x_{new} = x_{near} + \lambda \frac{x_{rand} - x_{near}}{\left\| x_{rand} - x_{near} \right\|} \tag{11}$$

In Eq. (11), x_{new} represents the new node. x_{near} represents the node closest to the random sampling point. x_{rand} represents a random sampling point. λ represents the extension step size. The RRT algorithm has strong randomness, resulting in a large number of redundant nodes. Path planning takes a long time. The RRT-Connect algorithm improves the search speed by incorporating the Connect heuristic algorithm on the basis of bidirectional RRT algorithm, which has a certain degree of directionality. The new node generation method of RRT-Connect algorithm is shown in Eq. (12).

$$\begin{cases} x_{new} = x_{near}\left(a + \varepsilon\cos\theta, b + \varepsilon\sin\theta\right) \\ \theta = \arctan\left(x_{target}(b) - x_{near}(b), x_{target}(a) - x_{near}(a)\right) \end{cases} \tag{12}$$

In Eq. (12), (a,b) represents the node coordinates. θ represents the growth angle between the line connecting the target node and the nearest node and the horizontal line. ε represents the minimum fixed step size. x_{target} represents the target node. The RRT-Connect greatly improves the efficiency of path planning. However, the mapping relationship between the joint space and workspace of the TLIR is complex, resulting in significant differences in the pose changes between the new node and the parent node in the workspace. It is difficult to apply to the obstacle crossing path planning. Therefore, the RRT-Connect algorithm is improved by improving joint motion, search step size, and setting intermediate random trees. During robot collision detection, when there is a significant change in the end pose of the workspace between two nodes, interpolation collision detection needs to be performed between the two nodes. At this point, it is difficult to distinguish the impact of different joint movements on the changes in workspace posture. Therefore, to simplify the collision detection process, a path search method based on single joint motion is proposed, which means that the child nodes only change one joint during the expansion process [18-20]. Although the single joint motion path search method can achieve clear correspondence between joint space and workspace pose. However, in joint space, different single joint movements can still cause changes in the workspace posture. Therefore, to simplify the search process, the fixed position step size is set within the workspace instead of the joint space. At this point, collision detection only needs to detect the sampling points and nearest nodes, which greatly reduces the workload of joint space collision detection. In addition, the RRT-Connect algorithm is prone to getting stuck in local search when encountering large obstacles. A large number of random sampling points from other directions need to be generated to cross the obstacle. Therefore, to alleviate the local search problem, a random tree with an intermediate point is set in the middle of the path. The improved RRT-Connect path planning process is displayed in Fig. 5.

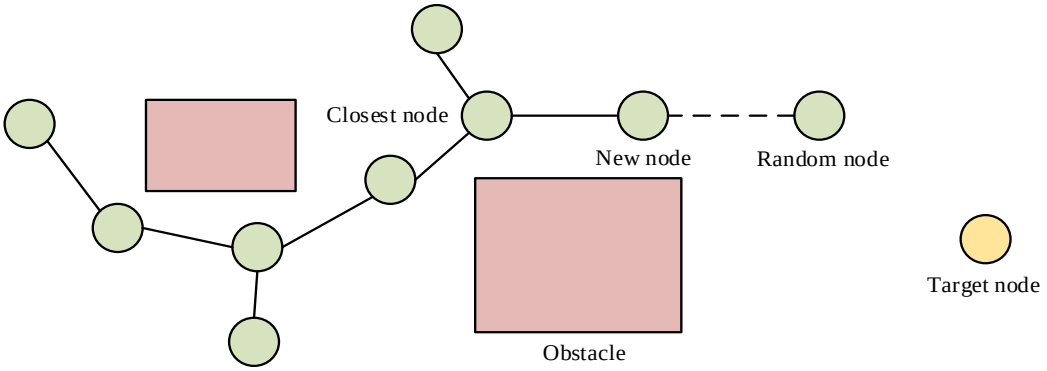

Fig. 4. Search tree extension plot of the RRT algorithm.

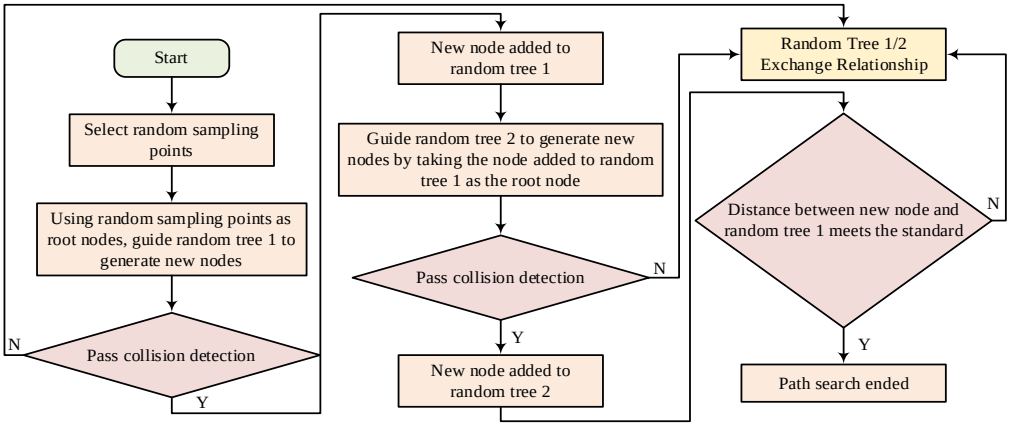

Fig. 5. The RRT-Connect path planning process.

From Fig. 5, firstly, a random sampling point is selected and used as the root node to guide random tree 1. A new node is generated. If the new node has not collided, it will be added to random tree 1. Otherwise, the node will be abandoned. After adding a new node to random tree 1, guide random tree 2 to generate a new node with that node as the root node. If the new node passes collision detection, it will be added to random tree 2. Otherwise, abandon the new node. After adding a new node to random tree 2, if the distance between the node and random tree 1 meets the standard, complete the path search. Otherwise, the relationship between the two random trees will be swapped. The improved RRT-Connect algorithm can obtain discrete path nodes. However, in the actual motion of the inspection robot, the trajectory of the push rod length needs to be planned to control the motion of the inspection robot. The trajectory of the push rod planned by the quintic polynomial interpolation method is shown in Eq. (13).

$$d(t) = m_0 + m_1 t + m_2 t^2 + m_3 t^3 + m_4 t^4 + m_5 t^5 \tag{13}$$

In Eq. (13), t represents the movement time of the push rod. m_0 - m_5 represent polynomial coefficients. The initial time is 0. The boundary condition is displayed in Eq. (14).

$$\begin{cases} d_1 = m_0 \\ v_1 = m_1 \\ a_1 = 2m_2 \\ d_2 = m_0 + m_1 t_2 + m_2 t_2^2 + m_3 t_2^3 + m_4 t_2^4 + m_5 t_2^5 \\ v_2 = m_1 + 2m_2 t_2 + 3m_3 t_2^2 + 4m_4 t_2^3 + 5m_5 t_2^4 \\ a_2 = 2m_2 + 6m_3 t_2 + 12m_4 t_2^2 + 20m_5 t_2^3 \end{cases} \tag{14}$$

In Eq. (14), d_1 and d_2 represent the initial length and termination length of the push rod, respectively. v_1 and v_2 represent the initial speed and end speed of the push rod. a_1 and a_2 are the initial acceleration and termination acceleration, respectively. t_1 and t_2 represent the initial and ending times, respectively. The coefficients of the five term equation can be obtained from the above equation, as shown in Eq. (15).

$$\begin{cases} m_0 = d_1 \\ m_1 = v_1 \\ m_2 = \dfrac{a_1}{2} \\ m_3 = \dfrac{20(d_2 - d_1) - (12v_1 + 8v_2)t_2 - (3a_1 - a_2)t_2^2}{2t_2^3} \\ m_4 = \dfrac{-30(d_2 - d_1) + (16v_1 + 14v_2)t_2 + (3a_1 - 2a_2)t_2^2}{2t_2^4} \\ m_5 = \dfrac{12(d_2 - d_1) - (6v_1 + 6v_2)t_2 - (a_1 - a_2)t_2^2}{2t_2^5} \end{cases} \tag{15}$$

Based on the quintic polynomial interpolation method, the speed, length, motion speed, and acceleration of the push rod are controlled, thereby achieving motion control of the inspection robot.

IV. Simulation Analysis of Obstacle Crossing Performance for TLIR

To test the obstacle crossing ability of the TLIR, simulation testing was performed. The obstacles selected in the experiment were the vibration damper and suspension clamp and insulator string. The lengths of the enclosure box for the vibration damper, suspension clamp, and insulator string were 50mm, 160mm, and 1150mm, respectively. The radii were 35mm, 45mm, and 100mm, respectively. The step size of the workspace was 30mm. The joint configurations of random tree root nodes for different obstacles were shown in Table I.

TABLE I. Joint Configurations of Random Root Nodes for Different Obstacles

Node	θ1/rad	d2/mm	θ3/rad	θ4/rad	θ5/rad	d6/mm	θ7/rad
Starting point of vibration damper	0.24	494.3	-0.24	0	-0.24	494.3	3.38
Midpoint of vibration damper	0.61	550.1	-0.61	0.44	-0.61	550.1	3.23
End of vibration damper	1.05	660.1	-1.05	0	-1.05	660.1	4.19
Starting point of insulator string	0.24	494.3	-0.24	0	-0.24	494.3	3.38
Midpoint of insulator string	0.56	586.0	-0.75	0.79	-0.56	577.0	2.71
End of insulator string	0.79	660.4	-0.79	0	-0.79	660.4	3.93

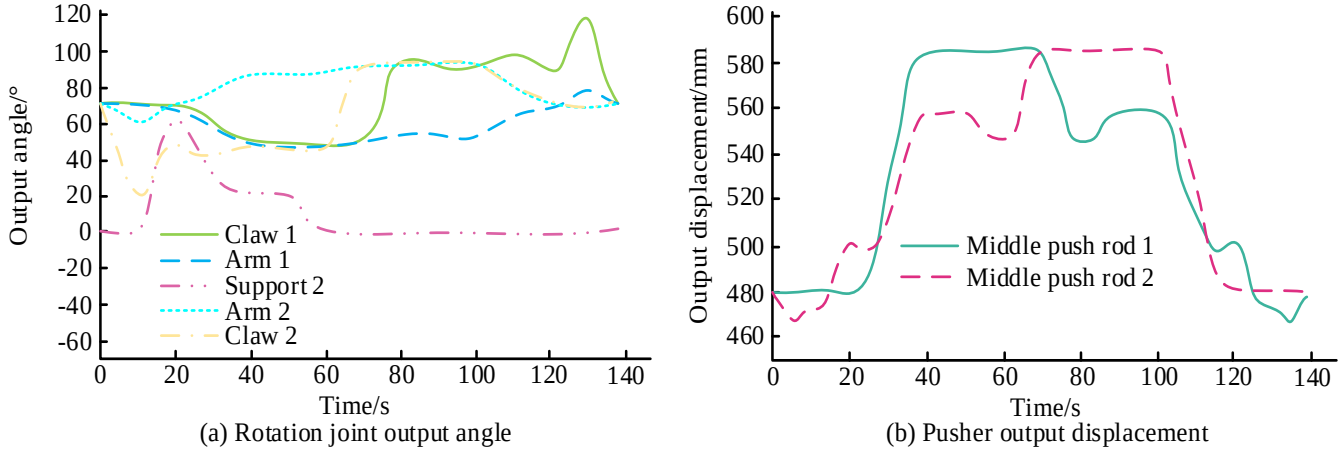
From Table I, when the inspection robot crossing different obstacles, the root node joint configuration of its random tree was different. When crossing the suspension clamp and insulator string, the output curve of the inspection robot is shown in Fig. 6.

In Fig. 6(a), when the crossing the suspension clamp and insulator string, the angle output range of claw 1 and arm 1 was (50°~120°) and (50°, 80°). The angle output ranges of the claw 2, bracket 2, and arm 2 were (20°, 90°), (0°, 60°), and (-60°, 0°). From Fig. 6(b), during the obstacle crossing process, the length output range of the push rods in numbers 1 and 2 was (468585)mm. According to Fig. 6, the end trajectory in the rear arm obstacle crossing is based on the front claw center as the reference point for the end base coordinate, and its path is the same as the front claw obstacle crossing trajectory. This proves that the symmetrical structure of the robot can simplify the obstacle crossing process by making the process of crossing obstacles with the backward paw the reverse movement of the front paw when crossing simple obstacles. The displacement of

each joint and push rod when the inspection robot crossed the suspension clamp and insulator string is shown in Fig. 7.

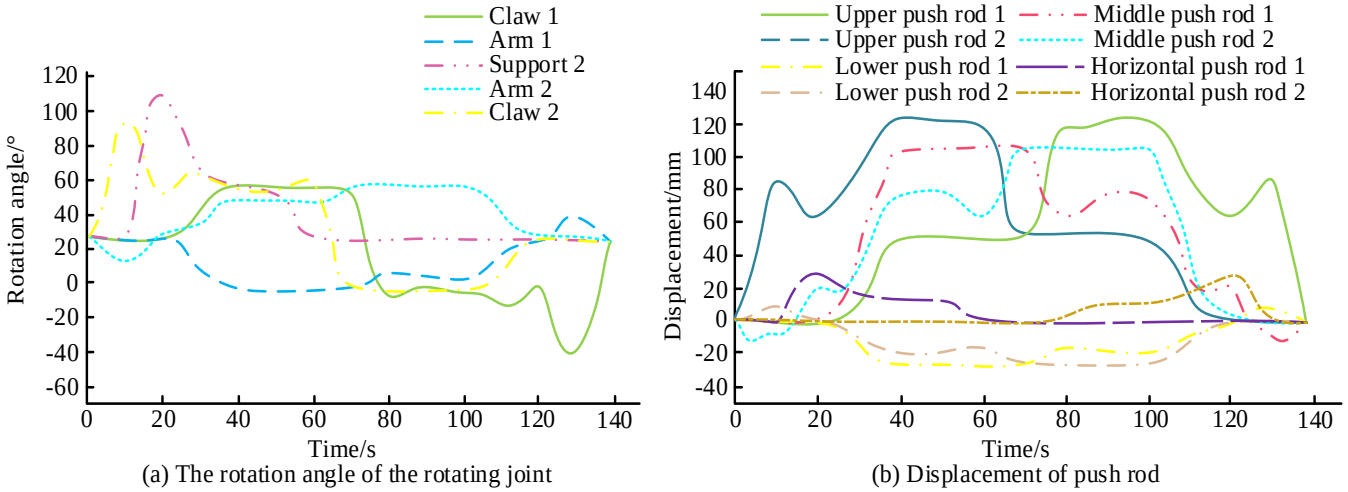
In Fig. 7(a), when crossing the suspension clamp and insulator string, the rotation ranges of claw 1 and arm 1 were (-50°~20°) and (-20°, 10°). The rotation ranges of claw 2, bracket 2, and arm 2 were (-20°, 50°), (0°, 60°), and (-10°, 20°). From Fig. 7(b), during the obstacle crossing process, the extension range of push rods 1 and 2 was (0, 125) mm. The extension range of the middle push rods 1 and 2 was (-15, 115) mm. The extension range of the lower push rods 1 and 2 was (-25, 0) mm. The extension range of the horizontal push rods 1 and 2 was (0, 30) mm. From Fig. 7, the motion process of the front claw under the reference mark when crossing obstacles is opposite to that of the rear claw when crossing obstacles under the reference mark. If the starting point of the obstacle crossing at a distance of 500mm from the hanging clamp on the wire is taken as the base coordinate, the simplified model of the rotation joint rotation angle and push rod displacement change process in the front claw obstacle crossing is mirrored to the rotation joint rotation angle and push rod displacement change process in the rear claw motion. From this, the robot's obstacle crossing movement is relatively stable. The output speed of each joint and push rod of the inspection robot is shown in Fig. 8.

From Fig. 8(a), when crossing the suspension clamp and insulator string, the rotational speeds of the claw 1 and arm 1 were (-7.5~7.5) deg/s and (-1.5, 1.5) deg/s. The rotational speeds of the claw 2, bracket 2, and arm 2 were (-7.5~7.5) deg/s, (-4, 11.5) deg/s, and (-1.5, 1.5) deg/s. From Fig. 8(b), during the obstacle crossing process, the telescopic speeds of push rods 1 and 2 were both (-13, 10) mm/s. The extension speeds of push rods 1 and 2 were both (-7.5, 8.5) mm/s. The telescopic speeds of the lower push rods 1 and 2 were both (-2.5, 2.5) mm/s. The telescopic speed of the horizontal push rods 1 and 2 was (-2.5, 6) mm/s. The speed change curve of each joint and push rod of the inspection robot was smooth, indicating that the acceleration value was not large. The motion of the inspection robot was relatively stable. When climbing over the shock absorber, the output curve of the inspection robot is shown in Fig. 9.



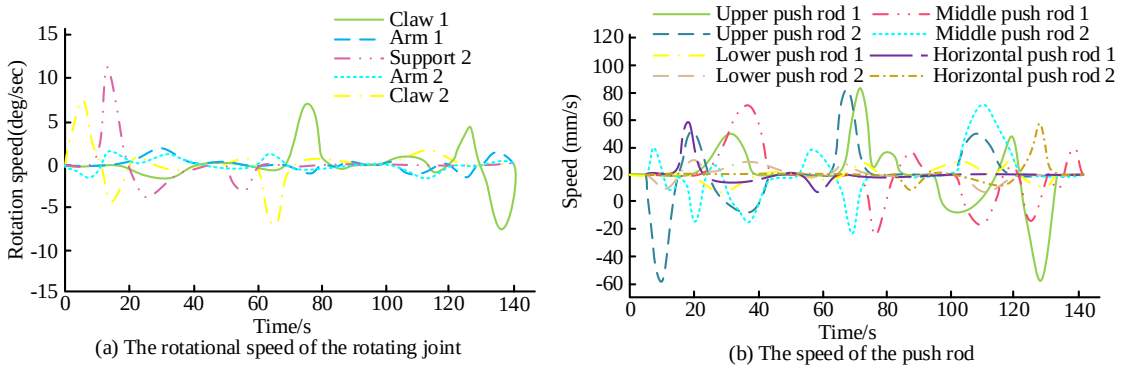
(a) Rotation joint output angle (b) Pusher output displacement

Fig. 6. Output curve of the inspection robot.



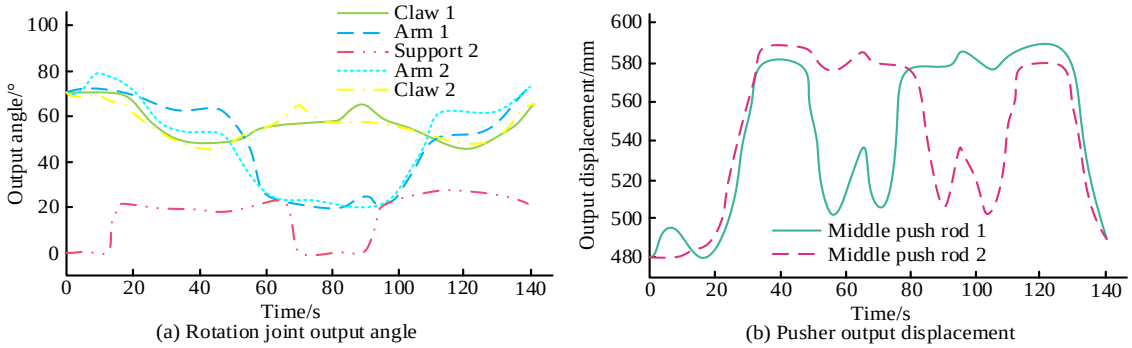
(a) The rotation angle of the rotating joint (b) Displacement of push rod

Fig. 7. Displacement of the joints and push rods of the inspection robot.



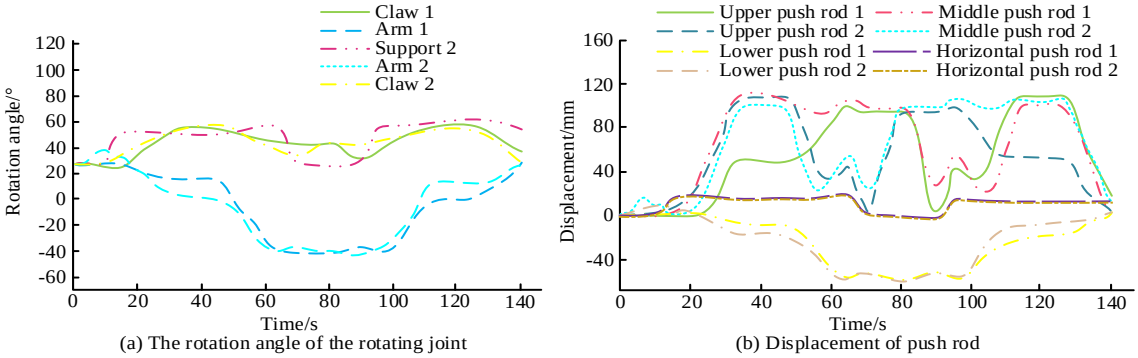
(a) The rotational speed of the rotating joint (b) The speed of the push rod

Fig. 8. Output speed of each joint and push rod of the inspection robot.



(a) Rotation joint output angle (b) Pusher output displacement

Fig. 9. Output curve of the inspection robot.



(a) The rotation angle of the rotating joint (b) Displacement of push rod

Fig. 10. Displacement of the joints and push rods of the inspection robot.

In Fig. 9(a), when overtaking the vibration damper, the angle output ranges of claw 1 and arm 1 were (50°~70°) and (20°, 80°). The angle output ranges of the claw 2, bracket 2, and arm 2 were (45°, 70°), (0°, 25°), and (0°, 25°). From Fig. 9(b), during the obstacle crossing process, the length output range of push rods 1 and 2 was (480, 590) mm. From Fig. 9, the obstacle crossing trajectory of the robot's front and rear claws over the shock absorber is basically consistent with the planned end trajectory. In order to save time, the trajectory of the rear claw passing through the end of the shock absorber does not need to be completely mirrored with the front claw, which can make it closer to the turning point of the planned path. When climbing over the vibration damper, the displacement of each joint and push rod is shown in Fig. 10.

From Fig. 10(a), the rotation ranges of claw 1 and arm 1 were (0°~22°) and (-50°, 10°) when overtaking the vibration hammer. The rotation ranges of the bracket 2, arm 2, and claw 2 were (0°, 25°), (-50°, 10°), and (0°, 22°). From Fig. 10(b), during the obstacle crossing process, the extension range of push rods 1 and 2 was (0, 100) mm. The extension range of the push rods 1 and 2 was (0, 110) mm. The extension ranges of the lower push rods 1 and 2 were (-60, 10) mm. The extension ranges of the horizontal push rods 1 and 2 were (0, 20) mm. When climbing over the vibration hammer, the output speed of each joint and push rod of the inspection robot is shown in Fig. 11.

From Fig. 11(a), the rotational speeds of the claw 1 and the arm 1 were (-1.5~1.5) deg/s and (-3, 2.5) deg/s when overtaking the damper. The rotational speeds of the bracket 2, arm 2, and claw 2 were (-3.5~3.5) deg/s, (-2.5, 3) deg/s, and (-27, 2) deg/s. From Fig. 11(b), during the obstacle crossing process, the extension speeds of push rods 1 and 2 were (-17, 13.5) mm/s and (-13.5, 17) mm/s, respectively. The extension ranges of push rods 1 and 2 were (-11, 11) mm/s. The extension speeds of

the lower push rods 1 and 2 were (-4.5, 3) mm/s and (-3, 4.5) mm/s, respectively. The stretching and retracting speeds of the horizontal push rods 1 and 2 were all (-4, 5) mm/s. When the inspection robot climbed over the vibration hammer, the speed change curve of each joint and push rod was smooth. It indicated that the motion of the inspection robot was relatively stable.

V. DISCUSSION

As an indispensable part of social production activities and people's lives, electricity plays an irreplaceable role in the development of the national economy. Overhead transmission lines are the hub responsible for transportation in the entire power system. It is necessary to conduct regular inspections and maintenance of high-voltage overhead transmission lines that are exposed to harsh natural environments all year round to ensure the safe and stable operation of the power transportation network. Compared with manual inspection, helicopter inspection, and drone inspection, online inspection robots have advantages such as low cost, high quality, and long operating time. To this end, the study conducted kinematic analysis on the inspection robot to understand its motion patterns during obstacle crossing. An obstacle crossing path planning algorithm based on an improved RRT-Connect algorithm was proposed. The experimental results showed that when the inspection robot crossed the insulator string of the suspension clamp, the angle output ranges of the first claw and the first arm were (50°~120°) and (50°, 80°). The angle output ranges of claw 2, bracket 2, and arm 2 were (20°, 90°), (0°, 60°), and (-60°, 0°). The corresponding rotational speeds were (-7.5~7.5) deg/s, (-1.5, 1.5) deg/s, (-7.5~7.5) deg/s, (-4, 11.5) deg/s, and (-1.5, 1.5) deg/s. The extension and contraction ranges of the upper/middle/lower/horizontal push rods were (0125) mm, (-15, 115) mm, (-25, 0) mm, and (0, 30) mm, respectively, with corresponding extension and contraction speeds of (-13, 10) mm/s, (-7.5, 8.5) mm/s, (-2.5, 2.5) mm/s, and (-2.5, 6) mm/s. According to the experimental results, the proposed inspection robot has stable changes in the angle (displacement) and velocity curves of its joints and push rods when crossing obstacles, without any abrupt changes. The same conclusion can also be observed from the graph of velocity and acceleration. At the same time, the velocity curves of push rods in each joint of the robot are smooth, and the acceleration values are not large. Therefore, the robot's obstacle crossing motion is relatively stable and has good kinematic performance. In addition, the output changes of each push rod obtained in the end path planning of the line patrol robot can enable the robot to complete the planned action along the predetermined trajectory at the obstacle crossing end.

VI. CONCLUSION

As the key to power transmission, transmission lines need to be regularly inspected to ensure safety and stability. The inspection robot has low cost and long running time in the inspection of transmission lines. It can promptly troubleshoot faults on transmission lines. To ensure that the inspection robot can achieve collision free motion in the inspection project, the kinematic analysis is conducted on the inspection robot to analyze the motion laws during obstacle crossing. An obstacle crossing path planning algorithm based on the improved RRT-Connect algorithm is proposed. In order to verify the effectiveness of the obstacle crossing method proposed in the study, simulations were conducted based on the obstacle crossing path of the robot's end effector. Real-time rotation angles, output displacement, and velocity curves of each joint and push rod during different obstacle crossing processes were obtained. Kinematic equations were used to further represent the variation curves of each joint. The output changes of each push rod obtained in the end path planning of the line inspection robot can enable the robot to complete the planned action along the predetermined trajectory at the obstacle crossing end, and ensure the stability of the inspection robot during obstacle crossing. Although the obstacle crossing method proposed in the study can effectively ensure the motion stability of the inspection robot, there are still many redundant trajectories in its workspace. Therefore, future work will focus on how to eliminate redundant trajectories.

Precision Machining of Hard-to-Cut Materials: Current Status and Future Directions

Tengjiao CUI
Shijiazhuang Institute of Technology, Shijiazhuang 050228, China
Shijiazhuang Tiedao University SiFang College, Shijiazhuang 051132, China

***Abstract*—Machining difficult materials like superalloys, ceramics, and composites is fundamental in industries where performance is paramount, such as the auto industry, aerospace, and medicine. These materials with relatively high strength, hardness, and high-temperature capabilities pose difficulties in machining, thus calling for improved precision machining technologies. This survey paper presents a detailed review of the current state of the art of precision machining of these difficult materials, along with advances observed in tools for cutting, machining techniques, and new technologies. They range from carbide, ceramics, super hard tools, and geometry of tools, and this topic also deals with tool coatings. The article also discusses specifics of the traditional and nontraditional machining processes: turning, milling, electrical discharge, and laser machining, as well as the relations between additive and hybrid manufacturing. The importance of new technologies or digital and intelligent manufacturing systems in enhancing the accuracy and productivity of machining is also illustrated. Furthermore, the paper also provides information on how digital and intelligent manufacturing technologies can enhance machining efficiency and accuracy. Moreover, future research will aim to minimize tool wear, enhance surface finish and integrity, and environmentally conscious machining. The paper concludes with a hopeful note on the potential of future research to revolutionize the precision machining industry, offering high performance and reliability in critical applications while maintaining a focus on sustainability.**

Keywords*—*Precision machining; hard-to-cut materials; cutting tools; machining processes; emerging technologies

I. Introduction

A. Context

Nowadays, many industrial sectors require construction supplies characterized by superior mechanical and functional features [1]. Construction materials exhibit exceptional hardness, abrasion resistance, temperature-resistant strength, enhanced thermal conductivity, and oxidation and corrosion resistance and are indispensable in a variety of high-demand industries, including aerospace [2], biomedical [3], electronics, and automotive [4]. Despite these unique features, these materials are regarded as hard to cut because of their poor machinability [5].

Recent advancements in cutting tools, including carbide, ceramics, and super-hard tools, have significantly improved the machinability of hard-to-cut materials [6]. Innovative tool geometries and coatings have further enhanced machining performance. Moreover, conventional and non-conventional machining methods such as turning, milling, Electrical Discharge Machining (EDM), and laser machining are gaining attention for their role in addressing these challenges [7]. Integrating hybrid machining techniques, including additive manufacturing, has opened new avenues for achieving greater precision and customization in the machining process [8].

B. Challenges

There are several major problems associated with machining hard-to-cut components, including the high levels of machining forces [9], the high levels of vibrations encountered in machining systems [10], the concentration of heat, the rapid increase in machining temperature [11], rapid tool wear, and catastrophic tool failure [12], as well as frequent instability loss and significant deterioration of surface finishes [13].

Maintaining surface integrity while improving efficiency is a critical challenge that hinders the machining of hard-to-cut materials [14]. Moreover, with increasing demands for sustainable practices, addressing environmental concerns in machining processes remains largely underdeveloped [15]. Sustainable machining, aimed at reducing energy consumption, tool wear, and waste generation, is becoming increasingly essential, but solutions are still in the early stages of implementation [16].

C. Contribution

The primary aim of this paper is to deliver a thorough overview of current advances in precision machining of hard-to-cut steels, focusing on the challenges and innovations in cutting tools, machining processes, and new technologies. By analyzing recent advances in material compositions, coatings, and geometries, as well as both conventional and non-conventional machining techniques, this article aims to provide comprehensive insights into state-of-the-art methods and practices. In addition, an attempt is made to identify future research directions to address existing challenges such as tool wear, surface integrity, and sustainability. Ultimately, the goal is to support continuous improvement in machining efficiency, accuracy, and sustainability in industries that rely on these demanding materials.

The novelty of this study lies in its exploration of integrating digital and intelligent manufacturing technologies to improve machining efficiency and accuracy. By reviewing these

advancements and suggesting future research avenues, the paper contributes to ongoing efforts to improve precision machining for high-demand applications across various industries.

II. Characteristics of Hard-to-Cut Materials

Materials with challenging machining characteristics possess exceptional mechanical and thermal properties, which make them indispensable for high-performance applications but also pose significant challenges during machining [17, 18]. As illustrated in Fig. 1, materials like ceramics, nickel-based superalloys, titanium alloys, and composites exhibit varying degrees of hardness, strength, thermal resistance, and other critical properties that directly impact their machinability. These inherent properties lead to issues like rapid tool wear, high cutting forces, and poor machinability, which compares key challenges across materials. Consequently, machining these materials requires specialized cutting tools and advanced techniques tailored to their specific characteristics [19]. Understanding these unique properties, as detailed in Table I, is essential for developing effective machining strategies that ensure precision, efficiency, and the desired surface quality of manufactured components.

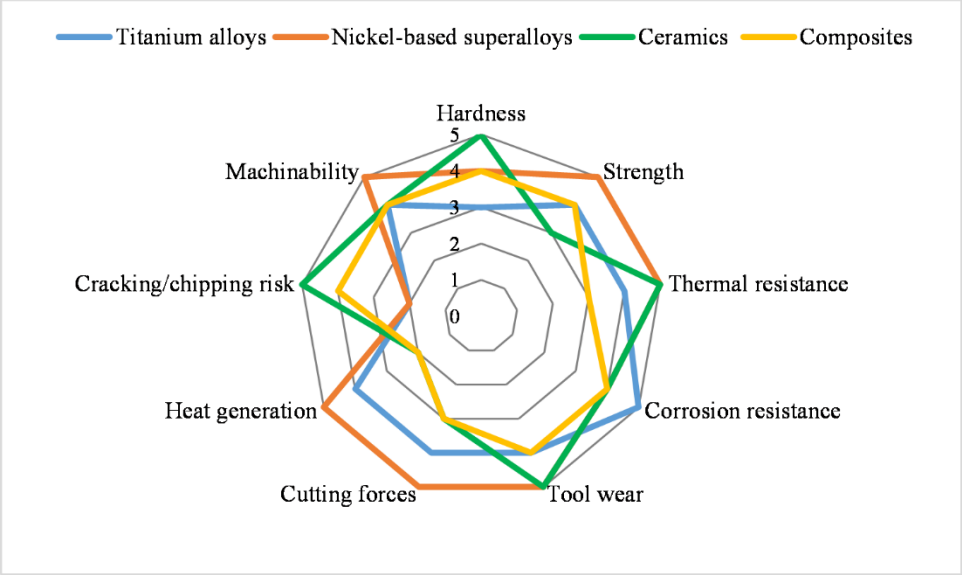

Fig. 1. Key properties and machining challenges of hard-to-cut components.

TABLE I. Comparative Characteristics and Machining Challenges of Hard-to-Cut Materials

Materials	Properties				Challenges					Relevant industries			
	High hardness	High strength	Thermal resistance	Corrosion resistance	Rapid tool wear	High cutting forces	Heat generation	Risk of cracking/chipping	Poor machinability	Aerospace	Automotive	Biomedical	Power Generation
Titanium alloys	Medium	High	High	Very high	High	High	High	Low	High	✓	✓	✓	
Nickel-based superalloys	High	Very high	Very high	High	High	Very high	Very high	Low	Very high	✓	✓		✓
Ceramics	Very high	Medium	Very high	High	Very high	Medium	Low	Very high	High	✓	✓	✓	
Composites	High	High	Medium	High	High	Medium	Low	High	High	✓	✓	✓	

A. Titanium Alloys

Titanium alloys, known for their outstanding biocompatibility, corrosion resistance, and strength-to-weight percentage, have become essential in aerospace, biomedical, and chemical processing [20]. Despite these advantages, machining titanium alloys presents significant challenges with cutting tools, given their strong chemical reactivity and limited thermal conductivity. These properties result in heat concentration in cutting areas, causing rapid tool wear and possible workpiece damage.

In addition, the high strength of titanium alloys increases cutting forces, further exacerbating tool wear and shortening tool life [21]. To mitigate these problems, various strategies are used, such as using advanced tool materials such as cemented carbide and ceramics, high-pressure cooling systems, and

optimizing cutting parameters. Innovations in tool coatings such as Titanium Aluminum Nitride (TiAlN) have also shown promise in improving tool performance and longevity. Understanding the machinability characteristics of titanium alloys is critical to developing efficient and precise machining procedures that satisfy the rigorous demands of high-performance applications [22].

B. Nickel-based Superalloys

Nickel-based superalloys like Hastelloy and Inconel are important materials for high-temperature and high-voltage uses, especially in the aerospace and power generation fields [23]. These alloys are valued for their superior mechanical characteristics under high temperatures, including their strength, stability, and resistance to corrosion. However, due to several factors, such materials are notoriously hard to machine. Nickel-based superalloys' thermal strength and work-hardening properties result in significant cutting forces and rapid tool wear.

Moreover, their poor thermal conductivity results in heat accumulating in cutting zones, increasing tool wear and potentially compromising the workpiece's surface integrity. Advanced machining techniques, such as super-hard cutting tools (e.g., cubic boron nitride), optimized cutting parameters, and high-pressure coolant systems, are essential to addressing these challenges. Coatings such as TiAlN and AlCrN on carbide tools can improve tool life and performance [24]. Understanding machinability issues and implementing effective machining strategies are critical to successfully manufacturing nickel-based superalloy components, ensuring reliability and performance in demanding applications.

C. Ceramics

Ceramics, such as cutting tools, medical devices, and aerospace components, are commonly employed in products with high hardness, wear resistance, and thermal stability. Their exceptional properties are ideal for high-stress, high-temperature environments [25]. However, ceramics are also extremely brittle and have low fracture toughness, which makes them difficult to process. The brittleness of ceramic causes cracking and chipping to occur during processing, which can significantly affect the final product's surface quality and dimensional accuracy.

Conventional machining methods often produce inadequate material removal and excessive tool wear coefficients. Advanced techniques like Laser-Assisted Machining (LAM), EDM, and Ultrasonic Machining (USM) are increasingly adopted to address these challenges. These methods help reduce cutting forces, increase material removal rates, and improve surface finish. Additionally, innovations in diamond-coated tools and fine-grain ceramic tool materials have shown promise in improving the machinability of ceramics. Understanding ceramics' unique properties and machining challenges is critical to developing effective machining strategies that ensure ceramic components' high precision and reliability.

D. Composites

Composites like Glass Fiber-Reinforced Polymers (GRP) and Carbon Fiber-Reinforced Polymers (CFRP) offer many advantages in the automotive, aerospace, and sports equipment fields for their excellent strength-to-weight balance, corrosion resistance, and adaptable properties [26]. Despite these advantages, machining composite materials presents significant challenges due to their heterogeneous and anisotropic nature. The different material properties within the composite structure lead to different wear on the cutting tools and cause problems, including matrix cracking, fiber pull-out, and delamination.

Conventional machining techniques often struggle to maintain the integrity of the fibers and the matrix, resulting in less accurate dimensional measurements and inferior surface finishes [27]. To mitigate these problems, advanced machining strategies like Abrasive Water Jet Machining (AWJM), laser machining, and ultrasonic-assisted machining are used. These methods provide greater control over the machining process, reducing damage and improving surface quality. In addition, developing special cutting tools with optimized geometries and coatings has improved the machinability of composite materials. Understanding the specific machining challenges and developing tailored strategies are critical to effectively and precisely manufacturing composite components, ensuring their performance and longevity in demanding applications.

III. Advances in Cutting Tools

Cutting tools have made significant progress, driven by the need to boost the machinability of hard-to-cut components. Modern cutting tools are designed to withstand extreme conditions when machining superalloys, ceramics, and composites. As detailed in Table II, tool materials, geometries, and coatings innovations have greatly improved tool efficiency, extended tool lifespan, and machining efficiency. The application of super-hard materials, including Cubic Boron Nitride (CBN) and Polycrystalline Diamond (PCD), as well as advanced coatings like Diamond-Like Carbon (DLC) and TiAlN, has resulted in better wear resistance and heat dissipation. Additionally, optimized tool geometries, including micro-textured surfaces and variable helix designs, have contributed to reduced cutting forces and improved chip evacuation. These advances are critical to overcoming hard-to-cut material challenges and enabling high-precision, high-efficiency machining processes.

A. Tool Materials

Carbide tools, ceramic tools, PCD, and CBN are among the most advanced materials used in cutting tools, thanks to their exceptional hardness, thermal stability, and wear resistance. As detailed in Fig. 2, these materials exhibit distinct features that make them useful for different machining applications. Understanding their comparative performance is essential for selecting the appropriate tool for specific machining tasks.

1) Carbide tools: Carbide tools are commonly used when cutting hard-to-cut materials for their extreme hardness, toughness, and wear resistance. Composed primarily of tungsten carbide particles bonded to a metallic cobalt matrix, these tools are designed to keep their cutting-edge and functional integrity even in extreme situations. Carbide tools are particularly effective in high-speed machining operations where they can withstand the heat generated without losing their hardness.

TABLE II. ADVANCES IN CUTTING TOOLS

Aspect	Description	Examples	Benefits
Carbide tools	Commonly used for their hardness, toughness, and wear resistance.	Coatings: TiAlN, TiCN, DLC. Improvements: Ultra-fine carbides, special bonding phases.	High-speed machining capabilities, reduced friction, improved thermal stability, and extended tool life.
Ceramic tools	Known for superior hardness, high-temperature stability, and resistance to wear and chemical erosion.	Materials: Si3N4, Al2O3, SiC. Innovations: Whisker-reinforced ceramics, fine-grained ceramics.	Maintains hardness at high temperatures, is suitable for high-speed machining, reduces the likelihood of thermal damage, and is excellent for interrupted cutting.
PCD tools	Polycrystalline diamond tools are ideal for non-ferrous metals, composites, and abrasive materials.	High hardness and thermal conductivity are excellent for surface finish and unsuitable for ferrous materials.	Longer tool life, higher cutting speeds, improved productivity, minimal delamination, and fiber pull-out in composites.
CBN tools	Cubic boron nitride tools, designed for ferrous materials, have high thermal stability and wear resistance.	Effective for hardened steels, cast iron, and superalloys.	Higher cutting speeds, reduced cycle times, improved efficiency, excellent precision, and tool longevity in high-stress conditions.
Optimized rake angles	Improves chip formation, reduces cutting forces, and minimizes tool wear.	Positive rake angles for better shearing action.	Smoother cuts, better surface finishes, improved tool life, and reduced machining forces.
Variable helix angles	Reduces vibration and chatter during machining.	Varying helix angle along the cutting edge.	A more stable cutting process, better material removal rates, tool life, and surface quality are needed.
Micro-textured surfaces	Reduces friction and improves lubrication.	Microscopic patterns or textures on cutting surfaces.	Lower heat generation, higher machining efficiency, less tool wear, and better surface finishes.
Specialized edge preparations	Enhances durability and performance of cutting tools.	Techniques: Honing, chamfering.	Increased tool strength, resistance to chipping, reduced crack initiation, and improved reliability and performance for brittle materials.
Customized geometries	Tailored to specific applications for optimal performance.	Features: Complex groove designs, variable pitch, advanced chip breakers.	Enhanced performance, reduced tool wear, improved machining efficiency, and better suitability for specific material and process requirements.

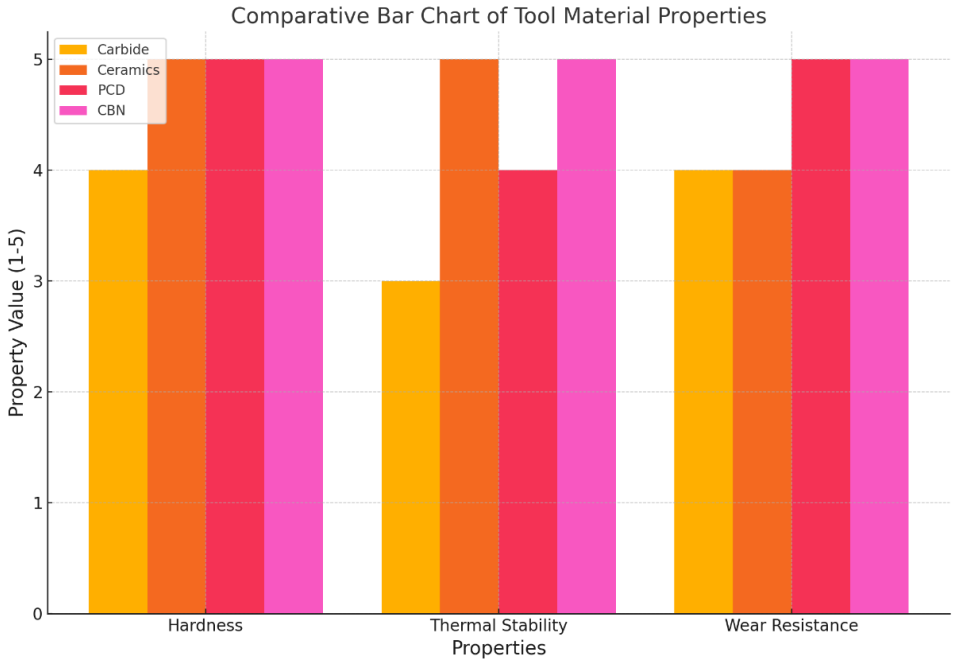

Fig. 2. Key properties of cutting tool materials.

The performance of carbide tools can be significantly enhanced by applying various coatings, improving wear resistance, thermal stability, and reducing friction. As illustrated in Fig. 3, different coatings like TiAlN, Titanium Carbonitride (TiCN), DLC, and AlCrN offer varying performance levels across these key metrics. Recognizing these variations is essential for choosing the most effective coating suited to the machining requirements.

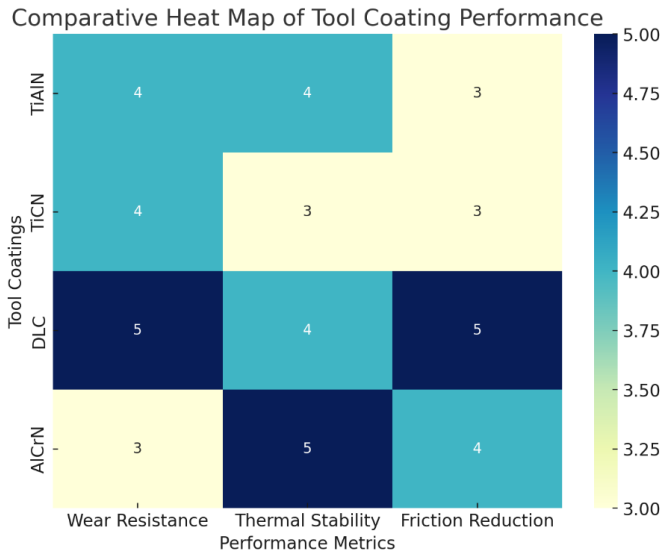

Fig. 3. Comparative heat map of tool coating performance.

Additionally, innovations in the microstructure and composition of cemented carbide tools have improved toughness and thermal cracking resistance. This includes the use of ultra-fine carbides that provide a balance between hardness and toughness and the incorporation of particular bonding phases to improve the overall performance of the tool.

2) Ceramic tools: Ceramic tools are highly effective at machining hard-to-cut items owing to their superior hardness, high-temperature stability, and wear and chemical erosion resistance. These tools are typically made of materials such as Silicon Carbide (SiC), Aluminum Oxide (Al2O3), and Silicon Nitride (Si3N4), which provide excellent mechanical properties even at elevated temperatures. This makes ceramic tools particularly suitable for high-speed machining applications where traditional tools may fail.

Ceramic tools can maintain hardness at temperatures that would soften other tool materials. This thermal stability enables higher cutting speeds and feeds, improving productivity while minimizing the thermal degradation of the workpiece. For example, silicon nitride-based ceramics are renowned for their toughness and resistance to thermal shock, enabling interrupted cutting operations.

Ceramic tools also benefit from advances in materials science, such as the development of whisker-reinforced ceramics. These materials contain silicon carbide whiskers in an aluminum oxide matrix, significantly improving fracture toughness and resistance to thermal shock. This makes them more robust under demanding machining conditions and extends their applicability to a wider range of hard-to-cut components.

However, ceramic tools' brittleness remains a challenge, as they are more prone to chipping and breaking under mechanical stress. To mitigate this, manufacturers have developed advanced tool geometries and surface treatments to improve the durability and performance of ceramic tools. For example, fine-grained ceramics and specially developed edge preparations help reduce the susceptibility to chipping.

3) Polycrystalline diamond and cubic boron nitride tools: PCD and CBN tools represent the pinnacle of cutting materials, distinguished by their exceptional hardness and wear resistance. These super-hard materials are specifically designed for the most demanding machining tasks with difficult-to-cut materials. PCD tools consist of fine diamond particles sintered in a metallic matrix under intense pressure and temperature. These tools have excellent thermal and hardness conductivity, providing excellent performance on non-ferrous metals, composites, and abrasive materials. The superior wear resistance of PCD tools enables longer tool life and higher cutting speeds, which translates into improved productivity and cost efficiency.

PCD tools are particularly effective in applications that require high surface quality, such as machining CFRP and aluminum alloys. Their ability to maintain sharp cutting edges ensures minimal delamination and fiber pull-out in composites while providing excellent surface finishes on metals. However, PCD tools are unsuitable for machining ferrous materials because chemical interactions at high temperatures lead to rapid tool wear. CBN tools are second only to diamonds in terms of hardness and are specifically designed for machining ferrous materials. CBN is synthesized by bonding cubic boron nitride grains with a ceramic or metallic binder. This creates a tool that can withstand extreme temperatures and maintain its cutting edge even under high-stress conditions.

CBN tools are particularly effective when machining hardened steels, cast iron, and superalloys. Their high thermal durability and abrasion resistance make them suitable for high-speed machining and finishing operations where precision and tool longevity are critical. CBN tools can operate at significantly higher cutting speeds than traditional carbide tools, reducing cycle times and improving overall efficiency. The development of advanced CBN grades and coatings has further enhanced their performance. These innovations have improved toughness and resistance to edge chipping, making CBN tools more versatile for a broader range of applications. In addition, new manufacturing techniques have enabled the production of CBN tools with complex geometries and expanded their applicability in precision machining.

B. Tool Geometries

Geometry affects the performance of cutting tools, particularly when dealing with hard-to-cut components. Advances in tool geometries have significantly improved cutting tool efficiency, precision, and life. Critical innovations in tool geometries include optimized rake angles, variable helix angles, and micro-textured surfaces designed to address specific machining challenges associated with difficult-to-machine materials. The rake angle of a cutting tool influences

chip formation, cutting forces, and heat generation. Optimized rake angles diminish cutting forces and minimize tool wear. Positive rake angles can improve the shearing action on difficult-to-cut metals, resulting in smoother cuts and better surface finishes. However, when choosing the rake angle, the sharpness must be balanced with the tool's strength to avoid premature failure.

Variable helix angles are designed to reduce vibration and chatter during machining, which is common when machining hard materials. By varying the helix angle along the cutting edge, these tools can disrupt the harmonic frequencies that cause chatter, resulting in a more stable cutting process. This improves surface quality, prolongs tool life, and results in higher material removal. Micro-textured tool surfaces are another significant advance in tool geometry. These tools have microscopic patterns or textures on their cutting surfaces to reduce friction and improve lubrication. The microtextures can serve as a reservoir for cutting fluids or can be used to break contact between the tool and the workpiece, thereby reducing heat generation and wear. This technology is particularly beneficial for machining difficult-to-machine materials where high temperatures and friction are a significant problem.

Edge preparation techniques such as honing and chamfering improve the durability and performance of cutting tools. For example, ground edges can improve tool strength and resistance to chipping, while beveled edges help reduce the formation of cracks in brittle tool materials such as ceramics and CBN. These unique edge treatments are tailored to the specific requirements of machining difficult-to-machine materials and ensure excellent reliability and performance. In addition to general advances, there is a growing trend toward customizing tool geometries for particular applications. This involves developing tools with unique features, such as complex groove design, variable pitch, and advanced chip breakers tailored to the particular requirements of the machining material and the machining process. Custom geometries can significantly increase performance, reduce tool wear, and improve machining efficiency.

IV. Machining Processes

Machining processes for hard-to-cut materials are constantly evolving to meet the unique challenges of these materials. Table III details that traditional machining methods, such as turning and milling, have been optimized with advanced techniques and technologies to increase their effectiveness. Non-conventional machining processes, including EDM, Laser Beam Machining (LBM), and USM, offer alternative approaches to achieving high precision and surface quality in these difficult-to-machine materials. Integration of these methods and innovations in machining strategies and process controls is essential to improving productivity, reducing tool wear, and ensuring the integrity of end components. This section covers conventional and non-conventional machining processes and highlights their applications, advantages, and advances.

The effectiveness of different machining processes in handling hard-to-cut materials varies significantly based on factors such as precision, surface finish, material removal rate, and tool wear. As shown in Fig. 4, conventional processes like turning and milling and non-conventional methods like EDM, LBM, and USM exhibit different strengths across these key metrics. Understanding these differences is crucial for selecting the appropriate machining process based on the specific material and application requirements.

TABLE III. Machining Processes for Hard-To-Cut Materials

Process	Description	Advantages	Limitations	Key Applications
Turning	Rotates the workpiece against a stationary cutting tool to remove material.	High precision, well-established, suitable for a variety of materials	Rapid tool wear, high cutting forces, heat generation	Aerospace, automotive, and biomedical components
Milling	Uses a rotating cutting tool to remove material from a stationary workpiece, creating complex geometries.	Versatile, high precision, capable of intricate details	High cutting forces, tool wear, heat generation	Aerospace, automotive, mold making, complex part manufacturing
EDM	Uses electrical discharges to erode the material, which is ideal for complex shapes and hard materials.	Precise, capable of intricate shapes, no mechanical stress	Slow process, limited to conductive materials, electrode wear	Turbine blades, injection molds, precision surgical instruments
LBM	Uses a focused laser beam to remove material, suitable for precise and complex shapes.	High precision, non-contact process, minimal heat-affected zone	High initial investment, material-specific challenges, potential thermal effects	Aerospace components, medical devices, microelectronic components, automotive parts
USM	Uses high-frequency ultrasonic vibrations with abrasives to remove material, which is effective for hard and brittle materials.	Non-thermal process, minimal mechanical stress, high precision	Slow material removal rate, tool wear, complex setup	Hard ceramic components, composite materials, precision surgical instruments, microelectronic components

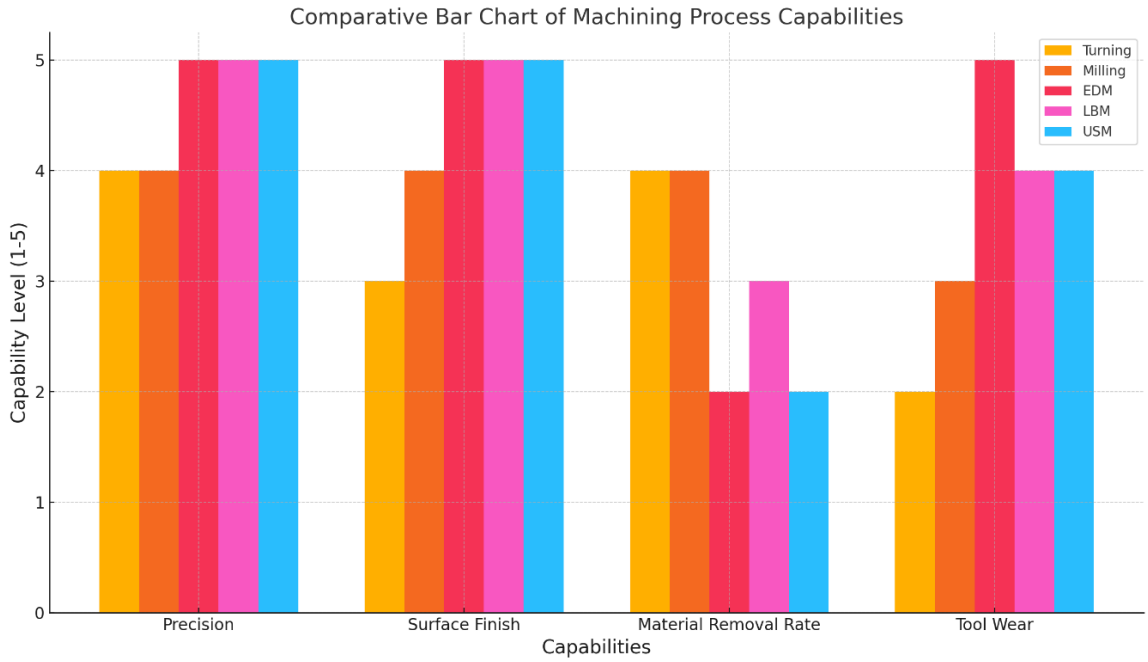

Fig. 4. Machining process capabilities.

A. *Conventional Machining*

1) Turning: Turning is a fundamental machining process often used to produce hard-to-cut materials. The workpiece is rotated against a stationary cutting tool, gradually removing material to achieve the desired shape and dimensions. While turning is a well-established process, machining difficult-to-machine materials such as titanium alloys, nickel-based superalloys, ceramics, and composites presents unique challenges that require specialized approaches and advanced technologies.

Turning hard-to-cut materials often leads to problems such as rapid tool wear, high cutting forces, and elevated temperatures in the cutting zone. These challenges can impact the surface finish, dimensional accuracy, and overall efficiency of the machining process. For example, the low thermal conductivity of titanium alloys causes heat to concentrate at the cutting edge, accelerating tool wear and potentially damaging the workpiece. Similarly, the work-hardening property of nickel-based superalloys increases cutting resistance, making it challenging to maintain tool sharpness and precision.

To overcome these challenges, using advanced tool materials and coatings is essential. Carbide tools with special coatings such as TiAlN and AlCrN offer improved wear resistance and thermal stability. Ceramic tools, known for their hardness and heat resistance, are also used for turning high-temperature materials. PCD and CBN tools are increasingly used due to their exceptional hardness and ability to maintain sharp edges, particularly in finishing operations.

Choosing the proper cutting parameters is crucial for successfully turning hard-to-cut materials. This includes optimizing cutting speed, feed rate, and depth of cut to balance tool life and machining efficiency. Lower cutting speeds are often used to reduce heat generation, while appropriate feed rates help control cutting forces and achieve a desired surface finish. High-pressure coolant systems effectively dissipate heat and lubricate the cutting zone, extending tool life and improving machining performance.

Innovative turning techniques such as multi-axis turning and high-speed turning have been developed to improve the performance and flexibility of the process. Multi-axis turning allows more complex geometries to be machined with greater precision and fewer setups. High-speed turning, made possible by advances in machine tool technology, helps reduce machining time and improve surface quality by operating at higher spindle speeds and feed rates. The integration of tool condition monitoring systems is becoming increasingly important. These systems use sensors and data analytics to monitor tool wear and predict failures, enabling timely tool changes and minimizing downtime. This real-time monitoring helps maintain consistent quality and improves overall process reliability.

2) Milling: Milling is a versatile machining process for shaping and contouring hard-to-cut materials. In milling, a rotating cutting tool removes material from a stationary workpiece, allowing the creation of complex geometries, slots, and intricate details. Despite its versatility, milling hard-to-cut materials such as titanium alloys, nickel-based superalloys, ceramics, and composites presents significant challenges due to their inherent properties.

Milling these materials requires high cutting forces, rapid tool wear, and significant heat generation. The brittleness of

ceramics and composites further complicates the process and increases the risk of chipping and delamination. Materials such as titanium and nickel-based superalloys have low thermal conductivity, resulting in heat concentration at the cutting edge, increasing tool wear, and compromising surface integrity.

To overcome these challenges, advanced tool materials such as carbide, ceramic, PCD and CBN are used. Carbide tools with special coatings such as TiAlN and DLC increase wear resistance and reduce friction, improving tool life and performance. Ceramic tools are ideal for high-speed milling operations due to their high hardness and thermal stability. PCD and CBN tools offer excellent edge retention and are particularly suitable for finishing operations in hard and abrasive materials.

The selection of suitable milling parameters is crucial for the efficient machining of hard-to-cut materials. This includes optimizing spindle speed, feed rate, and cut depth to balance tool life and machining efficiency. High-speed milling techniques coupled with advanced toolpath strategies help reduce cycle times and improve surface quality. Adaptive control systems and real-time monitoring further improve process stability and tool performance.

Innovative techniques such as trochoidal and high-feed milling were developed to meet the specific challenges of hard-to-cut materials. Trochoidal milling is a circular tool path that shortens the time the tool engages with the material, minimizing heat generation and tool wear. In high-feed milling, however, shallow cutting depths are used with high feed rates, which distributes the cutting forces more evenly and extends tool life.

Adequate coolant and lubrication strategies are essential when milling hard-to-cut materials to regulate heat and reduce friction. High-pressure coolant systems, cryogenic cooling, and Minimum Quantity Lubrication (MQL) techniques improve heat dissipation, tool life, and better surface finishes. These cooling methods are particularly beneficial for maintaining the tool's and the workpiece's structural integrity.

Implementing tool condition monitoring systems in milling operations enables real-time tool wear and performance assessment. These systems can use sensors and data analysis to predict failures and optimize tool change intervals, minimizing downtime and ensuring consistent machining quality. This proactive approach increases overall process reliability and efficiency.

B. Non-Conventional Machining

1) Electrical discharge machining: EDM is an unconventional process that has become an important method for machining hard-to-cut materials. EDM uses electrical discharges or sparks to remove material from the workpiece. This enables precise machining of complex geometries and hard materials that are difficult to machine using traditional methods. This process is particularly effective for hardened steels, superalloys, and conductive ceramics.

EDM works on the principle of spark erosion. The workpiece and electrode are immersed in a dielectric fluid, usually deionized water or oil. When a voltage is applied, a spark discharge occurs in the small gap between the electrode and the workpiece, generating intense heat (up to 12,000 °C) that melts and vaporizes a small portion of the workpiece material. The dielectric fluid cools and washes away the eroded particles, providing a clean machining environment.

There are two main types of EDM: wire EDM and die-sinking EDM. Wire EDM uses a thin, electrically conductive wire as an electrode to cut through the workpiece, making it ideal for producing intricate shapes and fine details. Die-sinking EDM, on the other hand, uses a pre-formed electrode to create cavities and complex contours in the workpiece, and it is commonly used in mold and die-making.

EDM offers several advantages when machining hard-to-cut materials. It can produce complicated shapes and high-precision components with excellent surface finish, regardless of the material's hardness. The absence of mechanical forces during machining eliminates problems related to tool wear and deformation common in traditional machining processes. EDM is also suitable for processing heat-treated materials without causing thermal deformation or internal stresses.

Despite its advantages, EDM has certain limitations. The process is relatively slow compared to traditional machining methods and is less suitable for mass production. In addition, EDM is limited to electrically conductive materials, which limits its scope. Electrode wear can also be a problem and requires frequent replacement and careful selection of electrode materials.

Recent advances in EDM technology focus on improving process efficiency, precision, and surface quality. Innovations such as high-speed EDM, multi-axis EDM, and adaptive control systems have improved the capabilities of EDM. High-speed EDM machines utilize advanced power and control systems to increase material removal rates and reduce machining time. Multi-axis EDM enables more complex geometries and greater accuracy by allowing simultaneous movements along multiple axes. Adaptive control systems optimize machining parameters in real time, improving process stability and tool life.

EDM is widely used in the aerospace, automotive, medical, and tool and mold industries. It is particularly valuable for producing components with complicated geometries, fine features, and high surface quality requirements. Typical applications include turbine blades, injection molds, and precision surgical instruments, whereas traditional machining methods are inadequate in accuracy and material integrity.

2) Laser beam machining: LBM is a high-precision, non-conventional machining process that uses a focused laser beam to remove material from the workpiece. This process is particularly effective for machining hard-to-cut materials such

as ceramics, superalloys, and composites, which are challenging to machine using traditional methods. LBM offers significant advantages in precision, flexibility, and the ability to machine complex shapes without direct contact with the workpiece.

With LBM, a high-energy laser beam is directed onto the surface of the workpiece. The intense energy of the laser beam heats, melts, and vaporizes the material in the target area. The material removal process is highly localized, minimizing the Heat-Affected Zone (HAZ) and reducing the risk of thermal deformation. Different lasers, such as CO2, Nd, and fiber, are used depending on the material and specific application requirements. Laser beam processing offers several notable advantages:

- Precision and accuracy: LBM can produce extremely fine features and intricate geometries with high precision and repeatability.
- Non-contact process: The lack of physical contact between the tool and the workpiece eliminates mechanical stresses and tool wear, enhancing the machining of brittle and hard materials.
- Minimal heat-affected zone: The localized nature of the laser beam minimizes thermal damage to surrounding material, maintaining the integrity and properties of the workpiece.
- Versatility: LBM can machine a wide range of materials, including metals, ceramics, polymers, and composites, making it suitable for various industrial applications.
- Despite its advantages, LBM also has some limitations:
- High initial investment: The cost of laser machining equipment can be significant, making it a considerable investment for manufacturers.
- Material-specific challenges: Different materials absorb laser energy differently, which can affect the efficiency and quality of the machining process. Optimizing parameters for each material is crucial.
- Thermal effects: Although minimal, there is still a risk of thermal effects such as micro-cracking or changes in material properties, particularly in sensitive materials.

Advances in laser technology have significantly improved the capabilities of LBM. High-power and ultra-short pulse lasers like femtosecond have improved material removal rates and machining precision. These lasers produce extremely short bursts of energy, minimizing heat diffusion and reducing the heat-affected zone. Beam delivery systems and control software advances have enabled more complex and precise machining operations. Due to its precision and versatility, LBM is widely used in various industries. Key applications include:

- Aerospace: Machining of turbine blades, intricate cooling channels, and other high-performance components made from superalloys and composites.
- Medical Devices: Manufacturing of precision surgical instruments, implants, and medical device components that require high accuracy and surface quality.
- Electronics: Fabrication of microelectronic components, Printed Circuit Boards (PCBs), and Micro-Electromechanical Systems (MEMS).
- Automotive: Production of precise components and tooling for high-performance engines and lightweight structures.

3) Ultrasonic machining: USM is an unconventional process that uses high-frequency ultrasonic vibrations to remove material from a workpiece. This technique is particularly effective for machining hard and brittle materials such as ceramics, glass, and advanced composites. USM offers significant advantages in precision, surface quality, and the ability to machine complicated shapes without substantial thermal or mechanical stress.

USM uses a tool vibrating at an ultrasonic frequency (typically 20 to 40 kHz) to strike abrasives onto the workpiece. The tool does not directly contact the workpiece but transfers energy through the abrasive particles suspended in the slurry. These particles act as cutting materials and erode the material from the workpiece through a combination of mechanical action and micro-chipping. The ultrasonic vibrations increase the effectiveness of the abrasive particles and lead to efficient material removal with minimal effort. USM offers several key advantages:

- Non-thermal process: USM does not generate significant heat during machining, eliminating thermal damage and preserving the workpiece's material properties.
- Minimal mechanical stress: The low amplitude vibrations used in USM induce minimal mechanical stress, reducing the risk of cracks and defects, especially in brittle materials.
- High precision and surface finish: USM can achieve high precision and excellent surface finishes, making it suitable for intricate and delicate components.
- Versatility: USM can machine various materials, including hard metals, ceramics, glass, and composites, offering broad applicability across different industries.

Despite its advantages, USM also faces some limitations:

- Slow material removal rate: Compared to other machining methods, USM has a relatively slow material removal rate, which can limit its application in high-volume production.
- Tool wear: The process's abrasive nature can lead to significant tool wear, necessitating frequent tool maintenance and replacement.

- Complex setup: The setup and maintenance of ultrasonic machining equipment require skilled operators and precise control systems.

Recent advances in ultrasonic machining have focused on improving process efficiency and expanding its applications. Innovations like multi-frequency ultrasound systems and hybrid machining processes have improved material removal rates and tool life. Hybrid processes that combine ultrasonic machining with other techniques, such as EDM or laser machining, leverage the strengths of both methods to achieve excellent results. Additionally, advancements in tool materials and abrasive slurries have improved performance and reduced wear. Due to its precision and ability to machine hard materials, ultrasonic machining is widely used in various industries. Key applications include:

- Aerospace: Machining of hard ceramic components, composite materials, and intricate features in high-performance parts.
- Medical devices: Manufacturing precision surgical instruments, dental tools, and medical implants that require high accuracy and smooth surfaces.
- Electronics: Fabrication of microelectronic components, optical devices, and advanced materials used in electronic packaging.
- Tool and die making: Production of complex molds, dies, and wear-resistant components from hard and brittle materials.

V. Conclusion

Precision machining of hard-to-cut materials remains a critical challenge and opportunity in modern manufacturing, driven by the need for high-performance components in the aerospace, automotive, biomedical, and electronics industries. This survey provided a comprehensive overview of the current state of precision machining techniques, focusing on conventional and non-conventional methods and highlighting advances in cutting tools, machining processes, and new technologies. Advances in cutting tool materials such as carbide, ceramic, PCD, and CBN have significantly improved the machinability of hard-to-cut materials by extending tool life, reducing wear, and enabling higher machining speeds. Innovative tool geometries and coatings also contribute to the efficiency and precision of the machining processes. Traditional machining methods, including turning and milling, have evolved with optimized cutting parameters, advanced cooling strategies, and real-time monitoring systems to meet the unique challenges of these materials. Meanwhile, unconventional machining techniques such as EDM, LBM, and USM offer alternative solutions for achieving high precision and complex geometries without causing thermal or mechanical damage.

Integrating digital technologies, including IoT, AI, and big data analytics, transforms precision machining and enables smarter, more efficient, and more adaptable manufacturing processes. These technologies improve process monitoring, predict tool wear, and optimize machining parameters in real time, improving productivity and quality. Future research and development should address the remaining challenges in precision machining, such as reducing tool wear, improving surface integrity, and developing more sustainable machining processes. Innovations in hybrid manufacturing processes and the continued development of digital and intelligent manufacturing technologies will play a critical role in overcoming these challenges and pushing the boundaries of what is possible when machining difficult-to-machine materials.

Analyzing VGG-19's Bias in Facial Beauty Prediction: Preference for Feminine Features

Nuno Fernandes[1], Sandra Soares[2], Joana Arantes[3]
School of Psychology, University of Minho, Braga, Portugal[1, 3]
Department of Education and Psychology, University of Aveiro, Aveiro, Portugal[2]

***Abstract*—From an evolutionary perspective, sexual dimorphism has been linked to perceived attractiveness, with masculine traits preferred in men and feminine traits in women. Moreover, symmetry is a strong predictor of facial attractiveness across both sexes. Recent advancements in the field of artificial intelligence have enabled algorithms to accurately predict facial attractiveness. This study aims to investigate whether these algorithms accurately replicate human judgments of attractiveness. We hypothesized that sexually dimorphic manipulations (masculinized men and feminized women) (H1), as well as symmetrized versions (H2), would elicit higher attractiveness ratings from a facial beauty prediction algorithm. Employing transfer learning, we trained six deep-learning models using four facial databases with attractiveness ratings (*n* = 6848). The top-performing model, VGG-19, demonstrated a high prediction correlation of .86 on the test set. Surprisingly, our findings revealed an interaction effect between sex and sexual dimorphism. Feminized versions of both men's and women's faces obtained higher attractiveness ratings than their masculinized counterparts. For symmetry, our results indicated that symmetrized faces were perceived as more attractive, albeit exclusively among women. These findings offer novel insights into the understanding of facial attractiveness from both algorithmic and human behavioral perspectives.**

***Keywords*—Deep learning; facial attractiveness; sexual dimorphism; symmetry; VGG-19**

I. Introduction

What makes a pretty face? The study of facial attractiveness is a multidisciplinary field that draws on knowledge from diverse disciplines, such as psychology, sociology, anthropology, and computer science [1-3]. Researchers in these disciplines employ diverse methods and approaches to explore the factors that contribute to facial attractiveness and its impact on social interactions and relationships.

In psychology, researchers investigate how people perceive and evaluate facial attractiveness, as well as the cognitive and neural mechanisms underlying this process [3]. They also explore the relationship between facial attractiveness and social cognition, such as the formation of impressions and romantic relationships [4-5]. Studies have shown that humans prefer associating with, dating, and mating with individuals considered facially attractive [6-8]. Additionally, attractive people tend to be perceived as more successful, enjoyable, and intelligent than unattractive people [4]. Specifically, research on human preferences for sexually dimorphic faces has garnered significant attention [9-10]. Sexual dimorphism in facial attractiveness refers to the physical differences in facial features that are considered more attractive in men and women. These differences in facial attractiveness are thought to be influenced by both evolutionary and cultural factors [see [11] for a comparison across five populations].

In sociology and anthropology, researchers explore how facial attractiveness and sexual dimorphism are related to cultural norms and values and how they shape social interactions regarding social status, power, and privilege [1]. Cross-cultural studies suggest a high consensus in facial attractiveness judgments across different populations [12-13]. However, research also indicates that cultural factors can shape perceptions of facial attractiveness, with different societies having distinct standards for what is considered attractive [14].

In computer science, computer vision researchers study how to create algorithms and models to predict facial attractiveness [2]. Explaining the functioning of deep learning models has recently gathered increasing attention from researchers and the wider public, including regulators and politicians [15-16]. While attractiveness prediction is of great use for the human-computer interaction field, it also raises significant moral and ethical questions. One of the primary concerns is whether beauty prediction algorithms reveal human-like psychophysical biases [17-18]. The study in [17] found that machine judgments of attractiveness displayed a preference for averaged faces and symmetrical faces, mirroring human judgments of attractiveness [19-20]. Additionally, the prediction of facial attractiveness holds clinical significance, particularly in the realm of plastic surgery [21-23]. To gain a comprehensive understanding of the complex issue of facial attractiveness, advancements in facial beauty prediction algorithms offer valuable insights. Furthermore, incorporating input from cognitive scientists in experimental design can enhance our understanding, especially in uncovering the decision-making processes behind algorithmic outputs.

A. Sexual Dimorphism and Attractiveness

From an evolutionary standpoint, males and females have evolved unique differences in their secondary sexual characteristics over time [24]. The development of more pronounced sexual dimorphic phenotypes – feminine traits for women and masculine traits for men – is considered attractive [9, 25], because it implies the inheritance of advantageous

genes favorable to offspring survival or reproductive success [26-27].

Evolutionary theories suggest that preferences for sexually dimorphic traits are associated with specific mating functions. For example, men may possess facial characteristics to indicate strength and dominance, such as an enlarged brow ridge, a thicker jawline, and a wider face [28]. Dominant men are considered more attractive by women [29-30], as they often achieve higher social status, thereby enhancing their capacity to provide essential resources for reproduction [31]. Additionally, masculinity is desirable as it signals higher testosterone levels [14, 32]. Since testosterone is immunosuppressive, compromising the body's ability to fight infections [33], only men with high genetic quality and robust immune systems can afford to invest in secondary sexual traits [34-35]. Therefore, men with more masculine traits are often perceived as healthier [36-37], and more attractive to potential mates [38-40].

Conversely, women may signal youth and fertility [41]. Feminine facial traits, such as a smaller jawline and a narrower face [26], indicate higher levels of estrogen, which correlate with superior reproductive qualities [42] and mating desirability [9, 25]. For instance, research has shown that both men and women rated photographs of women's faces captured during the fertile window of the menstrual cycle (late follicular) as more appealing compared to photographs taken during the non-fertile (luteal) phase [43]. Similarly, [44] explored the impact of facial shape transformations towards late follicular and luteal prototypes on male perceptions of attractiveness. Their findings revealed a distinct preference for faces resembling the late follicular phase, suggesting that subtle shape differences can sway men's preferences depending on a woman's menstrual cycle phase. During the late follicular period, a peak of estrogen and luteinizing hormone (LH) leads to ovulation and is followed by a rise in progesterone in the luteal phase [45-47]. This increased attractiveness may serve as an adaptive mechanism to enhance a female's perceived value in the mating pool during the phase of the cycle when the likelihood of conception is at its peak [43]. Ultimately, the preference for women's feminine facial features remains robust across the literature [10, 48-52].

B. Algorithms and Attractiveness

Early approaches to quantifying facial attractiveness were grounded in the notion that specific ratios and proportions of facial features are more appealing [17, 53-54] For example, the "golden ratio" or "phi" (1.618) has been used to measure facial proportions and attractiveness [56]. The idea is that if specific facial ratios, such as the distance between the eyes and the distance between the mouth and eyes, conform to phi, the face is more attractive. However, contemporary computer-based methods, including machine learning and deep learning algorithms, have shown more promising outcomes.

Machine learning offers a method that can be used to predict facial attractiveness by analyzing patterns in predefined facial features known to be associated with attractiveness [17, 53-54]. These models assess multiple hand-crafted features, such as symmetry, geometric ratios, and distances between landmarks. Another approach uses deep learning algorithms, such as Convolutional Neural Networks (CNNs), which also predict facial attractiveness. One advantage of CNNs is that they do not require pre-defined facial attributes, as they can extract useful features directly from raw images. Consequently, these models have achieved a relatively high correlation with the actual judgments of attractiveness [56-58].

Furthermore, leveraging transfer learning eliminates the need to develop an algorithm from the ground up, as it allows for the use of pre-existing models trained on large datasets, such as architectures from the Visual Geometry Group Network (VGG; [59]) or residual networks (ResNet) ([60]). Although these models were initially designed for image classification tasks, they can be fine-tuned for facial beauty prediction [61-63]. The fine-tuning process involves adjusting the model's parameters to better fit the new task, typically by training the final layers of the model on the new dataset. Once the model is fine-tuned, it can predict the attractiveness of new facial images. This approach has been widely used in attractiveness prediction tasks as it saves computational time and resources while improving performance [61-63].

The benchmark for training and evaluating facial beauty prediction algorithms is the SCUT-FBP5500 [64], with cutting-edge models achieving a Pearson correlation of .93 with human judgments of attractiveness [57]. However, despite the large number of images (n = 5500), attractiveness ratings were performed only by Asian raters. Therefore, this could be a potential limitation for generalizing the beauty prediction algorithms. Additionally, the high accuracy observed could be attributed to greater internal consistency in attractiveness judgments within the Asian population [10].

C. The Present Study

Despite significant advancements in facial beauty prediction algorithms, a gap remains in the literature regarding how these algorithms make their decisions. The main objective of this study is to investigate whether beauty prediction algorithms replicate human biases toward sexually dimorphic facial traits. We hypothesize that sexually dimorphic versions of male (masculinized) and female (feminized) facial images will be perceived as more attractive (H1). Moreover, we will manipulate symmetry, which is a well-established predictor of facial attractiveness [19,65-67]. We expect that symmetrized facial images of both men and women will be rated as more attractive (H2). Our secondary aim is to provide a benchmark for facial attractiveness prediction using multiple databases. This novel approach aims to enhance our understanding of how facial beauty prediction algorithms assess attractiveness and whether they support the sexual dimorphism and symmetry hypotheses.

II. METHOD

A. Materials

1) Databases: For the transfer learning phase, four databases were used: SCUT-FBP5500 [64]; Chicago Face Database (CFD) [68]; Karolinska Directed Emotional Faces (KDEF) [69]; and FACES [70], resulting in a total of 6,848 images. Attractiveness ratings across all datasets were

normalized to a scale from 0 to 1. An additional database, the Face Research Lab London (FRL-London; [71]), was used to create sexually dimorphic and symmetrized versions of faces, which were then evaluated for facial attractiveness by the trained model. Following common preprocessing practices for image data in deep learning tasks [59-60] pixel values were rescaled to the range of (0, 1) by dividing each pixel intensity value by 255. This normalization step ensures that the input features are appropriately scaled and facilitates efficient training of machine learning models, particularly neural networks, by mitigating issues such as vanishing or exploding gradients [72-73].

The SCUT-FBP5500 [64] dataset consists of 5500 frontal face images, including 2000 Asian females, 2000 Asian males, 750 Caucasian females, and 750 Caucasian males. Most of the faces have neutral expressions and simple backgrounds. The faces in the dataset were labeled with attractiveness ratings from 1 to 5 by 60 Asian raters aged 15 to 60.

The Chicago Face Database (CFD) [68] consists of 970 facial images displaying neutral, happy, threatening, and fearful expressions. The 158 volunteers who photographed included 37 Black males, 48 Black females, 36 White males, and 37 White females, ranging in age from 18 to 40 years. A sample of 1,087 raters made subjective ratings of the image's attractiveness on a 1–7 Likert scale, with each subject rating only 15 faces. Participants included 552 females, 308 males, and 227 who preferred not to disclose their gender, with an average age of 26.75 (SD_{age} = 10.54). They came from diverse racial backgrounds: 516 White, 117 Asian, 74 Black, 72 biracial or multiracial, 57 Latino, 18 other, and 233 who did not report their race.

The Karolinska Directed Emotional Faces (KDEF) [69] is one of the most widely used databases of human facial expressions. [74] presented subjective attractiveness ratings for a subset of 210 pictures from 70 Caucasian amateur actors (35 women and 35 men, aged between 20 and 30 years) with different facial expressions: angry, happy, and neutral. The sample of raters included 155 students from Portuguese universities (83.20% female; M_{age} = 23.73; SD_{age} = 7.24). Each participant rated the facial attractiveness of 36 pictures on a 1-7 Likert scale.

The FACES [70] is a set of facial images from 171 women and men categorized into three age groups: young (n = 58; age range: 19–31; M_{age} = 24.3; SD_{age} = 3.5), middle-aged (n = 56; age range: 39-55; M_{age} = 49.0; SD_{age} = 3.9), and older (n = 57; age range: 69-80; M_{age} = 73.2; SD_{age} = 2.8). Each individual displays six facial expressions: neutrality, sadness, disgust, fear, anger, and happiness, resulting in a total of 1026 pictures. Facial attractiveness evaluations were performed by 154 raters, all of whom were Caucasian and German. Each participant was randomly assigned to either set A or set B, which consisted of identical pictures of the same subjects and facial expressions, with only minor differences (e.g., head inclination angle). For the present work, only set A was considered. Each image was rated by a minimum of 8 and a maximum of 14 raters per age group by gender. Therefore, six attractiveness ratings were provided in the metadata of the original work. In our case, we used the average of these ratings on a scale from 1 to 100.

The Face Research Lab London (FRL-London) was chosen for the sexual dimorphic transformations [71], which consists of 102 neutral front faces (male = 52; female = 50; M_{age} = 26.9; SD_{age} = 7.07) from different ethnicities (69 White, 13 Black, and 20 Asian). We used only 100 photos from this database due to problems manipulating two male images (codes 005_03 Asian and 114_03 Black), resulting in an equal number of male and female facial images. This dataset included pre-delineated face shape templates of 189 coordinates for each image. Attractiveness ratings (on a 1-7 scale) were made by 2,513 people (age range: 17-90).

2) Algorithms: A set of six facial recognition models was used to determine which of these models would be the most adequate for facial attractiveness prediction. The selected models were: InceptionResNetV2 [75], MobileNetV2 [76], EfficientNetV2B0 [77], ResNet50 [60], Xception [78], and VGG-19 [59].

B. Procedure

The procedure was divided into three phases. Initially, we employed a transfer learning methodology across a range of models, followed by fine-tuning the one that yielded the most favorable results. In the second phase, we applied sexual dimorphic and symmetrical transformations of the images from the FRL-London dataset for further evaluation. Finally, we utilized the fine-tuned model to predict the facial attractiveness of the original, sexually dimorphic, and symmetrized versions of both female and male facial photos.

1) Transfer learning: We selected a set of six commonly used architectures with pre-trained weights for image classification problems from the Keras Applications Module: tf.keras.applications [79]. Then, we applied transfer learning to each model to predict facial attractiveness, similar to previous studies [61-63]). This involved freezing all layers except the last one, and transforming the initial classification problem into a regression problem by incorporating a final dense layer.

The models were trained for 100 epochs with patience set to 30 epochs, using the Adam optimizer with a learning rate of 0.001 and weight decay of 0.004. Adam is an "algorithm for first-order gradient-based optimization of stochastic objective functions, based on adaptive estimates of lower-order moments" [80]. A train/validation/test split of 60/20/20 size was used, resulting in 4110/1369/1369 images for the corresponding set. The model with the best results was the VGG-19 with a Pearson's correlation of .76 (*RMSE* = 0.094; *MAE* = 0.07).

The VGG-19 belongs to a series of deep neural networks from the Visual Geometry Group Network (VGG), also including VGG-11, VGG-13, and VGG-16 ([59]). These networks share their structure by having several blocks of convolutional layers connected to a final block consisted of three fully connected layers. The VGGNet has been trained on over one million images in 1000 classes [59]. Specifically,

VGG-19 has five blocks of convolution layers and one last block of three fully connected layers. A 3x3 Max Pooling layer connects all blocks. The first (size 64x64x64) and second (size 128x128x128) blocks have two convolutional layers, while the third (size 256x256x256), fourth (size 512x512x512) and fifth (size 512x512x512) blocks have four convolutional layers. Since VGG-19 showed the best performance for predicting facial attractiveness compared to the other architectures, we fine-tuned this model.

Therefore, we unfroze the 3-fully connected layers, whereas in the previous phase only the last regression layer was trainable. We used the same hyperparameters and train/validation/test sets. The model's performance on the test set increased from a Pearson's correlation of .76 to .84 (*RMSE* = 0.12; *MAE* = 0.10). Finally, we fine-tuned the model with the best parameters by unfreezing all the model's layers. We set the training for 10 epochs (patience of 5), using Adam optimizer with a learning rate of 0.00001 and weight decay of 0.004, to prevent overfitting [see [81] for a revision on hyperparameter optimization for fine-tuning]. A final correlation of .86 ($p < .001$) was achieved between the model's predictions and the test set (*RMSE* = 0.10; *MAE* = 0.08).

2) Image preprocessing: To achieve sexual dimorphic and symmetric transformations, we used the FRL-London [71] database. All image manipulations were performed using computer vision techniques provided by the Psychomorph software [82] and its web-based version, WebMorph [83]. Following previous research [52, 84-85], sexually dimorphic versions of each image were created using a 50% spatial linear transformation towards either a female avatar (feminized version) or a male avatar (masculinized version). The avatars (average faces) were generated by averaging 30 male faces (male avatar) and 30 female faces (female avatar). Additional information regarding theses methods can be found in [86]. Symmetrized versions of both the original and manipulated photos (feminized and masculinized faces) were created by mirror reversing the image and then combining one side of the original non-symmetrized photo with the opposite side of the reversed photo [67, 87].

3) Data analysis: The algorithm's prediction of attractiveness was used as the dependent variable in a linear mixed-effects model (LME) with three fixed main effects: sexual dimorphism manipulation (masculinized/feminized), symmetry (original/symmetric), and sex (male/female), along with the three-way interaction term. The photo's code was included as a random factor with varying intercepts to account for individual differences in attractiveness, as the model predicted attractiveness for multiple versions (sexually dimorphic and symmetric transformations) of the same individual [see [88] for a detailed explanation on LME models]. A post-hoc analysis using Bonferroni adjustment was performed for the observed significant effects. All statistical analyses were conducted using R Statistical Software (v4.3.1; [89]) using lme4 (v.1.1.34; [90]) and ggplot2 (v.3.4.4.9000; [91]) for plotting. The data and reproducible code are publicly available at [92].

III. RESULTS

The LME (estimated using REML) was composed of both main effects (sexual dimorphism manipulation, symmetry, and sex) and its three-way interaction term (Fig. 1). The model included the image's code as a random factor. The model's total explanatory power was substantial (conditional $R^2 = .93$), and the part related to the fixed effects alone (marginal R^2) was equal to .33. The model showed a statistically significant main effect of sexual dimorphism, $F(2, 490) = 64.02$, $p < .001$, symmetry, $F(2, 490) = 32.07$, $p < .001$, and sex, $F(1,98) = 49.74$, $p < .001$. For the interaction terms, the two-way interaction of sexual dimorphism by symmetry manipulation was shown to be statistically significant, $F(2,490) = 5.40$, $p = .005$, while the two-way interaction of sexual dimorphism and sex, $F(2,490) = 2.73$, $p = .066$, or the triple interaction of sexual dimorphism*symmetry*sex, $F(2,490) = 0.91$, $p = .40$, showed no significant results.

Post-hoc analysis using Bonferroni correction showed that feminized faces were rated as more attractive for both male and female images (H1). In the non-symmetric condition, feminized females were judged as more attractive than masculinized females, $t(490) = 4.41$, $p < .001$, 95% CI [0.01, 0.02], $d = 0.88$, as well as in the symmetric condition, $t(490) = 5.44$, $p < .001$, 95% CI [0.01 0.02], $d = 1.09$. Also, feminized males in the non-symmetric condition were rated as more attractive than masculinized ones, $t(490) = 5.47$, $p < .001$, 95% CI [0.01, 0.02], $d = 1.09$, as well as in the symmetric condition, $t(490) = 6.34$, $p < .001$, 95% CI [0.01 0.03], $d = 1.27$. Additionally, feminized manipulations were perceived as more attractive than the original faces for all conditions, except for females in the non-symmetrized version, $t(490) = 0.77$, $p = 1$, 95% CI [-0.01, 0.01], $d = 0.15$. Similarly, no differences were found between the masculinized versions and the original faces, except for that condition in which masculinized female photos were judged as less attractive than the original ones in the non-symmetrized versions, $t(490) = -3.64$, $p = .007$, 95% CI[-0.02, -0.01], $d = -0.73$.

For the symmetry main effect that was observed (H2), post-hocs revelated that symmetrized versions were only more attractive for feminized female faces, $t(490) = 4.43$, $p < .001$, 95% CI [-0.02, -0.01], $d = 0.89$, and masculinized female faces $t(490) = -3.41$, $p = .02$, 95% CI [-0.02, -0.01], $d = 0.58$, in comparison with the non-symmetrized ones. No differences were observed for males or between original photos.

Finally, supporting the sex main effect, in the non-symmetrized condition, feminized females were perceived as more attractive than feminized males, $t(118) = 6.12$, $p < .001$, 95% CI [0.03, -0.08], $d = 3.71$, with the same occurring for masculinized versions, $t(118) = 6.47$, $p < .001$, 95% CI [0.03, 0.08], $d = 3.92$, and original faces, $t(118) = 7.28$, $p < .001$, 95% CI [0.04, 0.09], $d = 4.42$. In the symmetrized condition, the same pattern was found, with feminized female photos being rated as more attractive than feminized male photos, $t(118) = 6.61$, $p < .001$, 95% CI [0.03, 0.08], $d = 4.01$, as well as masculinized versions, $t(118) = 6.90$, $p < .001$, 95% CI

[0.03, -0.09], d = 4.19, and original ones, $t(118) = 6.98$, $p < .001$, 95% CI [0.03, 0.09], d = 4.23.

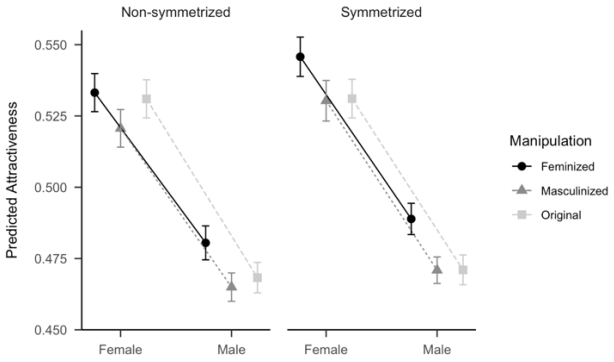

Fig. 1. The attractiveness ratings of VGG-19.

IV. DISCUSSION

The main aim of the present study was to investigate whether beauty prediction algorithms replicate human judgments concerning facial sexually dimorphic traits. We hypothesized that sexually dimorphic versions of male (masculinized) and female (feminized) facial pictures would be rated as more attractive (H1). Also, we expected that symmetrized versions of both male and female facial pictures would be perceived as more attractive (H2). Additionally, we aimed to provide a benchmark for facial attractiveness prediction using multiple databases.

The fine-tuned model was used to predict the attractiveness of symmetrized and non-symmetrized versions of masculinized, feminized, and original frontal facial images with neutral expressions from the FRL-London database. Surprisingly, our results showed that feminized manipulations were rated as more attractive compared to the masculinized versions for both male and female faces. Thus, we partially confirmed our first hypothesis (H1), as we expected a sexual dimorphism main effect, with feminized versions being preferred for females, but not for males. Moreover, despite the observed main effect of symmetry, post-hoc analyses suggested that symmetry increased facial attractiveness specifically for feminized and masculinized versions of female faces. Thus, the data also partially supported our second hypothesis (H2). Additionally, across all conditions, females were consistently rated as more attractive than males.

We achieved a Pearson correlation of .86 with the fine-tuned VGG-19 on the test set across four databases. Although slightly lower than state-of-the-art results (e.g., [57] with r = .93), our approach addresses a key limitation by reducing bias from relying solely on the SCUT-FBP5500 dataset. This offers a valuable benchmark for facial beauty prediction, encouraging future research to explore and improve on these findings.

A. Theoretical Implications

Firstly, our work contributes to understanding how facial beauty prediction algorithms make decisions. The consistent overall preference for feminine facial traits suggests that beauty prediction algorithms can implicitly learn human attractiveness preferences, like [17] findings. More recently, [18], using the VGG architecture, showed that DNNs use putative ratios (e.g., golden ratio) as essential attributes for predicting facial attractiveness, akin to human judgments. This convergence between algorithmic and human judgments underscores the complex interplay between facial features, attractiveness perception, and evolutionary pressures. Further investigation into the mechanisms underlying both facial attractiveness prediction and sexual dimorphism is therefore warranted.

1) Sexual dimorphism: Regarding our first hypothesis (H1), and despite our initial assumptions, feminized versions of both male and female faces were rated as more attractive. The preference for femininity in women is well-supported in the existing body of literature [10, 48, 50, 93-94]. However, there are mixed findings concerning the effect of sexual dimorphism on male attractiveness. Some research reports a stronger preference for more masculine male faces [95-100], while other studies suggest a preference for more feminine faces [10,37,97,101-104], or report no differences between masculinized and feminized versions of male faces [50,105-106].

A possible explanation for these diverse findings may be associated with the level of attractiveness from both the rater and the photo. For instance, [107] found that when judging attractive faces, both male and female participants favored masculine male faces over feminine ones. Conversely, in the less attractive condition, they preferred feminine male faces to masculine ones. Furthermore, [108] found that women's preferences for femininity in men's faces decreased after viewing images of highly attractive men. Since the predicted attractiveness in our results may be considered average, this could explain the lack of preference for masculinity. Moreover, there is an increased preference for masculinity among women who perceive themselves as attractive [102]. Furthermore, women perceived as having relatively low facial attractiveness by others, showed a preference for more "feminine" male faces when selecting partners for long-term relationships compared to short-term relationships [85].

Furthermore, enhancing masculine facial features may increase perceptions of dominance and negative attributes, such as coldness or dishonesty [10]. These aspects are considered significant by women within the context of relationships and paternal investment [10]. Subsequent research has unveiled that women prefer less masculine male faces in long-term relationships under specific conditions of environmental harshness, such as resource scarcity or elevated stress levels [39,109]. These findings align with the notion that men with more favorable genes (higher testosterone levels) invest less in the relationship, as they can afford to choose their mate [109].

However, it is important to note that this aspect remains ambiguous within the existing body of literature. In a recent study, women exhibited a preference for masculinized faces over feminized ones [100]. Notably, this preference for masculine male faces was more pronounced when assessing potential co-parenting partners compared to short-term

relationships [100]. Supporting these findings, [110] demonstrated that facial attractiveness, instead of facial masculinity influenced perceptions of paternal involvement.

Finally, hormonal changes occurring during the menstrual cycle may alter women's preference for sexually dimorphic cues. In women, the preference for masculinity is higher during the late follicular phase of the menstrual cycle (when fertility is high and progesterone level low) [111]. Similarly, [112] found that women tend to prefer masculinity in male faces around ovulation, while they prefer feminized male faces during the rest of the cycle. This likely indicates a balanced trade-off between the attraction to males who appear to ensure reproductive success and males who are perceived as capable and nurturing fathers.

2) Symmetry: Concerning our second hypothesis (H2), our results showed that the facial beauty prediction algorithm found symmetrized faces more attractive, but only for sexually dimorphic versions of female faces. Similar to our findings, machine learning models trained to predict facial attractiveness based on geometric facial features have been found to implicitly learn human psychophysical biases towards symmetric faces [53,113]. However, it is important to note that the specific characteristics that make symmetric faces more attractive, independent of their symmetry, are not definitively defined.

Since our results showed a preference for symmetric sex-dimorphic traits exclusively in female faces, insights from prior studies [97,114] suggesting an intercorrelation between symmetry and sexual dimorphism may shed light on why symmetrized male faces were not found more attractive than non-symmetrized versions. In a cross-cultural study, perceived sexual dimorphism demonstrated a correlation with symmetry measurements [97]. Additionally, research found that women's preferences for symmetry were positively correlated with preferences for masculinity in male faces and that men's preferences for symmetry were positively correlated with preferences for femininity in female faces [97]. Furthermore, [115] found that facial symmetry was associated with masculine facial cues in males, such as increased lower face length and cheekbone prominence [32,116]. Symmetry could potentially enhance the perception of masculinity or be interpreted by the algorithm as a cue of masculinity in male faces, which might explain why the effect was observed only for female faces.

Despite the critical role of symmetry in the perception of attractiveness, evidence suggests that sexual dimorphic cues may be more influential than symmetry in attractiveness evaluations, which supports our findings. For instance, [117] found that participants focused more on sexual dimorphic cues than on symmetry when selecting a partner for a romantic relationship. Furthermore, [118] altered symmetry within a face while keeping the mean size of facial features constant, revealing that symmetric faces were perceived as less attractive. Additionally, [119] found that symmetry enhances facial attractiveness by increasing perceived normality, suggesting that attractiveness perception may involve additional inferences about a face. Likewise, using a random forest machine learning algorithm to predict facial attractiveness, [20] found that shape averageness, dimorphism, and skin texture symmetry emerged as valuable features capable of yielding relatively precise predictions. However, it was observed that shape symmetry did not contribute significantly to the predictive accuracy.

3) Sex: Our findings indicate that the facial beauty prediction algorithm rated women as more attractive than men. This observation aligns with previous research that utilized neural networks with facial landmarks as input data [120], as well as studies based on human assessments of attractiveness [121-122]. Considering the sex effect observed, it could be argued that the algorithm's general preference for feminization may stem from an inclination towards feminine traits, regardless of the sex of the face being evaluated. However, several studies have highlighted the impressive capability of convolutional neural networks in sex recognition tasks, e.g., [123-124].

B. Limitations / Further Studies

There are some limitations mainly associated with the databases that warrant consideration. Novel research has revealed that beauty prediction algorithms trained using SCUT-FBP5500 images exhibit poor prediction accuracy when assessing faces from other databases [125]. There may be a cultural effect in our study, as the largest database consisted solely of Asian raters, potentially influencing preferences for masculinity in male faces. Research suggests that a preference for more masculine men is more pronounced in countries with higher economic and national health indices [103]. To prevent the model from overfitting to the characteristics of the SCUT-FBP5500 dataset, we included additional datasets with standardized frontal facial images.

Furthermore, there is an interrelationship between attractiveness and emotional expression [74,126,128]. Human raters consistently perceive attractive faces as more appealing [75,126], while positive emotions are more readily recognized in attractive faces [126-127]. While emotion recognition algorithms have advanced [128], they haven't yet integrated attractiveness ratings, and beauty prediction models typically overlook emotionality. Future research should explore whether algorithms replicate human biases regarding attractiveness and emotions, and examine their interaction with sexual dimorphism.

Additionally, integrating multiple databases with varying rating scales for facial beauty prediction can pose challenges, as noted by [125]. [129] addresses the challenge of standardizing Likert scales, noting that the mean may shift depending on the scale's point range. To address this issue, [129] suggests a rescaling system based on transitional probabilities. However, given that the scales from the selected datasets range from 1-5 to 1-100, we opted for a straightforward normalization to the 0-1 range. Nonetheless, using ordinal attractiveness judgments as scalar intervals presents a rescaling challenge. The interval properties of Likert scales are inherent to the data, influenced by observers' mean responses rather than the labels themselves [130]. Thus,

we advocate for a unified rating system for attractiveness datasets to enhance predictive models.

In this study, VGG-19 was trained using attractiveness ratings from both male and female evaluators who assessed photos of individuals from both the same and opposite sexes. From an evolutionary perspective, the sexual dimorphism hypothesis posits that individuals seek high-quality partners for reproduction. Therefore, the same-sex attractiveness judgments in these datasets may represent a potential limitation. However, as previously discussed, [107] demonstrated congruent attractiveness preferences among men and women, indicating a preference for masculinity in attractive male faces, whereas feminine traits were preferred in less attractive male faces. Additionally, earlier research, such as that by [131], did not find differences between same-sex and opposite-sex attractiveness preferences. Supporting the preference for sexual dimorphism, [81] reported that male participants rated masculinized versions of male faces as more attractive than feminine faces. Moreover, the self-rated sex-typicality appears to moderate this effect. For instance, individuals who perceive themselves as possessing more exaggerated sex-typical traits tend to exhibit stronger preferences for exaggerated sex-typical shape cues in faces of the same sex [132]. Further studies may explore whether same-sex or opposite-sex ratings could explain the observable effects. Therefore, researchers should consider incorporating this factor when developing future databases of facial attractiveness.

Furthermore, sexual orientation may influence preferences for sex-dimorphic face shapes. Research indicates that homosexual men tend to have a stronger preference for masculinity in male faces compared to other demographic groups [133]. However, there is evidence suggesting that sexual position moderates facial masculinity preferences [134-135]. Individuals' self-labeling as "top" or "bottom", as well as their preferences for their partner's sexual position, are indicative of their preferences for masculinity. Generally, individuals seeking a "top" as a romantic partner prefer more masculine faces than those seeking "bottoms" [134-135]. Additionally, homosexual women exhibited stronger preferences for masculinity in female faces compared to heterosexual women [133]. Thus, sexual orientation may be a crucial factor to consider in subsequent models. To account for this, we suggest that authors incorporate sexual orientation when developing databases of facial attractiveness and make this information available to other researchers.

V. Conclusion

The results of the present study align with previous findings in the psychological literature, which indicate a preference for femininity in both sexes. Moreover, we supported prior findings about a preference for symmetric faces. However, our results reveal an interplay between sexual dimorphism and symmetry, as the preference for symmetric faces was observed only in dimorphic faces, not in the original versions. Furthermore, our results provide a benchmark for developing beauty prediction algorithms using multiple databases. Future research could build on these findings by investigating additional cues of facial attractiveness. Overall, our findings suggest that beauty prediction algorithms can implicitly learn and replicate human biases regarding facial attractiveness.

Real-Time Self-Localization and Mapping for Autonomous Navigation of Mobile Robots in Unknown Environments

Serik Tolenov, Batyrkhan Omarov
Joldasbekov Institute of Mechanics and Engineering, Almaty, Kazakhstan

***Abstract*—This paper delves into the progressive design and operational capabilities of advanced robotic platforms, highlighting their adaptability, precision, and utility in diverse industrial settings. Anchored by a robust modular design, these platforms integrate sophisticated sensor arrays, including LiDAR for enhanced spatial navigation, and articulated limbs for complex maneuverability, reflecting significant advancements in automation technology. We examine the architectural intricacies and technological integrations that enable these robots to perform a wide range of tasks, from material handling to intricate assembly operations. Through a detailed analysis of system configurations, we assess the implications of such technologies on efficiency and customization in automated processes. Furthermore, the paper discusses the challenges associated with the deployment of advanced robotics, including the complexities of system integration, maintenance, and the steep learning curve for operational proficiency. We also explore future directions in robotic development, emphasizing the potential integration with emerging technologies such as artificial intelligence, the Internet of Things, and augmented reality, which promise to elevate autonomous decision-making and improve human-robot interaction. This comprehensive review aims to provide insights into the current capabilities and future prospects of robotic systems, offering a perspective on how ongoing innovations may reshape industrial practices, enhance operational efficiency, and redefine the landscape of automation technology.**

Keywords*—Robotic platforms; automation technology; LiDAR navigation; system integration; artificial intelligence; Internet of Things; human-robot interaction

I. Introduction

Simultaneous Localization and Mapping (SLAM) remains a cornerstone technology in the field of robotics, facilitating the autonomous navigation of mobile robots in environments unknown and unmapped. As the demand for autonomous systems spans industries—from automotive to agricultural and healthcare—SLAM has evolved from a theoretical concept to a critical component in real-world applications. This technology enables a robot to build a map of an unknown environment while simultaneously determining its location within that map. The iterative nature of SLAM—constantly updating and refining the map and the robot's location—makes it one of the most complex yet transformative technologies in modern robotics.

SLAM's significance is particularly pronounced in environments that are dynamic and unstructured, where pre-existing maps are unavailable or insufficiently detailed. In such scenarios, robots must rely on their onboard sensors and processing capabilities to navigate effectively and perform tasks autonomously [1]. The dual challenges of localization (the robot's ability to know its position relative to the environment) and mapping (the process of constructing an accurate, real-time map of the environment) are intertwined tasks that must be solved concurrently. This is because the accuracy of localization directly impacts the quality of the map generated, and vice versa [2]. Fig. 1 demonstrates the simultaneously localization and mapping problem.

Historically, the development of SLAM has been driven by advancements in sensor technology and computational methods. Essential to the process are various sensors that provide the raw data needed for map construction and localization. These typically include LiDAR (Light Detection and Ranging), RGB-D cameras (which capture color (RGB) and depth (D) data), inertial measurement units (IMUs), and stereo cameras [3]. Each sensor type offers different advantages and constraints; for example, LiDAR sensors are highly effective in distance measurement but can be costly and complex, whereas RGB-D cameras provide rich visual and depth data but may struggle in poor lighting conditions [4].

The complexity of SLAM algorithms varies significantly depending on the specific application and the environment. Algorithms must efficiently process vast amounts of data from multiple sensors to produce accurate and reliable localization and mapping outcomes. These algorithms are generally categorized into two types: filter-based and graph-based SLAM. Filter-based methods, such as the Extended Kalman Filter (EKF) SLAM, iteratively estimate the state of the map and the robot’s location [5]. Graph-based SLAM, on the other hand, constructs a graph where the nodes represent robot poses at different times, and the edges represent spatial constraints between these poses, solved optimally to reconstruct the robot’s trajectory and the map [6].

Calibration plays a crucial role in ensuring the accuracy of the data collected by the sensors. Incorrect calibration can lead to significant errors in localization and mapping. The calibration process involves determining the intrinsic (internal characteristics) and extrinsic (spatial relationships among different sensors) parameters. Noise is another critical factor impacting the SLAM system; it encompasses any error that deviates from the true measurements, such as sensor inaccuracies or environmental factors like electromagnetic interference [7].

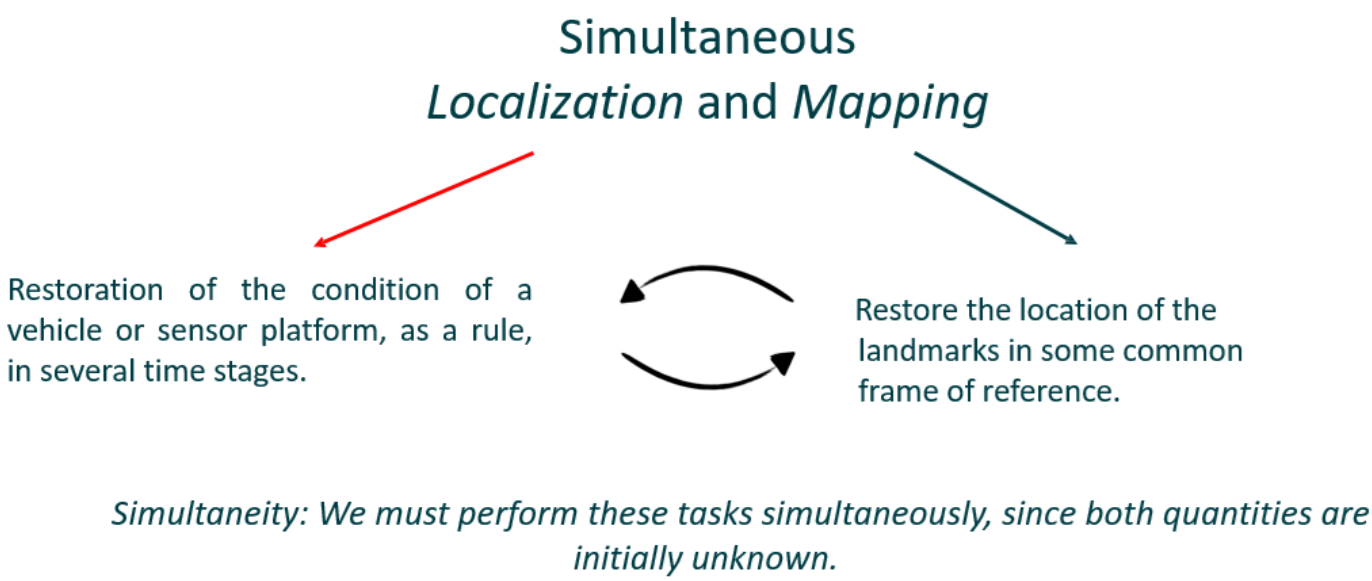

Fig. 1. Simultaneously locatiozation and mapping.

The uncertainty inherent in sensor data and the need for real-time processing make SLAM a computationally demanding task. The presence of noise and the potential for significant variability in environmental conditions mean that SLAM systems must be robust to a range of operational scenarios. As such, SLAM technology not only requires sophisticated algorithms but also powerful computational resources to handle real-time data assimilation and processing [8].

Recent developments in SLAM have seen the integration of machine learning techniques to enhance the adaptability and efficiency of SLAM systems. These approaches leverage the power of neural networks to improve feature extraction, data association, and even to predict environmental changes that might affect navigation [9]. Such innovations have opened new avenues for the application of SLAM in more complex and dynamic environments, pushing the boundaries of what autonomous robots can achieve [10].

Moreover, the integration of SLAM into various application domains has necessitated adaptations to meet specific operational requirements. For instance, autonomous vehicles use SLAM for real-time navigation and obstacle avoidance in urban environments, while agricultural robots use it to navigate between crops and perform tasks such as harvesting or planting. Each application presents unique challenges and requirements, influencing the choice of sensors, the design of algorithms, and the overall architecture of the SLAM system [11].

Overall, SLAM continues to be a vibrant field of research and application, driving forward the capabilities of autonomous robots. The ongoing evolution of sensor technologies, coupled with advances in computational algorithms and machine learning, promises to enhance the robustness, accuracy, and efficiency of SLAM systems, heralding new possibilities for automation across various sectors [12]. As this technology progresses, it will play a pivotal role in the realization of fully autonomous systems capable of operating in complex and evolving environments.

II. Problem Statement

The evolution of Simultaneous Localization and Mapping (SLAM) technology has been significantly influenced by various research efforts aimed at improving its accuracy, efficiency, and utility in diverse application domains. This section reviews the seminal and recent works that have contributed to the development of SLAM, highlighting the advancements in sensor technology, algorithmic approaches, and system integrations.

One of the foundational aspects of SLAM is the use of sophisticated sensor systems to capture environmental data essential for mapping and localization. Initial studies in SLAM primarily utilized laser range finders and sonar sensors due to their reliability in distance measurement [13]. However, with technological advancements, the use of RGB-D cameras and LiDAR sensors has become prevalent, especially in applications requiring detailed 3D mapping and object recognition [14]. These sensors not only provide depth information but also rich visual data, which is crucial for feature-based SLAM algorithms.

The development of algorithms for SLAM has seen a significant transformation from early filter-based methods to modern graph-based and machine learning-enhanced techniques. Filter-based methods, such as the Extended Kalman Filter (EKF) and the Particle Filter, have been widely used due to their robustness in online state estimation and their ability to handle the nonlinearities typical in real-world environments [15]. However, these methods often suffer from scalability issues when the environment size or the number of landmarks increases significantly [16]. This has led to the adoption of graph-based SLAM, which offers better scalability and accuracy by optimizing a graph structure that represents the spatial relationships among various poses and landmarks [17].

Graph-based SLAM algorithms, particularly those employing pose graph optimization, have revolutionized the way SLAM is implemented. These algorithms construct a network of constraints based on the relative measurements

between poses and landmarks, which is then optimized to find the most probable map configuration [18]. This approach not only improves the computational efficiency but also enhances the map's fidelity by reducing cumulative errors over long sequences.

The integration of machine learning techniques into SLAM has opened new avenues for enhancing the system's adaptability and performance. Deep learning, for instance, has been employed to improve feature extraction and association, a critical aspect of SLAM that affects the system's overall robustness and accuracy [19]. Neural networks have also been used to predict and compensate for the environmental dynamics that traditional SLAM systems might not handle well [20]. Moreover, machine learning algorithms have facilitated the development of semantic SLAM, which not only maps the environment but also understands and categorizes it into meaningful entities [21].

The calibration of sensors remains a critical issue in SLAM, as inaccurate sensor models can lead to significant localization errors. Research has focused on developing more robust calibration techniques that can be performed easily and reliably in-field [22]. These techniques ensure that the intrinsic and extrinsic parameters of the sensors are accurately determined, thus enhancing the overall reliability of the SLAM system.

Noise and uncertainty in sensor data are inherent challenges in SLAM that degrade the quality of localization and mapping. To address these issues, advanced statistical methods have been developed to model and mitigate the impact of noise and uncertainty [23]. These methods include robust estimation techniques that can identify and reject outliers in sensor data, thereby improving the SLAM system's resilience to environmental noise and sensor faults [24].

Recent advancements have also explored the use of SLAM in dynamic and unstructured environments, such as underwater, aerial, or disaster-stricken areas, where traditional SLAM techniques face significant challenges [25]. These environments require highly robust and adaptive SLAM solutions that can handle large variations in environmental conditions and sensor disruptions.

Furthermore, the application of SLAM technology has extended beyond robotic navigation to include tasks such as augmented reality, where real-time mapping and localization are crucial for overlaying virtual objects onto the physical world [26]. This demonstrates the versatility and widespread applicability of SLAM, making it a critical technology in various fields.

The related work in SLAM demonstrates a trend towards more integrated and intelligent systems capable of operating in increasingly complex environments. The continuous improvements in sensor technology, alongside innovations in computational algorithms and machine learning, are driving the evolution of SLAM towards systems that can not only navigate and map with high accuracy but also understand and interact with their environments in sophisticated ways [27-29].

Overall, the body of work surrounding SLAM encompasses a broad spectrum of research areas, including sensor technologies, algorithmic strategies, system design, and applications. Each study contributes to building a more comprehensive understanding of how autonomous systems can effectively perceive and navigate our world. The ongoing research and developments promise to enhance the capabilities of SLAM, pushing the boundaries of what autonomous systems can achieve, and broadening the horizon for future applications.

III. CHALLENGES

The primary challenge addressed in this research is the development of a robust Simultaneous Localization and Mapping (SLAM) system that efficiently integrates various sensory inputs to accurately navigate and map an environment in real-time. This entails the construction and refinement of a dynamic model that not only interprets and assimilates data from multiple sensors but also accounts for the inherent uncertainties and potential errors in sensor outputs. The effectiveness of a SLAM system hinges on its ability to synthesize this data to produce reliable, real-time updates of both the system's location (localization) and the structure of the environment (mapping).

Fig. 2. Sensor setup.

Fig. 2 displays various sensors commonly used in SLAM systems, including Cameras, Inertial Measurement Units (IMUs), LiDAR/Rangefinders, and RGB-D/Structured Light sensors. Each sensor type provides unique data essential for comprehensive environmental perception. Cameras offer visual information, IMUs provide movement and orientation data, LiDARs deliver precise distance measurements, and RGB-D sensors combine depth perception with visual data [30]. The integration of these diverse data streams is crucial for the development of a detailed and accurate map of the environment, as well as for the precise localization of the SLAM system within it.

Fig. 3. Sensor integration and mapping process.

Fig. 3 illustrates the process of sensor data integration and subsequent map generation. It shows a schematic representation of an autonomous vehicle (or drone), highlighting its trajectory and the environmental mapping it performs. Key aspects such as ego-motion estimation and calibration parameters are emphasized, indicating their roles in refining the system's performance. This figure underscores the dynamic interaction

between motion data and environmental mapping, crucial for real-time navigation and obstacle avoidance in autonomous systems [31].

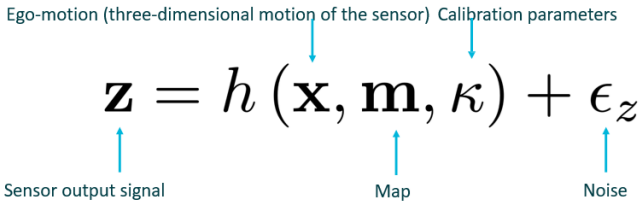

Fig. 4. SLAM system algorithmic process.

Fig. 4 introduces the mathematical model underlying the SLAM process. It describes the relationship between the sensor output signal (z), the system's state (x), the map (m), and the calibration parameters (κ), incorporating noise (εz) to account for measurement uncertainties. This model is central to the SLAM system as it forms the basis for algorithmic interpretations and adjustments made during the mapping and localization processes.

Expanding on the mathematical foundations, depicts the algorithmic workflow of a SLAM system. It illustrates how sensor inputs are transformed into a set of equations that the SLAM algorithm processes to update estimates of the system's state, the map, and calibration parameters [32]. This sequential representation highlights the continuous feedback loop essential for adaptive and responsive SLAM operations.

Also, Fig. 5 demonstrates the output from the SLAM system, showcasing the refined estimates of the system's state and the detailed environmental map. This visualization not only serves as a validation of the system's effectiveness but also illustrates the practical application of SLAM in real-world navigation scenarios.

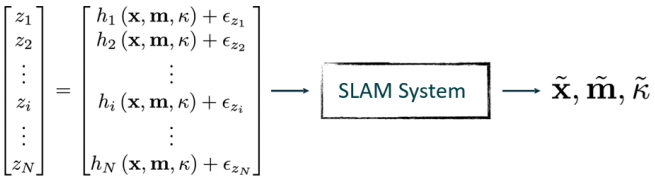

Fig. 5. Output visualization.

These figures collectively delineate the complexity of developing an effective SLAM system. They highlight the integration of multi-sensor data, the importance of accurate mathematical modeling, and the necessity of adaptive algorithms capable of continuous learning and refinement. Addressing these challenges through innovative solutions is fundamental to advancing the field of autonomous navigation and ensuring the practical deployment of SLAM systems in diverse and dynamically changing environments.

IV. Materials and Methods

In this section, we delineate the technical specifications and procedural framework utilized in the development and testing of the robotic platform. This section is structured to provide a comprehensive overview of the equipment, software, and methodologies employed to achieve the objectives stated in the study. It begins with a detailed description of the robotic system's hardware configuration, including all sensors and actuaries involved, followed by an exposition of the software algorithms used for tasks such as navigation, mapping, and task execution. We also outline the experimental setup and the conditions under which the robot was tested, highlighting any simulations or real-world scenarios that were employed. This thorough detailing ensures transparency and reproducibility of the results, offering insights into the practical applications and limitations of the robotic system in various environments. By elucidating these methods, we aim to provide a clear path for future research and development in robotic technologies, ensuring that subsequent innovations can build upon a solid foundation of well-documented experimental practices.

Fig. 6 illustrates the impact of sensor choice on the configuration of maps generated in a SLAM system. The figure presents three distinct visual representations derived from different sensor technologies, emphasizing how each sensor type influences the nature and detail of the resulting maps.

1) Left panel: Collection of Photos: This panel displays a point cloud visualization generated from a collection of photographs, likely obtained using photogrammetry techniques. The image showcases a highly detailed three-dimensional reconstruction of a complex architectural structure. The density and granularity of the points indicate high spatial resolution, allowing for detailed feature extraction and textural information which are crucial for creating accurate visual maps.

2) Middle panel: 2D LiDAR Scan: The middle image depicts a 2D LiDAR scan, characterized by its line-based representation which outlines a simple closed trajectory within a bounded environment. This scan typically provides precise distance measurements from the sensor to the surrounding obstacles, represented here by the clear, unambiguous lines [32]. The simplicity and clarity of the data focus on spatial relationships and obstacle detection, suitable for navigation and basic mapping tasks.

3) Right panel: 3D Image: The rightmost image demonstrates a 3D map constructed using advanced imaging techniques, possibly involving a combination of LiDAR and structured light sensors. This representation is not only three-dimensional but also includes color coding and textural overlays, indicating variability in elevation and possibly the integration of additional data types like thermal or multispectral imaging [33]. Such detailed maps are instrumental in applications requiring in-depth environmental analysis and feature-rich navigation.

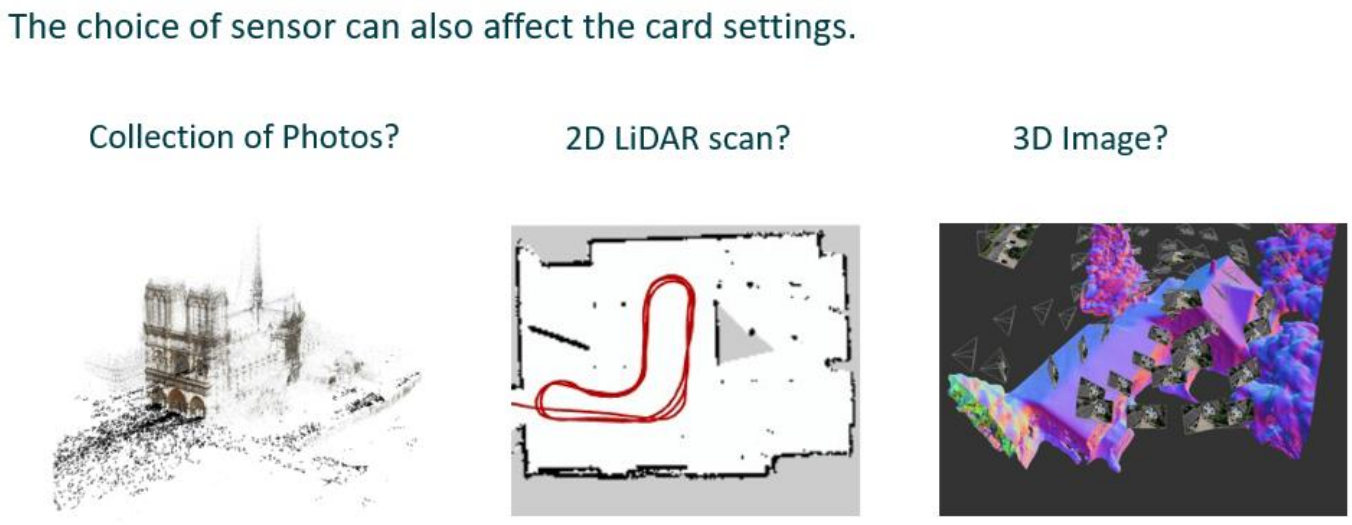

Fig. 6. The choice of sensor can also affect the card settings.

Fig. 6 presents an insightful depiction of the profound impact that various sensor technologies have on the fidelity, detail, and application suitability of maps generated through Simultaneous Localization and Mapping (SLAM) systems. This illustration serves to emphasize the pivotal role of sensor selection in the design and operational efficacy of SLAM-based applications [34], showcasing how each sensor type distinctly enhances the system's overall functionality and accuracy. The diversity in sensor capabilities is exemplified by the use of photogrammetry, which can yield highly detailed three-dimensional reconstructions; these are particularly valuable in scenarios where visual detail is critical. Conversely, 2D LiDAR scans, known for their precision and simplicity, become indispensable in navigation tasks focused on obstacle avoidance [35]. Moreover, the integration of 3D imaging techniques—which merge depth perception with high-resolution imagery—affords comprehensive environmental mapping capabilities. These are crucial for executing more intricate navigation and interaction tasks in robotic applications, facilitating advanced maneuvers and interactions within complex environments [36]. The strategic selection of sensors, therefore, not only influences the quality of the data collected but also significantly affects the adaptability and applicability of the SLAM system to varied operational contexts. As such, Fig. 6 not only highlights the technical considerations in sensor choice but also underscores their strategic importance in enhancing the robustness and versatility of SLAM technologies in dynamic settings.

The choice of sensor not only affects the quality of the data collected but also dictates the SLAM system's ability to function under various environmental conditions. For example, photogrammetric methods might be less effective in poorly lit conditions, whereas LiDAR systems can operate effectively in a range of lighting scenarios, offering versatility across different operational settings [37]. This adaptability is crucial for tailoring the SLAM approach to meet specific requirements, whether in indoor environments, outdoor landscapes, or areas with variable lighting and weather conditions.

Fig. 6 vividly captures the essence of how sensor technology choices directly influence the design and efficiency of SLAM systems. By highlighting the differences in map fidelity and application suitability offered by various sensors, the figure emphasizes the importance of strategic sensor selection. This ensures that SLAM systems are not only optimized for specific tasks but are also capable of performing effectively under the unique constraints of each application environment.

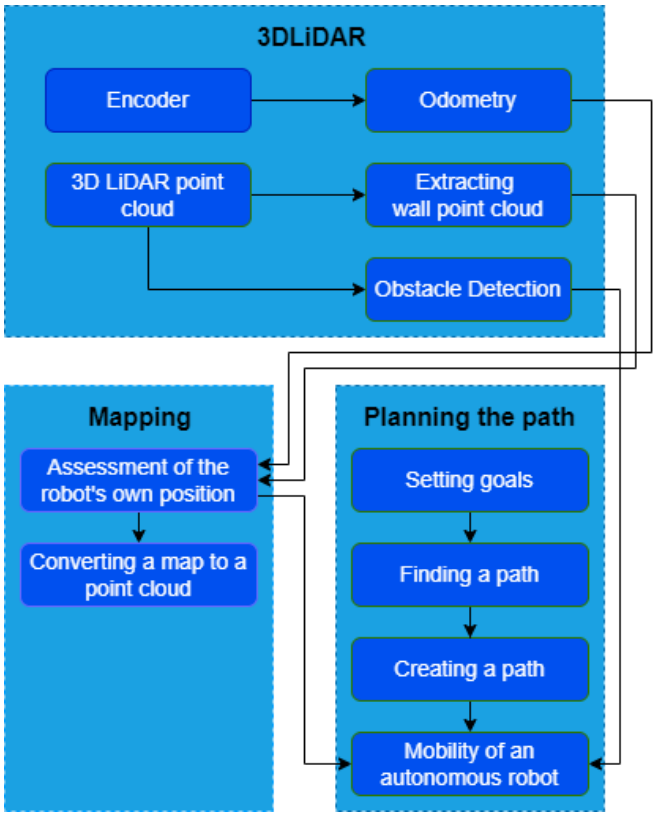

Fig. 7. Flowchart of the proposed system for navigation of the mobile robots.

Fig. 7 provides a schematic representation of the workflow involved in using 3D LiDAR technology for Simultaneous Localization and Mapping (SLAM) and path planning in autonomous robots. The diagram is divided into two main sections—Mapping and Planning the path—each containing multiple subprocesses that detail the steps and components involved in SLAM operations using 3D LiDAR.

1) 3D LiDAR Module:

a) Encoder: This component is responsible for encoding the raw data collected from the LiDAR sensor, preparing it for further processing.

b) Odometry: It computes the robot's change in position over time by analyzing the sequential data points captured by the LiDAR, which is crucial for tracking the robot's trajectory.

c) 3D LiDAR point cloud: This is the raw output from the LiDAR sensor, which includes a three-dimensional set of data points representing the distances to the surrounding objects.

d) Extracting wall point cloud: This process involves filtering the 3D point cloud to identify points that correspond to wall surfaces, which are critical for defining the structure of the environment.

e) Obstacle detection: Utilizing the data from the point cloud, this function detects and localizes objects that could impede the navigation of the robot, ensuring safe movement within the environment.

2) Mapping:

a) Assessment of the robot's own position: This step integrates the odometry and sensor data to determine the robot's current position within the map being constructed.

b) Converting a map to a point cloud: In this final step of the mapping phase, the map generated by the robot is converted back into a point cloud format, which can be used for further refinement and verification of the map's accuracy.

3) Planning the path

a) Setting goals: This initial step involves defining the destination or specific waypoints that the robot needs to reach.

b) Finding a path: Algorithms compute the optimal path to the goal, considering the map data and any detected obstacles.

c) Creating a path: This involves generating a navigable path, which includes adjusting for dynamic changes in the environment that might affect the planned route.

d) Mobility of an autonomous robot: The final output is the execution of the path, allowing the robot to move autonomously towards its goal while dynamically adjusting its course as necessary.

This flowchart effectively encapsulates the complex interactions between different components of a SLAM system equipped with 3D LiDAR technology. It highlights the critical role of each subprocess in achieving accurate localization, comprehensive environmental mapping, and efficient path planning, which are essential for the autonomy of mobile robots. The clarity and structure of the diagram provide a clear understanding of how these technologies are integrated to support the navigation capabilities of robotic systems.

V. Experimental Results

Fig. 8 showcases a graphical depiction of a 2D SLAM process visualized through a Python programming interface. The display captures a real-time simulation where the SLAM algorithm maps an environment based on data collected from a mobile robot equipped with LiDAR sensors. The predominant red lines illustrate the robot's orientation and the trajectory as it navigates the simulated setting. These lines represent both the paths traversed by the robot and the physical boundaries encountered, such as walls and obstacles, detected through its sensor array.

The demonstration environment is meticulously configured within a Python integrated development environment (IDE), underscoring the significant reliance on Python for the development and execution of the SLAM (Simultaneous Localization and Mapping) algorithm. This utilization of Python is emblematic of contemporary practices in the fields of robotics and automation, where Python's versatility and robust library support facilitate complex algorithmic development and testing [38]. The interface presents a dynamic visualization of the robot's movement, illustrating the ongoing process of mapping and localization that is central to SLAM operations. As the robot navigates through its environment, the visualization updates to display a network of red lines, representing the robot's path and the environmental boundaries it detects.

These red lines are not static; they evolve continuously as the robot acquires and processes new sensor data, thereby adjusting its internal map of the surroundings in real-time. This feature highlights the adaptive nature of SLAM systems, which must constantly refine their calculations based on incoming data to maintain accurate navigation and mapping. The ability to visually track these adjustments in real-time provides invaluable feedback during development and testing, allowing for immediate identification and resolution of any discrepancies in the algorithm's performance. Overall, the use of the Python IDE in this context not only enhances the efficiency of algorithm development but also enriches the analytical capabilities essential for advancing SLAM technology in robotic applications.

On the left side of the screen, a portion of the Python code involved in the SLAM operation is visible, hinting at the initialization of environment parameters and the integration of sensor data. In the bottom left corner, command line outputs possibly display log messages or computational diagnostics, aiding in the debugging and optimization of the algorithm. This visual and technical presentation in Fig. 8 not only underscores the practical application of SLAM technology in simulated environments for educational and development purposes but also highlights the robust capabilities of autonomous navigation systems in continuously updating and refining their understanding of complex environments.

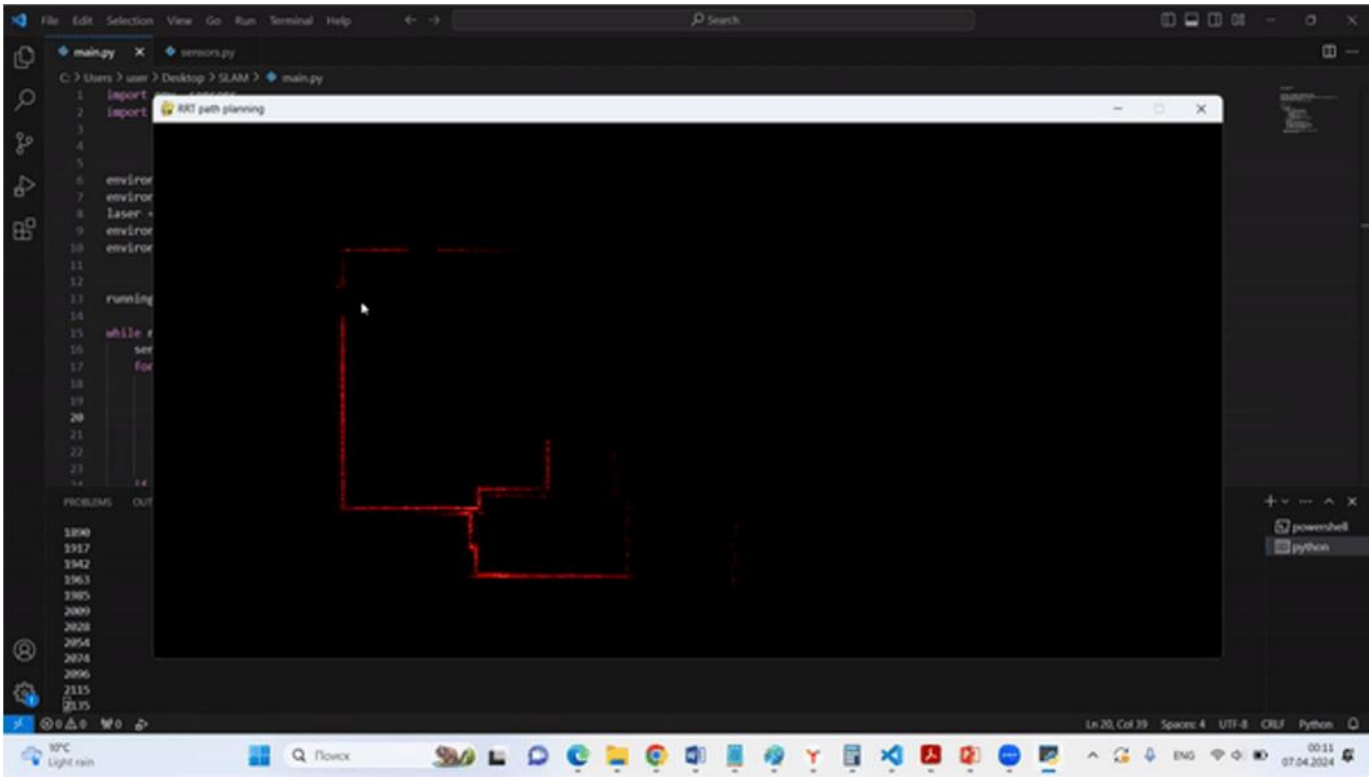

Fig. 8. Simultaneous start of localization and mapping.

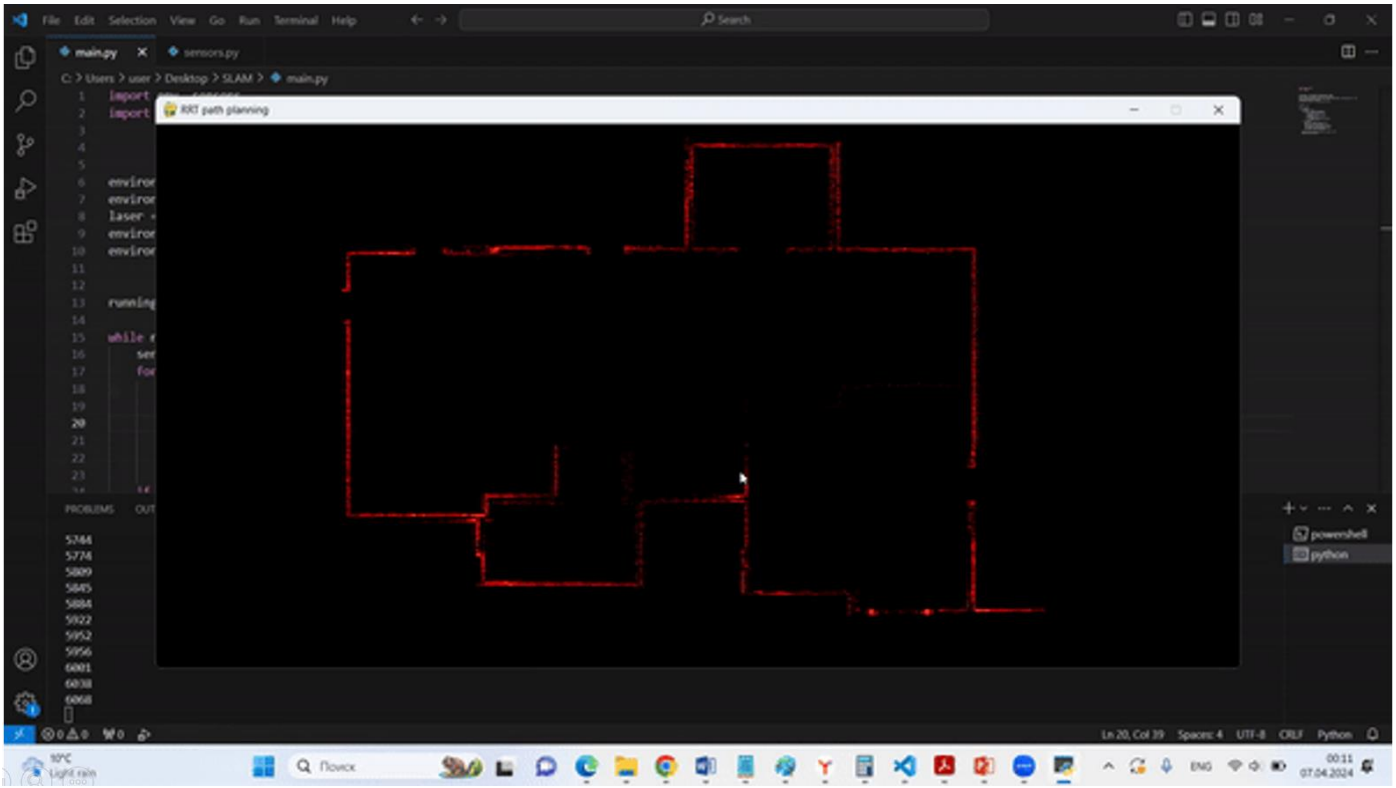

Fig. 9. Simultaneous localization and mapping for all rooms.

Fig. 9 provides a vivid depiction of a 2D Simultaneous Localization and Mapping (SLAM) process, visualized within a Python programming environment on a desktop computer's display. This image captures a real-time view of a SLAM algorithm in action, dynamically mapping an environment as navigated by a mobile robot. The visualization is characterized

by prominent red lines that illustrate the robot's trajectory and the environmental boundaries it detects. These lines, generated from data acquired via LiDAR sensors equipped on the robot, effectively demonstrate the robot's capacity to measure distances to various obstacles such as walls and other physical barriers. This functionality highlights the sophisticated integration of advanced sensor technology, which empowers the robot to navigate and map its surroundings with exceptional precision [39]. The display not only serves as a practical interface for observing the SLAM process but also underscores the critical role of advanced sensing and computational technologies in enhancing robotic navigation and environmental interaction.

Technically, this figure displays an open Python script on the left side of the computer screen, signifying that the SLAM process is governed by custom-developed software. This script is replete with various functions and libraries crucial for running the SLAM algorithm, incorporating components that manage sensor inputs and undertake intricate computational geometry calculations. The right side of the screen vividly exhibits the mapping output, which is dynamically updated, reflecting the environmental model as the robot processes new sensor data and recalibrates its trajectory accordingly. This facet of the interface not only visualizes the map's progressive evolution in response to the robot's movements but also accentuates the algorithm's capacity to swiftly adapt and refine the navigational path in real-time. This dynamic adaptation is crucial for maintaining accurate and reliable navigation, particularly in complex or changing environments, showcasing the robustness and flexibility of the SLAM technology in practical applications.

This visualization is pivotal in demonstrating the robot's adeptness in path planning and navigation, effectively showcasing the seamless integration of robotics, programming, and advanced sensor technologies. The ongoing updates to the environmental map, dictated by the robot's movements, underline the formidable real-time processing capabilities inherent in contemporary SLAM technologies. These advancements facilitate sophisticated navigation and autonomous movement, underscoring their capacity to address complex navigational challenges. Moreover, the robot's ability to recalibrate its trajectory based on live data exemplifies the dynamic interplay between the robotic hardware and its controlling software. This interaction highlights the critical role of SLAM in enhancing robotic responsiveness and improving operational efficiency across diverse applications. The depiction not only illustrates the technical sophistication of modern robotics but also points to broader implications for the future development of autonomous systems. These systems are increasingly capable of operating in varied and dynamically changing environments, pushing the boundaries of what can be achieved with autonomous robotic technology. This progress in SLAM technology not only enhances current robotic applications but also paves the way for future innovations in the automation sector.

Fig. 10 illustrates a mobile robotic unit equipped with a LiDAR sensor, demonstrating its navigation capabilities in an indoor environment with a wooden floor and plain walls. This robot, a compact, multi-wheeled vehicle, showcases advanced autonomous maneuverability facilitated by the mounted LiDAR system, which is visible on the top of the unit. The LiDAR sensor plays a critical role in the robot's ability to perceive its surroundings, enabling it to navigate smoothly and avoid collisions with obstacles that are not present in this particular scenario.

In the displayed action, the robot initiates a turn, which appears to be part of a routine exploration or mapping activity. The motion of the robot is fluid and precise, indicating robust control mechanisms and effective real-time processing of the LiDAR data to guide its movements. The environment itself, though minimally featured, serves as an ideal testing ground to illustrate the robot's basic operational functions, such as turning and straightforward locomotion.

Fig. 10. The proposed mobile robot.

This demonstration highlights the practical application of LiDAR technology in robotics for tasks that require autonomous exploration and mapping. The robot's design suggests it is possibly suited for a variety of applications, from domestic assistance to more complex industrial tasks that require navigation in tight spaces. The integration of LiDAR with the robotic hardware exemplifies the synergy between mechanical design and sensor technology, which is pivotal in advancing the capabilities of autonomous robotic systems.

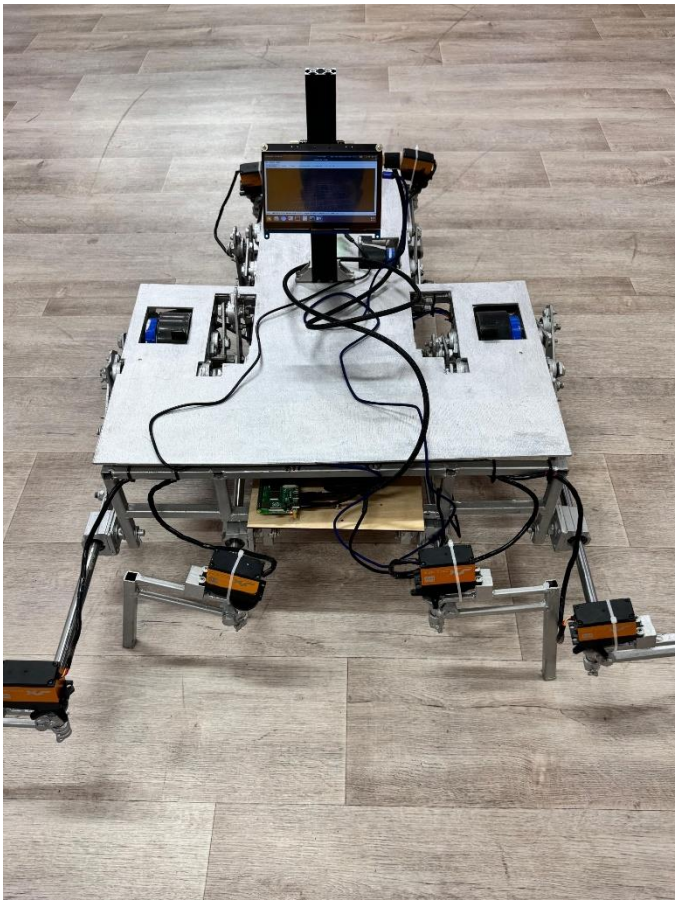

Fig. 11. A walking robot with simultaneous localization and mapping.

Fig. 12. Mobile walking robot.

Fig. 11 depicts an advanced robotic platform viewed from a top-down perspective, showcasing a complex assembly of mechanical and electronic components designed for multifunctional tasks. The robot is built on a rigid, rectangular base that supports a variety of sensors and actuators. Central to the structure is a vertical post mounted with a digital display, presumably serving as an interface for monitoring and control. The arrangement of components indicates a modular design, with multiple actuation units at the corners equipped with what appears to be servo motors, suggesting capabilities for precise movement control and adjustment.

The visible electronics and wiring underscore the robot's sophistication, with circuit boards and a tangle of wires that imply a high degree of integration and connectivity among the various subsystems. The platform is likely intended for indoor applications, as suggested by the clean and flat surface on which it is stationed. This robot could be utilized for experiments that require stability and precision, such as those in automation, material handling, or advanced manufacturing settings. The inclusion of multiple sensors and actuators hints at the robot's potential for complex tasks involving manipulation, positioning, and environmental interaction, reflecting a high level of engineering investment aimed at versatility and performance in controlled environments.

Fig. 12 presents a sophisticated robotic platform designed for precision and adaptability across varied operational settings. Mounted on a robust aluminium frame, the robot features several articulated limbs and joints, hinting at its capability for performing complex tasks and maneuvers. At the core of the platform, a vertical column rises to support a digital display and control unit, tools likely essential for monitoring operations in real-time and making necessary adjustments. This system is further augmented by a variety of sensors and devices, including a LiDAR sensor, which suggests its utility in spatial mapping and autonomous navigation.

The robot is depicted in an indoor laboratory environment, underscored by a meticulously organized background and structured flooring that suggest its utilization in controlled experimental or developmental activities. The scene is replete with an array of visible electronic components and a complex network of wiring, highlighting the robot's sophisticated technological integration. This elaborate configuration is not merely for complexity's sake but serves a practical purpose by endowing the robot with a remarkable degree of adaptability and functionality. Such features make the robot immensely versatile, apt for a spectrum of applications extending from automated material handling to intricate assembly tasks in both research and industrial settings. This adaptability is critical in

modern industries where the demands and functionalities required can vary significantly. Consequently, the robot's design caters to a broad range of tasks, enabling it to perform with high efficiency and adapt quickly to new challenges, illustrating the cutting-edge of current robotic capabilities and the potential for future advancements in automation technology.

The robot's design strategically emphasizes modularity and flexibility, enabling rapid modifications and enhancements that are tailored to specific operational and research demands. This adaptability is critical, allowing the robotic platform to evolve alongside changing technological landscapes and varying project requirements, thus significantly enhancing its applicability in dynamic industrial and research environments. By facilitating such adaptability, the system not only extends the frontiers of robotic automation capabilities but also exemplifies the continuous innovation characterizing the field of robotic engineering and design. This design philosophy ensures that the robotic system remains a valuable asset in progressive applications, effectively responding to emerging challenges and opportunities in automation technology.

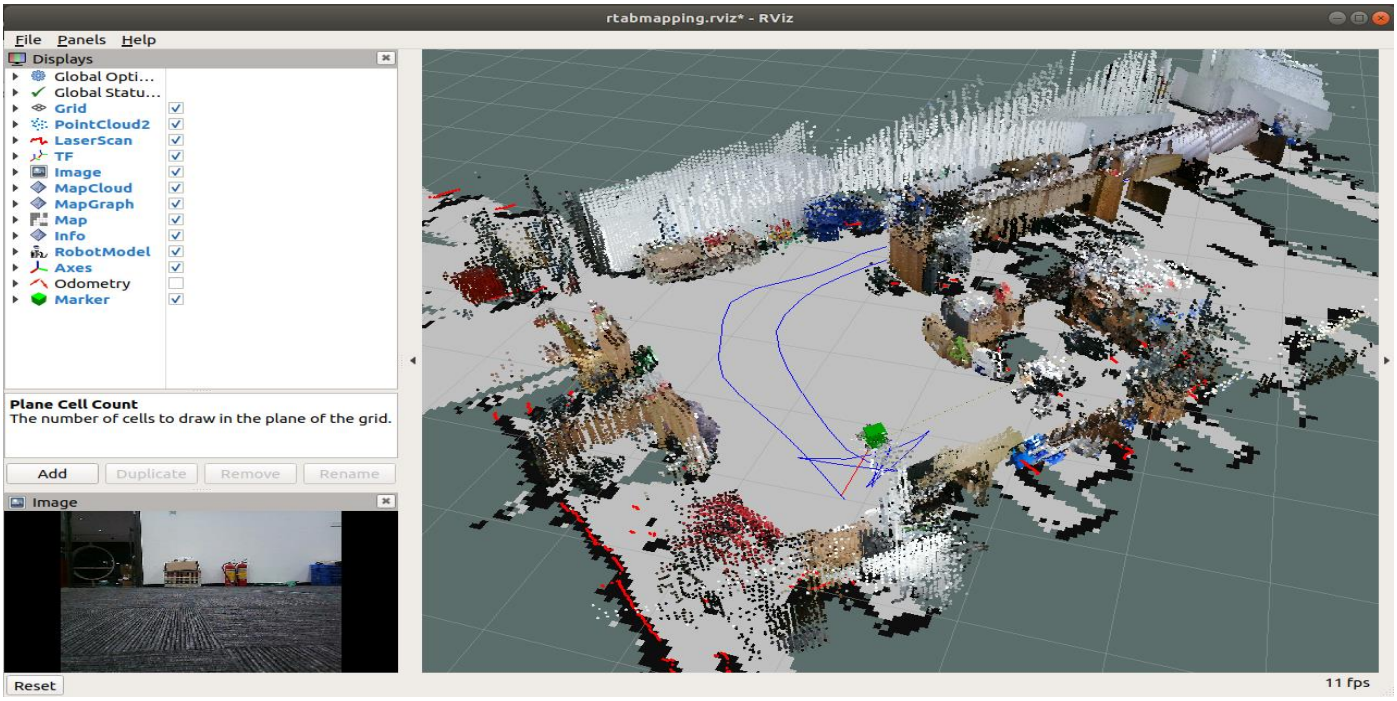

Fig. 13. 3D Simultaneous localization and mapping in mobile robots.

Fig. 13 illustrates the results of a 3D mapping process using advanced Simultaneous Localization and Mapping (SLAM) technology, displayed through the RViz visualization environment. The scene captures a comprehensive point cloud representation of an indoor environment, featuring a detailed and textured map constructed from data collected via sensors equipped on a mobile robot. The multicolored point clouds signify different objects and surfaces within the space, effectively distinguishing between floors, walls, furniture, and other objects based on their spatial and geometric properties.

The interface shown in the figure provides a clear view of various data layers and navigation paths. Blue lines depict the trajectory of the robot as it navigates through the environment, highlighting the path planning and movement executed during the mapping process. Each element in the RViz interface, such as point clouds, laser scans, and odometry data, is marked with checkboxes, allowing users to selectively view or hide different layers for better analysis and troubleshooting of the mapping data. The inset at the bottom left shows the real-world camera view corresponding to the robot's perspective, providing a ground-level context that complements the 3D spatial data. This integrated display aids in evaluating the accuracy and completeness of the SLAM process, essential for applications in autonomous navigation and robotic perception.

VI. Discussion

The development and implementation of sophisticated robotic platforms, as depicted in Fig. 12, illustrate significant advancements in the field of robotics and automation. These systems, equipped with articulated limbs, advanced sensor arrays, and modular frameworks, underscore a significant shift towards more adaptable and versatile robotic solutions. This section explores the implications of such technologies, focusing on their potential impact on industrial applications, challenges associated with their deployment, and the future trajectory of robotic systems design.

Adaptability and Application. The featured robotic platform is a prime example of the trend towards customization and flexibility in robotic system design. Equipped with a sturdy aluminum frame and multiple articulated limbs, the robot is capable of performing a wide array of tasks ranging from simple material handling to complex assembly operations [39]. The central integration of a digital display and control unit on a vertical column facilitates real-time monitoring and

adjustments, which are crucial in dynamic industrial environments. The inclusion of LiDAR sensors enhances the robot's navigation and spatial awareness capabilities, enabling it to perform tasks in unstructured environments that were traditionally challenging for automated systems [40]. Such versatility is increasingly demanded in industries where customization and adaptability to varied operational contexts are required.

Technological Integration and System Complexity The integration of diverse technologies, including advanced sensors and intricate wiring systems, brings about enhanced functionality but also introduces complexity in the maintenance and operation of these robots. The intricate array of components requires sophisticated diagnostic tools and skilled personnel for maintenance, which can increase operational costs [41]. Furthermore, the complexity may impact the system's robustness, as more components can lead to increased points of failure. However, the modular design approach mitigates some of these challenges by enabling easier upgrades and replacements, thus prolonging the system's operational life and adapting to evolving technological advances without necessitating complete system overhauls.

Challenges in Deployment. Deploying such advanced robotic systems in real-world industrial settings poses several challenges [42]. First, the initial cost of investment and integration into existing systems can be significant. Industries looking to adopt these technologies must consider not only the purchase and installation costs but also the training required for their workforce. Additionally, while the adaptability of the robot allows for its application in various settings, each new environment or task can require extensive reconfiguration and testing to ensure optimal performance. This adaptation process can consume time and resources, slowing down the integration process and potentially impacting production schedules.

Future Directions in Robotic Research and Development. Looking forward, the continuous evolution of robotic technologies promises even greater capabilities and more profound impacts on industrial and research applications. Future developments may focus on enhancing artificial intelligence and machine learning integrations, allowing robots to make more autonomous decisions based on real-time data analysis [43]. This advancement could lead to greater efficiency and precision in tasks such as predictive maintenance and complex decision-making processes. Additionally, the drive towards sustainable practices may influence robotic design, prioritizing energy efficiency and the use of environmentally friendly materials.

Moreover, the collaboration between robotics and other emerging technologies such as the Internet of Things (IoT) and augmented reality (AR) could further enhance the capabilities of robotic systems. For instance, IoT integration can enable a fleet of robots to communicate and operate in a coordinated manner, increasing productivity and efficiency. Meanwhile, AR can facilitate more intuitive interfaces for human-robot interaction, enhancing the usability of robotic systems in complex tasks.

VII. Conclusion

In conclusion, the exploration of advanced robotic platforms, as detailed in the provided analyses, underscores the significant strides made in the robotics and automation industry. The integration of complex sensor systems, articulated mechanical structures, and sophisticated control units within robust, modular frameworks exemplifies the technological evolution aimed at enhancing precision, adaptability, and functionality across various operational environments. These developments signify a pivotal shift towards more versatile automated solutions, capable of handling intricate tasks that require high levels of customization. The deployment of such technologies, despite the challenges associated with complexity and initial setup costs, promises substantial improvements in efficiency and operational capabilities for industries ranging from manufacturing to logistics. Looking forward, the continued advancement in robotics is expected to further merge with cutting-edge technologies like artificial intelligence, augmented reality, and the Internet of Things, broadening the scope of robotic applications and deepening their impact on industrial processes. This integration will not only refine the capabilities of robotic systems in terms of autonomy and decision-making but also enhance their interaction with human operators, thereby catalyzing a new era of innovation in automation that could fundamentally reshape industry standards and operational paradigms. As this field progresses, it will undoubtedly offer new opportunities and challenges, driving forward the capabilities and understanding of robotic systems in complex, dynamic environments.

Acknowledgment

This study was funded by the research project BR20280990 development, development of methods for solving fundamental problems of fluid and gas mechanics, new deformable bodies, and reliability of machines, mechanisms, robotics, energy efficiency.

Optimizing LSTM-Based Model with Ant-Lion Algorithm for Improving Thyroid Prognosis

Maria Yousef
Department of Computer Science, University of Petra, Amman, Jordan

***Abstract*—In the healthcare sector, early and accurate disease detection is essential for providing appropriate care on time. This is especially crucial in thyroid problems, which can be difficult to diagnose because of their many symptoms. This study aims to propose a new thyroid disease prediction model by utilizing the Ant Lion Optimization (ALO) approach to enhance the hyperparameters of the Long Short-Term Memory (LSTM) deep learning algorithm. To achieve this, after the preprocessing step, we utilize the entropy technique for feature selection, which selects the most important features as an optimal subset of features. The ALO is then employed to optimize the LSTM, identifying the optimal hyperparameters that can influence the model and enhance its efficiency. To assess the suggested methodology, we chose the widely used thyroid disease data. This dataset contains 9,172 samples and 31 features. A set of criteria was used to evaluate the model's performance, including accuracy, precision, recall, and F1 score. The experimental results showed that: 1) the entropy technique in the feature selection step can reduce the total number of features from 31 to 10; 2) the recommended strategy, which selected the optimal hyperparameter for the LSTM using the Alo algorithm, improved the classifier overall by 7.2% and produced the highest accuracy of 98.6%.**

Keywords*—Thyroid disease; LSTM; ALO; prediction model; optimization algorithm

I. Introduction

Incidences of thyroid illness have increased recently. The thyroid gland has one of the most significant functions in controlling metabolism. The thyroid gland secretes levothyroxine (T4) and triiodothyronine (T3), and irregularities in the gland can result in a variety of disorders [1]. Inadequate thyroid hormones can cause hyperthyroidism and hypothyroidism, the most prevalent disorders. If individuals with thyroid disease do not manage their metabolism and body weight appropriately, they may experience severe problems such as reduced taste, diminished smell, sadness, and memory loss. According to the World Health Organization, 20 million people have had some form of thyroid disease in the past 2 years [2]. Moreover, thyroid disorders affect 12% of the population at least once in their lives. Statistics indicate that we should not disregard thyroid-related illnesses lightly. As a result, the use of prediction systems for thyroid disease detection has grown in significance and is currently a field of research.

Health care professionals are always concerned with finding a cure for illnesses, so making an accurate diagnosis when a patient needs it is crucial. In the traditional way, only an experienced doctor is able to thoroughly assess the situation when predicting a thyroid problem; otherwise, it can be a challenging procedure that results in an incorrect diagnosis. A proactive prediction of thyroid illness is critical to appropriately treating the patient at the appropriate time, saving lives and medical [3].

Current data processing and computer technologies have made it possible to identify different forms of thyroid illness, such as hyperthyroidism and hypothyroidism, and forecast thyroid disease early on. These advances have also made machine learning and deep learning approaches more accessible. Most existing research efforts focus on binary classification issues, categorizing individuals as either thyroid sufferers or healthy. In contrast, there are very few multiclass-based detection methods. Prior research in this area also concentrated on directly implementing machine learning algorithms and contrasting their outcomes, regardless of the attributes employed, their significance, and their quantity, which impacts the models' accuracy and gives rise to the high-dimensionality problem. Despite the high accuracy of reporting techniques, their evaluation on less than 1000 samples yields inconsistent results. To address these concerns, this study presents the following contributions:

- Proposed a new thyroid prediction model that employs a long-short-term memory (LSTM) deep learning algorithm, bolstered by the Ant Lion Optimization (ALO) metaheuristic algorithm. This model serves as an enhanced machine learning-based method for predicting thyroid illness, specifically targeting a multi-class problem.
- Handling the high dimensionality problem and selecting the optimal subset of features that can enhance the model's performance through machine learning-based feature selection using an additional tree classifier.
- Demonstrate the impact of the ALO optimization algorithm on the performance of the LSTM classifier through the suggested experiments.

The rest of the article is structured as follows: Section II summarises the previous attempts to identify and classify thyroid-related illnesses. Section III provides a background on all of the algorithms and techniques used in this study. Section IV presents the suggested approach to solving the thyroid illness prediction issue. Section V describes the experimental results we achieved in our investigation, while Section VI presents the study's conclusion along with our inputs.

II. Related Work

This section covers summaries of many machines learning based thyroid disease prediction systems.

A study by [4] suggested a way to predict thyroid disease that uses five different classification algorithms: Random Forest (RF), Support Vector Machine (SVM), K-Nearest Neighbour (KNN), Multilayer Perceptron, and Naive Bayes. The authors of this paper gathered the dataset from the Iraqi population, which included 1250 male and female individuals ranging in age from 1 year to 90 years. It includes three types of classes: hypothyroidism, normal, and hyperthyroidism—as well as 17 attributes that represent patient information and relevant medical analyses. A comparison and implementation of several algorithms performances was conducted. The result shows that RF outperformed other algorithms in the ability to predict; it achieved 98% accuracy.

In an effort to improve the effectiveness of the KNN algorithm in thyroid prediction, Abbad Ur Rehman et al. [5] examined two well-known feature selection methods: chi-square feature selection and L1-norm feature selection. This study utilized two datasets for training one from KEEL dataset repository that contains 7200 cases, with 13 features and another from a registered hospital in Pakistan was used for testing. It contains 3300 instances and 11 features. After assessing the performance of unique distance functions of KNN, Euclidean and Cosine distance functions obtained 97% accuracy at the k value of 1 with the use of chi-square-based feature selection approach for new suggested dataset.

A comparative study on thyroid illness detection was conducted by [6]. In this study, the authors utilizing a multilayer neural network, a learning vector quantization-based neural network, and a probability-based neural network. This study uses the UCI machine learning database's thyroid illness dataset. There are five features and 215 samples in total. The experiment's findings demonstrated that neural network structures can effectively assist in thyroid illness diagnosis; the probability-based neural network outperformed other neural networks, achieving an accuracy rate of 94.8%.

Ahmad et al. in [7] described a mixed decision support system that uses k nearest-neighbour (kNN) weighted preprocessing, an adaptive neurofuzzy inference system (ANFIS), and linear discriminant analysis (LDA). The LDA-kNN-ANFIS approach starts with LDA, which lowers the illness dataset dimensionality and removes pointless features. The second step uses a kNN-based weighted preprocessor to preprocess a subset of the attributes. In the final step, the adaptive neurofuzzy inference system uses preprocesses, chosen characteristics as an input for diagnosis. The suggested technique tested the system's overall performance using a thyroid illness dataset from the University of California, Irvine's machine learning repository. The calculated classification analysis using this approach's accuracy, sensitivity, and specificity values came out to be 98.5, 94.7, and 99.7%, in that order.

III. BACKGROUND

A. Ant Lion Optimization (ALO)

It is a metaheuristic optimizer that draws inspiration from nature, the ALO algorithm emulates the natural predatory behaviour of ant lions [8]. The algorithm aims to resolve complex optimization issues by emulating the communication between antlions, representing superior solutions, and ants, representing potential answers. By building traps to catch other ants, antlions direct the hunt for the best answers [9]. The ALO algorithm successfully explores the search space by using a random walk mechanism for ants that is impacted by the placement of antlions. The ALO algorithm guarantees fast convergence to high-quality solutions and thorough coverage of the solution space by striking a balance between exploration and exploitation. To direct the search for the best answers, it makes use of heuristic data and pheromone trails [10], where the probability of the pheromone update is defined as follows:

$$P_i = \left[\frac{F_i^n}{\sum_i F_i^n}\right] \quad (1)$$

Where:

P_i: is a possibility that any path will be selected.

F_i^n: is the strength of the pheromone on every path.

The ALO algorithm is divided into two populations: an ant population and an antlion population. The general steps that ALO employs to alter these two sets and get the global optimum for a specific optimization issue are as follows:

- The primary search agents of the ALO are the Ant set, which is first initialized with random values.
- In every iteration, the fitness value of every ant is assessed using an objective function.
- Ants use random walks to get around the antlions in the search area.
- There is never an assessment of the antlion population. In actuality, antlions moved to the new placements of ants in subsequent iterations if the ants improved from their initial position, which they presumed to be on.
- Each ant has a single antlion, which updates its location whenever the ant becomes fitter.
- Additionally, there is an elite antlion that affects ant movement regardless of distance.
- Any antlion that surpasses the elite will be replaced by the elite.
- Once an end condition is satisfied, steps b through g are repeated.
- The elite antlion's location and fitness value are given back as the most accurate estimate of the global optimum.

By repeating this procedure, the ALO algorithm efficiently converges to optimum or nearly optimal solutions for a range of optimization issues. Fig. 1 displays the ALO algorithm flowchart:

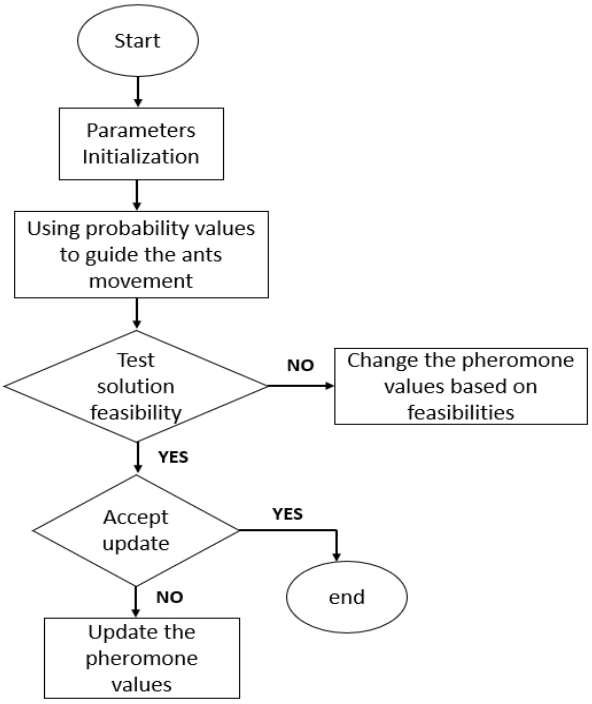

Fig. 1. ALO flowchart.

B. Long Short Term Memory (LSTM)

A unique kind of recurrent neural network (RNN) architecture was created to handle sequential input and overcome the shortcomings of conventional RNNs in identifying long-term relationships [11]. Long-term state memory (Long-term Memory) is achieved by LSTM networks through the use of memory cells that hold onto information over extended periods of time [12]. Each cell in LSTM consists of three gates: the input gate, the forget gate, and the output gate. These gates control the information flow by selecting which input elements to keep, which to reject, and which to go on to the subsequent time step [13]. For applications requiring time series, prediction processing, and other sequential data, LSTM networks are especially useful because they can learn to remember pertinent information and discard irrelevant data by dynamically modifying these gates.

The operation of an LSTM can be explained through the repetitive process that follows by each element in an ordered series. For each time step, the input gate determines how much a new input should impact the cell's current state. Conversely, the forget gate decides whether to remember parts of the previous cell state [14]. The output gate then generates the current output by merging the updated cell state with the new input. This output is not only forwarded to the following layer or ultimate prediction but also returned to the cell in order to analyze the subsequent element in the sequence. This approach enables LSTMs to learn relationships spanning several time steps, which is essential for modelling sequential data well. It also lets LSTMs keep an updated version of short-term memory at each step [15].

In traditional RNN, this repeating unit has a straightforward structure, such as the Tanh layer. While the LSTM and repeating modules have the same design, they differ in their architecture [16]. Rather than having a single neural network layer, Fig. 2 shows four layers that interact in a very special way.

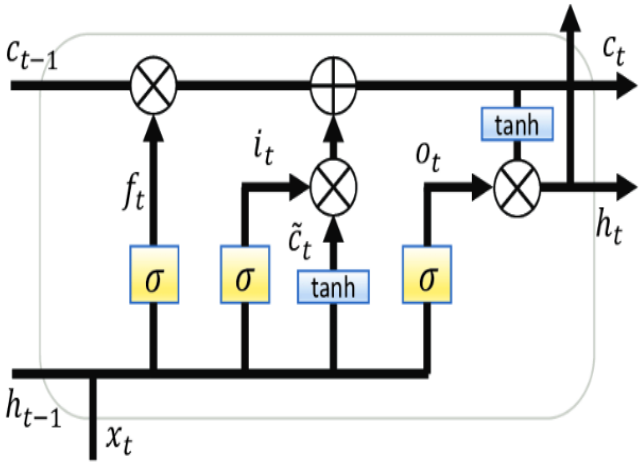

Fig. 2. LSTM architecture.

Where, h_t stands for the current layer's output, x_t for the current input, and h_{t-1} for the output of the previous layer. C_t indicates the current layer's cell status. While the symbols C_{t-1}, ft, and $\tilde{C}_t$ represent the cell state, forget gate layer, and candidate vector, respectively.

We can establish the system by using the forget gate layer given by Eq. (2):

$$f_t = \sigma(W_f . [h_{t-1}, x_t] + b_f) \quad (2)$$

Where, σ: is the sigmoid function, W_f :denotes the forget layer's weights, and b_f: denotes the forget layer's bias. Next, we employ the following Eq. (3), and (4) to update the input layer:

$$i_t = \sigma(W_i . [h_{t-1}, x_t] + b_i) \quad (3)$$

$$\tilde{C}_t = tanh(W_c . [h_{t-1}, x_t] + b_c) \quad (4)$$

Where, i_t : denotes the output of the input gate layer, W_i: denotes the weights of the input gate layer, b_i : indicates its bias, the output of the input candidate layer is represented by $\tilde{C}_t$. Tanh is the output obtained from the input candidate layer, W_c stands for the hyperbolic tangent function, and b_c is the candidate layer's bias. Next, we employ the following Eq. (5) to defined the output layer:

$$o_t = \sigma(W_o . [h_{t-1}, x_t] + b_o) \quad (5)$$

Where, the output of the output gate layer is represented by the symbol o_t. W_o, and $\boldsymbol{b_o}$, which stand for output gate weights and bias, respectively. Eq. (6) provides the output of the output gate layer. Eq. (6) yields the output of the output gate layer, and Eq. (7) provides the current cell state.

$$h_t = o_t * tanh(C_t) \quad (6)$$

$$C_t = f_t * C_{t-1} + i_t * \tilde{C}_t) \quad (7)$$

IV. Research Methodology

Fig. 3 illustrates the five primary steps of the suggested early diagnostic model. The first stage explains the Thyroid disease dataset. Preprocessing is the second stage, where the main goals are analysis, resizing, and enhancing the quality of the dataset. Using the decision tree entropy technique, features are selected in the third step to create the best possible subset of data. The LSTM-based model uses these as training vectors and then employs a meta-heuristic technique to maximize convergence and improve performance. Ultimately, a range of assessments will be conducted to classify the illness classes and evaluate the suggested system utilizing a variety of criteria.

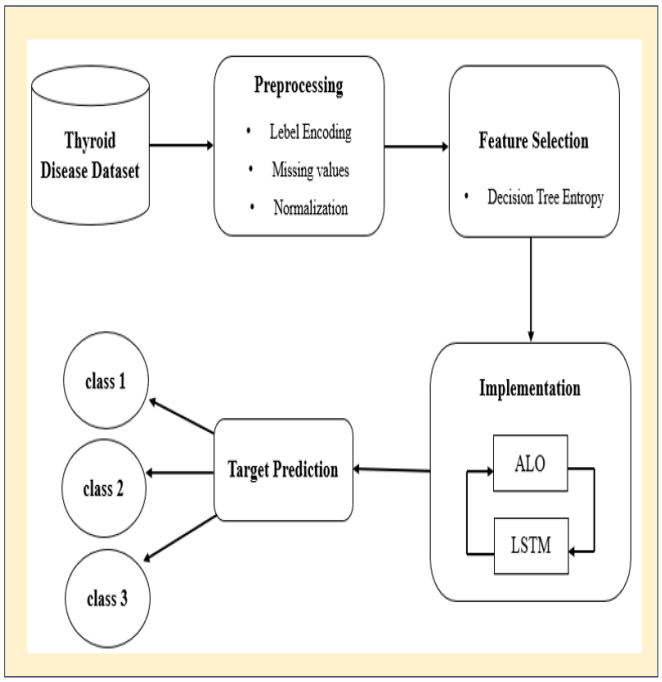

Fig. 3. The proposed system schema.

A. Thyroid Disease Dataset

This investigation used the thyroid dataset from the University of California, Irvine (UCI) repository [17]. We chose this particular data set because it is well-established in the field of thyroid illness classification from earlier studies. The 9,172 samples and 31 features in the dataset record a variety of medical characteristics and thyroid-related test findings. The main features contain patient demographic traits like sex and age, and multiple medical necessities and treatments such as sick, on_thyroxine, thyroid_surgery, TSH measurement, and pregnancy. The dataset also includes various thyroid hormone levels (TSH, T3, TT4, T4U, FTI, and TBG), with some missing values. Additionally, it records the referral source and a target variable, indicating the outcome or diagnosis. Additionally, the dataset contains many thyroid hormone levels with some missing data (TT4, T3, TSH, TT4, FTI, TBG, and T4U). It also logs the referral source and a target variable that indicates the diagnosis or outcome. This dataset is useful for analyzing thyroid diseases because it provides a comprehensive view of patient health and thyroid-related medical history. Table I displays a description of each feature.

TABLE I. ASD Dataset Features

Features	Description	Type
age	The patient age	integer
sex	Identifies a sex of patient	String
on_thyroxine	Whether the patient is taking thyroxine medication	Bool
on_antithyroid_meds	If the patient takes antithyroid medication	
query on thyroxine	Did the patient performed a thyroxine test?	
sick	Does the patient suffer from other diseases?	
pregnant	Whether patient is pregnant	
thyroid_surgery	Whether patient has undergone thyroid surgery	
I131_treatment	Whether the patient is receiving therapy with I131	
query_hypothyroid	Whether the person thinks they are hypothyroid	
lithium	If the patient takes lithium medication	
goitre	Whether the patient suffers from goitre	
tumor	If the patient has a tumour	
hypopituitary	Whether the patient has an overactive pituitary gland	Float
psych	If the patient takes psychiatric or psychological medication	Bool
TSH_measured	Whether TSH was measured in the blood	
TSH	TSH level in blood from lab work	Float
T3_measured	Whether a blood test for T3 was performed	Bool
T3	T3 level in blood from lab work	Float
TT4_measured	Whether TT4 was measured in the blood	Bool
TT4	T4 level in blood from lab work	Float
T4U_measured	Whether a blood test for T4U was performed	Bool
T4U	T4U level in blood from lab work	Float
FTI_measured	Whether a blood test for FTI was performed	Bool
FTI	FTI level in blood from lab work	Float
TBG_measured	If blood TBG levels were tested	Bool
TBG	TBG level in blood from lab work	float
referral_source	Refers to the healthcare facility or physician from whom the patient was referred for additional assessment, diagnosis, or treatment.	String
target	Final diagnosis	String
patient_id	Unique patient ID	

B. Preprocessing

The information prehandling process is regarded as a critical step in data mining tasks. Crude information frequently contains missing or erroneous data. This leads to a state of confusion in machine learning forecasting. This step includes cleaning, extracting, and modifying data into a suitable format for machine processing [18].

1) Label encoding: The categorical variables in the thyroid illness dataset used in this study consist of categorical values that must be converted into a quantitative form. The data is transformed into certain numerical forms using the one-hot encoding technique [19]. This labelling procedure assigns a value of 0 or 1 to each data point based on its category, enabling machine learning algorithms to differentiate between the two groups. During this phase, we convert data for features such as "sex", "sick", etc. from Boolean type values (yes/no) or (t/f) to binary values (1/0), as shown in Fig. 4.

1: age Numeric	2: sex	3: on_thyroxine	4: query_on_thyroxine	5: on_antithyroid_meds	6: sick	7: pregnant	8: thyroid_surgery	9: I131_treatment	10: query_hypothyroid
29.0	0	1	0	0	0	0	0	1	
29.0	0	1	0	0	0	0	0	0	
41.0	1	1	0	0	0	0	0	0	
36.0	1	1	0	0	0	0	0	0	
32.0	1	1	1	0	0	1	0	0	
60.0	1	0	1	0	0	0	1	0	
77.0	1	0	1	0	0	0	1	0	
28.0	0	0	1	0	0	0	1	0	
28.0	0	1	0	0	0	1	1	0	
28.0	0	0	1	0	0	1	0	0	
54.0	1	0	0	0	0	1	0	0	
42.0	1	0	1	0	0	1	0	0

51.0	1	0	0	0	0	0	0	0	
37.0	0	1	0	0	0	0	0	0	
16.0	1	0	0	0	0	1	0	0	

Fig. 4. Part of dataset after levelling.

2) Missing values: Missing data is a common issue, especially in the health industry. Almost every feature and patient record includes some missing data. Thyroid disease dataset has missing values for a number of features, including "TSH," "goitre," "TT4", and "T3." 3. Removing samples or features that have missing values is ineffective because it may lead to the loss of important information during the diagnosis process [20]. At this stage, we apply a filter approach that uses the mean of the training data to fill in the gaps and eliminate missing values from the dataset.

3) Normalization: The process of converting data into a suitable format that may be used for mining is known as data transformation. One method of data scaling is normalization, which is the act of bringing attribute values into a specified range [21]. The normalization strategy has been applied prior to the feature selection and modelling stages since varying attribute values make it more difficult to compare attributes and reduce the learning capacity of algorithms. Therefore, this study applied the Min-Max normalization approach to numeric data types. Each feature's greatest value is changed to 1, the lowest value to 0 [22], and all other values are transformed to a decimal interval. Fig. 5 shown the part of dataset after normalization.

Fig. 5. Part of dataset after normalization.

C. Feature Selection

The information prehandling process is regarded as a critical step in data mining tasks. Crude information frequently contains missing or erroneous data. This leads to a state of confusion in machine learning forecasting. This step includes cleaning, extracting, and modifying data into a suitable format for machine processing [18].

The extra tree classifier [25], using the training dataset, generates numerous decision trees at random. After dividing the decision tree's nodes, we apply either the entropy criteria or the Gini index. In our feature selection procedure, we used entropy measures [26]. The entropy is calculated using Eq. (8). The proportion of rows in the dataset with the label i is represented by pi, while the number c denotes the unique class labels.

$$Entropy(E) = \sum_{i=1}^{c} p_i log_2(p_i) \quad (8)$$

Entropy evaluates the information about the condition of the features with respect to the target. We calculate the entropy of the features derived from each choice, and identify the significant features by computing the cumulative entropy values for each feature. Referred to as the shortlisted features, this group of traits has a high entropy. Fig. 6 uses Multilevel Feature Selection (MLFS) [27] to illustrate the significance of the features. With n_estimators = 300 and max_depth = 21, we employed an ETC classifier for MLFS, which rated the features according to their value. In this step, entropy was able to reduce the number of features from 30 to 10. The subset of features with scores greater than 0.02 is selected to train the learning models, namely 'Thyroid_surgey', 'pregnant', 'tumor', 'psych','TSH','T3', 'TT4', 'T4U', 'FTI' and 'TBG'.

D. Implementation

This stage involves using the Ant Lion Optimizer (ALO) as an optimizer for an LSTM model. During the optimization process, we may modify the algorithm movement equations to update the LSTM model weights and biases. The goal is to find the ideal values for the model's parameters to minimize the loss function and enhance performance.

There are numerous essential steps in the suggested approach when utilizing the ALO algorithm to optimize the hyperparameters of LSTM networks. The first step is establishing the hyperparameter search space for the LSTM model, which includes variables like learning rate, batch size, number of LSTM layers, and number of neurons. An "ant" represents every potential solution in this area, while "antlions"

symbolize the ideal or nearly ideal solutions. ALO creates an initial population of ants, each representing a collection of hyperparameters. A roulette wheel selection procedure guides ants towards antlions at the start of each iteration to replicate their exploration and exploitation of the solution space. The LSTM model assesses each ant's fitness based on its performance. Ants update their locations in the search space based on their interactions with antlions, and either keep or modify the top-performing solutions—antlions—as needed. This iterative procedure continues until convergence to ensure that the chosen hyperparameters effectively maximize LSTM performance. The following steps explain how to achieve this:

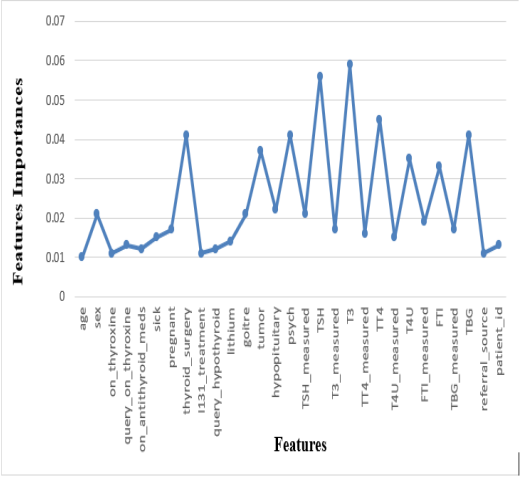

Fig. 6. Entropy value of the thyroid dataset features.

1) Initialization: Set random biases and weights at the beginning of the LSTM model. Determine how many antlions (M) and ants (N) are present. In the search area, place the ants at random starting points [28]. Set the antlions' starting positions at random throughout the search area. Decide on the maximum number of iterations (MaxIter).

2) Fitness evaluation: Use the objective function, which is usually the LSTM model's loss function, to determine each ant's and antlion's level of fitness [29].

3) Movement of ants: Every ant travels at random around the closest antlion inside a hypersphere. Ant movement is determined by the following formulas:

$$c_i(t) = Antlion_j(t) + l_c(t) \quad (9)$$

$$q_i(t) = Antlion_j(t) + h_q(t) \quad (10)$$

Where:

$c_i(t)$ and $q_i(t)$: represent the ith ant's lowest and maximum values at time t $Antlion_j(t)$: represents the location of the jth antlion at t. $l_c(t)$: represents the variable with the lowest value at time t among all variables is represented by $h_q(t)$: represents the variable that has the highest value at time t among all variables.

4) Movement of antlions: Within its capture radius, each antlion moves towards the most fit ant. The following equation determines how antlions move:

$$Antlion_j(t+1) = Antlion_j(t) + rand(). (Antlion_j(t) - X_f) \quad (11)$$

where, $rand()$ is a random value between 0 and 1, and $-X_f$ is the location of the fittest ant inside the capture radius of the jth antlion

5) Building trap: Utilizing a roulette wheel selection process, the fittest antlions are chosen according to their fitness scores [30]. To update the LSTM model's weights and biases inside their capture radius, the chosen antlions are employed.

6) Update: The movement equations are used to update the positions of every ant and antlion [31]. The revised antlion locations are used to update the weights and biases of the LSTM model. The modified LSTM model is used to reassess the fitness of each ant and antlion.

7) Termination: The algorithm ends when it reaches the maximum number of iterations or satisfies a stopping condition. where N represents the number of ants, M stands for the number of antlions, MaxIter signifies the maximum number of iterations, and lc(t) represents the lowest value of all the variables at time t [32].

Algorithm 1, written in Python, describes a classifying model for this study. The configuration of the LSTM model includes 50 units and a 972 softmax activation function to facilitate multi-class classification. The code utilizes the ALO algorithm to optimize the LSTM model. Through the model's training step, the ALO algorithm uses specific hyperparameters, such as 150 iterations and 15 ant lions.

Algorithm 1: Pseudocode of LSTM

```
# Define the LSTM-based model
model = Sequential ()
model.add (LSTM (units=50, input_shape= (time_steps,
num_features)))
model.add (Dense (units=num_classes,
activation='softmax'))
# Define the Ant Lion Optimizer
optimizer=AntLionOptimizer (num_iter=150,
num_antlion=15,
num_dimensions=model. count_params ())
# Compile the model
model. compile (optimizer=optimizer,
loss='categorical_crossentropy', metrics=['accuracy'])
# Train the model
model.fit (x_train, y_train, epochs=100, batch_size=32)
# Make predictions
predictions = model. predict(x_test)
```

V. Result and Discussion

To perform our experiments, we used the following software and hardware requirements: an Intel Core i7-6500U CPU with 16 GB of RAM and a clock speed of 4 GHz.

In the testing stage, we assessed how successfully the ALO_ LSTM-based model classified various kinds of thyroid illness.

After training the model on 80% of the dataset, we tested 30% to evaluate its performance. A confusion matrix [33], which included metrics like true positive, true negative, false positive, and false negative, was used to determine the results. Metrics including accuracy, recall, precision, and F1-Score were employed to assess the performance of the classification model. The following four parameters can be used to calculate the metrics and measurements that are employed.

1) True positive (TP): denotes correctly predicted positive values; in other words, it indicates that both the predicted and actual class values are true.

2) True negative (TN): these are the accurately predicted negative values, which indicate that neither the expected nor the actual class value is false.

3) False positive (FP): in situations where the predicted class is true but the actual class is false.

4) False negative (PN): This occurs when the predicted class is false, but the actual class is true.

The accuracy, recall, precision, and F1 score may be determined based on the previously mentioned parameters. These can be expressed as stated using the following equations:

$$Accuracy = \frac{TP+TN}{TP+FP+TP+TN} \quad (12)$$

$$\text{Precision} = \frac{TP}{TP+FP} \quad (13)$$

$$\text{Recall} = \frac{TP}{TP+FN} \quad (14)$$

$$F1 - score = \frac{TP}{TP+FN} \quad (15)$$

A. First Experiment

This study conducted two experiments to examine how the ALO metaheuristic algorithm may enhance the LSTM-based model's performance. In the first experiment, we employed the LSTM algorithms directly, regardless of the AlO, and used 'Adam' as an optimizer parameter. In contrast, in the second experiment, we used the ALO optimizer to improve the accuracy of the classification model. Table II shows the parameters used for LSTM in the first experiment. Where he Fig. 7 present the confusion matrix values used in determined the model performance.

TABLE II. THE LSTM PARAMETER FOR FIRST EXPERIMENTAL OUTCOMES

Parameters	Values
Model	Sequential
Hidden layer	4
Hidden unites	50
Neurons per hidden layer	30,30,30,1
Type of layer	LSTM
Activation hidden layer	Softmax
Epoch	100
Optimizer	ALO
Time step	1

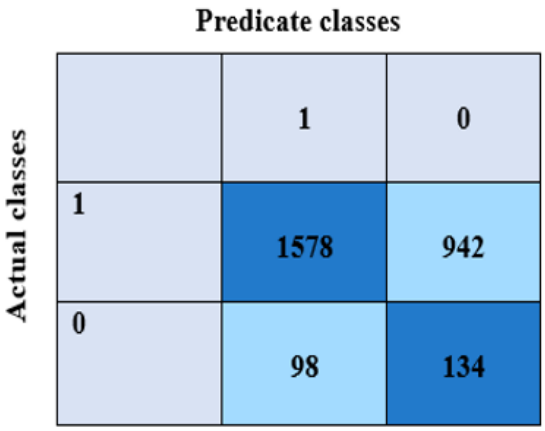

Fig. 7. Confusion matric of LSTM with Adam optimizer.

B. Second Experiment

The second experiment uses the ALO method as an optimizer for LSTM model parameters. Its purpose is to identify the optimum combination of weights and biases for the LSTM model, reducing the loss function while simultaneously speeding convergence through effective search space travel. The ALO algorithm employs specific hyperparameters, such as 150 iterations and 15 ant lions, during the model's training phase. The LSTM parameters for the second experiment are shown in Table III, and Fig. 8 details the confusion matrix from the second experiment. Additionally, Table IV displays the outcomes of our studies.

TABLE III. THE LSTM PARAMETER FOR SECOND EXPERIMENTAL OUTCOMES

Parameters	Values
Model	Sequential
Hidden layer	4
Hidden unites	50
Neurons per hidden layer	30,30,30,1
Type of layer	LSTM
Activation hidden layer	Softmax
Epoch	100
Optimizer	ALO
Time step	1

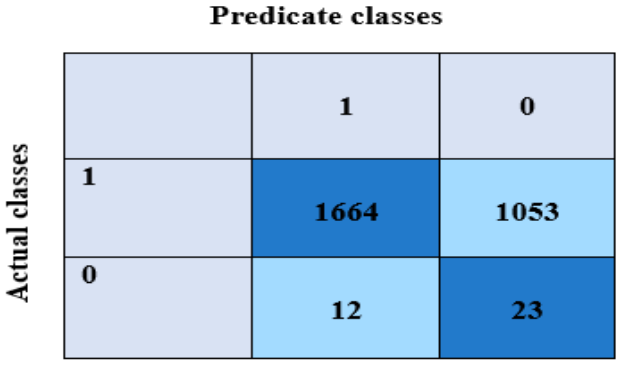

Fig. 8. Confusion matric of LSTM with ALO optimizer.

TABLE IV. COMPARATIVE CLASSIFICATION PERFORMANCES OF LSTM BASED MODEL

Models	Accuracy	Precision	Recall	F1 - score
LSTM based model	91.4%	94.1%	92.1%	93.1%
LSTM with ALO algorithm	98.6%	99.2%	89.6%	98.6%

Based on the findings, we conclude that the model performs well in every experiment, with high precision values ranging from 94.1% to 99.2%. This means that a high rate of the predicted positive instances is correct. The values of recall also show promising performance, ranging from 99.2% to 89.6%, meaning that a substantial proportion of the actual positive samples are predicted correctly. We establish the F1-scores at 98.9%, indicating a good overall performance and maintaining a balance between recall and accuracy. In the second experiment, the ALO algorithm produced an average accuracy, recall, and F1-score of 98.6%, indicating consistently strong classification performance across all classes. This indicates that the classification model is successful in correctly classifying the various thyroid disease classes.

From Table III, the recommended strategy, which selected the optimal hyperparameter for the LSTM using the AlO algorithm, improved the classifier overall by 7.2% compared to the achieved accuracy. With excellent accuracy and consistency across all criteria, the classification performance results show that the model performs robustly and consistently when it comes to differentiating between the different thyroid classes.

As mentioned in references [21], and [22], pre-processing and transforming the study's database into a regular form enhanced the performance of the proposed model. The use of the feature selection algorithm also helped to reduce the number of features used in training the model by focusing on the features with high impact and importance in the prediction process.

Additionally, after comparing the outcomes of the proposed strategy with those of alternative approaches found in the literature. It validates that, even with the same database but a different technique, the efficiency attained by the suggested system for prediction when using the ALO algorithm to enhance the performance of the LSTM algorithm surpasses other research with greater classification accuracy. It was also observed that although some previous research not employed any approaches in feature selection and these factors might have a big impact on how well the classification methods work.

VI. CONCLUSION

The primary goal of this research is to create a new model that predicts thyroid illness by combining the ALO metaheuristic algorithm with the LSTM algorithm. The proposed methodology is based on three steps: preprocessing, feature selection, and classification. By using the commonly used data on thyroid disorders, we trained and evaluated the proposed technique. We employed several metrics, such as accuracy, precision, recall, and F1 score, to assess the model's performance. The results of the experiments showed that 1) using entropy in the feature selection step can cut the total number of features from 31 to 10; and 2) using the ALO algorithm in the suggested strategy made the LSTM classifier 7.2% better overall and gave the best accuracy of 98.6%. The model's high level of accuracy and usefulness illustrate its practical relevance and significance in enhancing patient care. Future studies in this area should concentrate on investigating more intricate model architectures that are capable of capturing even more minute patterns in the thyroid data. Additionally, the model's performance might be improved, and more thorough insights could be obtained by employing different feature selection approaches other than the entropy technique used in this work. We can bridge these gaps and strive for innovative advancements. We can continue to refine the classification models for thyroid illnesses, enabling more accurate and reliable identification of thyroid diseases. This could revolutionize healthcare delivery and improve outcomes for individuals suffering from thyroid conditions.

ACKNOWLEDGMENT

We gratefully acknowledge University of Petra for their invaluable support and resources throughout this research. The realization of our project was significantly aided by our research group and all its members. Their unwavering support and the conducive academic environment provided invaluable assistance throughout this endeavour. Our heartfelt thanks to our colleagues and students for their insightful contributions and steadfast support.

Balancing Privacy and Performance: Exploring Encryption and Quantization in Content-Based Image Retrieval Systems

Mohamed Jafar Sadik, Dr. Noor Azah Samsudin, Dr. Ezak Fadzrin Bin Ahmad
Faculty of Computer Science and Information Technology (FSKTM),
Universiti Tun Hussein Onn Malaysia (UTHM), Batu Pahat, Johor 86400, Malaysia

***Abstract*—This paper presents three significant contributions to the field of privacy-preserving Content-Based Image Retrieval (CBIR) systems for medical imaging. First, we introduce a novel framework that integrates VGG-16 Convolutional Neural Network with a multi-tiered encryption scheme specifically designed for medical image security. Second, we propose an innovative approach to model optimization through three distinct quantization methods (max, 99% percentile, and KL divergence), which significantly reduces computational overhead while maintaining retrieval accuracy. Third, we provide comprehensive empirical evidence demonstrating the framework's effectiveness across multiple medical imaging modalities, achieving 94.6% accuracy with 99% percentile quantization while maintaining privacy through encryption. Our experimental results, conducted on a dataset of 1,200 medical images across three anatomical categories (lung, brain, and bone), show that our approach successfully balances the competing demands of privacy preservation, computational efficiency, and retrieval accuracy. This work represents a significant advancement in making secure CBIR systems practically deployable in resource-constrained healthcare environments.**

Keywords*—*Content-Based Image Retrieval (CBIR); Convolutional Neural Networks (CNN): Encrypted data; Feature extraction; Fully Homomorphic Encryption (FHE); medical imaging; privacy; quantization; retrieval accuracy

I. INTRODUCTION

Content-Based Image Retrieval (CBIR) systems play a vital role in managing digital images, as they support the sorting and retrieval of images based on their specific content like colour patterns, texture elements or shape structure beyond the external tags or descriptions. By eliminating manual annotation individuality and its limitations, this approach significantly outperforms traditional keyword-based retrieval methods by automating the task. By extracting features and indexing images according to those extracted data, CBIR systems can deliver more intuitive and reliable outcomes by predicating directly from the visual content of an image [1–3].

Incorporating encryption into CBIR systems introduces Encryption is being considered as an essential security element for CBIR systems because of the higher and severe requirements with a larger number of digital images to be protected from unauthorized access. By using encryption, sensitive information within images stays safe from unauthorized access, while still enabling the CBIR system to retrieve the required images. This is especially relevant in contexts where privacy is paramount and the image data is too sensitive to leave unencrypted [4–8].

The medical sector stands as a prominent example where the integration of encryption with CBIR is not just beneficial but essential. Medical images contain private patient information, and their retrieval requires the utmost care to maintain confidentiality. As such, medical image retrieval systems must adapt to perform effectively on encrypted data, ensuring that patient privacy is maintained without compromising the diagnostic value of the images [6, 9,10].

Investigating the technical side, the effectiveness of CBIR can be enhanced with the use of advanced machine learning models such as transformers and Convolutional Neural Networks. These pre-trained models have shown exceptional ability in feature recognition and extraction from large datasets, making them irreplaceable in encrypted image analysis. Transformers handle data sequence well, which can be critical in understanding image context, while Convolutional Neural Networks excel in pattern recognition due to their layered architectural design [11–16].

Quantization further refines the functionality of Convolutional Neural Networks in CBIR by compressing the models without significant loss of performance. This process reduces the demand on computational resources and is particularly advantageous for deploying sophisticated CBIR in environments with hardware limitations or where swift image retrieval is needed [17–20].

Despite the significant advances in Content-Based Image Retrieval systems, particularly in the realm of medical imagery, there remains a critical gap in the development of a generalized framework that seamlessly integrates robust encryption protocols. Current CBIR systems often face a trade-off between encryption strength and retrieval accuracy, with many falling short in providing a secure yet efficient retrieval process that caters to the highly sensitive nature of medical data [15,19, 21–23]. Additionally, the application of such systems is frequently constrained by the computational power required for processing and retrieving high-resolution medical images, which further complicates their deployment in resource-limited settings commonly found in healthcare environments.

Addressing these challenges, our study aims to propose a comprehensive framework for CBIR tailored to the medical domain. The goal is to craft a lightweight, secure encryption

algorithm that adequately protects patient confidentiality without affecting the system's ability to accurately retrieve and analyze medical images. Encryption alone, however, is not the primary focusing point of this framework. The proposed system also seeks to harness the power of Convolutional Neural Network-based pre-trained models, particularly the VGG-16 architecture well-known for its ability in image recognition tasks, to facilitate the feature extraction process in encrypted domains.

Furthermore, to tackle the issue of computational Furthermore, to tackle the issue of computational efficiency, the integration of a quantization approach is crucial. In order to deploy the vgg-16 model into practical usage, it is necessary that its memory footprint and computational needs are significantly reduced thereby making the solution suitable to be deployed even in work environment having low check for computational power. Our use case is under the same limit, by processing through quantization we hope to not only improve efficiency of our system but still keep a high retrieval performance which has been hard trade-off in many existing CBIR systems.

II. Contributions

There are three major contributions in this work to-wards medical CBIR:

A. Developing an Efficiency-Aware Framework

We illustrate a CBIR system for medical images, focusing on computational efficiency and accuracy as the main goals. The system is built for high-throughput needs of medical diagnostics with the modest computational resources common in healthcare settings.

B. Pre-Trained CNN Model

The cornerstone of our retrieval pipeline around which all other piece's center, the VGG-16 model is a pre-trained Convolutional Neural Network we use for feature extraction. In using this well-developed model, our framework can take advantage of its deep learning power to improve the accuracy in medical image analysis.

C. Advanced Approach to Quantization

The framework uses a variety of strategies to quantization, including max quantization, 99% percentile quantization, and Kullback-Leibler Divergence (KL) based quantization. These methods reduce the model's memory footprint and computational load, which is crucial for scalable and efficient CBIR deployment.

III. Literature Survey

A. Feature Extraction and Encryption Methods for CBIR

In the rapidly evolving field of cloud-based privacy-preserving image retrieval, researchers have embarked on a journey to balance the confidentiality of encrypted images with the necessity of efficient retrieval mechanisms. This literature survey begins with foundational encryption techniques that pave the way for more advanced retrieval methods, highlighting the journey from basic encryption to sophisticated integrations of cryptographic algorithms and machine learning models. It provides a comprehensive over-view of the state-of-the-art methods developed to ad-dress the dual challenges of maintaining privacy and ensuring practical utility in cloud environments.

Starting with encryption strategies for image security, works such as [5, 24, 25] introduce novel schemes focusing on the variation of Discrete Cosine Transform (DCT) coefficients, encryption of DC and AC coefficients using stream cipher and scrambling encryption, and the secure retrieval of images in the YUV color space, respectively. These foundational methods set the stage for the development of more complex retrieval mechanisms, emphasizing the need for encrypted images to be both secure and retrievable.

Building on these encryption methodologies, studies [25–29] delve into advanced retrieval mechanisms that operate within the constraints of encrypted do-mains. Huffman-code based retrieval, secure Local Binary Pattern (LBP) features, and the application of Markov processes exemplify the innovative approaches taken to extract meaningful information from encrypted images. These mechanisms showcase the progression towards retrieval systems that are not only secure but also capable of accurately identifying images similar to a query image.

Application-specific solutions, as discussed in works [30–33], further demonstrate the usefulness and practical implications of privacy-preserving image retrieval technologies. The introduction of privacy-preserving Scale-Invariant Feature Transform (SIFT), Convolutional Neural Network (CNN) frame-works for medical data, and systems like PIC (Privacy-preserving Image search system on Cloud) high-light the field's move towards addressing specific needs such as medical diagnosis aid and large-scale image search with fine-grained access control. These tailored approaches underline the importance of developing encrypted image retrieval systems that accommodate to the unique requirements of different domains, emphasizing the critical role of privacy in sensitive applications.

Lastly, comparative analyses and the proposal of new frameworks, as seen in [34–42], reflect the ongoing evolution and refinement of privacy-preserving image retrieval methods. By comparing homomorphic encryption-based techniques with feature/index randomization-based techniques and introducing novel frameworks like IES-CBIR for outsourced storage and retrieval, these works contribute to a deeper under-standing of the trade-offs between security, efficiency, and usability. The development of dynamic verifiable retrieval schemes and multi-indexed hashing approaches represents the cutting edge of research, aimed at improving the precision and security of image retrieval in cloud-based systems. We present a comparative analysis between each of the mentioned methods in Table I. It is found that non-of the existing methods have used VGG16 for encrypted CBIR. Furthermore, to the best of our knowledge, none of the existing works on Content-Based Image Retrieval (CBIR) have optimized the trained model through post-training quantization. Quantization techniques are pivotal for augmenting the computational efficiency of CBIR systems. By diminishing the bit-precision of neural network parameters, quantization paves the way for swifter and more energy-efficient computations across extensive hardware accelerators. This precision reduction not only accelerates computational speed but

also aids in energy conservation, rendering it an indispensable strategy for the deployment of large-scale CBIR systems.

As presented in Fig. 1, the general taxonomy of existing works in the field of Content-Based Image Retrieval (CBIR) can be categorized into four main areas, each focusing on different aspects and method-ologies to enhance privacy-preserving image retrieval. The first category, Encryption Methods for Image Retrieval, aims to develop and apply encryption techniques to secure image data while maintaining its retrievability. Approaches in this category include symmetric and asymmetric encryption schemes, homomorphic encryption for computation on encrypted images, and watermarking techniques for securely embedding retrieval information.

TABLE I. SUMMARY OF METHODS AND FEATURES IN ENCRYPTED CONTENT-BASED IMAGE RETRIEVAL (CBIR) AND RELATED APPLICATIONS

Work	Method of Encryption	Type of Features Extracted	Retrieval Model	Quantization
[24]	Permutation of DCT coefficients	Histogram at each frequency position	Unsupervised/Supervised retrieval using integrated distances and conditional probabilities	×
[25]	Stream cipher and scrambling encryption of DC and AC coefficients	AC coefficients histogram	Statistical comparison of histograms to return closest encrypted images	×
[27]	Stream cipher, permutation cipher for Huffman code	Encrypted Huffman-code histograms	Feature comparison to return similar content images	×
[29]	Color value substitution, block permutation, intra-block pixel permutation	Normalized histogram of encrypted visual words (BOEW model)	Direct similarity measurement between feature vectors on the cloud server side	×
[28]	Big-block permutation, polyalphabetic cipher	Secure Local Binary Pattern (LBP) features	Retrieval based on order-preserving encryption and secure LBP features	×
[43]	Stream cipher and permutation encryption for DCT coefficients	Transition probability matrices (Markov process), SVM classification	Feature extraction and classification to evaluate similarity between encrypted images	×
[30]	Homomorphic encryption	Privacy-preserving SIFT features	Secure SIFT feature extraction and representation in the encrypted domain	×
[32]	Homomorphic encryption	Wavelet-based image features	Secure CBIR for diagnosis aid systems with data confidentiality preservation	×
[33]	Not explicitly mentioned (uses encrypted images)	Features extracted by CNN	Privacy-preserving classification and retrieval using CNN framework	×
[40]	Homomorphic encryption vs. feature/index randomization	Not explicitly mentioned	Comparative analysis for confidentiality-preserving image search	×
[34]	Randomized binary encoding and Gaussian random matrix	Encrypted visual words	Secure index construction for large-scale image retrieval without decryption	×
[42]	Comparable encryption	Not explicitly mentioned	Encrypted image search scheme balancing efficiency and privacy	×
[37]	Feature descriptors extracted by CNN models, encrypted hierarchical index tree	Features extracted by CNN, hierarchical index tree	Similarity search for encrypted images using SEI with enhanced key privacy	×
[38]	Pre-trained CNN model, encrypted index based on K-means clustering	Features extracted by CNN	Dynamic verifiable retrieval over encrypted images (DVREI) scheme	×
[36]	ViT model and ITQ method for multi-indexed hashing (MIH)	Features extracted by ViT model, secure Hamming distance protocol	Privacy-preserving content-based image retrieval using MIH	×
[41]	Cryptographic techniques and secure indexing schemes	Not explicitly mentioned	Content-based retrieval over encrypted multimedia databases	×
[35]	Based on IES-CBIR scheme	Not explicitly mentioned	Outsourced privacy-preserving storage and retrieval in large shared image repositories	×
[44]	Encryption of difference matrices of RGB components (EDH-CBIR)	Euclidean distance between feature vectors to measure similarity	Euclidean distance	×
[45]	Permutation of big-blocks and substitution of binary code of DCT coefficients	Local Markov Features and Bag-of-Words Model	Efficient Content-Based Image Retrieval (CBIR) service for image owners with direct feature extraction	×
[46]	Thumbnail-preserving encryption (TPE)	HSV and uniform local binary pattern (ULBP) features	Thumbnail-Preserving Encryption (TPE)	×
[47]	Fully Homomorphic Encryption (FHE), Secure Multi-Party Computation (SMPC), AES, FPE	Local invariant features	CBIR, Attribute-Based Encryption (ABE), Functional Encryption (FE)	×
[48]	Asymmetric scalar-product-preserving encryption (ASPE)	Local invariant features	Invariant Features Selection	×
[49]	Watermark-based encryption	Dominant local patterns, Relative directional edge patterns (RDEP)	Dominant Local Patterns, Watermark Encryption	×
Ours	Multi-Tiered Texture and Color Encryption (MTTCE)	VGG-16 based features	Efficiency aware VGG-16 retrieval model with supporting three quantization modes	√

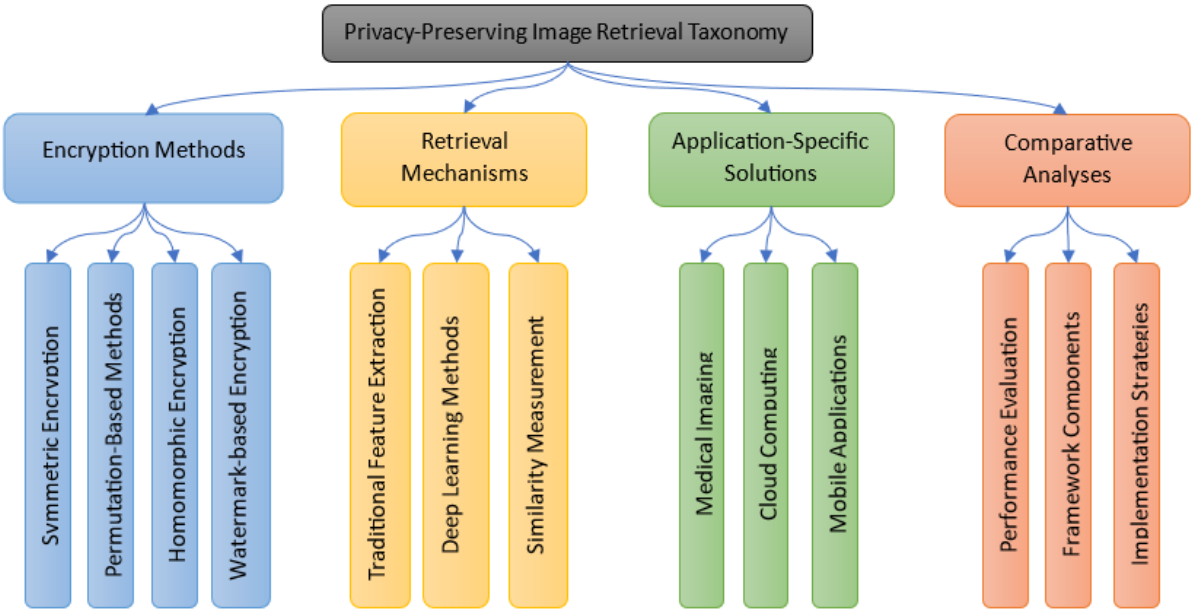

Fig. 1. The general taxonomy of existing works focuses on CBIR.

The second category, Retrieval Mechanisms and Feature Extraction, seeks to enhance the efficiency and accuracy of retrieval mechanisms by optimizing feature extraction and similarity measures. This involves traditional feature extraction methods such as SIFT, SURF, and HOG, as well as deep learning-based feature extraction using convolutional neural networks (CNNs) and similarity measures including Euclidean distance, cosine similarity, and advanced metrics tailored for encrypted data.

The third category focuses on Application-Specific Solutions for Privacy-Preserving Retrieval, developing tailored solutions that address specific application domains and their unique privacy requirements. The fourth and final category, Comparative Analyses and Framework Proposals, involves conducting comparative studies of existing methods and proposing comprehensive frameworks to guide future research and implementation in the field of CBIR. This taxonomy provides a structured overview of the diverse approaches and innovations aimed at enhancing the privacy and effectiveness of image retrieval systems.

B. Efficiency Optimization Methods

The quest for optimizing search efficiency in large-scale image databases has given rise to several innovative strategies in the realm of content-based image retrieval (CBIR). Among these, quantized deep learning frameworks have become a cornerstone for hashing-based retrieval systems. Hashing Nets tackles the challenge of limited storage space and computational resources, especially relevant for satellite remote sensing image retrieval and unmanned aerial vehicles (UAVs). The proposed Quantized Deep Learning to Hash (QDLH) framework introduces binarized weights and activation functions, creating a lightweight neural network that considerably reduces the demand on hardware resources [50]. This need for efficiency extends to other works, such as the application of deep model quantization and compression to CNNs on ASIC chips, achieving comparable performance to floating-point models with a mere 2-bit weights quantization [51].

Addressing the constraints of mobile device capabilities, the OMCBIR framework emerges with an innovative solution. It presents ALNet, an ultra-lightweight neural network that harnesses pointwise group convolution, channel shuffle, and a convolutional attention module, substantially minimizing the model's size without compromising on retrieval accuracy [52].

For the complex domain of remote sensing images, a different approach is introduced in (2021) with the APQ method. This method leverages a multi-scale attention-based CNN combined with an enhanced product quantization technique to efficiently compress features, significantly improving retrieval performance [53].

Furthermore, the domain of multi-label image retrieval presents its own set of challenges, particularly in maintaining semantic integrity within quantization errors. The Multi-label Contrastive Hashing (MCH) technique innovates with a curriculum strategy that carefully adjusts the quantization loss weight, fostering the preservation of multi-level semantic similarity more effectively than prior hashing-based retrieval methods [54].

C. Research Gap

Despite the remarkable progress in content-based image retrieval (CBIR) systems, there exists a visible gap in the domain of medical image retrieval, specifically concerning the post-training optimization of pre-trained models. Current literature prominently features methods optimized for general image databases or remote sensing images, focusing on quantization and hashing to enhance retrieval efficiency and reduce computational demands. These advancements, while substantial, are not directly translatable to the unique requirements and complexity of medical imaging.

Medical images, such as radiographs, MRI, and CT scans, present distinct challenges due to their high-dimensional data and the critical need for precision in feature extraction to capture clinically relevant information. Pre-trained models, often developed on natural image datasets, which may not naturally capture the specific features and diseases that are noticeable in medical images. Fine-tuning pre-trained models on medical datasets is a common strategy to transfer learning from one domain to another; however, there is an obvious absence of research into post-training optimization techniques that refine these models further for the medical domain.

Existing fine-tuning practices largely focus on adapting the pre-trained models to new datasets by retraining some layers while keeping others frozen. This method is beneficial but does not fully exploit the potential of the models to conform to the particularities of medical image analysis. Post-training optimization can involve techniques such as neural architecture search (NAS) tailored to medical datasets, advanced quantization specifically sensitive to medical imaging features, or specialized regularization strategies that address the overfitting risks associated with medical image datasets, which are often smaller and more variable than those used in the training of general models.

The absence of a dedicated post-training optimization phase means that while the models may perform well on general benchmarks, their efficacy in medical scenarios, where the margin for error is minimal, could be significantly enhanced. Such optimizations could lead to improvements in retrieval accuracy, relevance of retrieved images, and ultimately, clinical usefulness. Our article aims to investigate this gap, proposing a framework for post-training optimization of pre-trained models specifically fine-tuned for medical image retrieval, with the goal of maximizing the clinical relevance and accuracy of the retrieved results.

IV. METHODOLOGY

A. Problem Formulation

Given an encrypted image database and a feature extraction model, the system must efficiently process query images to retrieve and return images that are visually similar to the query image. This process involves encryption and decryption of images and features to ensure privacy preservation, requiring the system to address several key challenges:

1) Efficient and secure encryption and decryption mechanisms that maintain the usability and accessibility of the retrieval system.

2) The development of a robust feature extraction model that can effectively operate on encrypted images to extract meaningful features for identification.

3) The implementation of an effective identification and retrieval mechanism that can operate in the encrypted domain, ensuring privacy while maintaining high retrieval accuracy.

4) The development of a quantization of the trained retrieval model to enable efficiency and scalability.

5) The main objective is to achieve a balance between privacy preservation, computational efficiency, and retrieval effectiveness within a cloud-based CBIR system.

More formally, we write the problem based on the following entities and roles:

1) Data owner: The data owner possesses an image database $I = \{i_1, i_2, \dots, i_n\}$ consisting of n images. Each image in the database is encrypted using a unique key from the set $K = \{k_1, k_2, \dots, k_n\}$, resulting in an encrypted image database $E = \{e_1, e_2, \dots, e_n\}$. The data owner also trains a feature extraction model Ψ with E, which is capable of extracting features from encrypted images. The encrypted database E and the model Ψ are then uploaded to the cloud server for storage and deployment.

2) Cloud server: Serving as the backbone for storage and computational power, the cloud server stores the encrypted image database E and the feature extraction model Ψ. Upon receiving an encrypted query image EQ from a query user, the server processes E and EQ through Ψ to extract their features, $F_E = \{f_{e1}, f_{e2}, \dots, f_{en}\}$for the database images and F_{EQ} for the query image. The similarity between F_E and F_{EQ} is assessed using the Euclidean distance metric to identify the k most similar images. The identifiers of these images, $ER = \{er_{ID1}, er_{ID2}, \dots, er_{IDk}\}$, are then returned to the query user.

3) Query user: The query user is interested in retrieving images similar to a query image Q. The query image is first encrypted to EQ and then uploaded to the cloud server. After receiving the encrypted query result set ER from the cloud server, the query user sends these identifiers $ID^R = \{ID_{R1}, ID_{R2}, \dots, ID_{Rk}\}$ back to the data owner to obtain the corresponding decryption keys $RK = \{rk_{IDR1}, rk_{IDR2}, \dots, rk_{IDRk}\}$.

These keys allow the query user to decrypt the received images, resulting in the final retrieval set $R = \{r_{IDR1}, r_{IDR2}, \dots, r_{IDRk}\}$. We present the mathematical symbols used in this article in Table II.

TABLE II. THE SUMMARY OF NOTATIONS

Notations	Definitions
n	The size of the image dataset
m^2	Number of blocks
$I = \{i_1, i_2, \cdots, i_n\}$	The plaintext image dataset
$E = \{e_1, e_2, \cdots, e_n\}$	The encrypted image dataset
$K = \{k_1, k_2, \dots, k_n\}$	The set of security keys
$F_E = \{f_{e1}, f_{e2}, \cdots, f_{en}\}$	The encrypted image feature dataset
Q	The plaintext query image
EQ	The encrypted query image
F_{EQ}	The encrypted query image feature
Ψ	The feature extraction model
$\mathrm{ER} = \{\mathrm{er}_{\mathrm{ID1}}, \mathrm{er}_{\mathrm{ID2}}, \cdots, \mathrm{er}_{\mathrm{IDk}}\}$	The encrypted query result images
$\mathrm{ID}_R = \{\mathrm{ID}_{R1}, \mathrm{ID}_{R2}, \cdots, \mathrm{ID}_{Rk}\}$	The query result image ID
$\mathrm{RK} = \{\mathrm{rk}_{\mathrm{IDR\ 1}}, \mathrm{rk}_{\mathrm{IDR\ 2}}, \cdots, \mathrm{rk}_{\mathrm{IDRk}}\}$	The key corresponding to the resulting image
$R = \{r_{\mathrm{IDR1}}, r_{\mathrm{IDR2}}, \cdots, r_{\mathrm{IDRk}}\}$	The query result image
$\mathrm{sub}\,I = \{\mathrm{sub}\,I_1, \mathrm{sub}\,I_2, \cdots, \mathrm{sub}\,I_{m^2}\}$	Image subblock
$\mathrm{sub}\,E = \{\mathrm{sub}\,E_1, \mathrm{sub}\,E_2, \cdots, \mathrm{sub}\,E_{m^2}\}$	Encrypted image subblock

B. System Architecture

The sequence diagram showed in Fig. 2 presents the operational workflow of a privacy-preserving Content-Based Image Retrieval (CBIR) system, illustrating the interactions among three key entities: the Data Owner, the Cloud Server, and the Query User. The process begins with the Data Owner, who possesses a database of images intended for secure retrieval. This entity takes the initial steps by encrypting the image database, creating an encrypted image database (E), and developing a feature extraction model (Ψ). These components are crucial for ensuring privacy and facilitating feature-based image retrieval in an encrypted domain. Once prepared, the Data Owner uploads both the encrypted image database and the feature extraction model to the Cloud Server, a platform that provides the necessary storage and computational power for the system. Upon the system's readiness to handle queries, the Query User engages by first encrypting a query image (EQ) using a similar encryption methodology as the Data Owner. This encrypted query image is then uploaded to the Cloud Server, indicating the start of the retrieval process. The Cloud Server, leveraging the previously uploaded feature extraction model, processes both encrypted query image and encrypted image database to extract their respective features. Although the specific approach for measuring similarity is abstracted in this diagram, the Cloud Server identifies the k most similar images to the query and returns their identifiers (ER) to the Query User. The interaction between the Query User and the Data Owner is reinitiated when the Query User requests the decryption keys for the received images. The Data Owner responds by providing the necessary decryption keys (RK), enabling the Query User to decrypt and access the final retrieval set of images (R). This sequence diagram effectively encapsulates the secure and private workflow of a CBIR system, emphasizing encryption for privacy, cloud-based feature extraction and retrieval, and decryption for accessing the retrieved images, all while abstracting the complexities of similarity measurement and feature extraction details.

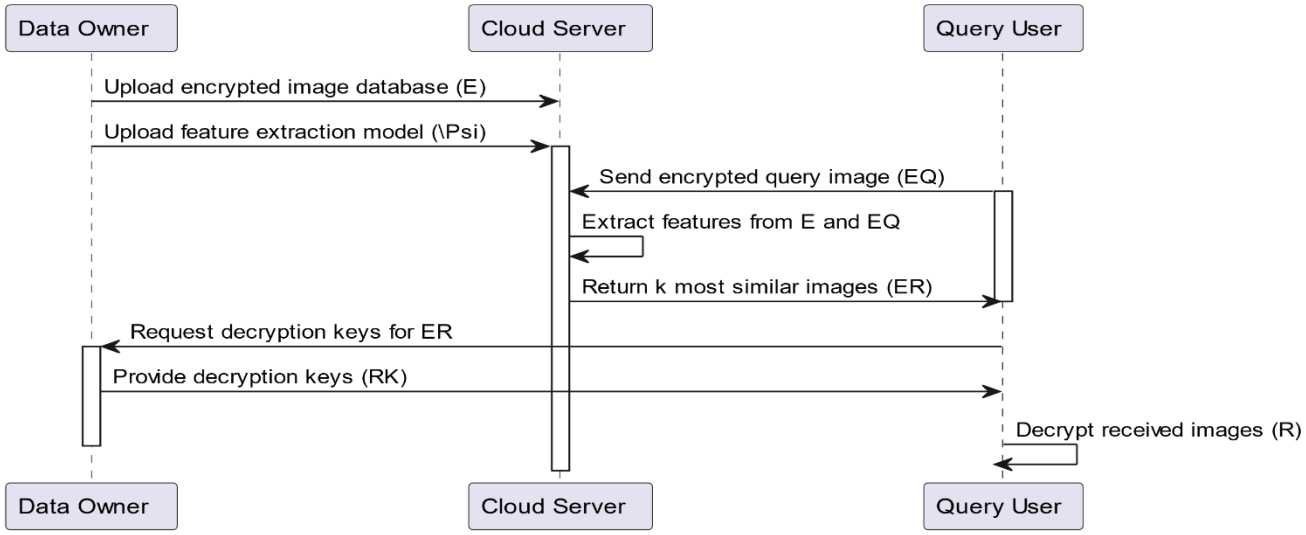

Fig. 2. Sequence diagram illustrating the operational flow of a privacy-preserving Content-Based Image Retrieval (CBIR) system.

C. Framework

The framework proposed in Fig. 3 provides a holistic view of encrypted image retrieval with modified VGG-16 architecture and state-of-the-art quantization methods. It helps in solving the dual issues of ensuring privacy through encryption and enabling efficient content-based image retrieval.

The process started with the encryption of data, all images from the training distribution were then encrypted and stored in cloud. This step makes certain that data privacy is met at every point of retrieval. The basis of the framework is a VGG-16 feature extraction module adjusted to work with encrypted images. Using the encrypted input image, convolutional layers and max pooling is applied on top of this leading to fully connected layers that give an output feature vector.

The same framework also introduces a key model optimization module just to keep the model's memory and efficiency. There are four quantization methods evaluated: Max Quantization, KL Quantization, 99 Percentile Quantization method and Full Model Method. These techniques were applied to the original model weights to obtain a quantized model that trades retrieval accuracy for computational and memory efficiency.

The quantized model is followed by a fine-tuning step on the encrypted dataset preparing its parameters, then to suit the encrypted medical images. The tuned model is then deployed to cloud where given query images while returns the K similar images in database.

The framework also covers secure user interaction flow as well. The users are able to send encrypted query images, receive the encrypted results and ask for decryption keys from data owners to obtain the recognized multimedia files. This means the secure conversion of text throughout its lifecycle as it is fetched.

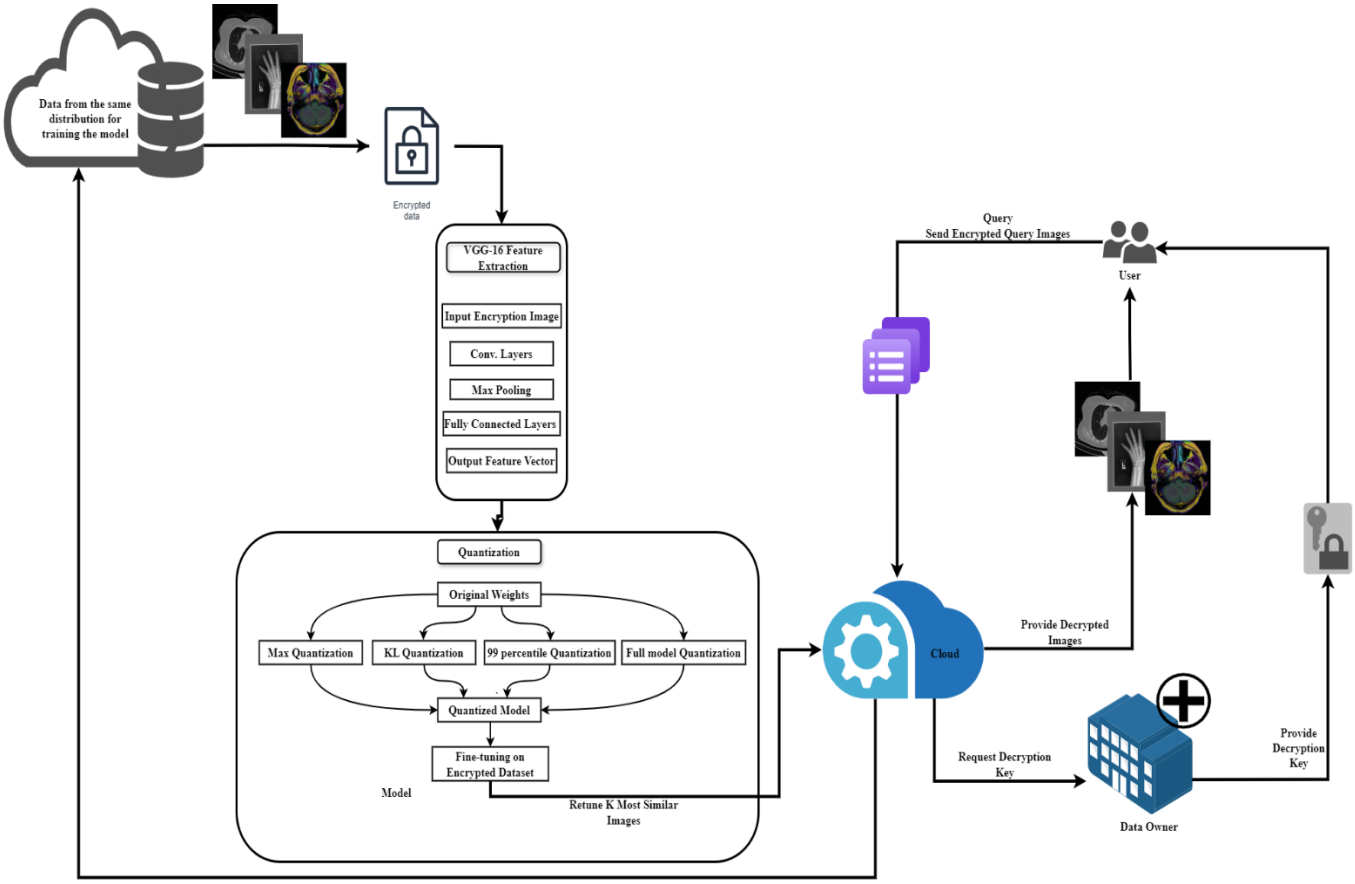

Fig. 3. Encrypted medical image retrieval framework using VGG-16 and quantization techniques.

In addition to support for advanced encryption, feature extraction and quantization as well secure user interactions this framework presents one of the most state-of-the-art tools in privacy-preserving content-based image retrieval especially useful e.g., when it comes to dealing with sensitive domains like medical imaging.

D. Encryption

The encryption algorithm detailed in the provided pseudocode is a comprehensive multi-stage process designed to enhance the security of content-based image retrieval (CBIR) systems. It ensures both local and global image information is encrypted, safeguarding essential retrieval features while preventing unauthorized access. By methodically encrypting local textures, global textures, and color information, this algorithm offers a robust solution to maintaining the privacy and security of image data in CBIR applications. The provided pseudocode outlines a multi-stage encryption algorithm designed to enhance the security of content-based image retrieval (CBIR) systems. The primary objective is to secure both local and global information of an image, ensuring that features necessary for retrieval are preserved while the image remains protected from unauthorized access. The algorithm begins with the input of an original image, denoted as I. The output of the algorithm is the encrypted image I_{enc} and the encryption key K, which is essential for decrypting the image. The start of the process involves dividing the original image I into non-overlapping subblocks, referred to as B_i . This segmentation is crucial as it sets the stage for detailed encryption targeting local textures within the image. In the first stage of encryption, the algorithm focuses on obscuring local texture information within each subblock. For every subblock B_i, the positions of the RGB channel values are scrambled. These scrambling hides local textures, making it difficult for unauthorized users to recognize patterns that could lead to information leakage. Next, the algorithm shifts to protect global texture information. This is accomplished by randomly scrambling the positions between the subblocks B_i. By shuffling these blocks, the spatial relationships within the image are altered, further confusing any attempts to understand the encrypted image's structure. The final stage of encryption deals with securing global color information. For each scrambled subblock B_i, the algorithm substitutes the RGB channel values and swaps the channels. This step not only secures the color information but also ensures that the value substitution is fixedly related to the position of the encrypted subblocks, adding an additional layer of complexity to the encryption scheme. To complete the encryption process, the algorithm generates an encryption key K using a built-in random function. This key is essential for the decryption procedure, allowing authorized users to reverse the encryption process and recover the original image. The processed subblocks are then combined to form the encrypted image $I_{\text{enc.}}$. The encrypted image is now secured, containing no recognizable original content, and can only be decrypted with the correct encryption key. The end of the algorithm marks the completion of the encryption process.

Algorithm 1: Multi-Stage Image Encryption for CBIR Systems

1. **Input:** Original Image I
2. **Output:** Encrypted Image I_{enc}, Encryption Key K
3. Start
4. Divide the original image I into non-overlapping subblocks B_i
5. **for** each subblock B_i **do**
6. Scramble the positions of the RGB channel values within B_i to hide local texture information
7. **end for**
8. Randomly scramble the positions between subblocks B_i to obscure global texture information
9. **for** each scrambled subblock B_i **do**
10. Substitute the RGB channel values and swap the channels to secure global color information
11. **end for**
12. Generate the encryption key K using a built-in random function
13. Combine the processed subblocks to form the encrypted image I_{enc}
14. **End**

It would summarize the encryption algorithm steps well and in a logical, flowing manner, the multistage operation will tend to be secure to CBIR systems more as it will protect the local histogram features and unlink global texture color information. Intrablock scrambling, interblock scrambling and channel substitution are combined to give strong encryption that can be used to provide protection from access to the image data without a key yet enable integrity for the features of useful image retrieval.

As an illustrating example, we present the results of applying the methods to medical images, showcasing a hand X-ray, an MRI brain scan, and a skull X-ray as depicted in Fig. 4. The original images show distinct medical details essential for diagnosis: the hand X-ray reveals the bone structure, the MRI scan distinguishes soft tissue contrasts within the brain, and the skull X-ray clearly outlines the facial bone anatomy. In their encrypted state, these images transform into a mosaic of indistinguishable colored blocks, effectively covering any diagnostic information and ensuring data privacy. The decrypted images, when compared with the originals, show no apparent loss of detail or quality, indicating that the encryption process is fully reversible and maintains the integrity of medical information. This demonstrates the encryption method's potential for securing sensitive health information as well as efficient storage and distribution of medical images are feasible while maintaining their reversibility for medical use. The encryption approach, therefore, strikes a balance between protecting patient confidentiality and preserving the utility of medical images for diagnostic purposes. This highlights the robustness of the encryption method in terms of its practical use in healthcare settings, where patient data protection is essential without limiting healthcare professionals' capability to examine and evaluate medical imaging as needed.

The security analysis of the algorithm is presented in the following steps:

Step 1: Dividing the Image into Subblocks

Let I be the original image of size $M \times N$. The image is divided into non-overlapping subblocks B_i of size $m \times n$, where $m \times n$ is a divisor of $M \times N$. Let k be the number of subblocks, so

$$k = \frac{M \times N}{m \times n} \quad (1)$$

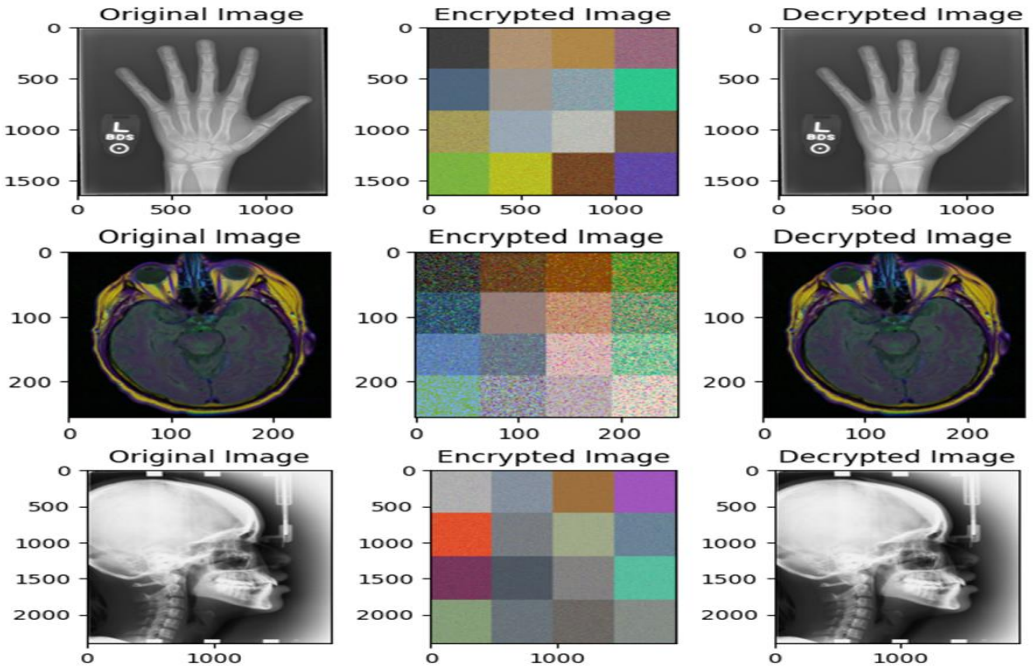

Fig. 4. Encryption process illustrated: original, encrypted, and decrypted states of medical images for secure image retrieval.

Step 2: Scrambling the RGB Values Within Each Subblock

For each subblock B_i, the positions of the RGB channel values are scrambled. The number of possible permutations for each subblock is $(m \times n)$!. Given k subblocks, the total number of possible permutations is:

$$(m \times n)!^k \quad (2)$$

This large permutation space ensures that local textures are effectively obscured.

Step 3: Scrambling the Positions of Subblocks

After local texture encryption, the subblocks are shuffled. The number of possible permutations of k subblocks is !. Combining this with the permutations from the previous step, the total number of possible configurations is:

$$(m \times n)!^k \times k! \quad (3)$$

This significantly increases the complexity, making it difficult for unauthorized users to reconstruct the original image based on subblock positions.

Step 4: Substituting RGB Values and Swapping Channels

For each subblock, the RGB channel values are substituted, and the channels are swapped. Suppose each RGB value can be replaced with any other value within the range $[0,255]$.

The number of possible substitutions for each channel is 256. Since there are three channels, the total number of possible substitutions for each subblock is:$(256)^3$

Swapping the channels adds an additional 3 ! permutations.

Therefore, the total number of configurations for each subblock considering color information is: Combining all the steps, the total number of possible permutations for the entire image encryption process is:

$$(m \times n)!^k \times k! \times (256)^3 \times 3! \quad (4)$$

This enormous number represents the total permutation space, which is computationally infeasible to brute force.

The encryption key K is generated using a built-in random function. The key must be sufficiently long and complex to cover the permutation space generated by the above steps. Assume the key length is L. The entropy of the key is:

$$(K) = L\log_2(N) \quad (5)$$

where, N is the number of possible values for each part of the key. A sufficiently large L ensures that the key space is large enough to resist brute-force attacks.

The security of this encryption algorithm is primarily based on the vast permutation space created by scrambling subblock positions, substituting RGB values, and swapping channels. The combined permutations create an extremely large key space, making brute-force attacks impractical. The algorithm's design ensures that both local and global features of the image are secured, providing robust protection against unauthorized access while maintaining the integrity necessary for effective CBIR system retrieval.

E. VGG-16

The VGGNet architecture, a highly influential convolutional neural network (CNN), was developed through a partnership between the Visual Geometry Group at the University of Oxford and Google DeepMind. It represents a significant evolution in the CNN landscape, building upon the foundational principles established by its predecessor, AlexNet. VGGNet has become well-known for its architectural depth and the use of uniformly small convolutional filters, specifically 3x3 kernels, which have set a new standard for feature extraction in image recognition tasks. As shown in Fig. 5, the architecture consists of a repeating pattern of convolution layers followed by 2x2 max pooling layers, maintaining the spatial hierarchy of the features being learned. This approach not only maintains the spatial hierarchy of the features being learned but also allows for an increase in the depth of the network without a corresponding explosion in computational complexity. By deepening the network, VGGNet significantly enhances the hierarchical feature learning process, capturing fine-grained details that are often crucial for accurate image classification. The VGGNet family comprises several models, among which the VGGNet-16 and VGGNet-19 are the most notable. These models are differentiated by the number of weight layers they contain: 16 and 19, respectively. Both have demonstrated remarkable performance on large-scale image recognition tasks, contributing to their widespread adoption in the field. The depth of these networks has proven to be a key factor in their ability to perform complex image classifications with high accuracy, making them particularly useful in applications where precision is critical. Furthermore, the impact of VGGNet extends beyond its immediate performance. The architecture has provided invaluable insights into the design of deep neural networks, influencing subsequent innovations in the domain. Its widespread use as a pre-trained model for a variety of tasks points out its significance because it provides a starting point for additional optimizing and adaptation for specialized applications, such as those in medical imaging and other fields where detailed feature detection is crucial [55–57].

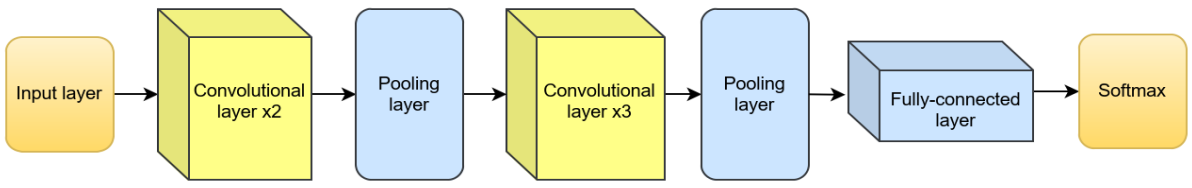

Fig. 5. Architectural flowchart of a deep convolutional neural network with repeating convolution and pooling layers, culminating in a softmax output.

F. Quantization

Content-Based Image Retrieval (CBIR) is a technique for retrieving relevant images from a database based on a given query image. When dealing with encrypted images, this task becomes more complex. To address this, we propose a method using a VGG-16 model with various quantization techniques to improve efficiency and performance. The first step involves applying quantization to the last layer of a pre-trained VGG-16 model. Quantization reduces the precision of the weights, leading to a smaller model size and faster computations. The quantization methods used include max quantization, KL quantization, 99 percentile quantization, and full model quantization. For max quantization, the maximum absolute value of the weights is calculated, and each weight is divided by this value. In KL quantization, the histogram of the weights is computed, and quantization thresholds are determined using Kullback-Leibler divergence, followed by quantizing the weights based on these thresholds. For 99 percentile quantization, the 99th percentile of the absolute weights is calculated, and weights are divided by this value. Full quantization applies quantization to all layers of the model. After quantization, the original weights of the last layer are replaced with the quantized weights, resulting in a quantized model. The quantization pseudocode is presented in Algorithm 2.

Algorithm 2: Quantization for Last Layer

1: **Input**: Trained model M, quantization mode *mode*
2: **Output**: Quantized model M'
3: W← weights of the last layer of M
4: **if** *mode* == "max" **then**

6: Fine-tune the quantized model Mon encrypted images
7: Perform image retrieval using the quantized model M'
8: **return** Retrieved images

G. Big O Notation

Quantization is a technique used to reduce the precision of the weights in a neural network, which in turn reduces the memory footprint and computational requirements of the model. Here's a complexity analysis of the memory usage after applying different quantization methods to the last layer of the VGG-16 model as described in the algorithms.

Let's denote the number of weights in the last layer of the VGG-16 model as W. Typically, these weights are stored as 32-bit floating-point numbers (i.e., each weight takes 4 bytes).

The memory usage for the last layer before quantization is:

$$\text{Μεμορψ}_{\beta\varepsilon\phi o\rho\varepsilon} = W \times 4\beta\psi\tau\varepsilon\sigma \quad (6)$$

Quantization reduces the precision of these weights, typically to 8-bit integers (i.e., each weight takes 1 byte). The memory usage after quantization depends on the number of weights and the quantization method used.

Quantization reduces the precision of these weights, typically to 8-bit integers (i.e., each weight takes 1 byte). The memory usage after quantization depends on the number of weights and the quantization method used.

Max quantization scales the weights based on the maximum absolute value. The quantized weights are stored as 8-bit integers, and an additional scaling factor needs to be stored (usually as a 32-bit float).

The memory usage for max quantization is:

$\text{Memory}_{\max} = W \times 1$ byte +4 bytes (scaling factor)

KL quantization uses histograms and thresholds determined using KL divergence. Similar to max quantization, the weights are stored as 8-bit integers, and additional parameters for thresholds may be stored (assuming negligible storage for histograms and thresholds compared to the number of weights).

H. KL Quantization

KL quantization uses histograms and thresholds determined using KL divergence. Similar to max quantization, the weights are stored as 8-bit integers, and additional parameters for thresholds may be stored (assuming negligible storage for histograms and thresholds compared to the number of weights).

The memory usage for KL quantization is:

$\text{Memory}_{\text{KL}} = W \times 1$ byte +4 bytes (scaling factor)

99 Percentile Quantization

99 percentile quantization scales the weights based on the 99th percentile of their absolute values. Again, weights are stored as 8-bit integers with an additional scaling factor.

The memory usage for 99 percentile quantization is:

$\text{Memory}_{99\%} = W \times 1$ byte +4 bytes (scaling factor)

Full quantization applies to all layers of the model. For simplicity, let's denote the total number of weights in the VGG-16 model as $W_{\text{total.}}$.

The memory usage for full model quantization is:

$$\text{Memory}_{\text{full}} = W_{\text{total}} \times 1 \text{ byte} + \text{scaling factors}$$

If there are L layers in the VGG-16 model, and each layer has a scaling factor, the memory usage for scaling factors is negligible compared to the total number of weights.

The memory usage complexity remains linear in terms of the number of weights, but the actual memory usage is significantly reduced due to the lower precision (8-bit vs. 32-bit). In summary, quantization effectively reduces the memory usage of the model by a factor of 4 (since 32-bit weights are converted to 8-bit weights), while the complexity in terms of the number of weights remains the same. This reduction is crucial for deploying models in resource-constrained environments and for speeding up computations during inference. In summary, quantization effectively reduces the memory usage of the model by a factor of 4 (since 32-bit weights are converted to 8-bit weights), while the complexity in terms of the number of weights remains the same. This reduction is crucial for deploying models in resource-constrained environments and for speeding up computations during inference.

V. Experimental Results and Analysis

The fundamental components and their parametric relationships in the proposed framework are systematically presented in Table III. The framework's architecture comprises three main parameter categories: encryption parameters, VGG-16 model configurations, and quantization methods. The encryption parameters, particularly the block size, represent a crucial design choice that determines the balance between security strength and feature preservation. Similarly, the RGB channel substitution parameter provides flexibility in controlling the degree of visual information protection while maintaining essential image characteristics for retrieval purposes. In the deep learning component, the VGG-16 model parameters - learning rate and batch size - establish the foundation for stable model training and resource utilization. The quantization parameters offer different approaches to model compression, each with its unique characteristics: max quantization prioritizes compression efficiency, 99% percentile quantization aims for balanced preservation of significant features, and KL divergence quantization focuses on maintaining statistical distributions. This systematic organization of parameters provides system designers with a clear framework for making informed decisions based on their specific requirements for privacy preservation, computational efficiency, and retrieval capability.

The study leveraged three distinct datasets, each encompassing 1200 medical images. The datasets were further segregated for training and validation, and testing purposes, employing a 1000:100:100 split, respectively. Notably, the datasets were categorized based on anatomical regions, specifically the lung, brain, and bone. This stratified and anatomically categorized data structure facilitated the robust evaluation of the proposed method across diverse medical imaging domains, we present our experimental design in Table IV.

TABLE III. Experimental Design for Comparing our Proposed Method with Benchmark

Parameter Category	Parameter	Value/Range	Trade-offs	Recommended Setting
Encryption	Block Size	1-8 blocks	- Larger blocks: Better retrieval, lower security - Smaller blocks: Higher security, poor retrieval	8 blocks for medical applications requiring balance of privacy and accuracy
	RGB Channel Substitution	0-255	Security vs. Feature quality	Application-dependent, moderate values (128-192) for balanced performance
VGG-16	Learning Rate	0.001	Training speed vs. Stability	0.001 (demonstrated optimal convergence)
	Batch Size	32	Memory usage vs. Training stability	32 (balances resource usage and stability)
Quantization	Max Quantization	Maximum value in layer	Compression vs. Accuracy	When maximum compression is needed
	99% Percentile	99th percentile value	Moderate compression with optimal accuracy	Default choice for most applications
	KL Divergence	Distribution-based	Computational complexity vs. Precision	When distribution preservation is critical

TABLE IV. Experimental Design for Comparing our Proposed Method with Benchmark

	VIT	VGG16
Experiments	Plaintext- encrypted image where block size (1,8)	Plaintext- encrypted image where block size (1, 8)
Pretrained	TRUE	TRUE
Num Classes	3	3
Optimizer	Adam	Adam
Learning Rate	0.001	0.001
Loss Function	CrossEntropyLoss	CrossEntropyLoss
Epochs	100	100
Batch Size	32	32

A. Encryption Quality Analysis

For the experimental evaluation of the encryption, we compare the encryption algorithm adopted with the widely recognized AES standard as shown in Table V. The comparison is grounded on a set of metrics that typically measure the efficacy of encryption methods in terms of security and the ability to resist statistical analysis.

- Entropy: Our algorithm records an entropy of 7.392, which indicates a substantial amount of randomness, although slightly less than the optimal value of 8. This suggests that while the algorithm introduces randomness, there may be room for improvement. The AES, in an unusual turn, shows an entropy value extremely close to zero, which typically would suggest a lack of randomness; however, this could imply a perfect encryption where the output is indistinguishable from a completely random source.
- MSE (Mean Squared Error): In this evaluation, a higher MSE between the original and encrypted images indicates stronger encryption. The MSE for our algorithm is significantly higher than that of AES, suggesting that our method may provide a more robust alteration of pixel values, thereby potentially increasing security.
- SSIM (Structural Similarity Index): The SSIM for our algorithm is noticeably higher than that of AES, implying that the structural integrity of the image is somewhat retained. In contrast, AES's lower SSIM reinforces its role as a robust encryption standard by substantially altering the image structure to secure the data effectively.
- PSNR (Peak Signal-to-Noise Ratio): The lower PSNR associated with our algorithm complements the high MSE, affirming the extensive alteration from the original image. Meanwhile, AES exhibits a higher PSNR, which is usually indicative of a decryption process that maintains image quality. However, in the encryption phase, a lower PSNR may be more desirable as it indicates a greater level of distortion.

B. Image Retrieval Performance Analysis

The confusion matrices and the classification metrics presented in Fig. 6(a), 6(b), and 6(c) illustrates the performance of a Vision Transformer (ViT) based image retrieval system under different conditions: plaintext images and images encrypted using 8 blocks and 1 block encryption. These matrices provide insight into how encryption affects the model's ability to correctly classify images into one of three categories: bone, chest, and MRI.

TABLE V. COMPARATIVE EVALUATION OF ENCRYPTION METRICS: OUR ALGORITHM VERSUS AES

Metric	Our Algorithm	AES
Entropy	**7.392129887**	1.4426951601859516e-10
MSE	**12766.02**	2625.48
SSIM	0.273204	**0.00283838**
PSNR	**7.070247655**	13.93870288

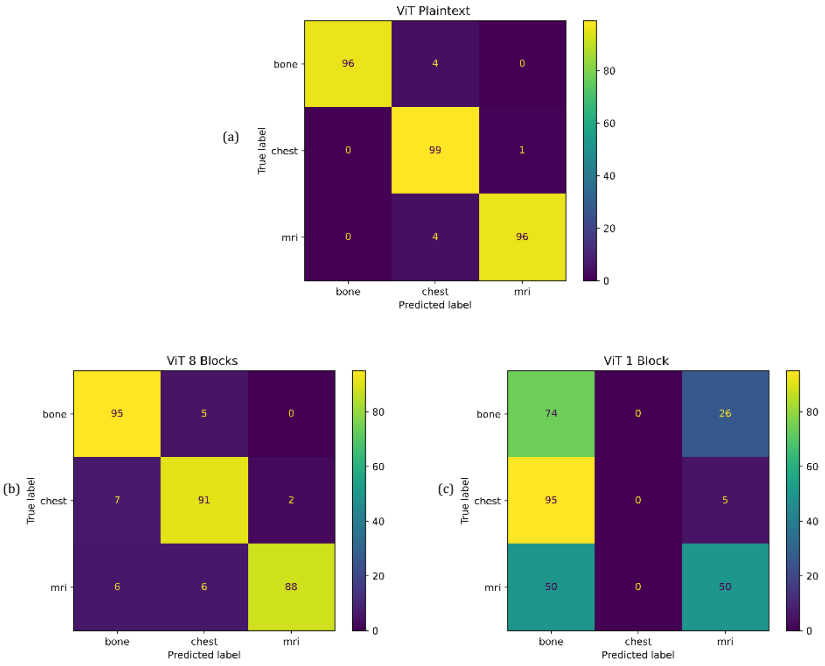

Fig. 6. Confusion matrix of ViT based image retrieval (a) plaintext (b) encrypted domain using 8 block encryption (c) encrypted domain using 1 block encryption.

In the plaintext scenario, the performance of the ViT model is well-exemplified since correctness can be identified with great precision for each category in three classes. It is particularly very high for the classes of bone and MRI, of which only few images can misclassify. The chest category provides a high accuracy impression too but slightly messes up with the remaining categories. A high true positive rate for each class actually represents that the model was well tuned for the features of each class.

The 8 blocks encryption has somewhat degraded performance. It still maintains relatively high accuracy, though an increase in misclassification is seen, especially with the bone and chest categories. A minimal decrease in accuracy is observed in the MRI category. This hints that most probably the model starts having difficulty extracting features when receiving high-encryption images. That is one possible reason for the weakness in performance, considering that encryption puts noise in images, thus blurring features that our model depends on for classification.

With 1 block encryption, the performance drops significantly, most notably in the bone and MRI categories. The model's ability to correctly identify bone images is drastically reduced, and there is a considerable increase in the misclassification of MRI images as bone or chest. The SSIM for this encryption level is likely quite low, indicating that the structural integrity of the images is heavily compromised, and the model is unable to extract meaningful features for accurate classification.

The gradual performance decline across the matrices from plaintext to 1 block encryption illustrates the trade-off between security and usability in encrypted domains. It underscores the challenge of maintaining feature extraction capabilities for classification tasks while also securing the images against unauthorized access or analysis. This balance is crucial in applications where both the confidentiality of the data and the accuracy of automated systems are of paramount importance.

1) ViT-based image retrieval: Table VI presents overall classification metrics for a Vision Transformer (ViT) based image retrieval system, comparing performance across three different categories (Bone, Chest, MRI) and three models: ViT Plaintext, ViT 8 Blocks, and ViT 1 Block.

ViT Plaintext exhibits exceptional performance with accuracy rates hovering around 98% for all categories. The precision is perfect for 'Bone' and nearly so for 'MRI', indicating almost no false positives for these categories. 'Chest' has a slightly lower precision, which suggests a few more false positives but still maintains a high recall, indicating it successfully identified most true 'Chest' cases.

ViT 8 Blocks shows a drop in performance across all metrics, which is expected as the encryption level increases. Accuracy for 'Bone' and 'Chest' categories decreases by about 4-5%, and for 'MRI' by 3%, compared to the plaintext model. Precision sees a more notable decline, particularly for 'Bone' where it drops by over 12%. This suggests that the 8-block encryption introduces enough ambiguity to affect the model's ability to correctly identify features specific to 'Bone' images.

'MRI' retains high precision but suffers in recall, indicating that while most 'MRI' predictions are correct, the model fails to identify all 'MRI' images, likely due to feature loss in the encryption process. ViT 1 Block shows a significant decrease in performance.

For 'Bone', the accuracy and precision are notably lower, and the recall is moderately high, which may indicate a higher number of false negatives. In 'Chest', precision is undefined, which occurs when the denominator in the precision calculation is zero; this happens if there were no predictions made for the 'Chest' category or all predictions were incorrect. The recall for 'Chest' is 0%, confirming the model did not correctly identify any 'Chest' images. For 'MRI', both precision and recall have decreased significantly, with accuracy being marginally better than 'Bone' but still substantially lower than in the other models.

2) VGG-16-based image retrieval: As provided in Fig. 7(a), 7(b) and 7(c), The confusion matrices and classification results for the VGG-16-based image retrieval present a comprehensive view of the model's performance across three different settings: plaintext, 8-block encryption, and 1-block encryption domains.

TABLE VI. OVERALL CLASSIFICATION METRICS OF VIT BASED IMAGE RETRIEVAL

Model	Category	Accuracy (%)	Precision (%)	Recall (%)
ViT Plaintext	Bone	98.67	100.00	96.00
	Chest	97.00	92.52	99.00
	MRI	98.33	98.97	96.00
ViT 8 Blocks	Bone	94.00	87.96	95.00
	Chest	93.33	89.22	91.00
	MRI	95.33	97.78	88.00
ViT 1 Block	Bone	43.00	33.79	74.00
	Chest	66.67	Undefined	0.00
	MRI	73.00	61.73	50.00

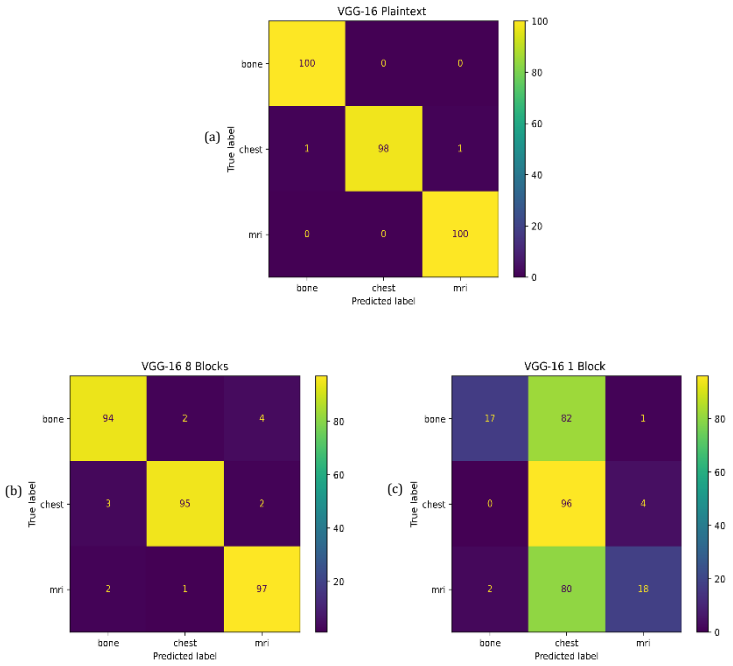

Fig. 7. Confusion matrix of VGG-16 based image retrieval (a) plaintext (b) encrypted domain using 8 block encryption (c) encrypted domain using 1 block encryption.

In the plaintext scenario, the VGG-16 model demonstrates near-perfect classification accuracy, with an impressive 99.33% accuracy across all categories. The precision and recall rates are equally outstanding for the 'Bone' and 'MRI' categories, both hitting 100% in recall, indicating that every relevant image was correctly retrieved. 'Chest' images also show a high level of precision and recall, indicating that the model can distinguish between these medical images with high reliability in an unencrypted domain.

Moving to the 8-block encryption domain, there is a slight but noticeable decrease in performance. The accuracy remains high at 95.33%, yet there are marginal drops in precision and recall for the 'Bone' category, indicating a slight increase in both false positives and false negatives. The Chest and MRI classes lost little accuracy, indicating that encryption adds some ambiguity, however, the model can identify features for retrieval quite effectively.

The 1-block encryption domain delivers quite different findings. The accuracy dropped to 43.67%, indicating that at such high levels of encryption, the model was unable to classify images correctly. Interestingly, the 'Chest' category shows a high recall, suggesting that while the model can identify 'Chest' images, it does so with a high rate of false positives as reflected in the lower precision rate. 'Bone' and 'MRI' categories exhibit poor recall rates, indicating a majority of relevant images are missed, yet when they are identified, they tend to be correct, as shown by the higher precision rates.

Overall, the matrices and results in Table VII highlight the challenges posed by encryption on the ability of CBIR systems to maintain high retrieval performance. They underscore the need for specialized approaches to manage encrypted image data, especially as the strength of encryption increases and significantly impacts the extraction of features critical for accurate image retrieval.

TABLE VII. OVERALL CLASSIFICATION METRICS OF VGG-16 BASED IMAGE RETRIEVAL

Model	Category	Accuracy (%)	Precision (%)	Recall (%)
VGG-16 Plaintext	Bone	99.33	99.01	100.00
	Chest	99.33	100.00	98.00
	MRI	99.33	99.01	100.00
VGG-16 8 Blocks	Bone	95.33	94.95	94.00
	Chest	95.33	96.94	95.00
	MRI	95.33	94.17	97.00
VGG-16 1 Block	Bone	43.67	89.47	17.00
	Chest	43.67	37.21	96.00
	MRI	43.67	78.26	18.00

3) Quantized VGG-16 based image retrieval: In evaluating the performance of the quantized VGG-16 models for image retrieval, we can interpret the provided confusion matrices for each quantization technique as shown in Fig. 8(a), 8(b), 8(c) and 8(d):

a) VGG-16 8 Blocks Final Layer Quantized (Max): The model shows high performance with most 'Bone', 'Chest', and 'MRI' images correctly identified, evidenced by the high numbers on the diagonal of the confusion matrix. There is a slight confusion between the 'Bone' and 'MRI' categories, and to a lesser extent with 'Chest'. However, with 93 out of 100 correct predictions for both 'Bone' and 'Chest' categories, the model demonstrates robustness under the max quantization method.

b) VGG-16 8 Blocks Final Layer Quantized (KL): The model performance is slightly reduced under KL quantization, particularly in the 'Chest' category, where we see a decrease to 91 correct predictions and an increase in misclassification as 'MRI'. The 'MRI' category also shows a minor decrease in performance, with 95 correct predictions. This suggests that the KL quantization may introduce some information loss that affects the model's classification ability.

c) VGG-16 8 Blocks Final Layer Quantized (99%): Under the 99% percentile quantization, the model's performance improves, with 'Bone' and 'MRI' classifications seeing an uptick in correct predictions to 95, and 'Chest' holding steady at 93. This indicates that the 99% percentile method effectively maintains crucial information for image classification.

d) VGG-16 8 Blocks Fully Quantized: The fully quantized model reveals a drastic change in the confusion pattern, with most 'Bone' and 'Chest' images being misclassified as 'MRI'. While this may appear to be a major decline in model performance, it is worth noting that such a high degree of quantization is likely to significantly reduce the model's size and computational requirements. This trade-off between size and accuracy may be beneficial in specific applications where computational efficiency is prioritized over classification accuracy.

Table VIII presents classification metrics for a VGG-16 model with the final layer quantized under different schemes: maximum, KL divergence, 99%, and fully quantized, across medical image categories (Bone, Chest, MRI). The performance metrics detailed—accuracy, precision, and recall—provide insights into the impact of these quantization methods on the model's ability to effectively process encrypted medical images segmented into 8 blocks.

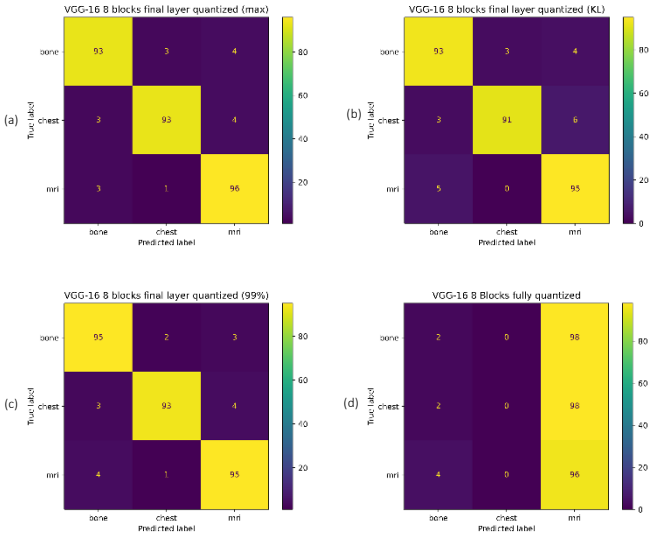

Fig. 8. Confusion matrix of Quantized VGG-16 based image retrieval (a) max (b) KL encryption (c) 99% percentile (d) fully quantized.

TABLE VIII. CLASSIFICATION METRICS OF QUANTIZED VGG-16 FOR DIFFERENT FINAL LAYER QUANTIZATION TYPES MAXIMUM, KL, 99%, AND FULLY QUANTIZED

Model	Category	Accuracy (%)	Precision (%)	Recall (%)
VGG-16 8 blocks final layer quantized (max)	Bone	0.94	0.939	0.93
	Chest	0.94	0.958	0.93
	MRI	0.94	0.923	0.96
VGG-16 8 blocks final layer quantized (KL)	Bone	0.93	0.920	0.93
	Chest	0.93	0.968	0.91
	MRI	0.93	0.904	0.95
VGG-16 8 blocks final layer quantized (99%)	Bone	0.946	0.931	0.959
	Chest	0.946	0.968	0.93
	MRI	0.946	0.940	0.95

For models where only the final layer is quantized using the maximum, KL divergence, and 99% methods, the results indicate relatively robust performance with minor variations across the different types of quantization. Accuracy remains consistently high, around 0.94 to 0.946, under the maximum and 99% quantization types, with slight decreases in the KL quantized version to 0.93. This minimal variance suggests that moderate quantization of the final layer does not drastically affect the model's ability to classify medical images accurately.

Precision and recall metrics show more variation. In the maximum quantization scenario, precision is high across all categories but slightly lower for MRI at 0.923, while recall is highest for MRI at 0.96, indicating good sensitivity. Under KL quantization, precision peaks for Chest images at 0.968, whereas recall is slightly reduced for Chest and MRI. The 99% quantization appears to balance both precision and recall effectively, particularly showing a notable improvement in Bone recall to 0.959.

However, a stark contrast is observed when the model is fully quantized. The accuracy decreases to 0.326 in all categories, while precision and recall also see a substantial decline, except for MRI recall which surprisingly stays high at 0.96. A significant decrease in performance highlights the challenges and possible drawbacks of full model quantization, especially in complex applications like as medical image classification, where accuracy and responsiveness to features are important.

The analysis underscores the necessity of careful consideration in the extent of quantization applied within neural networks, especially in medical settings where accuracy and reliability are crucial. Moderate quantization of the final layer preserves functionality, while full quantization severely impairs performance, suggesting that a balanced approach is essential for maintaining the efficacy of encrypted image retrieval systems.

VI. Discussion

In this discussion, we delve into the intricacies of implementing the VGG-16 model for encrypted and quantized image retrieval, focusing on the trade-offs between security, efficiency, and effectiveness. We explore the optimization of encryption and quantization methods to achieve optimal performance in a Content-Based Image Retrieval (CBIR) system.

1) The VGG-16 model was selected for the image retrieval task due to its deep architecture, which is highly effective in capturing complex textural details and spatial hierarchies in images. This characteristic is especially beneficial in medical imaging, where precise feature extraction is crucial for accurate classification and diagnosis. VGG-16's use of small, 3x3 convolutional kernels allows for a deeper network that can learn a rich hierarchy of features at multiple scales, making it a robust choice for both plaintext and encrypted image retrieval systems. The model's well-documented success in various image recognition tasks supports its adoption in exploring the impacts of encryption and quantization on medical image analysis.

2) The Role of Encryption and the Effectiveness and Security Balance Encryption plays a critical role in ensuring the confidentiality and security of sensitive data, such as medical images, in a CBIR system. However, as demonstrated by the performance metrics across different encryption granularities, there is a significant trade-off between security and the effectiveness of image retrieval. While high encryption levels (e.g., 1-block encryption) offer stronger data protection, they severely degrade the quality of features available for the model to learn and identify, leading to poorer classification accuracy and recall rates. Conversely, lighter encryption (e.g., 8-blocks) provides less security but maintains higher usability of the data, allowing for more effective feature extraction and image retrieval. Balancing these aspects requires a strategic approach to encryption that considers the specific needs for security versus the operational requirements for image analysis and retrieval.

3) Optimization of Encryption for Achieving Required Performance To optimize encryption for performance, it is essential to tailor the encryption methods to the specific characteristics of the data and the requirements of the retrieval system. For medical images, where detail and accuracy are paramount, adopting an encryption approach that preserves more structural and textural integrity—such as region-specific encryption or varying encryption levels based on the sensitivity of the image content—might be more suitable. Techniques such as homomorphic encryption could also be explored, as they allow certain types of computations to be carried out on encrypted data, thus maintaining privacy without sacrificing the ability to perform effective image retrieval. Additionally, optimizing the trade-off between block size in encryption and feature extraction needs is crucial, as smaller blocks increase security but reduce the quality of features, impacting model performance.

4) The Role of Quantization and the Efficiency and Effectiveness Trade-Off Quantization addresses the need to reduce the computational complexity and storage requirements of deep learning models, making them more suitable for deployment in resource-constrained environments such as mobile devices or in cloud-based architectures where computational efficiency is critical. The quantization of VGG-16, particularly at the final layer, has demonstrated the possibility of maintaining relatively high accuracy and precision with minor trade-offs in performance. However, fully quantized models exhibit a significant drop in performance, highlighting the delicate balance between efficiency and effectiveness. Quantization introduces noise and approximation errors into the model, which can degrade the accuracy if not managed carefully. The choice of quantization technique—maximum, KL divergence, or percentile-based—impacts how much of the critical information is preserved and thus the overall effectiveness of the model. Striking a balance between reducing computational demands and maintaining high classification accuracy is essential, particularly when dealing with high-stakes applications like medical diagnostics.

VII. Conclusion and Future Work

The fundamental problem of this study is in the development of a Content-Based Image Retrieval system that can effectively optimize the trade-off between privacy for encrypted images and computational efficiency and retrieval effectiveness. This is of utmost significance, particularly in fields where privacy and accuracy are closely related, such as in medical imaging. The proposed system is designed to efficiently handle an encrypted database of images, prioritizing the extraction of features and retrieval of images.

The primary objective of this study has been to investigate the VGG-16 architecture, which has gained recognition as a very efficient deep convolutional network for extracting high-level features from few imagine samples. Two essential modifications for preparing the model for encrypted domains were making adjustments to the granularity and applying quantization techniques in the last layer of the model. The primary objective of these approaches is to investigate the feasible and controlled impacts of encryption and quantization on the performance of a model.

Research findings indicated that VGG-16, in general, maintained a high level of accuracy in classifying plaintext images, but its performance declined as the level of detail arose. Therefore, it is the encryption with a granularity of 1-block that significantly and severely affects the ability of this model in accurately classifying images into particular classifications such as bone or MRI. The impact of quantization was considerably less severe but it became quite significant when the entire model was completely quantized. Research findings indicate that although a certain level of encryption and quantization can possibly be achieved with no impact on performance, over use of these techniques results in significant performance impairment.

One of the primary limitations of this study is the focus on a single model architecture (VGG-16) and a limited set of encryption and quantization strategies. Future research could explore other architectures like ResNet or EfficientNet, which might interact differently with encryption and quantization. Additionally, experimenting with newer encryption techniques like homomorphic encryption could offer insights into less disruptive methods. Further exploration into adaptive encryption and quantization strategies that dynamically adjust based on the content sensitivity and retrieval needs could also enhance system performance and usability.

Moreover, incorporating more sophisticated metrics for assessing the quality of retrieved images, such as structural similarity indexes or perceptual quality measures, could provide a deeper understanding of how encryption and quantization affect the perceived quality of images. Future studies should also consider the implementation of these systems in real-world applications, evaluating their practicality and efficiency in operational environments.

Tracking Computer Vision Algorithm Based on Fusion Twin Network

Xin Wang
Software Institute, Hunan College of Information, Changsha, 410016, China

***Abstract*—Deep learning technology has promoted the rapid development of visual object tracking, among which algorithms based on twin networks are a hot research direction. Although this method has broad application prospects, its performance is often greatly reduced when encountering target occlusion or similar objects in the background. In response to this issue, a method is proposed to integrate channel and spatial dimension attention mechanisms into the backbone architecture of twin networks, to optimize the algorithm's recognition accuracy for tracking targets and its stability in changing environments. Then, a region recommendation network based on adaptive anchor box generation is adopted, combined with twin networks to enhance the network's modeling ability for complex situations. Finally, a new visual tracking algorithm is designed. Through comparative experiments, the success rate of the former increased by 0.6% and 0.9% respectively on the two datasets, and its accuracy also increased by 1.2% and 1.8% accordingly. The success rate of the latter increased by 1.5% and 1.2% respectively in the two datasets, and the accuracy also increased by 1.2% and 0.6% respectively. From this, the improved algorithm can improve the performance of target tracking and has certain application potential in visual target tracking.**

***Keywords*—Visual tracking; twin network; integration; attention mechanism; self-adaption**

I. Introduction

Fatigue driving has become an important factor in causing traffic accidents, posing a serious threat to social safety and public health. Currently, although there are various fatigue driving detection models based on computer algorithms, they still face many challenges in practical applications, such as poor comfort, susceptibility to external factors such as lighting, masks, sunglasses, low detection accuracy, and poor real-time performance [1]. With the successful application of deep learning in object detection, some studies have begun to use detection techniques to guide the development of object tracking technology [2]. Xin et al. proposed a new Siamese adaptive learning network for visual tracking to address the manually adjusting parameters. The designed method took spatial alignment and model learning state as criteria for anchor quality evaluation, and employed Gaussian mixture distribution for adaptive allocation instead of IoU-based anchor allocation. The experimental results showed that the tracker had superiority on benchmarks GOT-10k, and LaSOT [3]. In order to address the issue of retaining much unfavorable background information in association operations, Jun W et al. proposed an effective feature recognizer that included channel and spatial attention modules to focus on key information. The representation capability was optimized. Experiments on six benchmark tests showed that the designed tracker outperformed other trackers. Especially, it achieved 80.4% AUC on TrackingNet and 68.4% AUC on GOT-10k during real-time operation [4]. Due to the insufficient control accuracy and stability of current virtual vision tracking technology, Jianbin et al. designed a new intelligent algorithm on the basis of human-computer interaction and virtual vision tracking technology to improve the overall performance of virtual vision tracking. The designed model was efficient, with tracking accuracy more than 10% higher than traditional methods [5]. Di et al. found that the discriminative model for predicting object tracking models was susceptible to interference from similar objects and required much-labeled data for training during actual use. Therefore, two methods were proposed to enhance the robustness of target tracking against interference from similar objects: multi-scale region search and response map processing based on Gaussian convolution. A large number of experiments showed that the enhancement function implemented in the tracking framework enhanced its robustness. The tracker based on self-supervised training had excellent tracking performance [6]. The existing Siamese trackers are insufficient to effectively distinguish between targets and the fluctuation interference embedded in the two branches of information, resulting in inaccurate classification and localization. Therefore, Liu et al. proposed two novel sub-network spaces for spatial feature embedding to optimize the discriminative ability of trackers in the embedding space and their adaptability to complex tracking scenarios. Compared with the most advanced trackers, the proposed tracker had competitive tracking performance in background clutter and similar object attributes, verifying the effectiveness of the method [7]. To solve the tracking drift caused by inaccurate initial positions in most existing trackers, Han et al. proposed a deep learning method that could generate accurate positions of objects given their rough positions. The proposed method was applied in the tracking process to improve the accuracy. A large number of experiments in object tracking benchmark testing verified its effectiveness [8]. Due to the lack of attention on the channel dimension in current trackers, their potential tracking capabilities are hindered. Therefore, Shaochuan et al. used a novel spatial channel converter that integrated information conveyed by features along both spatial and channel directions. To quantify temporal smoothness, a jitter metric that measured the cross-frame variation of predicted bounding boxes was proposed as a function of parameters like center displacement, area, and aspect ratio. Several well-known benchmark datasets demonstrated its robustness [9].

In the field of computer vision tracking, although some progress has been made in research, fatigue driving detection

technology still faces multiple challenges. Firstly, existing models have shortcomings in terms of comfort, which may cause unnecessary interference to drivers. Secondly, sensitivity to external factors such as lighting, masks, sunglasses, etc. affects the accuracy and robustness of detection. In addition, detection accuracy and real-time performance are also key areas that need to be improved in current technology. For example, although the Siamese adaptive learning network proposed by Xin et al. performed well on GOT-10k and LaSOT benchmark tests, further optimization is still needed to improve tracking accuracy and stability. The effective feature recognizer proposed by the military and others has optimized its representation ability, but there is still room for improvement in real-time performance. The new spatial feature embedding subnetwork proposed by Liu et al. has optimized the recognition ability of trackers, but its adaptability in complex tracking scenarios still needs further verification. Although the deep learning method proposed by Han et al. can generate accurate positions of objects, there is still room for improvement in dealing with tracking drift caused by inaccurate initial positions.

To address these drawbacks, this study proposes a visual tracking algorithm based on traditional dual networks, combining attention mechanism and adaptive anchor box generation to improve the algorithm performance. The attention mechanism helps the algorithm to focus on key information and improve the efficiency of target feature extraction, while the adaptive anchor box generation is able to evaluate the anchor quality more accurately, using a Gaussian mixture distribution for adaptive allocation, thus improving the target tracking performance in complex environments.

II. Computer Vision Algorithm Based on Twin Network Tracking

A. Twin Network Visual Tracking Based on Attention Mechanism

In fatigue driving detection, the characteristic of computer vision algorithms is that they can analyze the driver's behavior and physiological signals in real time, such as blink frequency, head posture, etc., to determine whether they are in a fatigue state. However, existing algorithms often have low detection accuracy due to factors such as background interference and lighting changes [10]. To this end, an improved algorithm is proposed by introducing an attention mechanism to extract useful features. The designed structure utilizes multi-layer linear fusion to integrate different levels of feature information, thereby enhancing the recognition accuracy and robustness for fatigue states. Its structure is shown in Fig. 1.

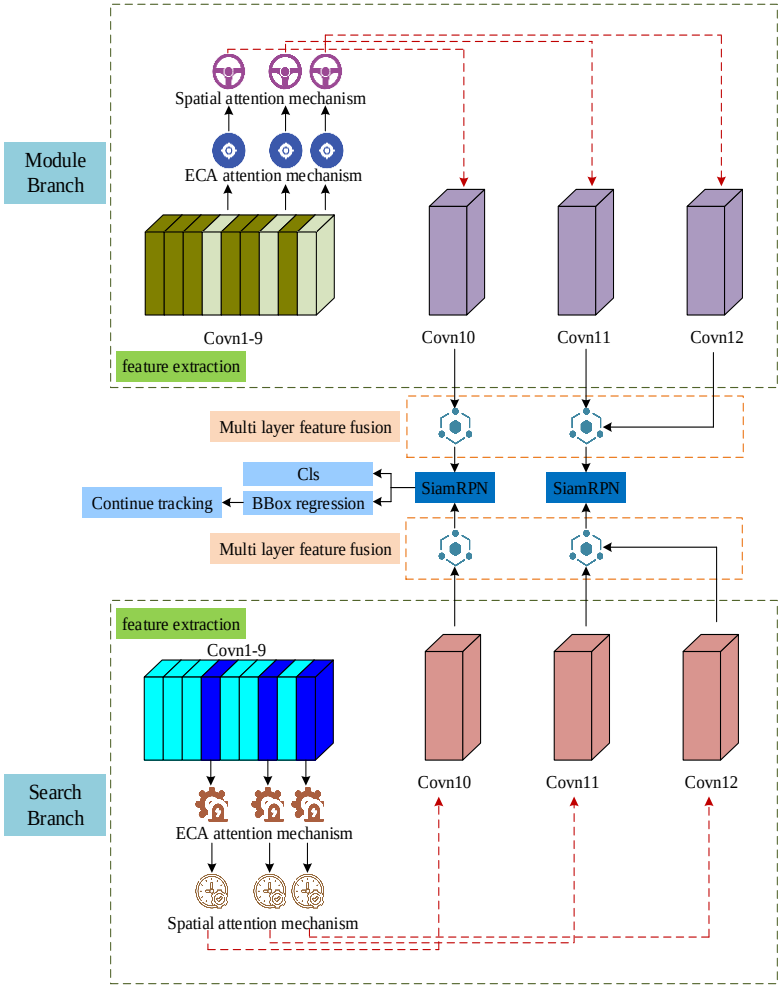

Fig. 1. Structure diagram of twin network target tracking algorithm incorporating attention mechanism.

From Fig. 1, the algorithm optimizes the feature extraction process in target tracking tasks by integrating channel and spatial attention mechanisms, thereby improving the performance of the tracking algorithm. Through analysis, it is found that striking a balance between accuracy and efficiency in target tracking is crucial [11]. Specifically, the research adopts the SiamRPN++ framework and makes improvements and adjustments based on it. Firstly, for the optimization of feature extraction, this method is similar to a fine filter. It can filter out feature information that is not conducive to target tracking, and only retain key information that helps improve tracking performance. This ensures the significant differences in feature responses across channels and spaces, providing a more accurate basis for subsequent similarity calculations. Secondly, in order to improve algorithm performance, effective fusion of feature information can be achieved through improvements to the backbone network. It includes two main parts: module branch and search branch. Both branches use Covin1-9 as the initial feature extraction layer and apply ECA attention mechanism and spatial attention mechanism to optimize feature representation capability. In the module branch, the features after passing through Covin1-9 are sent to the SiamRPN module for target tracking, and then the BBox regression is used to further accurately locate the position of the target [12]. In addition, the module branch also performs multi-layer feature fusion operations, combining features of different depths to obtain richer information. In the search branch, multi-layer feature fusion operations are also performed, but the fusion is performed after Covn1-9, indicating that this branch may be more focused on extracting and processing low-level features. This design fully utilizes the advantages of attention mechanism, enabling the network to output more accurate feature information, as shown in Fig. 2.

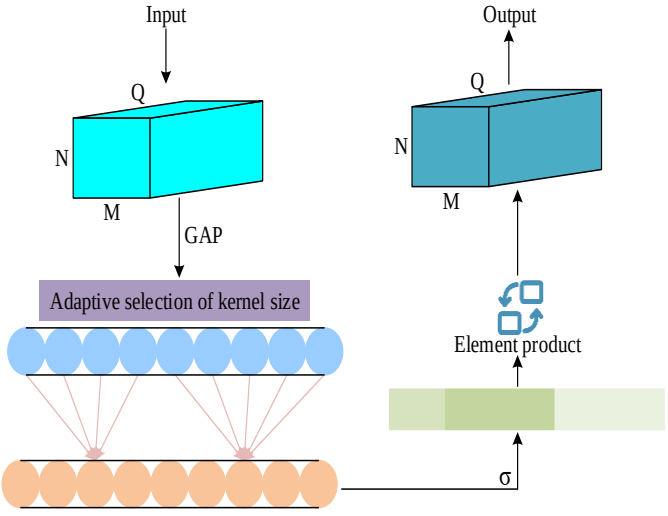

Fig. 2. Structure diagram of channel attention mechanism module.

From Fig. 2, the main purpose of the channel attention mechanism is to capture key feature information. It significantly enhances the network's performance in feature extraction by assigning higher weights to the target feature channel [13]. Then, the weights of each channel are obtained through the activation function, as shown in Eq. (1).

$$f(z)=\frac{1}{1+e^{-z}} \tag{1}$$

In Eq. (1), $f(z)$ represents the activation function. z represents the initial weight. The channel attention related feature map is shown in Eq. (2).

$$F_{ECA,i}=\omega_i \times F_i \tag{2}$$

In Eq. (2), $F_{ECA,i}$ is the attention feature map. ω_i is the weight on channel i. F_i is the original feature map on channel i. The output ω_i of each channel is weighted and summed all the features y_i^j within its receptive field, and then generated by the activation function σ, as shown in Eq. (3).

$$\omega_i=\sigma\left(\sum_{j=1}^{k}\alpha_i^j y_i^j\right), y_i^j \in \Omega_i^k \tag{3}$$

In Eq. (3), y_i^j represents the j-th element in Ω_i^k. α_i^j signifies the weight of the j-th element in the i-th channel. These weights are obtained through learning and are used for weighted combinations of different features. Then the corresponding weight of the size is generated, as shown in Eq. (4).

$$\omega=\sigma\left(CID_k(y)\right) \tag{4}$$

In Eq. (4), CID is a one-dimensional convolution. The size of k determines the coverage of interaction, and its relationship with the number of channels is shown in Eq. (5).

$$D \approx \exp(\gamma \times k - b) \tag{5}$$

In Eq. (5), D signifies the channels. γ and b represent empirical values. k can be determined by the number of channels D, as shown in Eq. (6).

$$k=\left|\frac{\log_2(D)}{\gamma}+\frac{b}{\gamma}\right| \tag{6}$$

To reduce the impact of background noise on target tracking and make the network more focused on the target itself. The study introduces the spatial attention mechanism, which weights different spatial positions of the feature map to focus on the key areas of the target object, while suppressing interference from background or irrelevant areas [14-15]. This helps the network automatically learn and focus on the key spatial positions of the target object, such as edges, corners, etc., thereby improving the recognition and tracking accuracy of the target. Its structure is shown in Fig. 3.

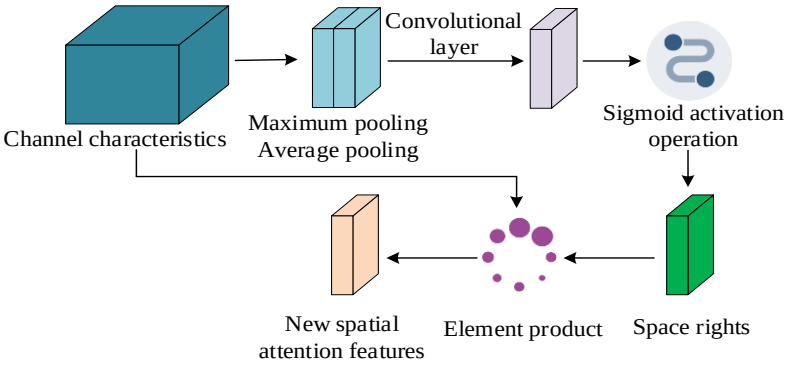

Fig. 3. Structure diagram of spatial attention mechanism module.

From Fig. 3, the input feature map first extracts deep features through convolutional layers, and then normalizes the output using the Sigmoid activation function, laying the foundation for subsequent spatial attention operations. The spatial attention mechanism multiplies the Sigmoid activated output with the original feature map through element multiplication operation. This operation achieves spatial position weighting of the feature map, focusing on key areas of the target (such as edges and corners) while reducing the interference of background noise. The weighted feature map is further processed through convolutional layers and combined with max pooling and average pooling techniques to extract global feature information. After these features are fused, they are refined again through convolutional layers. The generated spatial feature map significantly enhances the representation ability of the target area.

Finally, the spatial attention features is shown in Eq. (7).

$$M_S(F)=\sigma\left(f^{7*7}\left(\left[F_{avg}^{s};F_{\max}^{s}\right]\right)\right) \tag{7}$$

In Eq. (7), σ is the activation operation. F_{avg}^{s} is the average pooling feature. $F_{\max}^{s}$ is the maximum pooling feature. Then, multi-layer feature linear fusion is performed, and the fusion process is shown in Eq. (8).

$$\begin{cases}\hat{F}_4=\sum\left(F_4,F_5\right)\\ \hat{F}_3=\sum\left(F_3,\hat{F}_4\right)\end{cases} \tag{8}$$

In Eq. (8), $\hat{F}_4$ represents the fused mid-level feature map. F_4 represents the mid-level feature map. F_5 represents the deep feature map. $\hat{F}_3$ represents the shallow feature map after fusion. F_3 represents the shallow feature map.

B. *Twin Network Visual Tracking Algorithm Integrating Adaptive Anchor Box Generation*

Although introducing attention mechanisms and multi-layer linear fusion can optimize the extraction accuracy and the robustness of algorithms, there are still some potential drawbacks. Firstly, the attention mechanism may increase the computational burden of the model, especially when dealing with rich channel and spatial position weights. Secondly, the model may overfit the training data, resulting in candidate boxes that cannot cover specific targets, thereby reducing its generalization ability on unseen data. Therefore, this study introduces a new adaptive anchor box to reduce manual intervention, enabling the model to automatically learn and generate candidate boxes based on the semantic information of the image itself, while reducing the computational burden of the attention mechanism. Its structure is displayed in Fig. 4.

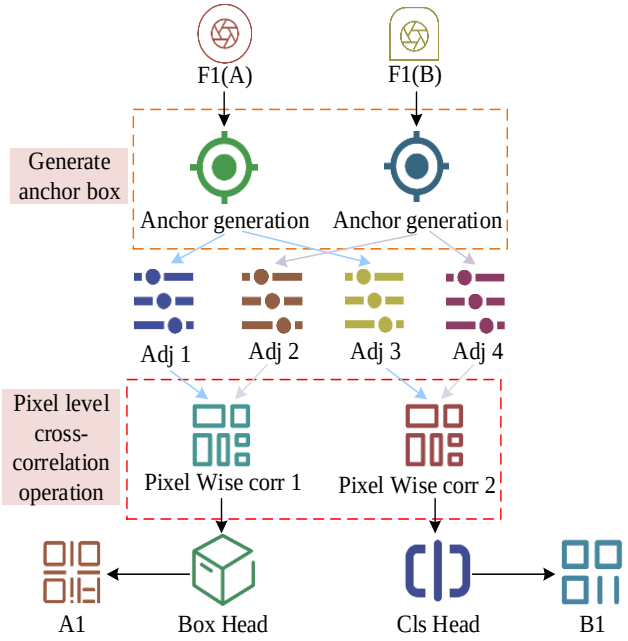

Fig. 4. Network structure diagram of adaptive generation anchor box region recommendation.

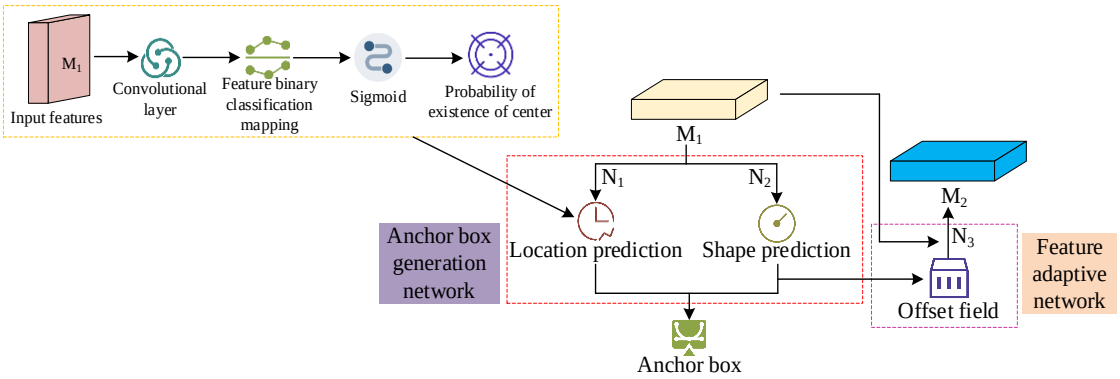

Fig. 5. Structure diagram of learnable generation module.

From Fig. 4, the input image generates feature maps through two convolutional layers F1 (A) and F1 (B), which are used for anchor box generation. Anchor boxes are generated at multiple scales (Adj 1 to Adj 4) through preset proportions and sizes to accommodate targets of different sizes and shapes. Subsequently, pixel level cross-correlation operations are performed between feature maps to generate Pixel Wise corr 1 and Pixel Wise corr 2 feature maps by calculating the correlation of corresponding pixel points, enhancing the spatial position information and correlation between features. These processed feature maps are further fed into the Box Head and Cls Head modules. Box Head is responsible for accurately regressing the coordinates of the target bounding box, while Cls Head performs classification tasks and predicts the target category for each anchor box. By optimizing the position and size of the anchor box, a detection box is ultimately generated to complete object detection. Based on the finer grained cross-correlation operations, the generated feature boundaries are made clearer [16]. This improves the success rate and accuracy of target tracking, thereby achieving more precise target tracking results. The core structure of generating anchor boxes is shown in Fig. 5.

From Fig. 5, the module has two parts: one is the anchor box generation network, which is used to generate unique anchor boxes, and the other is the feature adaptive network. The input features are convolved to obtain a binary classification map, and then the probability of center existence is obtained through the Sigmoid activation function; Next, this probability value is input into the anchor box generation network to generate anchor boxes. At the same time, the input features are fed into the feature adaptive network to obtain three features: N1, N2, and N3. Finally, these three features are input together with the anchor box into the localization prediction and shape prediction to obtain the final offset field. This method can infer the position and shape of the anchor box, as displayed in Eq. (9).

$$p(x,y,w,h \mid I) = p(x,y \mid I)\, p(w,h \mid x,y,I) \tag{9}$$

In Eq. (9), $p(x,y,w,h \mid I)$ represents the position and shape of the target. $p(x,y \mid I)$ represents that anchor boxes have different probabilities of appearing at different positions [17]. Convolutional neural networks automatically learn feature representations of images through a series of convolutional layers. The study employs a two channel convolutional sub network, and these features are subsequently used for classification tasks. Two channels independently predict the width and height of the corresponding anchor box, allowing the predicted box to more accurately fit the actual size of the target object, as displayed in Eq. (10).

$$\begin{cases} w = \sigma * s * e^{dw} \\ h = \sigma * s * e^{dh} \end{cases} \tag{10}$$

In Eq. (10), w is the width. h is high. σ is the empirical value. s is the step size. This study conducts deformation convolution with offset to obtain adaptive feature maps based on anchor box shapes at different positions, as shown in Eq. (11).

$$f_i^{'} = N_3\left(f_i, w_i, h_i\right) \tag{11}$$

In Eq. (11), $f_i^{'}$ is the convolved feature. N_3 is the deformable convolution. f_i is the original feature. (w_i, h_i) is the shape of the anchor box corresponding to the position. In the application of adaptive anchor box region recommendation network, the loss function is one of the key factors in the training process, which is applied to measure the difference between the predicted and the true situation [18-19]. Therefore, the study combines learning position and shape branches to form an adaptive anchor box loss function. By minimizing this comprehensive loss, the model can learn more accurate object detection and tracking capabilities [20]. Its expression is shown in Eq. (12).

$$L = \lambda_1 L_{loc} + \lambda_2 L_{shape} + L_{cls} + L_{reg} \tag{12}$$

In Eq. (12), L_{loc} is the position loss, which is used to measure the difference in position (i.e. the coordinates of the bounding box) between the predicted box and the real box. L_{shape} signifies the shape loss, used to measure the difference in shape (i.e. the aspect ratio of the bounding box) between the predicted box and the real box. By optimizing this loss, the model can better learn the shape features of the target object. L_{cls} is the classification loss, and L_{reg} is the regression loss, used in object tracking to measure the distance between the

predicted and the true boxes. λ_1 and λ_2 are used to balance the relative importance of position loss and shape loss in the total loss. In the position prediction branch, the loss function is displayed in Eq. (13).

$$L_{loc} = -\alpha(1-p)^{\gamma}\log(p) \tag{13}$$

In Eq. (13), α and γ represent the empirical values of the parameters. p signifies the probability of positive samples. In the shape prediction branch, the loss function can be used to optimize shape prediction without calculating the objective, as shown in Eq. (14).

$$L_{shape} = L_1\left(1-\min\left(\frac{w}{w_g},\frac{w_g}{w}\right)\right)+L_1\left(1-\min\left(\frac{h}{h_g},\frac{h_g}{h}\right)\right) \tag{14}$$

In Eq. (14), L_1 represents the smoothing loss. w_g signifies the real frame width, and h_g signifies the height. w signifies the candidate box width, and h signifies the height. After generating adaptive anchor boxes, the study will also use pixel level cross-correlation operations to represent features with higher quality, as shown in Fig. 6.

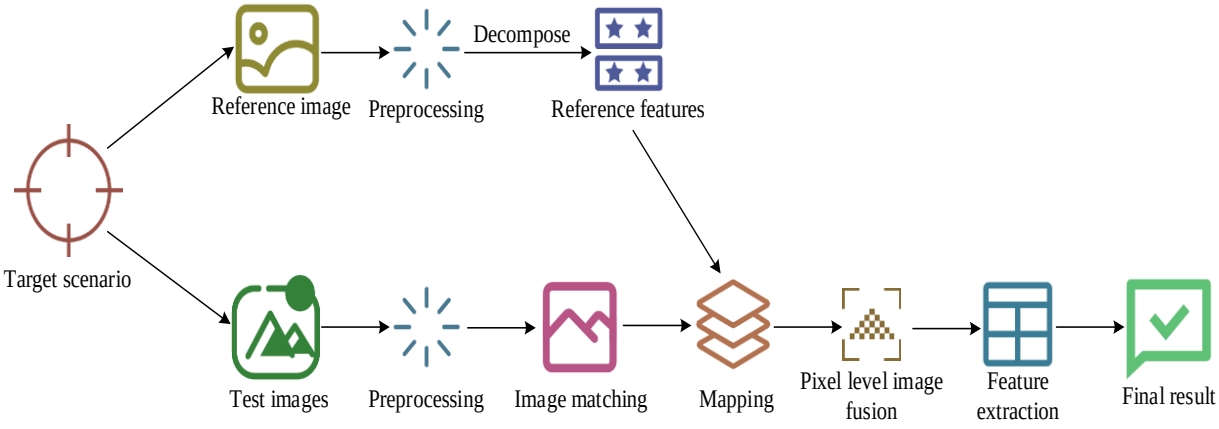

Fig. 6. Pixel level cross-correlation specific process.

From Fig. 6, in the object detection process, comparing the reference features with the test features generated after pre-processing of the test image, each part acts as a kernel to achieve deep interaction at the pixel level. After pixel level cross-correlation operation, high-quality features are sent to the mapping module for further processing. After optimization by the feature extraction module, detection results containing the precise position and category of the target are generated to avoid the target feature blurring. The process of generating fused images is shown in Eq. (15).

$$A = \left\{ A_i \mid A_i = Z_i * X \right\}_{i\in\{1,..,n\}} \tag{15}$$

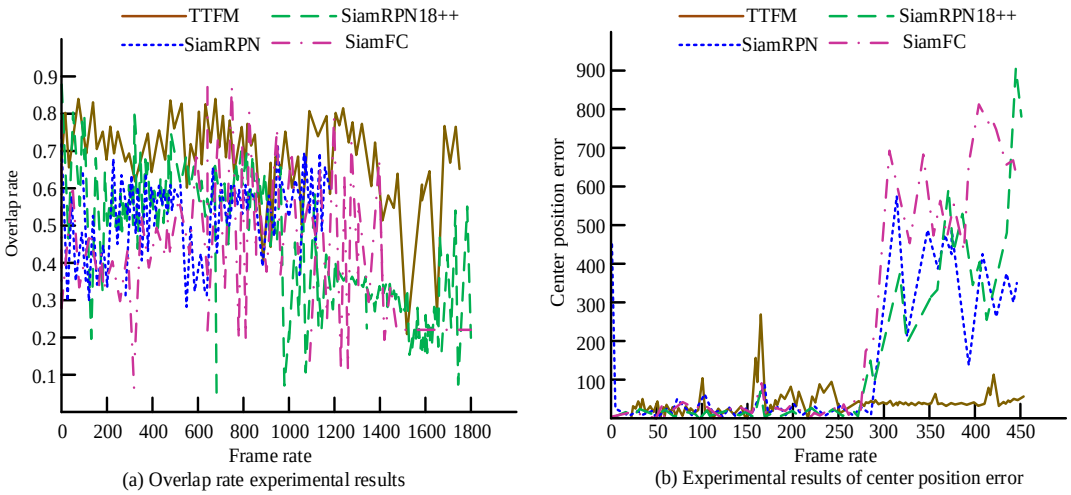
In Eq. (15), Z_i is the decomposed convolution kernel. $*$ signifies the convolution operation. X signifies the feature of the search area.

III. Results and Discussion

A. Analysis of Twin Network Visual Tracking Based on Attention Mechanism

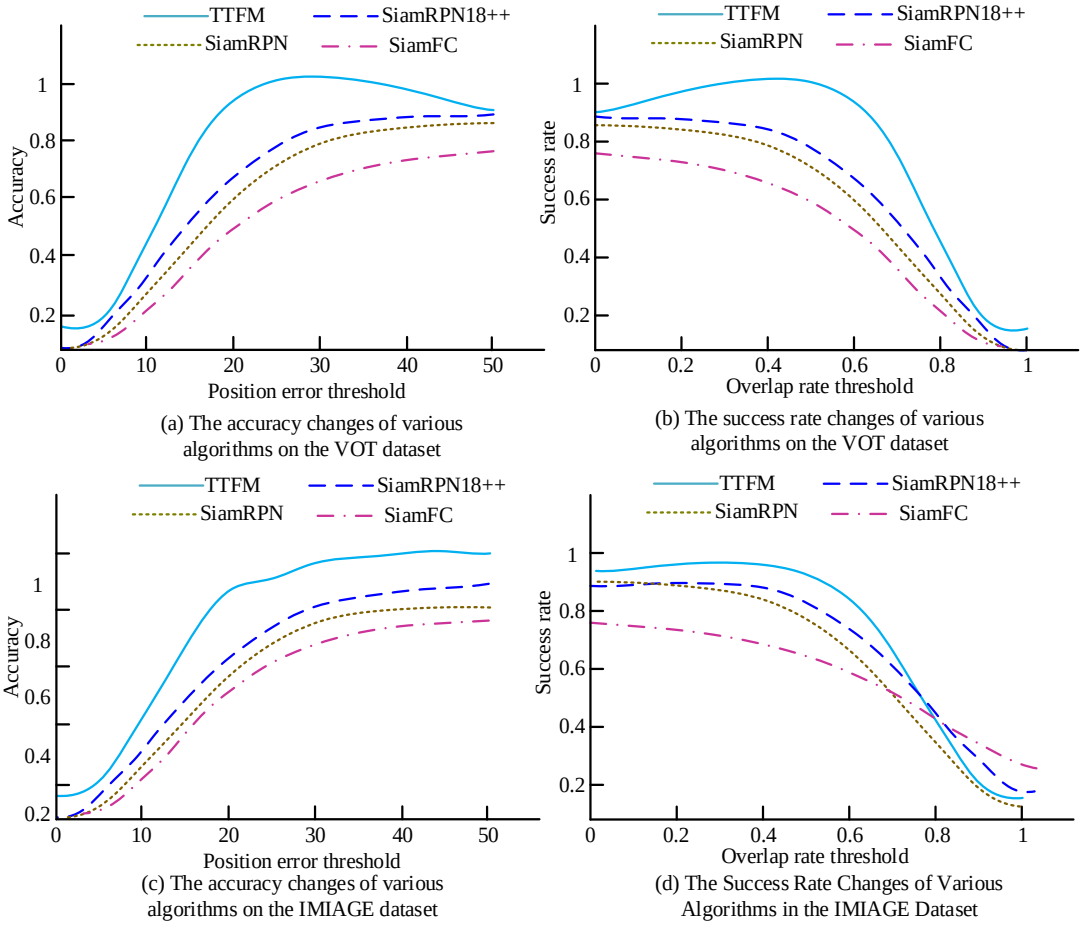
In order to solve the low accuracy and poor robustness in traditional fatigue driving recognition, a twin network visual tracking algorithm on the basis of attention mechanism is proposed. To verify the performance of the proposed TTFM in target tracking in complex environments, particularly its robustness against interference factors such as lighting changes, occlusion, and size variations, the study first conducts multiple comparative experiments to assess the advantages of TTFM algorithm in tracking accuracy and efficiency. Fig. 7 displays the results, taking the center position error of overlap rate as the evaluation index.

From Fig. 7, the TTFM algorithm had the best overlap rate of 0.75, indicating the best performance. Compared with other algorithms, the optimized TTFM algorithm increased the average overlap rate by 0.156%, effectively optimizing the efficiency of feature expression and target feature extraction. This lays the foundation for improving target tracking performance in complex environments. The TTFM algorithm performed well in tracking error at the center position of the sequence, with the smallest error. Compared with other basic algorithms, the TTFM algorithm reduced the center position error by 5.84, 30.63, and 43.42 pixels, respectively. When the target was subject to complex background interference such as changes in lighting, occlusion, and size, the TTFM algorithm significantly reduced the center position error. To further validate the effectiveness and performance improvement of the TTFM algorithm in single target tracking tasks. This study tested the commonly used VOT dataset and IMIAGE dataset, which contain visual tracking data under different adverse conditions such as lighting, to evaluate the improvement of TTFM algorithm and its generalization ability. The results are shown in Fig. 8.



(a) Overlap rate experimental results (b) Experimental results of center position error

Fig. 7. Comparison analysis curve of overlap rate and center position.



(a) The accuracy changes of various algorithms on the VOT dataset

(b) The success rate changes of various algorithms on the VOT dataset

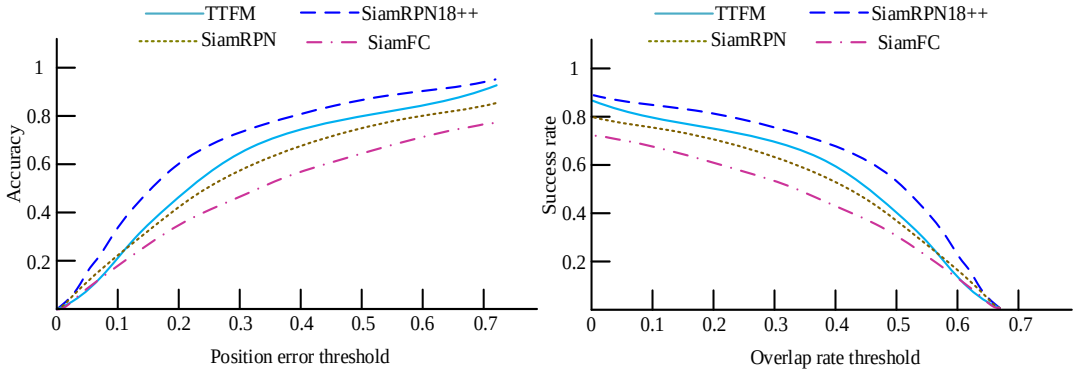
(c) The accuracy changes of various algorithms on the IMIAGE dataset

(d) The Success Rate Changes of Various Algorithms in the IMIAGE Dataset

Fig. 8. Success rate and accuracy on the VOT dataset.

From Fig. 8, the TTFM algorithm had excellent performance on the VOT dataset. Compared with the other three methods, the TTFM achieved obvious improvements in overall success rate and accuracy. Specifically, on the VOT dataset, the overall success rate of the TTFM algorithm reached 0.504, with an increase of 0.6% compared with the average success rate of other algorithms. Similarly, its accuracy also reached 0.642, with an increase of 0.9% compared with the average accuracy of other algorithms. However, the four algorithms do not change much in the IMIAGE dataset dataset,

indicating that these four algorithms have good generalization ability. The outstanding performance of the TTFM algorithm on the VOT dataset is mainly attributed to the feature extraction and fusion strategy proposed in the research. The algorithm significantly enhances the ability to extract useful features by introducing attention mechanisms, which is particularly important in complex scenarios. Secondly, the algorithm utilizes multi-layer linear fusion technology to integrate feature information from different levels, which not only enhances the richness of features, but also improves the accuracy and robustness in identifying fatigue states. To further validate the generalization ability of these algorithms, additional tests are conducted on the TrackingNet dataset, keeping hyper-parameters such as learning rate unchanged. Fig. 9 presents the experimental results.



(a) Accuracy (b) Success rate

Fig. 9. Success rate and accuracy on the TrackingNet dataset.

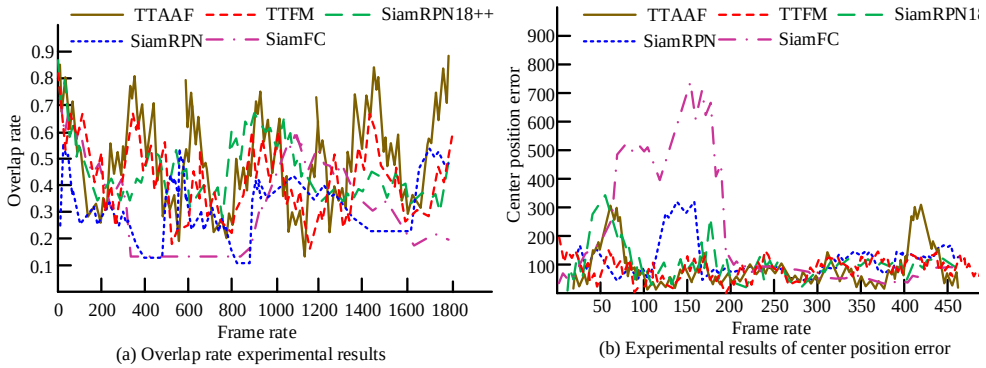
From Fig. 9, the TTFM performed better than the other three methods. For accuracy, the TTFM algorithm performed best when the position error threshold was low, ultimately converging to 0.830, while SiamFC performed better at higher position error thresholds. In the success rate, the TTFM algorithm performed well when the overlap rate threshold was high, while SiamFC performed well at lower overlap rate thresholds. The success rate and accuracy of the TTFM algorithm were 0.542 and 0.763, which were not significantly different from their performance in the VOT dataset. Overall, the TTFM algorithm performed the best on the TrackingNet dataset, especially for data containing occlusion attributes, averaging 0.4% and 3.3% higher than other algorithms. Compared with the VOT dataset, the performance of these three methods varied significantly. TTFM demonstrates superior tracking performance in complex environments. Therefore, the TTFM has better tracking performance and generalization ability, which is suitable for various complex tracking scenarios.

B. Analysis of Twin Network Visual Tracking Algorithm Integrating Adaptive Anchor Box Generation

From the analysis of the twin network visual tracking on the basis of attention mechanism, the tracking algorithm for preliminary components has good performance. Based on this, the study further optimizes it by introducing adaptive anchor box generation. To verify the repeatability and center position error of the twin network visual tracking algorithm that integrates adaptive anchor box generation, comparative analysis experiments are carried out on the VOT dataset, as presented in Fig. 10.

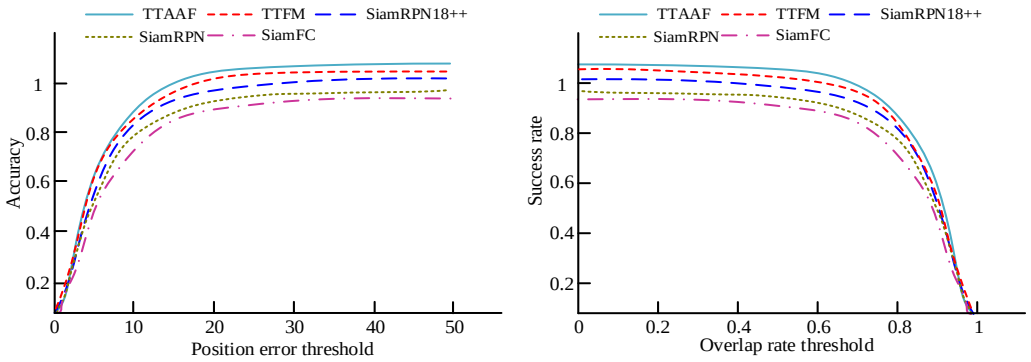
From Fig. 10, the improved algorithm had the best overlap rate. The improved algorithm performed well in terms of overlap rate, with an average overlap rate increase of 0.126 and an average center position error reduction of 23.450 pixels. The excellent performance of the improved algorithm in terms of overlap rate is mainly attributed to its innovative structure and mechanism. Firstly, the algorithm enhances the extraction of key behavioral and physiological signal features, such as blink frequency and head posture, by introducing attention mechanisms. These features are crucial for determining whether the driver is fatigued. Secondly, the application of multi-layer linear fusion effectively integrates feature information from different levels, enhancing the richness of features and the robustness of algorithms. To verify the tracking performance, comparative experiments are performed on the VOT dataset, as shown in Fig. 11.

From Fig. 11, the TTAAF algorithm performed best when the position error threshold was low, while SiamFC performed better when the position error threshold was high. In the success rate, the TTAAF algorithm performed well when the overlap rate threshold was high, while SiamFC performd well at lower overlap rate thresholds. Overall, the TTAAF algorithm performed the best on the VOT dataset, with an overall success rate and accuracy of 0.831 and 0.862, respectively, which were on average 0.3% and 0.5% higher than other algorithms. Especially for data containing occlusion attributes, the success rate and accuracy of the TTAAF algorithm were 0.642 and 0.753, which were on average 0.2% and 0.4% higher than other algorithms. Therefore, the TTAAF has better tracking performance and generalization ability, which is suitable for various complex tracking scenarios. In addition, the results of the four algorithms on the TrackingNet dataset are shown in Fig. 12.



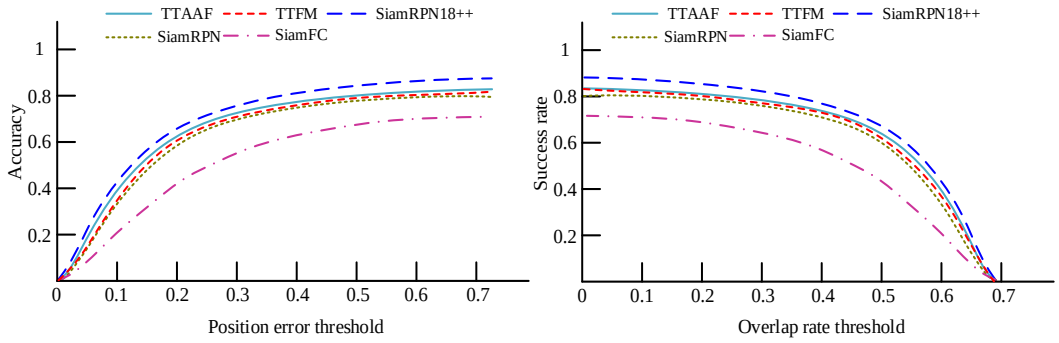
(a) Overlap rate experimental results (b) Experimental results of center position error

Fig. 10. Comparison analysis curve of overlap rate and center position.



(a) Accuracy (b) Success rate

Fig. 11. Success rate and accuracy on the VOT dataset.



(a) Accuracy (b) Success rate

Fig. 12. Success rate and accuracy graph on the TrackingNet dataset.

Fig. 12 is a comparison chart of the accuracy and success rates of four algorithms on the tracking network dataset. The horizontal axis represents the position error threshold and overlap threshold, and the vertical axis represents the accuracy and success rate. The blue dashed line represents TTAAE, the red solid line represents TTFM, the green dashed line represents SiamRPN++, and the purple dashed line represents SiamFC. From Fig. 12 (a), it can be observed that as the position error threshold gradually increases, the four curves gradually decrease. Within a smaller range of position error thresholds, the TTAAF algorithm has the highest accuracy, followed by TTFM, then SiamRPN++, and finally SiamFC; When the position error threshold is greater than 0.3, the accuracy of SiamFC exceeds SiamRPN++. Fig. 12(b) shows the trend of success rate with respect to the overlap rate threshold. It can be seen that as the overlap rate threshold increases, the four curves show an upward and then downward trend. Within a larger range of overlap rate thresholds, the TTAAF algorithm has the highest success rate, followed by TTFM, then SiamRPN++, and finally SiamFC; when the overlap rate threshold is less than 0.3, the success rate of SiamFC exceeds that of SiamRPN++. Combining the two graphs, it can be concluded that the TTAAF algorithm has the best overall performance on the tracking network dataset, with an accuracy and success rate of 0.932 and 0.962, respectively, which are 0.3% and 0.5% higher than other algorithms. Especially when dealing with occlusion attribute

data, the performance of TTAAF algorithm is particularly outstanding, with accuracy and success rates of 0.642 and 0.753, respectively, which are 0.2% and 0.4% higher than other algorithms. This indicates that the TTAAF algorithm has good robustness in handling occlusion attribute data. Finally, it was applied to the actual target tracking process, and the experimental results are shown in Fig. 13.

From the experimental results in Fig. 13, it can be seen that there are differences in the performance of the target tracking algorithm in different scenarios. In scenes marked as' Normal ', the algorithm can successfully track targets, even in situations where there is occlusion or complex background between targets, as shown in the images in the upper and lower left corners, the algorithm can still accurately identify and track targets. However, in the scenario marked as' Tracking failed ', the tracking ability of the algorithm is challenged. The image in the upper right corner shows that when the target is partially obscured by the sofa, the algorithm cannot continue tracking the target, which may be due to confusion between the target features and background features, resulting in tracking loss. In the image in the lower right corner, the target also failed to track after entering the room due to changes in lighting and increased background complexity. This indicates that the algorithm may have limitations when dealing with lighting changes and complex backgrounds. In addition, the image on the right side of the middle shows that the algorithm can maintain tracking even when the target is moving rapidly, indicating that the algorithm has a certain robustness to dynamic scenes.

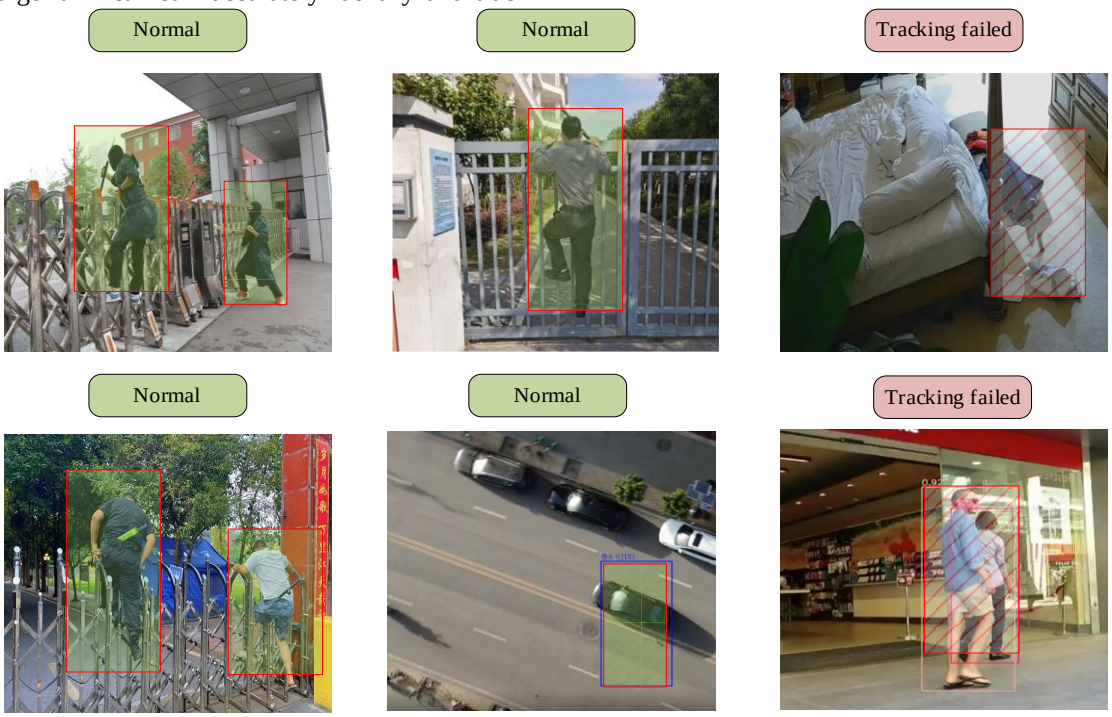


Fig. 13. Algorithm application effect interface diagram.

C. *Analysis of Twin Network Visual Tracking Algorithm Integrating Adaptive Anchor Box Generation*

A dual network visual tracking algorithm based on attention mechanism has been proposed to solve the problems in traditional fatigue driving detection, such as poor comfort, sensitivity to external factors, low detection accuracy, and poor real-time performance. By introducing attention mechanisms, algorithms can more effectively extract key features and improve target tracking performance in complex environments.

In the research of fatigue driving detection technology, this study proposes a visual tracking algorithm based on dual networks, which combines attention mechanism and adaptive anchor box generation. Compared with other methods in literature, it shows significant performance improvement. For example, the twin adaptive learning network proposed by Xin et al. performed well in GOT-10k and LaSOT benchmark tests, but the method proposed in this study can significantly reduce center position errors and improve tracking accuracy and robustness when dealing with complex background interference such as lighting changes, occlusion, and size changes [2]. The effective feature recognizer proposed by Jun W et al. optimized the representation ability, but there is still room for improvement in real-time performance [4]. In contrast, the overall success rate and accuracy of the algorithm in this study on the VOT dataset reached 0.831 and 0.862, respectively, which were 0.3% and 0.5% higher than other algorithms on average. Especially when processing occlusion attribute data, the success rate and accuracy were 0.2% and 0.4% higher than other algorithms on average, demonstrating better tracking performance and generalization ability.

The reasons and mechanisms for these results are as follows: the algorithm introduces attention mechanism, which can effectively filter out feature information that is not conducive to target tracking, retain key information, and improve feature extraction efficiency. Meanwhile, multi-layer linear fusion integrates feature information from different levels, enhancing feature richness and algorithm robustness. In addition, adaptive

anchor box generation reduces manual intervention and improves target tracking performance.

In summary, the dual network visual tracking algorithm based on attention mechanism proposed in this study has made significant progress in improving the accuracy and robustness of fatigue driving detection, providing an effective technical means for fatigue driving recognition in practical applications. Future research can further optimize algorithms to improve their adaptability and real-time performance in different driving scenarios, in order to better serve road safety and public health.

IV. CONCLUSION

Aiming at the challenges in fatigue driving detection, a visual tracking algorithm based on twin networks was proposed. Firstly, the TTFM algorithm was proposed. Then the TTAAF algorithm was optimized on the basis of the TTFM. The two algorithms proposed in the study performed well on multiple benchmark datasets, effectively improving the accuracy and robustness of target tracking. Specifically, the TTFM optimized the feature extraction process by introducing channel and spatial attention mechanisms, significantly enhancing the algorithm's ability to extract useful features. On the VOT dataset, the overall success rate and accuracy of the TTFM reached 0.504 and 0.642, with an average improvement of 0.6% and 0.9% compared with other algorithms. On the TrackingNet dataset, the success rate and accuracy of the TTFM algorithm were 0.542 and 0.763, especially for data containing occlusion attributes, which were on average 0.4% and 3.3% higher than other algorithms. Compared with TTFM, the TTAAF algorithm reduced manual intervention by adaptively generating anchor boxes, allowing the model to automatically learn and generate candidate boxes based on the semantic information of the image itself. On the VOT dataset, the overall success rate and accuracy of the TTAAF algorithm were 0.831 and 0.862, which were on average 0.3% and 0.5% higher than other algorithms. On the TrackingNet dataset, the TTAAF algorithm performed equally well, with an overall success rate and accuracy of 0.932 and 0.962, respectively, which were on average 0.3% and 0.5% higher than other algorithms. In summary, both algorithms proposed in the study have effectively improved the performance of target tracking, especially robustness in complex environments. This provides strong technical support for practical applications such as fatigue driving detection. Although significant progress has been made in this study, there are still some shortcomings. For example, the algorithms had high computational complexity and requires further optimization to improve real-time performance. Meanwhile, the robustness of the algorithm still needs to be improved for target tracking under extreme lighting conditions.

Graph Neural Networks and Dominant Set Algorithms for Energy-Efficient Internet of Things Environments: A Review

Dezhi Liao*, Xueming Huang
School of Information Engineering, Huizhou Technician Institute, Huizhou, 516000, Guangdong, China.

***Abstract*—The widespread usage of Internet of Things (IoT) devices opens up new opportunities for automated operations, monitoring, and communications across various industries. However, extending the lifespan of IoT networks remains crucial because IoT devices are energy-limited. This study investigates the convergence of Graph Neural Networks (GNNs) and dominant set algorithms to extend the longevity of IoT networks. GNNs are neural networks that capture complex relationships and node interactions based on graph-structured data. With these capabilities, GNNs are extremely effective at modeling IoT network dynamics, where devices are connected and whose interactions have a significant impact on performance. In contrast, dominant set algorithms are defined as an approach in which nodes of a network function as agents or leaders to perform resource-efficient and resource-distributed communication. A further detailed overview leverages existing techniques to describe GNNs' role in optimizing dominant set algorithms and discusses integrating these technologies into addressing energy efficiency challenges in IoT settings.**

***Keywords*—Internet of Things; energy efficiency; dominant set; Graph Neural Networks**

I. Introduction

A. Context

In the last few years, technology has profoundly reached all areas of society and has transformed them. As technology has progressed during the last couple of shows, it has dramatically shifted our way of life and how we communicate, work, and live. Ultimately, all these lead to our lives based on data-driven decisions and greater connectedness. The digital transformation also benefits from the presence of potentially billions of connected objects, which now can be transformed into intelligent and connected ones through the Internet of Things (IoT) [1]. IoT encompasses a vast range of physical devices, from everyday items like refrigerators and thermostats to complicated equipment for industrial use [2]. These devices feature software, sensors, and a variety of components specifically engineered to capture and transmit data through the Internet [3].

The advancement of connectivity enhances the functionality and convenience of technologies [4]. The rapid growth of the Internet of Things (IoT) is fueled by advancements and widespread online access [5]. At the core of IoT is computing, which seamlessly integrates computers into our routines without us even noticing it. IoT design enables it to work discreetly in the background. Offers users a multitude of benefits and options. In industries and sectors today, IoTs are widely applied to show their flexibility and versatility [6]. One of the most relatable instances is how IoT transforms household tasks within residences, with the help of home technologies, making our daily lives more efficient and convenient.

B. Motivation

Energy efficiency is a critical concern in designing and operating IoT networks, given that most IoT devices operate on limited energy sources such as batteries, which are often difficult or impractical to replace [7]. The continuous operation of these devices, responsible for tasks ranging from environmental monitoring to smart city infrastructure, requires minimizing energy consumption to extend the network's life and ensure uninterrupted operations [8].

Typical ways to boost energy efficiency, like other algorithms such as duty cycling, energy-aware routing, and clustering algorithms, are often difficult to scale or adjust to changing network conditions. With the growth of IoT networks, these problems have become more apparent, and there is a need for new intelligent solutions to solve them. Significant energy savings can be achieved by reducing the number of active nodes through techniques such as dominant set algorithms and optimizing network operations using Graph Neural Networks (GNNs). These new ideas allow for quick changes to the network as they happen, cutting down on energy use and making IoT systems work better and last longer overall.

C. Contribution

The present study contributes to IoT network optimization. First, a comprehensive overview of the combination of GNNs and dominant set algorithms is provided, highlighting the potential of these ideas to enhance the energy efficiency of IoT networks. Second, existing methods are systematically reviewed, and several insights are provided regarding how GNNs are employed to optimize dominant sets and minimize energy consumption dynamically. Third, current challenges and limitations of traditional approaches are identified, and the synergistic use of GNNs and dominant set algorithms as a novel solution to these problems is proposed. Finally, future research directions are outlined, and the importance of scalability, real-

time adaptation, and security for developing more efficient and sustainable IoT networks is highlighted.

II. BACKGROUND

This section presents basic information on concepts and technologies that underpin the integration of GNNs and dominant set algorithms for energy efficiency in IoT networks.

A. IoT

The IoT, coined by Kevin Ashton in 1999, represents a global infrastructure in which physical and virtual entities are connected through advanced communications technologies. As defined by the International Telecommunication Union (ITU), IoT enables innovative services. As shown in Fig. 1, the IoT essentially represents a vast network of devices capable of collecting data, exchanging operational information, and performing autonomous tasks. Integrating sensors into various devices, from cell phones to home appliances, makes this functionality possible.

Fig. 1. IoT-related sectors.

An IoT ecosystem includes web-enabled devices with processors, sensors, and communications hardware to collect, transmit, and process data. Collected data is typically transferred to cloud platforms or processed locally before being shared with other connected devices to initiate actions [9]. While human interaction for configuration, guidance, or data access is still possible, IoT devices work independently of each other. IoT applications use specific connectivity, network, and communication protocols. In particular, IoT has the potential to leverage machine learning, a subset of artificial intelligence, to optimize data processing and improve system dynamics. IoT generates and analyzes enormous amounts of data in real-time, driving big data analytics. IoT enables companies to monitor employee performance across multiple locations and optimize operations.

B. Graph Neural Networks

GNNs represent a practical paradigm for processing graph-structured data, demonstrating exceptional performance across diverse domains, including physical systems, protein structure analysis, and knowledge graph management [10, 11]. Graphs can be classified based on edge directionality (directed or undirected), node and edge homogeneity (homogeneous or heterogeneous), and structural complexity (graphs or hypergraphs). Directed graphs exhibit unidirectional edges, while undirected graphs imply bidirectional relationships between connected nodes. Homogeneous graphs contain a single node and edge type, whereas heterogeneous graphs accommodate multiple types. Hypergraphs extend the graph concept by allowing edges to connect arbitrary numbers of vertices. Fig. 2 shows examples for each graph type up to this point.

A directed (simple) graph is formally defined as a tuple $G = (V, E)$, where V is a set of nodes and E is a set of directed edges represented as tuples. A directed (generalized) hypergraph is a similar tuple with hyperedges and a numbering map f_i for each edge to indicate node order. These graphs are considered elementary, as other graphs can be constructed from their composition. Directed graphs are undirected if $(u, v) \in \mathcal{E}$. In this case, edges can be represented as sets rather than tuples. Directed hypergraphs are undirected if $f_i: x \rightarrow \{0\} for\ all\ (x, f_i)_i \in \mathcal{E}$.

A multigraph is a graph where edges or nodes can appear multiple times. A heterogeneous graph is one where nodes or edges have different types. These types can be formally appended to nodes and edges. An attributed graph is one where nodes or edges are associated with attributes, represented by node and edge attribute functions. If only nodes have attributes, it's called node-attributed, and if only edges have attributes, it's called edge-attributed. The graph is considered weighted if edge attributes are a subset of edge types.

The core principle of GNNs is to iteratively aggregate information from neighboring nodes and integrate this aggregated data into the representation of the central node [12]. This process, known as spreading, repeats itself over several layers. Each layer includes aggregation and update operations formulated as follows.

$$Aggregation: n_v^{(l)} = Aggregator_l(\{h_u^l, \forall u \in N_v\})$$
$$Update: h_v^{(l|+1)} = Updater_l(h_u^l, n_v^{(l)}) \quad (1)$$

h_u^l represents the node u's representation at layer l, while $Aggregator_l$ and $Updater_l$ denote the respective functions for aggregation and update at layer l.

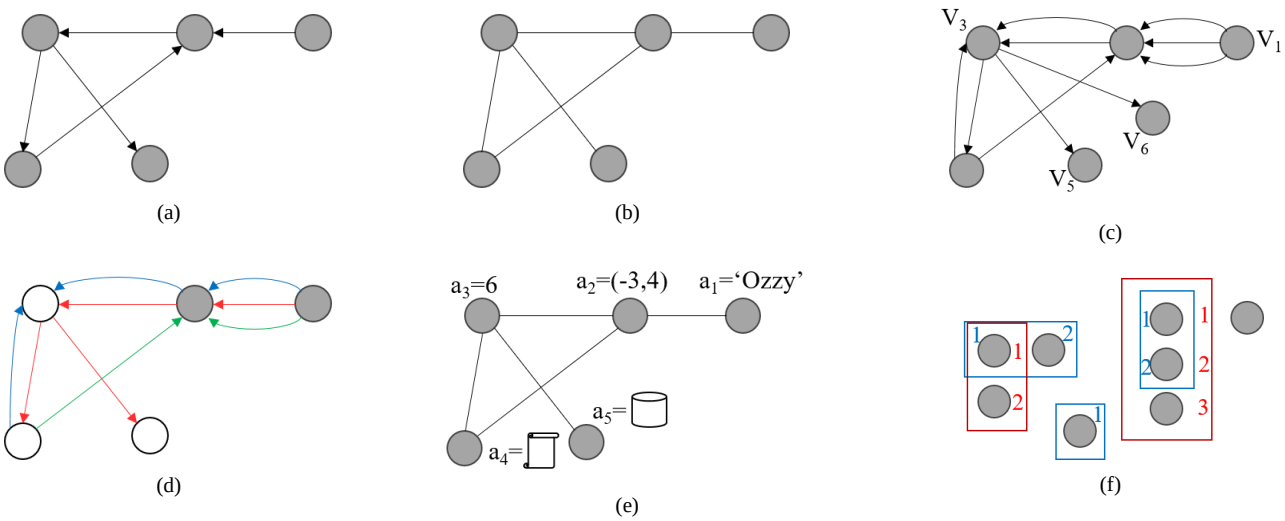

Fig. 2. An overview of different graph types: directed (a), undirected (b), multigraph (c), heterogeneous (d), attributed (e), and directed hypergraph (f).

TABLE I. COMPARISON OF AGGREGATION AND UPDATE OPERATIONS ACROSS DIFFERENT GNN FRAMEWORKS

Framework	Aggregation operation	Update operation
HGNN	Aggregates information using hyperedge convolution, where the node representations are transformed through a learnable matrix and normalized using degree matrices.	Updates node representations with a non-linear activation function applied to the aggregated information.
GGNN	Aggregates information uniformly from neighboring nodes using mean pooling.	Updates node representations using a gated recurrent unit, integrating the aggregated information iteratively.
GAT	Aggregates information from neighbors using an attention mechanism, where the contribution of each neighbor is weighted based on its relevance.	Updates node representations by applying a non-linear activation function to the weighted aggregation of neighbors' information.
GraphSAGE	Aggregates information from a sampled subset of neighbors using various pooling strategies (mean, sum, max).	Updates node representations by concatenating aggregated neighbor information with the underlying node representation and applying a learnable transformation.
GCN	Aggregates information using a weighted sum of neighbor representations, where the weights are derived from a normalized adjacency matrix.	Updates node representations by applying a non-linear activation function to the aggregated information.

Aggregation strategies include uniform treatment of neighbors (mean pooling) and weighted contributions based on attention mechanisms. The update step integrates the neighborhood information with the central node representation to create a refined node representation. Various techniques have been proposed to effectively combine these components, including GRU mechanisms, concatenation with non-linear transformations, and summation. Generally, five prominent GNN frameworks are commonly employed in IoT networks, each with distinct aggregation and update mechanisms, as summarized in Table I.

1) Hypergraph Neural Network (HGNN): This framework excels at capturing higher-order data correlations within hypergraph structures [13]. The hyperedge convolution layer defined by Eq. (2) uses a non-linear activation function, a learnable transformation matrix ($W^{(l)}$), and degree matrices for edges (D_e) and vertices (D_v) to calculate node representations.

$$Aggregation: N^{(l)} = D_v^{-\frac{1}{2}} E W^0 \tilde{D}_e^{-1} E^T D_v^{-\frac{1}{2}} H^{(l)}$$
$$Update: H^{(l+1)} = \delta\left(W^{(l)} N^{(l)}\right) \quad (2)$$

2) Gated Graph Neural Network (GGNN): GGNN incorporates a Gated Recurrent Unit (GRU) for the update step [14]. While effective, its iterative nature over all nodes can hinder scalability on large graphs.

$$Aggregation: n_v^{(l)} = \frac{1}{|N_v|} \sum_{j \in N_v} h_j^{(l)}$$
$$Update: h_v^{(l+1)} = GRU\left(h_v^{(l)}, n_v^{(l)}\right) \quad (3)$$

3) Graph Attention Network (GAT): Recognizing the varying influence of neighbors, GAT employs an attention mechanism to differentiate neighbor contributions [15]. The attention function, typically $LeakyReLU\left(a^T \left[W^{(l)} h_v^{(l)} \oplus W^{(l)} h_j^{(l)}\right]\right)$, assigns weights to neighbors based on their relevance.

$$Aggregation: n_v^{(l)} = \sum_{j \in N_v} a_{vj} h_j^{(l)}, a_{vj} = \frac{exp\left(Att\left(h_v^{(l)}, h_j^{(l)}\right)\right)}{\sum_{k \in N_v} exp\left(h_v^{(l)}, h_j^{(l)}\right)}$$
$$Update: h_v^{(l+1)} = \delta\left(W^{(l)} n_v^{(l)}\right) \quad (4)$$

4) GraphSAGE: This framework introduces neighborhood sampling to manage computational efficiency, followed by

aggregation (mean, sum, or max pooling) and concatenation for the update step [16].

$$Aggregation: n_v^{(l)} = Aggregator_l(\{h_u^l, \forall u \in N_v\})$$
$$Update: h_v^{(l+1)} = \delta\left(W^{(l)}.\left[h_v^{(l)} \oplus n_v^{(l)}\right]\right) \quad (5)$$

5) Graph Convolutional Network (GCN): GCN simplifies the aggregation process by approximating the graph Laplacian's eigendecomposition [17]The node representation is updated iteratively based on Eq. (6), which involves a non-linear activation function, a learnable transformation matrix, and adjacency weights.

$$Aggregation: n_v^{(l)} = \sum_{j \in N_v} d_{vv}^{-\frac{1}{2}} \tilde{a}_{vj} d_{jj}^{-\frac{1}{2}} h_j^{(l)}$$
$$Update: h_v^{(l+1)} = \delta\left(W^{(l)} n_v^{(l)}\right) \quad (6)$$

C. Dominant Set Algorithms

Dominant set algorithms identify subsets of nodes within a network capable of representing or leading a group of nodes, optimizing communication and resource allocation [18]. In the context of IoT networks, where energy efficiency is paramount, dominant set algorithms are crucial in minimizing the number of active nodes required for effective network operation [19]. By designating certain nodes as "dominant," these algorithms reduce overall communication overhead, conserving energy.

Let $G = (V, E)$ be a graph representing the IoT network, where $V = \{v_1, v_2, \ldots, v_n\}$ is the set of IoT nodes, and E is the set of edges representing the communication links between these nodes. A dominant set $D \subseteq V$ is a subset of nodes such that every node $v \in V$ is either in D or adjacent to at least one node in D. The goal is to minimize the size of the dominant set D while ensuring network coverage. This can be mathematically expressed as:

$$Minimize\ |D| \quad subject\ to \quad \forall v \in V, v \in D\ or\ \exists\ u \in D\ such\ that\ (u, v) \in E \quad (7)$$

In energy-constrained IoT networks, the energy consumption of a node v_i is denoted by $E(v_i)$. The total energy consumption of the dominant set D can be expressed as:

$$E(D) = \sum_{v_i} E(v_i) \quad (8)$$

The objective is to minimize $E(D)$ while maintaining a dominant set that covers the entire network, ensuring that:

$$Minimize\ E(D) \quad subject\ to \quad D\ is\ a\ dominant\ set\ of\ G \quad (9)$$

Traditional dominant set algorithms often rely on heuristic or optimization-based approaches to select the most suitable nodes. These algorithms typically consider node degree, connectivity, and proximity to other nodes. For instance, a common approach is to iteratively select the node with the highest degree (most connections) as part of the dominant set:

$$Select\ v_i \in V\ \ such\ that\ degree\ (v_i) \geq degree(v_j) \forall v_j \in V \quad (10)$$

This process is repeated until all nodes are either in the dominant set or adjacent to a node in the dominant set.

One of the main challenges of traditional dominant set algorithms is their static nature. They do not easily adapt to the dynamic conditions of IoT networks, such as fluctuating energy levels or changing network topologies. The computational complexity of finding the optimal dominant set can also be high, especially in large-scale IoT networks.

These limitations have spurred research into more advanced methods, such as integrating dominant set algorithms with machine learning techniques like GNNs. By leveraging the learning capabilities of GNNs, it is possible to develop more sophisticated dominant set algorithms that can dynamically adjust to real-time network conditions, offering a more robust solution for energy-efficient IoT network management. For example, GNNs can predict each node's energy consumption and connectivity dynamics, leading to a more effective and adaptive selection of the dominant set.

D. Energy Efficiency in IoT Networks

Energy efficiency is a paramount concern in the design and operation of IoT networks due to the inherent constraints of IoT devices, which often rely on limited power sources such as batteries. The operational lifespan of these devices and, by extension, the network depends heavily on how efficiently energy is utilized. Given that IoT networks are typically deployed in large numbers and diverse environments, ranging from smart cities to remote agricultural fields, the challenge of maintaining energy efficiency while ensuring continuous, reliable operation is critical. As shown in Fig. 3, the energy consumption in IoT networks is influenced by several factors, including:

1) Communication overhead: Data transmission and reception are among the most energy-intensive activities in IoT devices. The frequency of communication, the distance over which data must be transmitted, and the protocol used all significantly impact energy usage.

2) Idle listening: Nodes in an IoT network often consume energy while listening for potential communication, even if no data is transmitted. This idle listening can account for a substantial portion of energy expenditure.

3) Computation: Local processing tasks, such as data aggregation, encryption, or decision-making algorithms, consume energy. Although typically less than communication activities, computation energy must still be managed effectively, especially in devices with minimal processing power.

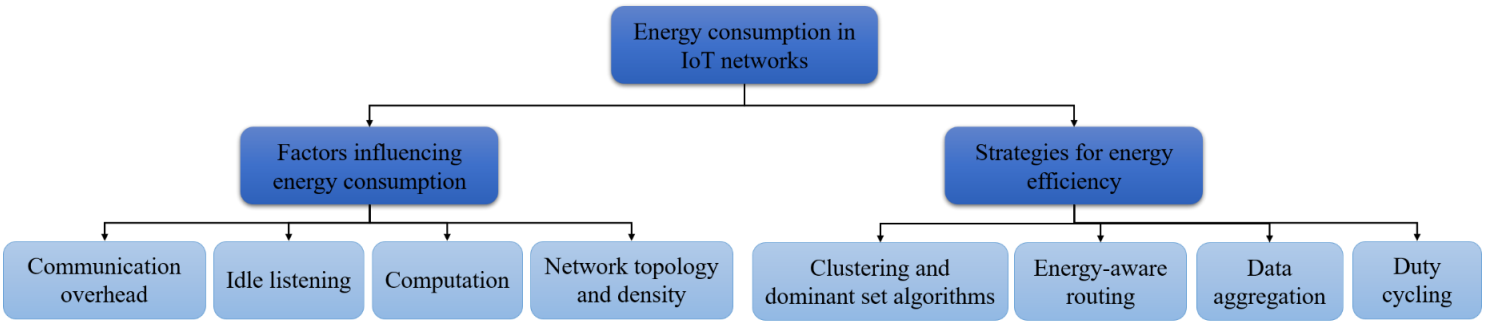

Fig. 3. Energy consumption in IoT networks.

4) Network topology and density: The arrangement and density of nodes within the network affect the routing paths and the number of hops required for data transmission, influencing energy consumption. Dense networks might reduce transmission distances but increase interference and collisions, while sparse networks might require longer transmission distances.

Various strategies have been developed to enhance energy efficiency in IoT networks, including:

1) Duty cycling: This technique involves turning off a device's radio transceiver when it is not needed, thus reducing energy consumption during idle periods. However, the challenge lies in coordinating wake-up times among nodes to maintain network connectivity.

2) Energy-aware routing: Routing protocols in IoT networks can be designed to consider the remaining energy of nodes when selecting routes, thus balancing energy consumption across the network and avoiding the depletion of individual nodes.

3) Clustering and dominant set algorithms: Clustering techniques group nodes into clusters with a designated cluster head, reducing the number of nodes involved in long-distance communication. As discussed in the previous section, dominant set algorithms are a form of clustering that selects a subset of nodes to manage communications, reducing energy consumption.

4) Data aggregation: Reducing the amount of data transmitted by aggregating or compressing data at intermediate nodes can significantly lower energy consumption. This strategy reduces the number of transmissions required and the volume of data sent [20].

Despite the effectiveness of these strategies, challenges remain, particularly in scaling these methods to large and heterogeneous networks, where nodes may have vastly different energy capacities, processing powers, and communication requirements. Furthermore, the dynamic nature of IoT networks, where nodes may move, join, or leave the network, complicates the implementation of static energy-saving techniques.

III. GNNs and IoT Networks

A. GNNs for Node Representation and Feature Learning

GNNs are effective tools for manipulating and examining graph-based data. This is especially useful for IoT networks, in which devices (nodes) and their connections (edges) naturally form graphs. One of the main advantages of GNNs is their capacity to acquire efficient node representations and extract significant characteristics from the graph. These features may be used for various downstream tasks like optimization, prediction, and classification.

Within IoT systems, individual nodes symbolize devices with distinct features, like energy levels, communication range, computing power, and connectedness to other nodes. The connections between nodes, such as the ability to directly interact with one another, are represented as edges in the graph. Conventional approaches to representing nodes typically depend on predetermined characteristics or rules, which may not completely portray the many relationships and interdependencies in a changing network environment.

GNNs address this constraint by acquiring node representations influenced by the overall network topology. This is accomplished by passing a message in which each node continuously changes its representation by gathering information from neighboring nodes. The whole procedure may be represented numerically in the following manner [21].

$$h_v^{(k)} = \sigma\left(W^{(k)}.AGGREGATE\left(\left\{h_u^{(k-1)}: u \in N(v)\right\}\right)\right) \quad (11)$$

Where $h_v^{(k)}$ is the representation of node v at the k^{th} iteration, $N(v)$ denotes the set of neighbors of node v, *AGGREGATE* is a function that combines the representations of neighboring nodes (e.g., sum, mean, max), $W^{(k)}$ is a learnable weight matrix for the k^{th} layer, and σ is a non-linear activation function (e.g., ReLU).

During this repeated process, the encoding of each node $h_v^{(k)}$ includes the node's characteristics, the characteristics of its neighboring nodes, and the wider network context. GNNs can acquire comprehensive and contextually aware representations of nodes, which are very useful for tasks like clustering, dominant set selection, and energy-efficient routing in IoT

networks. GNNs may capture many crucial components of the network via the learned features, including:

1) Node centrality: This feature denotes the significance or impact of a node inside the network.

2) Connectivity patterns: It comprehensively represents local and global network configuration, including identifying nodes that form clusters or key routes.

3) Energy consumption patterns: It uses predictive analysis to identify nodes more likely to spend more energy depending on their position in the network. This allows for proactive load balancing.

GNNs may enhance decision-making processes in IoT networks by using these acquired characteristics. In the dominant set method, nodes with high centrality and low energy consumption are prioritized as leaders. This optimization aims to improve network coverage and energy efficiency. Utilizing GNNs for node representation and feature learning in IoT networks offers the following benefits:

1) Scalability: GNNs can effectively manage networks of significant size by gaining knowledge in a decentralized and concurrent fashion.

2) Adaptability: The learned representations may be continuously modified as the network grows, enabling immediate adjustment to changes in network structure or node conditions.

3) Generalization: GNNs can apply learned knowledge to diverse network setups, which allows them to remain strong and effective even when faced with varied situations and network architectures.

B. GNNs for Clustering and Dominant Set Selection

GNNs have shown substantial promise in improving IoT network clustering and dominant set selection procedures. Clustering represents categorizing nodes (IoT devices) into smaller groups, known as subsets or clusters. Each cluster is led by a cluster head, who handles communication and coordination inside the cluster. Dominant set selection is a notion that involves choosing a subset of nodes to serve as leaders or representatives responsible for controlling communication throughout the whole network. These processes are essential, enhancing energy efficiency, lowering communication overhead, and lengthening IoT networks' lifespan.

Conventional clustering methods often depend on fixed rules or predetermined standards, which may not completely adjust to the dynamic nature of IoT environments. GNNs provide a more adaptable and data-oriented clustering method by using acquired representations of nodes that include both the local and global structure of the network.

Within the realm of clustering, GNNs generate embeddings reflecting the similarity between nodes, taking into account their characteristics and connections. These embeddings may be used to create clusters more informedly. Nodes that possess comparable energy levels, communication patterns, or responsibilities within the network may be categorized together, establishing more efficient clusters. Mathematically, after learning node representations h_v through a GNN, clustering can be performed by applying a clustering algorithm, such as k-means, directly on these embeddings [21].

$$Cluster\ assignment = k - means(\{h_v | v \in V\}) \quad (12)$$

This methodology guarantees the formation of clusters based on acquired, multi-dimensional characteristics that include intricate interconnections and dependencies within the network instead of merely depending on unprocessed, pre-established criteria.

Dominant set selection entails identifying a subset of nodes that can efficiently handle communication and data aggregation for the whole network. Conventional approaches for choosing dominating sets often include picking nodes based on node degree, closeness, or energy levels. Nevertheless, these approaches may be constrained by their fixed characteristics and incapacity to adjust to evolving network circumstances.

GNNs can be used to dynamically improve the selection of dominant sets by learning to predict the most suitable nodes as representatives. This prediction considers both the network's current state and likely future situations. The method can be defined as a node classification problem in which the GNN is trained to categorize nodes into dominant (leader) or non-dominant (follower) groups based on their acquired embeddings [21].

$$y_v = GNN(G, v) \quad (13)$$

where, y_v is the predicted label for node *v*, indicating whether it should be included in the dominant set. The GNN model considers the entire graph *G* and the specific node *v*, using the message-passing framework to aggregate information from neighboring nodes and the broader network. The inclusion of a node in the dominant set may be determined by a range of acquired characteristics, including:

1) Energy efficiency: Nodes with more remaining energy may be prioritized to prevent the depletion of crucial nodes.

2) Network centrality: Nodes centrally positioned or with excellent connections are more suitable since they can effectively interact with other nodes.

3) Load balancing: The GNN may spread the predominant function across numerous nodes to prevent certain nodes from becoming bottlenecks.

The use of GNNs in clustering and dominate set selection has noteworthy ramifications for IoT networks, especially when conserving energy and ensuring network lifespan is of utmost importance.

1) Smart cities: Within urban IoT networks, GNNs can enhance the arrangement of sensors and devices into clusters, decreasing energy use while ensuring a reliable connection and efficient data processing.

2) Industrial IoT: In industrial environments, GNNs may effectively oversee the management of crucial monitoring devices, reducing energy depletion in vital nodes.

3) Environmental monitoring: For IoT networks deployed in remote or difficult-to-access areas, GNNs can help form optimal clusters and select dominant sets that minimize energy usage, extending the network's operational lifespan.

IV. Dominant Set Algorithms in IoT Networks

A. Traditional Dominant Set Algorithms

Traditional dominant set methods were previously employed in IoT networks to enhance network efficiency and minimize energy use by choosing a subset of nodes that efficiently handle communication and data aggregation duties. These algorithms identify a "dominant set" of nodes that may include the whole network, guaranteeing that every node is either a member of the dominant set or is directly linked to a node in the dominant set. This method effectively minimizes the required communication since it only involves a small number of critical nodes in transmitting messages and handling data. This saves energy across the network.

The greedy algorithm is a frequently used method for identifying a dominant set. It operates by repeatedly selecting nodes with the greatest degree (i.e., the nodes with the most connections) to be included in the dominant set. The reasoning is that nodes with a high degree are more likely to include a significant percentage of the network, decreasing the number of nodes required in the dominating set. The fundamental procedures of a greedy dominating set algorithm may be summarized as follows:

Start with an empty set $D = \emptyset$.

Select the node v with the maximum degree in the remaining graph and add it to D.

Remove v and its neighbors from the graph.

Repeat until all nodes are either in D or have a neighbor in D.

Heuristic techniques are often used to enhance the efficiency of selecting dominating sets. These approaches may include other factors such as node energy levels, proximity to other nodes, or the general structure of the network. For instance, a heuristic may prioritize nodes with more energy to prevent the dominant set from rapidly exhausting its resources.

Computing the precise minimal dominating set in large-scale IoT networks may be computationally burdensome. Approximation algorithms provide a means to discover solutions close to optimum efficiently. These algorithms generally ensure that the size of the dominating set is within a certain ratio of the ideal size. An example of a well-recognized approximation technique is the 2-approximation algorithm. This approach ensures that the dominating set it discovers will be no more than twice the size of the best answer.

B. Challenges in Existing Approaches

Although conventional dominating set algorithms have played a crucial role in enhancing the energy efficiency of IoT networks, they still face some difficulties, as outlined in Table II. With IoT networks' growing complexity and dynamism, certain limitations in current techniques have been revealed. These problems highlight the need for more sophisticated approaches to effectively manage contemporary IoT systems' distinct requirements.

A major obstacle classic dominating set algorithms face is their dependence on static network assumptions. These methods typically function using a static snapshot of the network, assuming that the network's architecture, node connection, and energy levels stay unchanged throughout the network's operation. Nevertheless, IoT networks include an intrinsic dynamism, where nodes can join or depart from the network, relocate to new positions, or encounter variations in energy levels. Using a static technique may lead to the formation of inefficient dominating sets that do not adjust to the changing circumstances of the network. This can result in inefficiencies in both energy usage and communication.

TABLE II. Challenges of Conventional Dominant Set Algorithms in IoT Networks

Challenge	Description	Impact on IoT Networks
Static network assumptions	Dependence on a static snapshot of the network, assuming fixed architecture, node connections, and energy levels.	Leads to inefficient dominating sets that do not adapt to dynamic network changes, resulting in energy inefficiencies and communication issues.
Scalability issues	Increasing computational complexity as the network size grows, making it difficult to find efficient dominating sets in large-scale networks.	Limits the applicability of conventional methods in large-scale IoT networks, causing performance bottlenecks and reducing overall network efficiency.
Energy unawareness	Focus on network coverage and connectivity without considering the varying energy levels of individual nodes.	Causes rapid depletion of selected nodes' energy, leading to uneven energy distribution and shortening the overall network lifespan.
Lack of real-time adaptability	Inability to adapt to real-time changes in the network, such as node mobility or environmental fluctuations.	Results in the use of outdated configurations, leading to inefficiencies in energy use and increased energy consumption.
Suboptimal node selection	Reliance on simple heuristics like node degree or proximity, which may not consider the complex factors affecting network performance.	May result in the selection of nodes that are not optimally suited to act as leaders, reducing the network's overall efficiency and effectiveness.
Security vulnerabilities	Algorithms not designed with security in mind, making them susceptible to attacks like node compromise or denial-of-service (DoS) attacks.	Leaves IoT networks vulnerable to security breaches, as crucial nodes in the dominating set may be targeted by adversaries, disrupting network operations.

As the size of IoT networks grows, the computational intricacy of conventional dominating set methods becomes a notable issue. Discovering the most efficient or nearly efficient dominating set in a vast network may be a demanding and time-consuming computing task. The complexity of these algorithms increases exponentially as the number of nodes in the network rises, making it unfeasible to apply them to large-scale IoT networks without experiencing significant performance limitations. The limited scalability of conventional techniques hinders their usefulness in contexts with broad and constantly growing IoT networks.

Traditional dominant set algorithms often focus on optimizing network coverage and connectivity without fully considering the varying energy levels of individual nodes. In many cases, these algorithms may select nodes with low remaining energy to be part of the dominant set, leading to rapid depletion of those nodes' power reserves. This "energy blindness" can result in uneven energy distribution across the network, with some nodes exhausting their energy supply quickly while others remain underutilized. Consequently, the overall network lifespan may be shortened as key nodes fail prematurely due to energy depletion.

Another notable constraint is the lack of real-time adaptability of conventional dominant set methods to network changes. IoT networks often function in dynamic settings characterized by fast changes in circumstances, such as mobile IoT scenarios or networks installed in harsh and fluctuating environments. Conventional algorithms, usually created to calculate a dominating set by a single network examination, have difficulty keeping up with these modifications. Consequently, they could persist in using obsolete settings, resulting in inefficiencies and heightened energy use.

Classic dominant set methods often rely on node degree, proximity, or simple heuristics to select a node. However, these criteria may not necessarily result in the most energy-efficient or effective dominant set. These criteria sometimes fail to include the intricate and multi-faceted elements that impact the functioning of an IoT network, such as the diverse responsibilities of nodes, environmental circumstances, or the unique communication patterns inside the network. This may lead to the selection of nodes not optimally suited to act as leaders, reducing the network's overall efficiency.

Security is a crucial problem in several IoT applications. Conventional dominating set algorithms, on the other hand, are often not developed with security as a primary consideration. The algorithms' static and predictable nature renders them susceptible to assaults, such as node compromise or denial-of-service (DoS) attacks. In these attacks, an adversary targets crucial nodes in the dominating set to disrupt the network. Conventional methods might leave IoT networks vulnerable to possible security breaches without inherent mechanisms to adjust to such threats.

C. Enhancements through GNN Integration

Incorporating GNNs with conventional dominant set techniques signifies notable progress in overcoming the constraints of current methodologies in IoT networks. As summarized in Table III, GNNs can effectively represent and analyze intricate data structures through graphs. This makes them a powerful tool for improving the process of selecting dominating sets and clustering in IoT settings. GNNs provide a flexible, scalable, and adaptable framework for this purpose. This part examines the integration of GNNs with dominant set algorithms to address the issues related to static assumptions, scalability, energy efficiency, and real-time adaptation.

TABLE III. ENHANCEMENTS PROVIDED BY GNN INTEGRATION WITH DOMINANT SET ALGORITHMS IN IOT NETWORKS

Enhancement	Description	Impact on IoT Networks
Dynamic network adaptation	GNNs continuously update node representations in real-time as network conditions evolve, ensuring the dominant set adapts to current network states.	Maintains optimal performance and energy efficiency by dynamically responding to node mobility, energy changes, and communication patterns.
Scalability and efficiency	GNNs handle large-scale IoT networks efficiently through parallel processing and distributed computing, minimizing global calculations.	Enhances scalability of dominant set algorithms, making them suitable for large-scale deployments like smart cities and industrial IoT systems.
Energy-aware node selection	GNNs incorporate energy-awareness into node selection by analyzing current and historical energy data, prioritizing nodes with higher remaining energy.	Extends network lifetime by preventing the premature depletion of key nodes and ensuring balanced energy consumption across the network.
Improved node representation	GNNs generate rich, context-aware representations of nodes that include their characteristics and network context, enabling more informed dominant set selection.	Optimizes energy consumption and maintains network coverage by selecting strategically positioned, well-connected nodes for the dominant set.
Real-time decision making	GNNs support continuous updates and real-time decision-making in volatile network conditions, allowing for ongoing adjustments to the dominant set.	Ensures the network remains efficient and resilient even in dynamic environments like mobile IoT networks or uncertain deployment areas.
Security and robustness	GNNs enhance network security by detecting and responding to abnormal patterns, such as compromised nodes, and adjusting the dominant set accordingly.	Increases the resilience of IoT networks against security threats by proactively isolating or bypassing suspicious nodes, maintaining overall network integrity.

GNNs provide a significant improvement by being able to adjust to changing network circumstances in real-time. Contrary to conventional dominant set techniques that usually function with fixed network snapshots, GNNs continuously modify node representations as network circumstances evolve. GNNs accomplish this dynamic adaptation by using the message-passing process, which involves iteratively updating the representation of each node depending on the information it receives from its neighboring nodes. GNNs can adapt the dominating set to match the current state of the network, which includes factors such as node mobility, changes in energy levels, and different communication patterns. This ensures that GNNs can maintain maximum performance and energy efficiency as the network develops.

GNNs have an innate ability to scale, which makes them highly suitable for accommodating large-scale IoT networks. Conventional dominant set techniques sometimes encounter difficulties due to the high computing cost of finding the most effective nodes within extensive networks. GNNs, on the other hand, are capable of effectively managing enormous graphs via the use of parallel processing and distributed computing. By acquiring data from local neighborhoods in the network, GNNs minimize the need for global calculations, enabling scalable solutions as the network expands. The capacity to scale allows dominating set algorithms to be improved with GNN in large-scale IoT deployments, such as smart cities or industrial IoT systems, where conventional methods may struggle.

One significant benefit of combining GNNs with dominant set algorithms is the capacity to include energy-awareness in selecting nodes. GNNs can analyze node information, such as current energy levels, historical energy use, and connection, to learn and anticipate trends in energy consumption throughout the network. This data may be used to prioritize nodes with more remaining energy or to divide the communication workload equally across the network, thereby preventing the premature exhaustion of crucial nodes. Using GNNs for node selection, focusing on energy efficiency, extends the network's lifetime. This is achieved by preventing any one node from being excessively burdened, resulting in a more equitable distribution of energy consumption.

GNNs are very efficient in acquiring comprehensive and contextually aware representations of individual nodes within a network. The acquired representations include not only the immediate characteristics of the nodes (such as energy levels and connections) and the wider structural environment in which these nodes function. The GNN's learned embeddings include several aspects of a node, such as its centrality, its position in the network, and its closeness to other important nodes. These improved representations enable a more advanced and knowledgeable selection of dominating sets, where the chosen nodes are well-connected and strategically positioned to optimize energy consumption and sustain network coverage.

GNNs can efficiently handle and acquire knowledge from constantly changing data, making them especially powerful when network circumstances are volatile. In scenarios like mobile IoT networks or networks deployed in uncertain areas, GNNs can consistently update the dominating set as nodes relocate or as environmental conditions change. This real-time decision-making capability guarantees the network maintains its efficiency and resilience, even when faced with continuous changes. GNNs may be used with reinforcement learning methods to improve their capacity to adapt and optimize over time, leading to ongoing improvements in the performance of the dominant set algorithm.

By incorporating GNNs into dominant set algorithms, the security and resilience of IoT networks are improved. GNNs may be taught to detect and react to abnormal patterns in a network that may suggest security risks, such as nodes that have been hacked or strange traffic patterns. GNNs may safeguard the network from assaults and preserve its general operation by adapting the dominating set to bypass or isolate suspect nodes. The proactive strategy towards security, together with the robust adaptability of GNNs in managing network dynamics, leads to a more resilient IoT network that can survive various problems.

V. Conclusion

The exponential expansion of the IoT has introduced fresh prospects for automation, surveillance, and communication in several fields. Nevertheless, the energy efficiency of these networks continues to be a significant obstacle because of the constrained power resources of IoT devices. This research has examined the combination of GNNs with dominant set algorithms as a new method to improve the energy efficiency and operational longevity of IoT networks. We have examined conventional dominating set algorithms, emphasizing their use in minimizing communication overhead and preserving energy in IoT networks. Nevertheless, these approaches encounter substantial obstacles, such as their fixed characteristics, problems with expanding to larger scales, insufficient capacity to adjust in real-time, and inadequate consideration of energy fluctuations among nodes. To overcome these restrictions, incorporating GNNs presents a favorable option, as it brings about dynamic adaptability, scalability, energy-conscious node selection, and enhanced node representation, all of which are crucial aspects of IoT network management.

The GNN-based advances outlined in this research, including dynamic network adaptability, real-time decision-making, and security upgrades, signify significant progress compared to conventional methods. These improvements enable IoT networks to be more robust, streamlined, and capable of managing the intricacies of contemporary IoT settings. Nevertheless, there are still obstacles to overcome, such as the need for GNN models that can be easily expanded and operate well, the implementation of strong security and

privacy measures, and the meticulous handling of trade-offs between energy efficiency and other factors. To fully harness the capabilities of GNN-based dominant set algorithms in IoT networks, it is essential to prioritize ongoing research and development in this field. To construct more intelligent and adaptable IoT networks that match the expectations of future applications, we may solve difficulties and explore new avenues, such as integrating GNNs with other optimization methods. The combination of GNNs and dominant set algorithms provides a robust foundation for developing IoT networks that are both sustainable and energy-efficient, enabling them to operate well in dynamic and resource-limited contexts.

Development of Traffic Light and Road Sign Detection and Recognition Using Deep Learning

Towards Safe and Robust Sensor-Perception System of Autonomous Vehicle Development Research

Joseph M. De Guia[1], Madhavi Deveraj[2]

Energy Research Institute (ERI@N), Nanyang Technological University, Singapore[1]

***Abstract*—Traffic light and road sign violations significantly contribute to traffic accidents, particularly at intersections in high-density urban areas. To address these challenges, this research focuses on enhancing the accuracy, robustness, and reliability of Autonomous Vehicle (AV) perception systems using advanced deep learning techniques. The novelty of this study lies in the comprehensive development and evaluation of real-time traffic light and road sign detection systems, comparing state-of-the-art models including YOLOv3, YOLOv5, and YOLOv7. The models were rigorously tested in a controlled offline environment using the Nvidia Titan RTX, followed by extensive field testing on an AV test vehicle equipped with sensor suite and Nvidia RTX GPU. The testing was conducted across complex urban driving scenarios at the CETRAN proving test track, JTC Cleantech Park, and NTU Singapore campus. The traffic light detection and recognition (TLR) results demonstrate that YOLOv7 outperforms YOLOv5 and YOLOv3, achieving a mean Average Precision (mAP@0.5) of 93%, even under challenging conditions like poor lighting and occlusions. While the traffic road sign detection (TSD) mAP@0.5 of 96%. This superior performance highlights the potential of YOLOv7 in enhancing AV safety and reliability. The conclusions underscore the effectiveness of YOLOv7 for real-time detection in AV perception systems, offering crucial insights for future research. Potential implications include the development of more robust and accurate AV systems, capable of safely navigating complex urban environments.**

***Keywords*—Artificial intelligence; autonomous vehicle; traffic light recognition; road sign detection; YOLO; real-time object detection**

I. INTRODUCTION

Traffic light and road sign violations are a significant concern in Singapore, contributing to the rising number of traffic accidents, particularly at intersections. In 2023, over 31,815 red-light running violations were recorded, leading to numerous collisions and injuries at intersections [1]. Reports from the Singapore Police Force and Channel NewsAsia highlight the growing trend of drivers running red lights, resulting in dangerous collisions and fatalities [2]. The WHO Global Status Report on Road Safety 2023 also emphasizes that traffic signal violations are a major cause of road traffic injuries and fatalities globally [3]. These violations are especially problematic in high-density areas like the Central Business District (CBD) and busy residential and school campus zones, where the volume of both vehicular and pedestrian traffic is high. The failure to obey traffic signals in these areas can lead to hazardous situations, such as collisions with pedestrians at crossings or crashes involving multiple vehicles at junctions.

To address these challenges, recent research in AV development has focused on the integration of advanced perception systems that can accurately detect and classify traffic lights [4] and road signs in real-time [5]. These systems, leveraging deep learning algorithms and high-precision sensors, are designed to operate effectively even under challenging conditions such as poor lighting or heavy rain. By ensuring that AVs can reliably recognize and respond to traffic lights and signs, these technologies hold the potential to significantly reduce traffic violations, prevent accidents, and enhance overall road safety. Refer to Fig. 1 for the demonstration of the detection capability of the proposed TLR and TSD system.

(a) (b)

Fig. 1. Traffic light and road sign detection results. (a) The system accurately identifies a green light (95% confidence) and a red right arrow (94% confidence) at night. (b) The system detects a zebra crossing sign with 85% confidence in daylight. These results demonstrate the system's ability to detect and classify signals and signs across varying lighting conditions, essential for AV safety.

Previous studies have explored various approaches to traffic light and road sign detection, including traditional image processing techniques, machine learning models, and more recently, deep learning methods. While traditional methods offered limited success due to their inability to generalize across different environments and lighting conditions, deep learning has emerged as a powerful tool to improve the accuracy and robustness of real-time object detection and classification [4][5].

Notable advancements include the use of convolutional neural networks (CNNs) in models such as Fast R-CNN [6], SSD [7], and YOLO (You Only Look Once) [8], which have demonstrated superior performance in detecting a wide range of objects in images.

However, despite these advancements, challenges remain in achieving high recognition accuracy and stability under diverse and dynamic environmental conditions. Environmental variability, including changing lighting and weather conditions, as well as occlusions by other objects, can hinder accurate detection [9]. Real-time processing constraints, such as the need for high computational efficiency and low latency, further complicate the deployment of these systems [10]. Additionally, generalizing detection models across diverse geographical regions, handling data annotation and training challenges, and ensuring robustness against adversarial attacks and physical manipulation are ongoing issues [11].

Considering these challenges, this research focuses on advancing real-time detection and recognition of traffic lights and road signs using state-of-the-art deep learning techniques. By exploring the performance of different YOLO variants - YOLOv3 [12], YOLOv5 [13], and YOLOv7 [14], this study aims to improve the recognition accuracy and stability of AV perception systems. The research is particularly focused on high-risk areas such as junctions and pedestrian crossings, where the need for precise and reliable detection is paramount.

The novelty of this work lies in its comprehensive approach to evaluating and improving AV perception systems under real-world conditions. By conducting extensive testing in complex urban environments, this research contributes to filling critical gaps in current AV technologies. The study's objectives include the development and deployment of an optimal model for traffic light detection and recognition (TLR) and traffic road sign detection (TSD), evaluating system performance to enhance accuracy and reliability, and reporting the results of real-world testing. Our threefold contribution to the research:

- Performance Evaluation and Enhancement: The study conducted comprehensive evaluations of the perception system, leading to improvements in detection accuracy, robustness, and reliability, particularly under challenging environmental conditions.
- Comparative Analysis of YOLO Variants: The research compared the performance of multiple YOLO variants - YOLOv3, YOLOv5, YOLOv7 in real-time detection tasks, providing insights into their strengths and weaknesses in the context of AV perception systems.
- Real-World Testing and Validation: The research involved testing, verification, validation, and self-assessment of the deployed model in real-world test environments, including diverse urban scenarios in Singapore.
    - Ultimately, this research aims to contribute to the advancement of AV technologies, ensuring their safe and effective integration into public roadways.
    - The paper is divided into six sections. Section II describes the related works to TLR and TSD recognition research. In Section III we present in details of the TLR and TSD perception development in the AV research platform. Section IV is the Methodology describing our design, development, and evaluation of TLR and TSD systems in the AV research platform sensor and perception systems using custom-trained YOLO variant models. The results and discussion of the evaluation and assessment is presented in Section V. Finally, in conclusion, lesson learnt, and future research direction to further enhance the features and capabilities of the perception system is presented in Section VI.

II. Related Works

The integration of sensors and perception algorithms is crucial in AV systems for accurately identifying and categorizing objects like traffic lights, traffic signs, and road markings on public roads. These elements are essential for road safety and traffic management. However, real-time detection of these elements is challenging due to varying environmental conditions, such as changes in lighting, occlusions, image quality issues, motion blur, and glare. These challenges highlight the need for selecting appropriate sensor modalities (e.g., cameras, LiDAR, RADAR) and optimizing perception algorithms to enhance the reliability of AV systems. Several studies have focused on overcoming these difficulties, emphasizing the importance of real-time automation in AVs, particularly at traffic junctions, pedestrian crossings, and roundabouts, where accurate detection and recognition are crucial for preventing collisions and ensuring pedestrian safety.

Early research in TLR relied on rule-based and classical machine learning detectors, which were eventually outperformed by deep learning-based methods. These learning-based detectors significantly improved precision and recall, demonstrating the potential of deep learning for enhancing detection accuracy [15]. The use of stereo cameras has also been proposed to enhance tracking capabilities, particularly for object localization and motion estimation [16]. Addressing data imbalance issues in training datasets is crucial, as seen with the LARA and LISA traffic light databases, where uneven data distribution across traffic light states requires data-centric approaches to improve model performance [17].

Deep learning methods, especially Convolutional Neural Networks (CNNs) and YOLO detectors, have shown promise in TLR. For example, YOLOv3 achieved an AUC of 90.49% and a precision of 50.32% on the LISA dataset [18]. Suggestions for improvement include testing models under nighttime conditions and using ensemble methods like SSD and R-FCN [19]. Advanced methods have been explored, such as using CNNs for traffic light color recognition and integrating Faster R-CNN with k-means clustering, achieving an average precision (AP) of 83%, which increased to 90% for objects larger than 8 pixels [20]. However, challenges remain, including high false positive rates and ensuring consistent classification [21]. The development of large-scale, high-variance datasets like the DriveU Traffic Light (DTLD) dataset, recorded across 11 cities, has been a significant contribution, providing valuable resources for training and evaluating CNN-based models [22].

Traffic road signs provide crucial information that is essential for the decision-making process and safety of autonomous vehicles (AVs). These signs, including speed limits, danger warnings, and directional guidance, are vital for ensuring safe navigation. For instance, when an AV detects a "School ahead" or "Hospital ahead" sign, it can adjust its speed and exercise increased caution. However, detecting traffic signs is challenging due to factors like lighting variations, changes in scale, weather conditions, occlusions, and rotations. Various approaches, including traditional object detectors like Support Vector Machines (SVMs) and pattern matching techniques, have been explored to address these challenges [23]. Despite their application, these methods often struggle with detecting small-scale traffic signs or performing well under difficult conditions [24].

Recent advancements in traffic sign detection have leveraged CNNs and YOLO detectors. While region-based networks and one-stage detectors face limitations in detecting small-scale signs, Region-Proposal Networks (RPNs) have shown superior performance [25]. The integration of Inception V2 for feature extraction has led to competitive results in benchmarks like the German Traffic Sign Detection Benchmark (GTSDB) [26]. A notable method involved generating traffic sign proposals using a color probability model and the Maximally Stable Extremal Region (MSER) detector, followed by an SVM classifier to filter out false positives and categorize signs [27]. Another approach introduced "Capsule Networks," which capture complex spatial relationships, enhancing detection accuracy [28]. Additionally, a model using a single CNN to estimate the location and boundary of traffic signs has improved performance in detecting small and occluded signs [29].

III. Traffic Light and Traffic Road Sign Detection Development for AV Research Platform

The TLR and TSD systems are integral components of the perception system in the AV test vehicle. TLR processes camera or sensor data to detect and interpret traffic light signals, coordinating with the vehicle's path planning and decision-making systems to ensure appropriate actions like stopping or proceeding. TSD captures and processes images to identify and interpret road signs, influencing the vehicle's driving behavior. These systems were tested and validated in the AV research platform's test vehicle at the CETRAN [30] proving test track and along public roads in Cleantech Park and NTU Singapore campus.

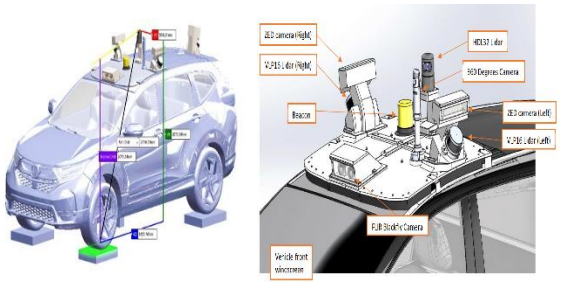
A. AV Research Platform, Test Vehicle & Test Region

The AV research platform uses a Honda CR-V Hybrid Electric Vehicle (HEV) as a medium-size SUV test vehicle to develop and test the AV prototype's sensor and perception systems. The platform integrates high-performance, reliable hardware components with reference autonomous driving software (ADS), ensuring compatibility and robustness. Refer to Fig. 2 for the AV prototype research platform test vehicle.

1) Hardware: The selection process prioritizes commercial off-the-shelf (COTS) items from OEM manufacturers, certified for AV development. It emphasizes CPU and GPU capabilities for efficient parallel processing of sensor data and decision-making tasks. The custom-built industrial PC with an Intel Core i9, 64GB DDR4 RAM with NVIDIA GPU RTX 3080 and AGX Orin is recommended for handling deep learning-based perception algorithms and real-time image processing. The GPU's energy-efficient design and small form factor are well-suited for complex algorithms, while its compatibility with ROS ensures seamless integration into the vehicle.

2) Sensors suite: The sensor perception system integrates various key sensors, including LiDAR, cameras, GNSS+RTK, IMU, and ultrasonic sensors, to enable comprehensive environmental awareness. The LiDAR provides 360º 3D images with high accuracy and long-range sensing, while the GNSS system combined with the local RTK network SiReNT, ensures precise positioning. The IMU offers reliable measurements of angle, angular velocity, and acceleration. Visual perception is achieved through a FLIR Blackfly camera mounted on the front view of the vehicle, providing short- and long-range 2D images, and a Mynteye/ZED stereo camera for full-field 3D measurements. Ultrasonic sensors enhance distance detection, contributing to the AV's robust perception capabilities, particularly in environments with complex traffic lights and road signs. Refer to Table I for the Vision Sensors Filed of View (FoV) device measurements.

3) Software stack: The software stack, built on ROS and running on Ubuntu 18.04, includes sensing, perception, planning, and control software packages for ADS, enabling SAE level 3 autonomy. It processes real-time data from front-facing cameras, LiDAR, and GNSS+IMU+RTK for environmental awareness, employing deep learning algorithms like YOLOv3 for object and traffic light signal recognition. Object tracking uses 2D and 3D data fusion from vision and LiDAR detectors to prevent collisions. The perception system predictions guide the ADS in making decisions regarding objects, obstacles, and traffic signals.

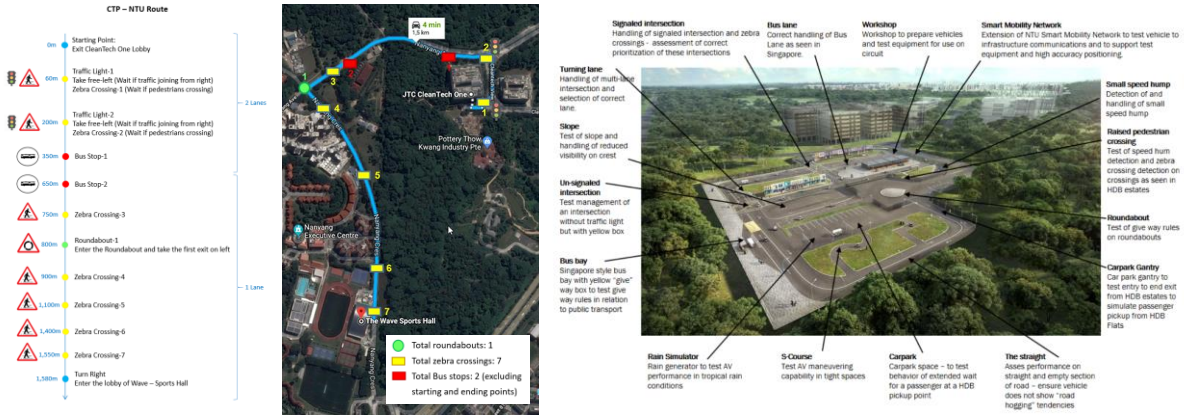


(a) (b)

Fig. 2. (a) The AV research test vehicle equipped with (b) roof-mounted sensor suite for detecting obstacles, pedestrians, traffic lights, road signs, and vulnerable road users. This sensor data supports decision-making, navigation, and control in complex environments.

TABLE I. Field of View (FoV) of Vision Sensors

Sensor	FoV Vertical	FoV Horizontal
LIDAR - HDL 32	+10 to -30 Degrees	360 Degrees
LIDAR - VLP16	+15 to -15 Degrees	360 Degrees
CAMERA - FLIR Blackfly	45 Degrees	60 Degrees
CAMERA - ZED 2	120 Degrees	120 Degrees



(a) (b)

Fig. 3. The image shows designated AV test regions at NTU's campus and CETRAN proving ground. (a) The map highlights key testing locations such as zebra crossings, bus stops, and intersections along the NTU route. (b) The CETRAN facility showcases urban driving scenarios like S-curves, carpark gantries, and smart mobility networks, critical for evaluating AV performance.

4) Testing region. The CETRAN test track facility, managed by NTU at the NTU Smart Campus Cleantech Park in Jurong Innovation District replicates urban road conditions in Singapore. This facility includes the traffic lights and road signs, bus stops, pedestrian crossings, and tropical weather scenarios like heavy rain. This facility allows for controlled, realistic testing of AVs, providing the flexibility to experiment with various AV features without on-road traffic risks. It has a proving ground for assessing AV performance and safety, validating designs for transport, and guiding AV development and certification. The site supports the NTU AV project team's progress toward Level 3 autonomy, with additional trials conducted on selected NTU campus roads approved by the transportation regulator. These trials are part of a milestone testing regime required before public road trials, focusing on mixed bi-directional traffic routes at NTU Clean Tech Park (CTP) and NTU The Wave Sports Centre. The trials routes shown in Fig. 3 covered areas (a) NTU - CTP - NTU The Wave Sports Centre, (b) CETRAN.

B. Traffic Lights Detection and Recognition

The TLR system is vital for the safe navigation of AVs especially in urban environments. It primarily uses camera detection, with sensor data fusion to enhance reliability and reduce false positives. The system applies pre-processing steps like color segmentation and edge detection to images before isolating regions of interest (ROI) to focus on likely by LiDAR and radar for obstacle traffic light locations, reducing computational load inputs, supplemented computational load inputs, supplemented. Initially, YOLOv3 was used for real-time detection and classification of traffic lights, balancing speed, and accuracy. YOLOv3 predicts bounding boxes and classifies traffic light states with confidence scores to minimize false positives, with temporal smoothing algorithms ensuring consistent recognition across frames. The detection process integrates with the path planning module to send a stop or go commands based on traffic light status.

To further enhance detection accuracy and performance, newer versions of YOLOv5 and YOLOv7 were introduced. YOLOv5 improved feature extraction and accuracy for small objects, while YOLOv7 offered enhanced detection capabilities with advanced backbone architectures and layer aggregation, improving performance in complex environments. Both versions provided improved computational efficiency, crucial for real-time operations, and better generalization across diverse conditions, ensuring high reliability. Their modular design also allows for future enhancements, making the system adaptable to evolving AV technology needs.

C. Traffic Road Sign Detection

The TSD system is vital for autonomous driving, enabling vehicles to accurately interpret and respond to road signs, ensuring safe and compliant navigation. The process starts with integrating camera sensors that capture real-time video feeds for detecting road signs. These images undergo pre-processing, such as text and color normalization and edge enhancement, to emphasize features relevant to road signs. The system isolates regions of interest (ROI) to optimize the detection process by focusing computational resources on areas likely to contain road signs.

We run an experiment for YOLOv5 and was chosen for its efficiency in real time object detection, offering a good balance between speed and accuracy. YOLOv5 predicts bounding boxes and classifies road signs into categories like stop signs and speed limits. The recognition module interprets these signs and passes the information to the decision-making module, which adjusts the vehicle's actions accordingly, such as modifying speed based on detected speed limit signs. To further improve detection accuracy and reliability, YOLOv7 was considered, offering enhanced performance and better generalization across different environmental conditions, making the detection system more robust in diverse scenarios. The detection and decision-making process involves sensor integration, pre-processing, detection architecture (starting with YOLOv5 and progressing to YOLOv7), and recognition, with each stage contributing to the system's overall efficiency and performance in AV) applications.

IV. METHODOLOGY

This section outlines the methodology employed for the development and evaluation of TLR and TSD and recognition systems in the AV research platform sensor and perception systems using custom-trained YOLO variant models. The methodology is divided into five key components: Dataset Selection, Preparation, and Preprocessing; Model Implementation; Training and Optimization; Performance Evaluation; and Comparative Analysis; and Experiment.

A. Dataset Selection, Preparation, and Preprocessing

The dataset selection, preparation, and preprocessing involved utilizing the nuances images with 2D annotations [32] and the Singapore Traffic Road Sign Dataset [33]. These datasets provide a comprehensive set of images capturing various Singapore public roads, featuring traffic lights and road signs under different environmental conditions, including daytime, night time, and light rain [34]. This diversity in the dataset is crucial for ensuring the model can generalize across various scenarios, enhancing the robustness of the AV perception system.

The custom and curated datasets used include:

- Traffic Light Dataset: Consists of approximately 700,000 image frames annotated with 17 object labels, including traffic lights with signal color status.
- Traffic Road Sign Dataset: Contains 100,000 image frames with 2,549 labels in 1,778 images across 22 class labels.

1) Data preparation is essential for ensuring effective learning and reliable real-world performance. Annotation Format was converted to YOLO-compatible formats, including class, and bounding box coordinates. Data Splitting involved dividing the datasets into training (75%), validation (15%), and testing (10%) sets, which allowed for the assessment of the model's generalization capabilities on unseen data. Class Balance was analyzed, and techniques like oversampling and class weighting were employed to address imbalances. Strategies included combining similar road sign classes and augmenting underrepresented nighttime images through targeted data augmentation and synthetic data generation. This approach aimed to balance the dataset and enhance the model's generalization ability, resulting in 1,321 training images, 279 validation images, and 178 testing images, which helped reduce the risk of overfitting.

2) Preprocessing steps involved normalization, resizing, and augmentation to further improve the model's generalization capabilities. Normalization scaled pixel values to a common range [0, 1] by dividing them by 255, ensuring consistent input feature scaling, which is crucial for the convergence of gradient-based optimization algorithms. Image Augmentation included transformations such as rotation, scaling, flipping, and color adjustments (brightness, contrast, hue, and saturation) to increase dataset diversity and simulate real-world conditions, including varying lighting and weather scenarios, to improve performance under challenging conditions like low light. A significant challenge during augmentation was the introduction of unrealistic distortions, leading to overfitting, which was mitigated by carefully tuning augmentation parameters and conducting a pilot run to evaluate the effects of each technique on model performance.

B. Model Implementation

The model implementation phase involved transforming the theoretical framework into a functional system by selecting appropriate model architectures, configuring them to meet task-specific requirements, and setting up the training environment.

1) Model architecture customization: The YOLO models—YOLOv3, YOLOv5, and YOLOv7—were selected for their optimal balance between speed and accuracy, making them well-suited for real-time applications. To enhance detection accuracy, predefined anchor boxes were recalculated using k-means clustering to better match the aspect ratios of objects like traffic lights and road signs, resolving issues with mismatched default settings. Adjustments to the number of convolutional layers and filters were made to balance accuracy and inference speed, with overfitting being mitigated by introducing dropout layers and L2 regularization, particularly in YOLOv7. Additionally, modifications to the head and neck structure, including the feature pyramid network (FPN) layers, improved detection performance for objects of varying sizes, such as distant traffic lights. Hyperparameters such as learning rate, batch size, and momentum were fine-tuned, with initial training instability due to a high learning rate being resolved through the use of a cosine annealing learning rate schedule.

2) Pre-training, environmental setup, and model initialization: The models were initialized with pre-trained weights from YOLO models trained on the COCO dataset, which were then fine-tuned on the specific traffic light and road sign dataset. The training environment was set up with GPUs, such as the Nvidia Titan RTX, and included essential software dependencies like PyTorch and CUDA to ensure efficient training. Challenges with GPU memory limitations during large batch size training were addressed using mixed-precision training, which reduced memory usage while maintaining computational efficiency. Proper initialization and checkpointing were also crucial for ensuring stable training throughout the process.

C. Training and Optimization

The goal of the training and optimization process was to maximize model performance, ensuring high accuracy and robustness in detecting and classifying traffic lights and road signs under various conditions. The process involved several key steps:

1) Training process: The training process began with the initialization of pre-trained weights, such as yolov5l.pt, which provided a foundation for fine-tuning the model according to the specific dataset requirements. Data augmentation techniques, including random cropping, scaling, and flipping, were employed to improve the model's generalization across various scenarios. Hyperparameters, such as learning rate,

momentum, batch size, and the number of epochs, were meticulously tuned to strike a balance between training speed and model accuracy. The Stochastic Gradient Descent (SGD) optimizer with momentum was used to update model weights, aiding in faster convergence. The loss function was carefully designed with components for object classification, bounding box regression, and objectness score, with balanced weighting to ensure the model-maintained focus on both localization and classification accuracy. A key challenge in this process was preventing the model from disproportionately prioritizing one aspect over the other, which was effectively managed by adjusting the loss function weights through experimentation.

2) Optimization techniques: The optimization techniques employed focused on enhancing convergence speed, stability, and generalization. A cosine annealing scheduler was used for dynamic learning rate adjustments, incorporating a warm-up phase at the start to stabilize early training and prevent gradient explosions. Regularization methods, such as weight decay and dropout, were implemented to mitigate overfitting, especially during later epochs on smaller datasets. Early stopping and the use of strong dropout layers were particularly effective in preserving model performance. Data augmentation through Mosaic was crucial in increasing dataset diversity, addressing the challenge of limited data for rare road signs. Early stopping and checkpointing strategies helped avoid overfitting and preserved optimal model weights when further training risked degrading validation performance. Mixed precision training on Nvidia GPUs efficiently managed memory resources, reduced training time, and maintained high model performance. Additionally, a grid-based hyperparameter search combined with cross-validation was used to identify the best combination of learning rates, batch sizes, and momentum values, resulting in improved model convergence.

D. Performance Evaluation

The performance evaluation phase focused on assessing the effectiveness and reliability of the trained models using a comprehensive set of evaluation metrics and scenario-based testing.

1) Evaluation metrics such as mAP, IoU, and F1 score were used to evaluate the models. mAP provided an overall measure of detection performance across different object classes by averaging the precision-recall curve. IoU quantified the overlap between predicted bounding boxes and ground truth, giving insight into localization accuracy. The F1 score, which balances precision and recall, was critical for assessing the model's ability to accurately classify and detect objects without missing or falsely detecting them.

2) Scenario-based testing trained models were deployed in various real-world conditions to evaluate their robustness and generalization capabilities. Testing was conducted in diverse environments, including urban settings with varying lighting, weather conditions, and traffic dynamics. The models were tested on the CETRAN proving test track and in multiple regions of the NTU campus, each presenting challenges like mixed bi-directional traffic, complex road layouts, and variable lighting conditions. This approach ensured the models performed reliably across a range of scenarios, reflecting the diverse conditions an AV might encounter in real-world operations.

E. Comparative Analysis

1) Quantitative analysis: The quantitative analysis compared the performance of YOLOv3, YOLOv5, and YOLOv7 using metrics such as mAP, IoU, F1 score, and inference speed (FPS). YOLOv5 and YOLOv7 demonstrated superior mAP scores compared to YOLOv3, particularly excelling in detecting smaller objects and distinguishing between different traffic signal colors and road signs, which are crucial for AV perception systems. YOLOv7 outperformed both YOLOv3 and YOLOv5 in terms of inference speed, making it ideal for real-time applications that require quick decision-making. Additionally, YOLOv5 offered a good balance between speed and accuracy, making it suitable for scenarios where both factors are important. YOLOv7 also exhibited a more optimized trade-off between accuracy and model size, enabling it to run efficiently on AV hardware platforms like the Nvidia Titan RTX and Nuvo-6108GC.

2) Qualitative analysis: The qualitative analysis focused on the models' real-world performance and their ability to generalize to diverse and challenging environments. YOLOv5 and YOLOv7 exhibited better robustness across various environmental conditions, including different lighting and weather scenarios, compared to YOLOv3. YOLOv7 produced fewer false positives and negatives, particularly in cluttered scenes with multiple objects, while YOLOv5 performed well but showed slightly more false negatives in low-light conditions. In scenario-specific performance, YOLOv7 was preferred for scenarios requiring high accuracy, such as detecting smaller, less visible road signs, whereas YOLOv5 provided balanced performance across different test regions like the NTU campus and CETRAN proving test track.

F. Experiment

1) Environmental setup: The environment setup involved both hardware and software configurations to optimize the training and deployment of the models. The models were trained offline using an Nvidia Titan RTX GPU, selected for its ability to manage large datasets and complex models like YOLOv3, YOLOv5, and YOLOv7. For real-time inference and performance evaluation during field testing, the models were deployed on the AV test vehicle's perception system, which is equipped with an Nvidia RTX GPU within the Nuvo-6108GC. The training was conducted using the PyTorch framework, supported by key libraries such as OpenCV, TensorBoard, and YOLO-specific tools for data augmentation and anchor generation. A Linux-based OS, optimized for CUDA operations, was used for both offline and onboard systems. Data management involved storing datasets on high-speed SSDs to reduce loading times during training, and for field testing,

model weights and necessary datasets were preloaded onto the AV's onboard system.

2) Model implementation and training: The model implementation and training process began with the utilization of pre-trained YOLOv3, YOLOv5, and YOLOv7 models, originally trained on the COCO dataset. These models served as a foundation and were fine-tuned for specific tasks related to TLR and TSD. Custom training involved loading datasets consisting of 700,000 image frames for traffic lights and 100,000 for road signs into the training environment. The fine-tuning process focused on optimizing hyperparameters and applying data augmentation techniques like mosaic and mixup to enhance model robustness. Continuous validation monitoring was crucial in detecting overfitting and adjusting training strategies as needed. Optimization techniques included the use of a cosine annealing scheduler for dynamic learning rate adjustments, and regularization techniques like weight decay and dropout to prevent overfitting. Early stopping was employed to avoid unnecessary computation, and mixed precision training was utilized to efficiently manage memory resources, allowing for larger batch sizes without compromising training speed or accuracy.

3) Deployment and field testing: The deployment and field-testing phase involved transferring the optimized model weights to the AV perception system, enabling the AV test vehicle to process and respond to visual inputs in real-time during field tests. Field testing was conducted in key regions within NTU's campus, including the CETRAN proving test track and NTU-Clean Tech Park, where the environments presented complex traffic scenarios to evaluate the models' traffic light and road sign recognition capabilities. During these tests, real-time logging and analysis of model predictions were carried out, focusing on critical metrics such as detection accuracy, false positive/negative rates, and inference speed, to assess the performance of the deployed models.

4) Analysis and iteration: The analysis and iteration phase involved post-field-testing analysis, where performance data from each test was reviewed and verified to identify weaknesses and areas for improvement, especially in cases where the model struggled to correctly identify traffic lights or road signs under varying environmental conditions. Based on these analyses, the models were refined further through fine-tuning, retraining with augmented datasets, or architectural adjustments to better align with AV system requirements. Once optimized and validated, the models were deployed for long-term testing and evaluation in the AV test vehicle, with continuous monitoring and updates as new data and scenarios emerged.

V. Results and Discussion

A. Detection Model for Traffic Lights

The training process for the TLR model demonstrated a progressive improvement across multiple metrics as training epochs progressed. The loss curves, including box loss, object loss, and classification loss, reveal the training dynamics and model convergence behavior. The box loss started at a relatively, higher value and gradually decreased over the training epochs, indicating that the model was improving in accurately predicting the bounding boxes for detected objects. The object loss also followed a declining trend, suggesting that the model was becoming better at identifying whether an object exists in each bounding box. Similarly, the classification loss reduced as training continued, which shows that the model's ability to correctly classify the detected objects improved over time.

1) Epochs of significant improvements at *epoch 30-50*: Notable improvements were observed in this range, where the precision and recall metrics showed significant jumps. The loss curves also depicted steeper declines during these epochs, indicating faster convergence. *Epoch 90-110:* Another period of significant improvement occurred, particularly in the mAP metrics. The model's ability to detect objects with higher accuracy at varying IoU thresholds improved markedly.

2) Challenges encountered toward the later stages of training, particularly after epoch 120, signs of overfitting began to emerge. This was indicated by a plateau in validation metrics such as mAP@0.5 and mAP@0.5:0.95, while the training metrics continued to improve. Overfitting was also suggested by the increase in validation losses despite the continual decrease in training losses. In the early epochs (0-20), the model showed some signs of underfitting, where the precision and recall metrics were relatively low, and the loss values were high. This phase was marked by a slower reduction in losses and a gradual improvement in detection metrics.

The initial training results for the TLR model reveal a detailed analysis of the model's performance in recognizing various traffic light states, including "RedLeft," "Red," "GreenLeft," and "Yellow." The model showed moderate accuracy, with a precision of approximately 86% and a recall of about 80%. The mAP at an IoU threshold of 0.5 (mAP@0.5) reached around 86%, while the more stringent mAP@0.5:0.95 was approximately 65%. These results indicate that while the model performs adequately in many cases, there is room for improvement, particularly in distinguishing between similar traffic light states, which is crucial for making safe and accurate driving decisions in real-world AV applications. Refer to Table II for the summary of the training model results. The confusion matrix shows that the model was relatively accurate in distinguishing between different traffic light states, but there were instances of misclassification, particularly between visually similar states. For example, the model sometimes confused "RedLeft" with "Red" or "GreenRight" with "GreenLeft." The F1-Confidence curve further illustrates the model's precision and recall balance across different confidence thresholds, showing an optimal F1 score of 0.83 a confidence threshold of 0.65, which suggests the model can be further optimized to improve overall performance. Another observation in the initial model tested offline using recorded image bag files, where several issues were identified. This likely due to instance distribution imbalance. Specifically, there was an imbalance in the number of samples for objects and traffic lights, as well as between daytime and night time samples. Although the model was able to detect some of the traffic light status, it failed to identify the green right signal due to its proximity to another

green traffic light signal. Another observation on the system fails to identify a traffic light status that is present in the scene. This can be problematic because it means that the detector missed an object it was supposed to detect. This can add to the false negative detection. Refer to Fig. 4 and Fig. 5 for the observation.

TABLE II. SUMMARY OF THE INITITAL TRAINING RESULTS TRAFFIC LIGHT DETECTION MODEL – YOLOV3

Metric	Results
Dataset	TLR Dataset
Precision	86%
Recall	80%
F1 score	0.83 at 0.65
mAP @0.5	86%
mAP @0.95	65%
Inference Speed (ms/image)	12 ms/frame
Model Size (Parameters)	44M

(a) (b)

Fig. 4. The image compares traffic light detection with ground truth validation. (a) The original scene without detected objects. (b) The system successfully detects and labels two red traffic lights with confidence scores of 0.63 and 0.53. Ground truth annotations are used to validate the system's accuracy in real-world conditions.

(a) (b)

Fig. 5. The image demonstrates the system's detection and recognition capabilities under challenging conditions. (a) Left: the system detects multiple red traffic lights and a 'mandatory left' sign during heavy rain. (b) Right: in low visibility, the system accurately identifies a construction site and split signs but misses a 'give way' sign and a red traffic light (false negatives highlighted in red).

The model's inference speed is an essential factor, particularly for real-time applications like autonomous driving. The model demonstrated an inference speed of approximately 12 milliseconds per image, which is fast enough for real-time detection tasks. Additionally, the model parameter size is around 44 million (44M), striking a balance between complexity and computational efficiency.

Evaluating the performance of a model for deployment in an AV it is important to consider the trade-offs between accuracy, inference speed, and model size. In this case, the model's inference speed of 12 milliseconds per image is sufficient for real-time applications, but the trade-off is a relatively moderate accuracy, particularly under more stringent evaluation conditions (mAP@0.5:0.95). For deployment in an AV test vehicle, a balance must be struck between accuracy and speed. If higher accuracy is required, more complex models or ensemble methods could be used, though this would likely reduce inference speed. Conversely, if speed is prioritized, a more streamlined model might be necessary, though this could compromise accuracy.

The TLR model exhibits moderate accuracy and a fast inference speed, making it suitable for real-time applications in AV. However, the performance of the model could be improved by addressing class imbalances, enhancing data augmentation techniques to better handle variations in lighting and angles, and fine-tuning the model's hyperparameters. Additionally, considering more advanced architectures or employing ensemble learning methods could help improve accuracy and robustness, particularly in distinguishing between visually similar traffic light states. For deployment in an AV test vehicle, this model could serve as a baseline, but further refinements may be necessary depending on the specific requirements for accuracy and speed in the target application. Balancing the trade-offs between accuracy and inference speed will be critical to ensuring that the model meets the operational demands of real-time autonomous driving. Refer to Table III for the summary of the TLR performance results.

B. Detection Model for Traffic Road Signs

The initial training results for the three YOLOv5 models—YOLOv5s, YOLOv5m, and YOLOv5l—demonstrate different strengths in detecting and recognizing traffic signs, varying in accuracy, speed, and computational demands. As training progresses, there is a consistent decrease in losses related to bounding box regression, object classification, and class prediction, indicating that the models are effectively learning. The reduction in metrics like train/box loss, which starts at 0.11157 and decreases to around 0.0235, suggests improved accuracy in predicting object locations and class labels.

Performance metrics such as precision, recall, and mean Average Precision (mAP) also improve throughout training. Precision stabilizes and exceeds 0.93, while recall shows a steady increase, indicating the model's ability to capture more relevant objects. The mAP metrics, including mAP_0.5, reach approximately 0.96 by the end of training, reflecting the model's effectiveness across various IoU thresholds. Refer to the summary Table IV training and Table V performance.

TABLE III. TRAFFIC LIGHT DETECTION PERFORMANCE RESULTS

Model	Precision (%)	Recall (%)	F1 Score (%)	mAP@0.5	mAP@0.95	Inference Speed (fps)	Model Size
YOLOv3	86	80	83	0.86	0.65	12	240
YOLOv5	90	87	88.5	0.90	0.68	28	140
YOLOv7	93	90	91	0.93	0.70	22	120

TABLE IV. SUMMARY OF TRAINING RESULTS TRAFFIC ROAD SIGN – YOLOV5

Model	Batch Size	Precision	Recall	mAP @0.5	mAP @0.95	Inference Speed (ms/image)	Model Size (Parameters)
YOLOv5s	16	90%	85%	90%	58%	7 ms	7M
YOLOv5m	32	92%	88%	93%	61%	10 ms	21M
YOLOv5l	64	93%	87%	94%	60%	14 ms	47M

TABLE V. TRAFFIC ROAD SIGN DETECTION PERFORMANCE RESULTS

Model	Precision (%)	Recall (%)	F1 Score (%)	mAP@0.5	mAP@0.95	Inference Speed (fps)	Model Size
YOLOv3	92	90	91	0.92	0.70	25	240
YOLOv5	94	92	93	0.94	0.72	28	140
YOLOv7	96	94	95	0.96	0.74	22	120

Validation losses, which decrease consistently alongside training losses, indicate strong generalization to unseen data and a low risk of overfitting. The learning rates, initially set high and gradually reduced, facilitate faster convergence early on and fine-tuning later in the training process.

Despite the strong performance, further improvements could be achieved through advanced augmentation techniques, fine-tuning hyperparameters, or applying model pruning and quantization to reduce model size and inference time. These adjustments would enhance the model's suitability for deployment in resource-constrained environments like an AV test vehicle, where the trade-off between accuracy and inference speed is crucial.

C. Field Testing in Real-World Scenarios

Field testing of TLR and road TSD models was conducted on the AV test vehicle using the Nuvo-6108GC PC environment equipped with an NVIDIA RTX GPU. The goal was to evaluate the model's performance in real-world scenarios reflective of Singapore's urban conditions. Testing occurred across test regions: the CETRAN proving test track, JTC Cleantech Park, and NTU's campus, each presenting distinct challenges. The CETRAN test track, designed for AV testing, replicates various Singaporean urban road elements, offering a controlled environment for rigorous testing without the risks of live traffic. This site allowed for comprehensive assessment of the AV's manoeuvrability through city driving scenarios [31].

1) Test regions and specific challenges. CETRAN facility provided a geofenced, controlled environment showcasing urban scenarios like S-curves and carpark gantries, crucial for evaluating AV performance. Traffic lights and road signs were readily available for evaluation without traffic interference. NTU-Clean Tech Park (CTP) - The Wave Sports and Recreation Centre featured mixed bi-directional traffic, creating a complex environment to test the model's ability to accurately detect and classify traffic lights and road signs amidst dynamic vehicle movements and varying traffic density. The Nuvo-6108GC, with its NVIDIA RTX GPU, supported the real-time processing needs of advanced deep learning models, achieving an average inference speed of 12ms per frame, suitable for urban traffic scenarios. The model demonstrated robust detection, maintaining high precision and recall metrics across various conditions, including challenging lighting and complex traffic scenarios.

2) Challenges observed during field testing. The model performed well overall, but low-light scenarios occasionally reduced detection accuracy for certain road signs. The model navigated intersections and recognized pedestrian crossings effectively, though closely spaced traffic lights sometimes caused minor detection delays. The model maintained detection capabilities in light rain, but heavy rain introduced reflections that occasionally confused the perception system.

D. Lessons Learned

The performance evaluation of the model development and deployment in the AV research platform focused on enhancing safety and robustness, particularly in image recognition, motion speed profiles, and obstacle detection at critical areas like junctions and pedestrian crossings. Several test scenarios, including encounters with pedestrians and other vehicles, provided insights that guided improvements in design and safety approaches.

1) Model development and training revealed that the choice of model architecture significantly impacted the balance between detection accuracy and inference speed. YOLOv7 excelled in complex urban environments but required higher computational resources. Data augmentation techniques like mosaic and mixup were essential in improving the model's robustness across diverse conditions, though issues with data

imbalance, particularly in night time scenarios, highlighted the need for a balanced training dataset.

2) Deployment and real-time inference showed that fine-tuning was necessary to optimize real-time performance. While YOLOv7 offered the highest accuracy, its computational demands resulted in slightly slower inference times, particularly in high-traffic environments where quick decision-making was crucial. This trade-off emphasized the need for further optimization to handle scenarios with high visual complexity.

3) Field testing observations across the CETRAN proving test track, NTU-Clean Tech Park, and NTU campus highlighted YOLOv7's superior detection accuracy, especially in identifying over 95% of traffic lights and road signs. However, the model's inference speed sometimes lagged in complex traffic scenarios, making YOLOv5 a more balanced choice in environments requiring rapid processing. False positives and negatives were noted, particularly in varying lighting conditions, underscoring the need for improved robustness against environmental noise and challenging conditions like heavy rain and glare. Our team also tested to other testing site to verify the performance of the object detection using other use case in the golf range [35] and integrated wildlife recreation area [36] how the model performs in a different field testing and observation.

4) Post-field-testing analysis involved a detailed review of model failures, particularly under low-light and adverse weather conditions, which led to higher false-negative rates. The analysis stressed the importance of enhancing data augmentation and possibly integrating additional sensors like LiDAR. While YOLOv7 achieved impressive metrics under ideal conditions (precision of 95%, recall of 93%, F1 score of 94%, and mAP@50 of 0.95), these dropped under challenging conditions, indicating a need for further refinement. Inference speed was 22 fps for YOLOv7, compared to 28 fps for YOLOv5, highlighting the trade-offs between speed and accuracy.

VI. Conclusion

This research made significant advancements in AV perception systems by evaluating performance, comparing YOLO variants, conducting real-world testing, and developing a comprehensive testing framework. YOLOv7 emerged as the best-performing model, achieving a mAP@0.5 of 93% for Traffic Light Recognition (TLR) and 96% for Traffic Sign Detection (TSD), even in challenging environments such as low-light and occlusion scenarios. Its superior precision and recall, with F1 scores of 91% for TLR and 95% for TSD, demonstrated its suitability for real-time AV applications. YOLOv5, while slightly less accurate, provided a strong balance between speed and accuracy, making it adaptable for various conditions.

Real-world testing in urban environments, including the CETRAN proving test track and NTU campus, validated YOLOv7's reliable performance and its readiness for deployment in AV systems. A significant contribution of the study was the development of a scenario-based testing framework that included continuous performance monitoring and model refinement. This framework helped identify and correct model weaknesses, enhancing performance and robustness.

The research offers critical insights for AV developers and researchers, particularly on balancing speed, accuracy, and robustness in real-world applications. Future work could focus on exploring hybrid models that integrate YOLO with Transformer-based architectures, testing in diverse environments such as rural areas and highways, incorporating multi-modal data (LiDAR, RADAR), and exploring adversarial robustness testing.

***Abstract*—X-ray dosimetry practices are guided by international standards and regulatory agencies to ensure the safety of patients, radiation workers, and the general public. This paper introduces the Smart X-ray Geiger Data Logger, a comprehensive system designed to enhance radiation safety through integrated detection, control, and dose evaluation. This study is based on the M4011 Geiger-Müller tube, exploiting ionization effects to measure radiation doses accurately. The system features an advanced algorithm for real-time exposure risk assessment, ensuring adherence to safety limits during medical procedures. Equipped with Wi-Fi connectivity, the device facilitates seamless data transmission and integration with centralized databases for comprehensive exposure monitoring and historical data analysis. The MQTT protocol is utilized for secure and efficient data transmission, ensuring the protection of sensitive information. A user-friendly interface provides instant feedback on radiation levels, cumulative doses, and procedural safety, supported by visual indicators and auditory alarms for immediate alerts. Experimental validation demonstrates the system's reliability in various settings, confirming its utility in optimizing radiation protection strategies and fostering safer environments in the healthcare field.**

I. Introduction

X-rays are a form of electromagnetic radiation with wavelengths shorter than visible light. They were discovered by Wilhelm Conrad Roentgen in 1895. X-rays have the ability to penetrate most substances, and they are widely used in medical imaging, industry, and scientific research. In medical applications, X-rays are commonly used for imaging bones and internal structures, helping diagnose and monitor various medical conditions [1-3].

X-ray dosimetry involves the measurement and assessment of the absorbed dose of X-ray radiation received by human tissue. The primary goal is to quantify the amount of energy deposited in a specific area, which is crucial for various applications, including medical imaging and radiation therapy [4].

Ongoing research aims to develop new dosimetry techniques, materials, and technologies to enhance accuracy, sensitivity, and efficiency in measuring X-ray doses. To illustrate, Fum et al. [5] worked on Monte Carlo (MC) methods in fluoroscopy-guided interventions for clinical dosimetry, with potential advancements in dynamic, deformable phantoms and automated image-based alignment for enhanced patient specificity. To efficiently and expeditiously assess X, γ, and neutron radiation fields concurrently, Yang et al. [6], developed a portable multifunction radiation detection system employing LaBr3(Ce) crystal, LASO neutron detector, and high-range GM counter, data measured transmitted to a PC through a USB interface. Johnson et al. [7] survey cutting-edge approaches for X-ray dose detection, such as semiconductor detectors and digital dosimeters, underscoring their enhanced precision and quicker response times compared to conventional techniques. Furthermore, Garcia et al. [8] assess the implementation of automated X-ray dose tracking systems in hospital settings, revealing a 25% reduction in incidents of excessive radiation exposure among patients. Brown et al. [9] explores advanced dosimetry methods like real-time dosimeters and patient dose mapping, which significantly bolster X-ray imaging safety, resulting in a 40% enhancement in radiation dose control. Moreover, Thomas et al. [10] spotlight recent advancements in X-ray dose monitoring technologies, including wearable dosimeters and machine learning algorithms, which collectively lowered radiation exposure by 20% in clinical environments.

Excessive exposure to X-rays poses significant health risks, including radiation burns, radiation sickness, and an increased risk of cancer. As X-ray technology is widely used in medical imaging, it is crucial to monitor and control the radiation dose received by individuals to ensure their safety. Traditional methods of measuring X-ray exposure can be inadequate or cumbersome, leading to the necessity for a more efficient, accurate, and user-friendly solution. In this context, Wilson et al. [11] investigate the development of portable X-ray dose detectors utilizing microelectromechanical systems (MEMS), demonstrating their high accuracy and ease of use in clinical trials. On the other hand, Smith et al. [12] delve into recent advancements in real-time monitoring of X-ray doses during radiological procedures, utilizing advanced sensor arrays to achieve a 30% decrease in patient radiation exposure. Meanwhile, Robinson et al. [13] analyze the complexities of real-time X-ray dose management through case studies, proposing solutions that integrate dose monitoring systems to enhance safety compliance by 50%. Martinez et al. [14] explore the integration of artificial intelligence to enhance X-ray dose detection and monitoring, revealing that AI algorithms enhance detection accuracy by 25% and reduce false positives by 30%. Lastly, Silva et al. [15] describe the development of low-cost X-ray equipment including an X-ray machine, a Geiger detector, and a goniometer, aimed at facilitating accessible study and experimentation in X-ray physics.

To address the critical need for real-time, precise monitoring of X-ray exposure, we developed the Smart X-ray Geiger Data Logger. This device can provide immediate feedback on radiation doses including instant and cumulative dose, enabling users to take timely actions to minimize exposure. Otherwise, our solution is particularly valuable in medical environments, ensuring that patients and healthcare workers are not subjected to unnecessary radiation. Additionally, the Smart X-ray Geiger Data Logger is a handheld device used to detect, control and evaluate X-ray doses. It operates based on the ionization effect produced when radiation interacts with a gas inside the Geiger-Muller tube. By employing advanced algorithm for exposure risk assessment, the Smart X-ray Geiger Data Logger can improve radiation safety management, protecting health and enhancing overall safety standards.

This paper is structured into two main sections: The first section comprehensively explores the materials and methods employed in the study, detailing the experimental setup, equipment specifications, and data collection procedures. The second section is dedicated to presenting and discussing the results obtained from the experiments. It analyzes the findings in the context of existing solutions, discusses implications for the field, and explores potential avenues for further research.

II. Materials and Methods

A. X-Ray Doses

Dosimeters are employed in medical field to monitor personnel radiation exposure during diagnostic X-ray procedures and in occupational application to ensure that radiation workers are not exposed to harmful levels of radiation. To evaluate the risk of excessive dose absorption, we based on the effective dose of the body, which is a measure used in radiology to estimate the overall risk of harm from ionizing radiation exposure. It takes into account the different sensitivities of various tissues and organs in the body to radiation.

The calculation of effective dose involves three main steps: first, determining organ and tissue weighting factors (Table I), which reflect the varying sensitivities of different tissues and organs to radiation and are set by organizations like the International Commission on Radiological Protection [16]. Second, calculating the absorbed dose, the energy deposited per unit mass in a specific organ or tissue, measured in gray, based on radiation type, energy, and exposure conditions. Finally, the effective dose is obtained by multiplying the absorbed dose in each organ or tissue by its respective weighting factor and summing these values across all exposed organs and tissues.

It's important to note that the effective dose is an estimate of the overall risk and not a direct measure of the biological effect on an individual. It is a useful concept for comparing and managing radiation risks in different exposure scenarios. Absorbed dose is the amount of energy imparted by ionizing radiation per unit mass of irradiated material. It is measured in gray (Gy) in the International System of Units (SI). Absorbed dose can be calculated using dosimeters, devices specifically designed to measure the energy deposited by X-rays in a given material. However, there are various types of dosimeters used in X-ray dosimetry, including ionization chambers, thermoluminescent dosimeters (TLDs), semiconductor detectors, and film badges.

TABLE I. Organ and Tissues Weighting Factor

Tissue or Organ	ICRP 103
Gonads	0.08
Lung	0.12
Colon	0.12
Stomach	0.12
Breast	0.12
Bladder	0.04
Liver	0.04
Esophagus	0.04
Thyroid	0.04
Skin	0.01
Bone surface	0.01
Brain	0.01

The principal function of an X-ray dosimeter based on ionization chambers is to measure and quantify the ionizing radiation exposure from X-rays. Ionization chambers operate by detecting the electrical charge produced when X-ray photons ionize the gas molecules within the chamber [17-19]. Likewise, TLD dosimeters play a crucial role in assessing radiation exposure by utilizing the thermoluminescent properties of certain materials to measure the amount of energy absorbed from ionizing radiation [20-25]. In other hand, Semiconductor detectors for X-rays serve as key tools for detecting and measuring ionizing radiation in various applications [26-29], their high sensitivity, spatial resolution, and fast response time make them valuable in diverse applications, including medical imaging, industrial inspection, and radiation monitoring. Finally, X-ray dosimeters based on film badges are practical tools for monitoring ionizing radiation exposure, offering wearable, cost-effective, and dose-history recording solutions for individuals working in environments where X-rays are present [30-32].

In our case, we used the ionization chamber M4011 Geiger-Müller Tube shown in Fig. 1. The interaction of X-ray photons with gas, leading to the formation of ion pairs (positive and negative charges) within the chamber. An electric field applied within the ionization chamber separates these ion pairs, and the resulting electric current or charge is quantified. This current's magnitude is directly proportional to the degree of ionization, which correlates with the radiation dose. Converting the measured charge into a radiation dose, typically expressed in Sieverts (Sv), enables a quantitative evaluation of absorbed radiation. Renowned for their precision and reliability across a broad spectrum of energies, ionization chambers find application in diverse fields such as medicine, industry, and research.

Fig. 1. M4011 Geiger-Müller tube.

B. X-Ray Doses Detection and Assessment

Dose quantities, such as entrance surface dose (ESD) and organ or effective dose, are often used to assess and report radiation exposure in medical imaging. To effectively measure,

display, control, and monitor these doses, we have developed the Smart X-ray Geiger Data Logger, as shown in Fig. 2.

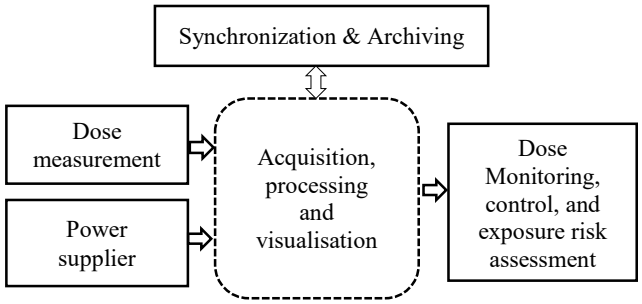

Fig. 2. Smart X-ray Geiger Data Logger for measurement and monitoring of X-ray doses in medical imaging.

The Smart X-ray Geiger Data Logger is an innovative device designed for the collection, control, monitoring, and evaluation of X-ray doses. Its primary purpose is to ensure the safety and protection of individuals from excessive X-ray exposure, thereby reducing the risk of radiation-induced diseases such as cancer.

The device is equipped with its own battery and power adapter, ensuring continuous operation even in the absence of an external power source. It includes memory storage for dose data, allowing offline access to historical exposure information. Built-in Wi-Fi capability allows the device to connect to a database for data acquisition and retrieval. The MQTT protocol is utilized for secure and efficient data transmission, ensuring the protection of sensitive information. An auditory alarm and LED indicators are activated when the absorbed dose exceeds predefined safety limits, providing immediate alerts to the user. Additionally, the device features a specialized algorithm for exposure risk assessment. Before proceeding with a new examination, the algorithm evaluates the risk based on the reference dose for the upcoming exam and the cumulative dose previously received. If the total dose does not exceed the safety limit, the device grants permission for the new exam. Otherwise, it warns the user of the potential risks and suggests alternative procedures.

The Smart X-ray Geiger Data Logger is a versatile tool that empowers individuals to continuously monitor and control their X-ray exposure, ensuring their safety. In medical settings, it helps radiology departments and doctors in making informed decisions about X-ray examinations, enhancing patient safety. Biomedical technicians and engineers benefit from using the device during the installation, maintenance, checkup, startup, and calibration of X-ray equipment, as it helps control their exposure to scattered radiation. Radiology technicians also find it invaluable for managing their radiation exposure during daily operations. The primary objectives of the Smart X-ray Geiger Data Logger are to validate the necessity of X-ray doses, avoid unnecessary exposure, safeguard individuals from excessive radiation, prevent radiation-related diseases, and assist healthcare professionals in optimizing patient care.

In the pursuit of measuring values, our preference leaned towards the M4011 Geiger- Müller tube, chosen for its specific attributes (380-450V, 25 pulse/minutes) [33]. This selection aligns harmoniously with the requirements of our solution. As for the power supply, we integrated a lithium battery featuring 3300 mAh and 3.7V.

Fig. 3 illustrates the diagram of our device and the connections between its various components. At the heart of our system lies the ESP32 board, assuming a central role in managing data acquisition, executing algorithmic processing, and presenting results on the display. Beyond these functions, it acts as a crucial facilitator for seamless communication among the diverse elements within our system. Boasting a robust 32-bit dual-core microcontroller that operates at clock frequencies of up to 240 MHz, the ESP32 board distinguishes itself with its integrated Wi-Fi and Bluetooth capabilities, making it highly suitable for a wide array of IoT (Internet of Things) applications. These boards exhibit varying amounts of Flash memory for program storage and RAM for data storage, the specific sizes of which depend on the model. Noteworthy is the ESP32's intentional design for power efficiency, supporting a range of power modes to optimize energy consumption, particularly beneficial for battery-operated devices [34].

The RadiationD V1.1 board is engineered for precise radiation detection and measurement, incorporating vital features such as powering and adapting the M4011 Geiger-Müller tube. The TP4056 module enhances its functionality with efficient charging of single-cell lithium-ion or lithium-polymer batteries, integrating thermal regulation, overcurrent protection, and reverse polarity protection for safe operation. In Smart X-ray Geiger Datta Logger, the DS3231 real-time clock module ensures precise time synchronization and event logging, facilitating accurate timestamping of radiation readings. This capability is crucial for monitoring radiation dose accumulation over time and correlating exposure data with specific events or patient movements. Additionally, the ILI9341 TFT LCD controller on the board supports essential functions for display management and high-quality graphics rendering, enhancing usability in radiation monitoring applications.

The user interface consists of two main parts. The first part is dedicated to the dashboard, which displays real-time dose measurements, cumulative dose, and the set of exams for the patient. The second part is dedicated to X-ray dose risk assessment. Before any new examination, the patient can select the new exam type, and the system will check the dose associated with this procedure along with the cumulative dose. If the combined dose exceeds the safety limit, the system will alert the user that the selected procedure is risky and suggest choosing an alternative.

The exposure risk assessment is based on X-ray dose references (Table II) for common procedures [35-36]. This algorithm applies the three fundamental principles of radiation protection: Justification, Optimization and Limitation.

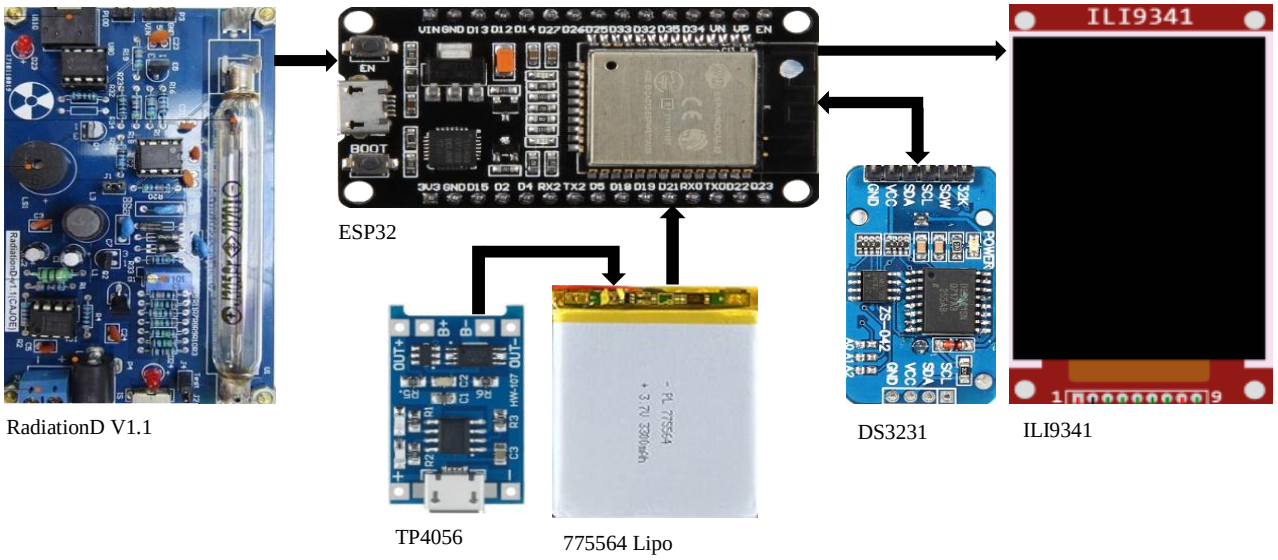

Fig. 3. Smart X-ray Geiger Data Logger diagram.

TABLE II. X-RAY DOSE REFERENCES FOR COMMON PROCEDURES

Procedure	Effective dose mSv
Chest CT	6.1
Abdomen CT	5.3
Brain CT	1.6
Cardiac CT	1.7
Lumbar RS	1.4
Extremity RS	0.1
Chest RS	0.1
Mammography	0.21
Dental	0.25

The Smart X-ray Geiger Data Logger, illustrated in Fig. 4, is engineered to fulfill the objective of measuring, displaying, controlling, and monitoring radiation doses. By embodying these capabilities, it not only upholds stringent principles of radiation safety but also enhances overall radiation protection protocols.

Fig. 5 depicts the flow chart of our solution algorithm. The process begins with powering ON the device and establishing a connection to the database. The user interface then displays real-time dose measurements, cumulative dose, and scheduled exams. The patient selects the type of new exam to be performed, and the device retrieves the dose information associated with the selected exam. The system calculates the total dose by adding the new exam dose to the cumulative dose and evaluates whether this total dose exceeds the safety limit. If it does, a warning message is displayed; if not, the system grants permission for the exam. After the exam, the cumulative dose is updated in the database. The system then checks the updated cumulative dose against the safety limit. If the cumulative dose exceeds the limit, an audible notification is activated and a red LED is turned on. If it does not exceed the limit, the device returns to the dashboard, ready for the next operation, and re-authenticates with the database.

Fig. 4. Smart X-ray Geiger Data Logger for radiation dose measurement and monitoring.

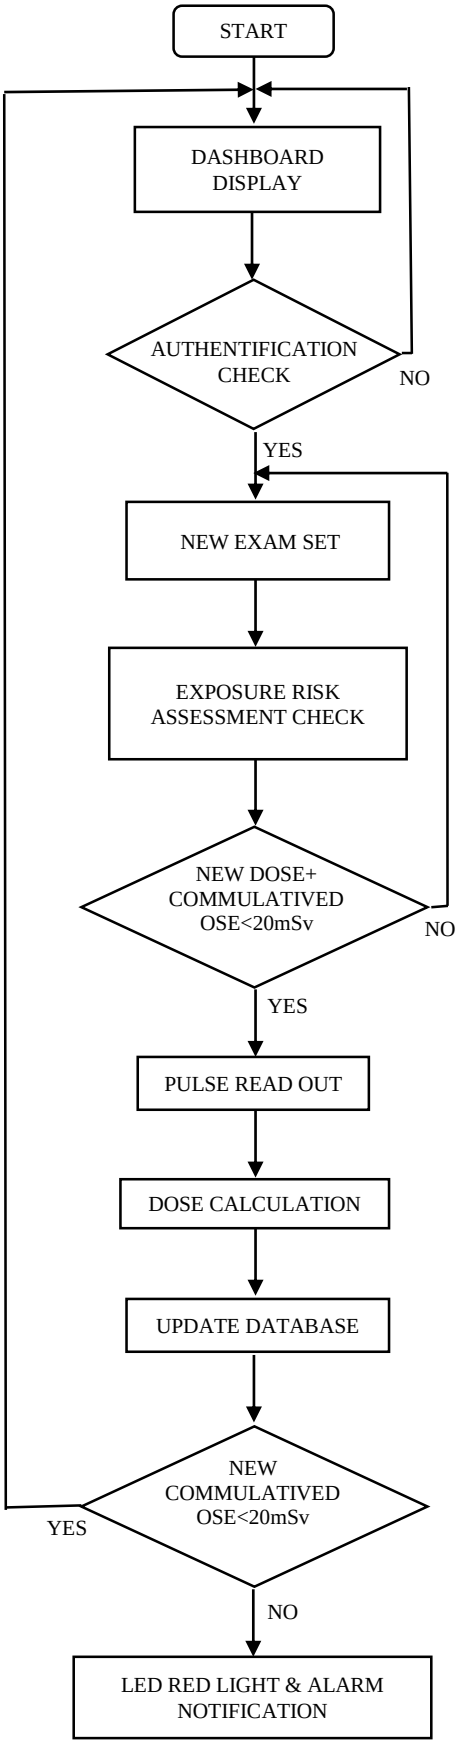

Fig. 5. Algorithm flowchart for radiation dose management system.

III. Results and Discussion

In diagnostic radiology, X-ray dosimetry is essential to optimize imaging procedures and minimize unnecessary radiation exposure to patients. This includes techniques such as computed tomography (CT), fluoroscopy, and conventional radiography. Concerning radiation in therapy, X-ray dosimetry plays a critical role in planning and delivering precise doses of radiation to cancerous tissues while sparing surrounding healthy tissues.

Exposure to prolonged or heightened levels of ionizing radiation elevates the risk of developing cancer, with the specific type and likelihood of cancer contingent upon the organs affected. Robust statistical evidence indicates an increased cancer incidence among populations exposed to substantial radiation doses, as exemplified by survivors of atomic bombings in Hiroshima and Nagasaki [37]. Additionally, elevated radiation doses have the potential to induce heritable genetic mutations. Acute exposure to high doses of radiation can precipitate Acute Radiation Syndrome, characterized by symptoms such as nausea, vomiting, diarrhea, and, in severe cases, damage to organs and tissues, with the severity directly proportional to the dosage.

Radiation protection agencies rely on sophisticated models to project the lifetime risk of cancer resulting from radiation exposure, accounting for variables such as age, gender, and radiation type.

An experiment utilizing the E7239GX Toshiba X-ray tube device was conducted to measure scattered radiation doses across different parameters, as outlined in Table III. This study was undertaken to evaluate the levels of scattered radiation generated under varied operational conditions, a critical factor in assessing radiation safety protocols and refining imaging techniques in medical environments. All measurements were recorded using our Smart X-ray Geiger Data Logger and cross-verified with the BR-6 Geiger counter device, as depicted in Fig. 6. This comprehensive approach ensures accurate data collection and validation, contributing to enhanced understanding and management of radiation exposure in clinical settings.

Fig. 6. Verification of scattered radiation measurements using smart X-ray Geiger Data Logger and BR-6 Geiger counter.

TABLE III. Parameters and Corresponding Scattered Radiation Doses Measured with E7239GX Toshiba X-ray Tube Device

High Voltage (kV)	Filament Current (mA)	Distance from the Source (m)	Dose for Scattered Radiation (uSv)
70	100	1	4.71
70	50	1	4.41
70	20	1	4.36
80	50	1	4.44
90	50	1	4.50
100	50	1	4.53
110	50	1	4.55
70	100	2	1.17
70	50	2	1.10
70	20	2	1.09
80	50	2	1.11
90	50	2	1.12
100	50	2	1.13
110	50	2	1.13

In summary, adjusting high voltage (kV) and filament current (mA) affects the quality and quantity of the X-rays produced, which in turn influence the dose for scattered radiation at different distances from the source. Lowering kV or mA can reduce radiation exposure but may affect image quality, while increasing distance from the source decreases radiation intensity but requires compensation with higher kV or mA settings to maintain diagnostic quality.

However, the amount of scattered radiation dose received can vary significantly depending on several key factors. These include the type of material through which the X-rays scatter, such as bone or soft tissue, and the angle at which scattering occurs. Distance from the radiation source plays a critical role as well, with intensity decreasing according to the inverse square law as distance increases. Effective shielding and room design are crucial in minimizing scattered radiation exposure, as they can absorb or redirect scattered X-rays away from personnel. Patient positioning also influences exposure levels, as different positions can direct scattered radiation towards different areas of the exam room. Additionally, factors related to X-ray equipment, such as tube voltage, current settings, and beam collimation, directly impact the amount of scattered radiation generated.

To manage the power supply, control the Geiger-Müller tube, and acquire measured dose values, we utilized the RadiationD V1.1 board. Fig. 7 illustrates the board's diagram, structured around several key components.

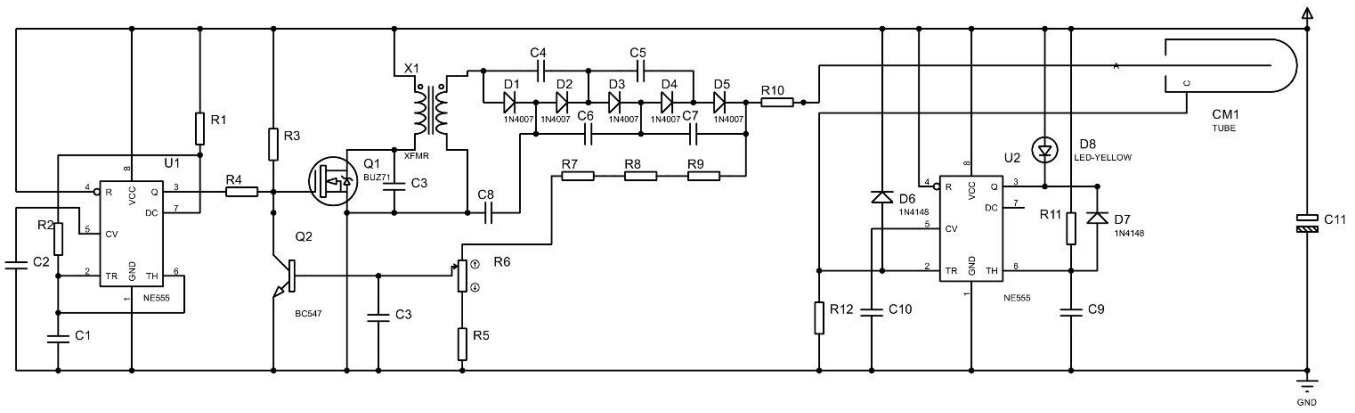

Fig. 7. RadiationD V1.1 board.

The first key component is the Square-Wave Generator Block. This block is tasked with generating a carrier signal that drives the system. The precise timing signals produced by this block ensure synchronization within the system, providing a stable foundation for the subsequent components to function correctly. Next, the High Voltage Power Supply plays a crucial role. This circuit converts the low voltage from the battery to the high voltage required to operate the Geiger-Müller tube, typically in the range of 350-500V. This component is essential for the stable operation of the Geiger-Müller tube, ensuring it receives the necessary high voltage to detect radiation accurately.

The Geiger-Müller Tube itself is a cylindrical tube filled with inert gas that becomes ionized when radiation passes through it. The ionization process generates electrical pulses, which are the primary signal used to detect radiation. This tube is the core of the radiation detection process, as it directly responds to ionizing particles. Capturing these pulses is the job of the Pulse Detection Circuit. This circuit typically consists of a resistor-capacitor (RC) configuration connected to the Geiger-Müller tube. It detects the electrical pulses generated by the tube when radiation is present. This detection circuit is crucial for converting the ionization events within the tube into readable electrical signals.

Finally, the Amplification and Timing Regulation component processes the detected pulses. This part of the board amplifies the pulses to ensure they are strong enough for accurate measurement. Additionally, it regulates the timing to ensure precise dose calculations. Accurate amplification and timing regulation are vital for providing reliable radiation dose values, ensuring that the detected signals are processed correctly.

Fig. 8 represents different amounts of X-ray radiation, depicted as a random signal. This figure illustrates the varying intensities and frequencies of X-ray radiation generated over a period of time, showcasing the fluctuating of radiation levels in the X-ray field.

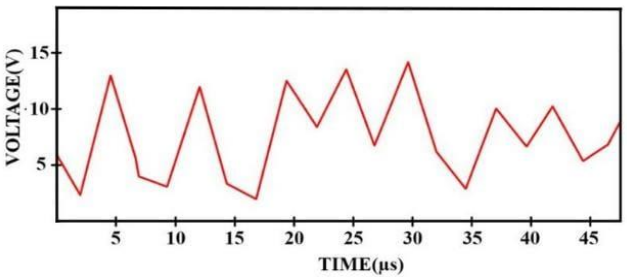

Fig. 8. Different amounts of x-ray radiation represented by a random signal.

Fig. 9 shows the high voltage generated for the Geiger-Müller tube's function. This figure highlights the conversion process from the low voltage power supply to the high voltage necessary for the operation of the Geiger-Müller tube. The stability and consistency of this high voltage are crucial for accurate radiation detection.

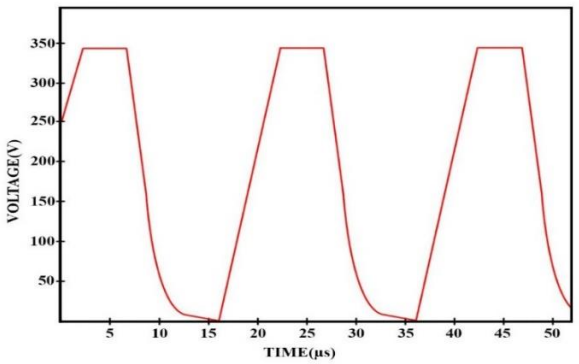

Fig. 9. High voltage generated for Geiger-Müller tube operation.

Fig. 10 represents the pulse detected by the Geiger-Müller tube, which will be transmitted for further processing. This figure demonstrates the output of the pulse detection circuit, showing the discrete electrical pulse generated in response to ionizing radiation passing through the Geiger-Müller tube. These pulses are then amplified and timed correctly for accurate radiation dose measurement and data analysis.

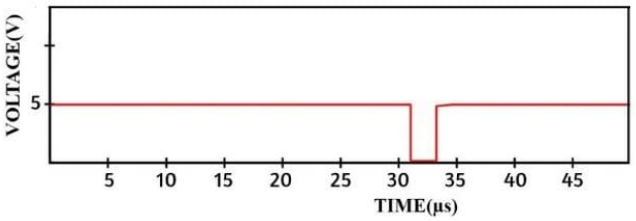

Fig. 10. Pulse detected by the Geiger-Müller tube for processing.

This study illustrates critical components and operational procedures essential for simulating X-ray doses. Among them, the RadiationD V1.1 board is prominently featured, serving as integral hardware for the detection system. These visual representations also depict different levels of X-ray radiation, demonstrating the system's sensitivity and response capabilities. Additionally, the figures demonstrate the generation of high voltage required for Geiger-Müller tube operation, underscoring its pivotal role in detecting radiation. Furthermore, they detail the pulses detected by the Geiger-Müller tube, providing insights into the electrical responses triggered by simulated radiation events. Together, this study offers a comprehensive overview of the experimental setup and operational mechanisms on simulating X-ray doses.

IV. Conclusion

In this study, we introduced the Smart X-ray Geiger Data Logger, a novel device designed for integrated detection, control, and dose evaluation of X-ray radiation. This device addresses the critical need for real-time monitoring and precise measurement of radiation doses in medical imaging and other applications. By leveraging the ionization effect within the Geiger-Müller tube and advanced algorithmic processing, the Smart X-ray Geiger Data Logger offers significant advancements in radiation safety management.

Through our experimental setup and data collection procedures, we demonstrated the device's capability to accurately measure and monitor X-ray doses, providing immediate feedback on both instant and cumulative radiation exposure. The integration of a robust algorithm for exposure risk assessment ensures proactive management of radiation safety, alerting users to potential risks and suggesting alternative procedures when safety limits are approached or exceeded. The Smart X-ray Geiger Data Logger stands poised to contribute significantly to the advancement of radiation safety practices, ensuring enhanced patient care and occupational safety across medical sectors.

Looking forward, the Smart X-ray Geiger Data Logger marks a significant advancement in radiation monitoring, providing healthcare professionals a vital tool for optimizing radiation exposure management.

***Abstract*—Image classification is a domain where Deep Neural Networks (DNNs) have demonstrated remarkable achievements. Recently, Vision Transformers (ViTs) have shown potential in handling large-scale image classification challenges by efficiently scaling to higher resolutions and accommodating larger input sizes compared to traditional Convolutional Neural Networks (CNNs). However, in the context of adversarial attacks, ViTs are still considered vulnerable. Feature maps serve as the foundation for representing and extracting meaningful information from images. While CNNs excel at capturing local features and spatial relationships, ViTs are better at understanding global context and long-range dependencies. This paper proposes a feature map ViT-specific adversarial example attack called Feature Map ViT-specific Attack (FMViTA). The objective of the investigation is to generate adversarial perturbations in the spatial and frequency domains of the image representation that allow deeper distance measurement between perturbed and targeted images. The experiments focus on a ViT pre-trained model that is fine-tuned on the ImageNet dataset. The proposed attack demonstrates the vulnerability of ViTs to adversarial examples by showing that even allowing only 0.02 maximum perturbation magnitude to be added to the input samples gives 100% attack success rate.**

Keywords*—Vision transformers; adversarial attacks; DNNs; vulnerabilities; feature maps; perturbations; spatial domains; frequency domains

I. Introduction

Deep Neural Networks (DNNs) have emerged as highly effective image classification tools. Convolutional Neural Networks (CNNs) recognize the input image data by the convolutional layers to identify and capture local patterns and spatial hierarchies of features [1]. On the other hand, Vision Transformers (ViTs) represent the input image data as sequences of patches and leverage the self-attention mechanisms to capture long-range dependencies and global context in images [2]. Therefore, ViTs can be more effective than CNNs in long-range interactions and achieve state-of-the-art performance on various image classification benchmarks.

Feature maps are fundamental for representing and extracting valuable information from images in DNN classification models. ViTs are better at understanding global context and long-range dependencies than CNNs [3]. ViTs divide the input image into patches and then flatten and embed them into tensors. These tensors are then fed into a transformer encoder, which learns to attend to different patches and their relationships.

From the security perspective, the adversarial robustness of the ViT models is a significant challenge, specifically in a domain such as image classification. Adversarial attacks intentionally manipulate the models by inserting small perturbations into the input image data to deceive them, resulting in incorrect predictions of the input image while appearing normal to humans, called adversarial example attacks. Adversarial perturbations are critical in understanding the vulnerabilities of the ViT models to adversarial examples.

The existent studies of adversarial perturbations have focused on two main areas: the spatial domain and the frequency domain [4]. In the spatial domain, the representation of the input images is extracted directly from the pixel values which is typically used in attacks such as gradient-based adversarial attacks [5]–[10]. The frequency domain including low-frequency and high-frequency is another perspective that can be used to generate perturbations in selected frequency regions [4]. The representation of the input images in the frequency domain is transformed through methods like the Discrete Cosine Transform (DCT) [11]. Prior research has indicated that CNNs are vulnerable to high-frequency noise and ViTs are vulnerable to low-frequency noise [12]. These findings have contributed to the emergence of frequency-based adversarial attacks, including [11], [13]–[17].

In this research paper, our objective is to investigate the potential impact of introducing an adversarial example attack by generating the adversarial perturbations in the spatial domain but with some potential influence from the frequency domain. We introduce the FMViTA attack that uses the ViT feature maps of the perturbed and the target images to optimize the adversarial perturbations. For deeper comparison, the cosine similarity loss function is used to measure the similarity between feature maps. The ViT model itself can learn to capture frequency-related information through its self-attention mechanism. This means that the feature maps used for cosine similarity might contain some frequency-based representations, especially since we take the mean feature maps from the intermediate blocks. While the ViT feature maps are not considered directly spatial domains, they are still influenced by the spatial arrangement of the image patches. However, adding adversarial perturbations to the input image is a direct pixel-level operation happening in the spatial domain. Furthermore, for imperceptibly added, we clamp adversarial perturbations.

We, however, do not intend to make a strength transferable adversarial example attack; we pose a direction of generating perturbation by using more deeper comparison methods to optimize the perturbations generated. Our results demonstrate

that using FMViTA method can indeed manipulate a ViT model to classify a set of five input images as other target images with 100% attack success rate, while we only allowing 0.02 maximum perturbation magnitude to be changed. The contributions of this paper are summarized as follows:

- We employ a cosine similarity loss function for deeply measuring the similarity between the perturbated and the target feature maps of the images to optimize the perturbation patterns.
- We also propose a novel Feature Map ViT-specific Attack method named FMViTA that takes one input image and runs it against a target image to generate a perturbated image that looks like the input one but classifies as the target image.
- We demonstrate the results of using FMViTA against a ViT for five input and target images.

The rest of the paper is organized as follows: Section II briefly gives a background and reviews the related works. In Section III, we provide our methodology, including the threat model. Experiments setup and results are presented in Section IV. Finally, the conclusion is made in Section V.

II. Background and Related Work

A. Adversarial Attacks in DNNs

The adversarial attacks can be broadly classified by the attack goals to evasion, poisoning, backdoor, and privacy attacks. In evasion attacks, the goal is to cause misclassification at test time, such as in the adversarial example attacks [18]. In the poisoning attacks, the goal is to inject poisonous data that can manipulate the DNN model's training. The goal of the privacy attacks is to steal information from the DNN models. Backdoor attacks can be considered both evasion and poisoning attacks because adversaries inject poisonous data called triggers into legitimate DNN models at training time and misclassify the model once the trigger is activated at test time [19].

From another point of view, adversarial attacks can be classified based on the accessibility of the adversaries. In this context, adversarial attacks can be either white-box or black-box attacks. White-box attacks are powerful because adversaries can access the architecture and parameters of a DNN model. On the other hand, black-box attacks are more challenging because the adversaries can only access the input and output data from a DNN model. Gray-box attacks are situated between white-box and black-box attacks. In these attacks, the adversaries possess limited knowledge of the model's architecture and parameters.

In addition, depending on the goals of the attacks, adversarial attacks can be classified as targeted and untargeted. In untargeted attacks, the goal is to misclassify the DNN classification model to output any other class. In the targeted attacks, the goal is to misclassify the DNN classification model to classify the input as a particular class. In this paper, our attack method is considered a targeted gray-box adversarial example attack. However, the method could be developed to generate other types of attacks.

B. Adversarial Example Attack Methods

The earlier adversarial example attacking phenomena were proposed by Szegedy et al. [18]. Since then, various methods for creating highly powerful perturbations have been put forward in academic literature. Goodfellow et al. [5] first introduced the concept of adversarial examples using a gradient-based method called the Fast Gradient Sign Method (FGSM). In this method, the gradient of the loss function is used with respect to the input data to generate the small perturbation that maximizes the loss function, which can be conceded as a white-box attack. On the other hand, Kurakin et al. [6] improve the FGSM by running multiple iterations of the attack. However, the method showed that there would still be a gap in accuracy between the perturbed results and the being ones. Later researchers use momentum [7] approaches to further enhance the adversarial example attacks. Dong et al. [8] proposed the Momentum Iterative Fast Gradient Sign Method (MI-FGSM) to increase the success rate of the black-box attacks, which improves the transferability of the adversarial example attacks. Other enhancements were proposed as well, such as the Ensemble Momentum Iterative FGSM (EMI-FGSM) [9] and VMI-FGSM and VNI-FGSM [10].

Frequency-based adversarial example attacks have been developed in the literature to generate adversarial perturbations. Recently, Duan et al. [11] proposed another way of crafting adversarial examples named AdvDrop. Instead of adding perturbations, they drop existing details from clean images from frequency components. The results demonstrate that AdvDrop can achieve high attack success rates on ImageNet dataset. Guo et al. [15] focus on the low frequency adversarial perturbation for black-box attacks. The authors demonstrate the effectiveness of this technique by successfully fooling the Google Cloud Vision platform with an unprecedented low number of only 1000 model queries . Jin et al. [17] introduced a novel white-box attack known as the Frequency and Spatial Consistency Based Adversarial Attack (FSA). The results show that the FSA method can enhance the success attack rates, with a maximum improvement of 28.98% observed across various attack methods and models.

C. Adversarial Robustness of Vision Transformer

ViT is state-of-the-art for image classification that uses a transformer architecture to process image patches and generate predictions [20]. As ViTs continue to gain popularity and are being deployed in various domains, the robustness of ViTs to adversarial attacks becomes essential.

According to Aldahdooh et al. [21] Vanilla ViTs or hybrid ViTs are more robust to adversarial attacks than CNNs, particularly under Lp-norm or adaptive attacks. The findings demonstrate that increasing the number of attention blocks may increase the robustness to transfer attacks but not white-box attacks. Shao et al. [22] claim that ViTs are less sensitive to high-frequency perturbations than CNNs and MLP-Mixers. That is because ViTs contain less high-frequency features, which have a high correlation with their robustness against different frequency-based perturbations. In addition, in ViTs, introducing convolutional or token-to-token blocks for learning high-frequency features can improve classification accuracy, but at the cost of adversarial robustness. Furthermore, modern

CNNs may borrow some of ViTs techniques to bridge the performance gap as well as the adversarial robustness gap.

Paul and Chen [23] have compared the robustness of ViTs and CNNs models against frequent corruptions and perturbations using six different ImageNet datasets. Their findings suggest that ViTs have better robustness performance than CNNs on some of the datasets, and that the robustness of both models can be improved by fine-tuning on corrupted data. Overall, the study highlights the potential of ViTs as a promising alternative to CNNs in computer vision tasks, especially when it comes to robustness. Joshi et al. [24] analyzed the underlying distinctions between the ViT and CNN models. Unlike convolutional networks, vision transformers use a patch token-based self-attention mechanism. By creating a block sparsity based adversarial token attack, their study found that ViT models are more sensitive to token attacks than CNN models. This highlights the need for robustness evaluation of transformer-based models against adversarial attacks. It also suggests that further research is required to improve the security of vision transformers.

III. Methodology

A. Threat Model

We use the threat model to define our FMViTA attack scenario. We focus on image classification; nevertheless, the technique can be easily extended to other domains. In this threat model, we assume that the adversary has limited knowledge of the model's architecture and parameters. In addition, the adversary does not have access to the training data. The attack is considered a gray-box adversarial attack. The adversary's objective in this threat model is to embed perturbations into the input images to make them perturbed in order to fool the ViT classification model to classify them as target images' classes.

B. Attack Method

We formulate FMViTA as an optimization problem to generate perturbed images. The optimization is based on minimizing the distance between feature representations of the perturbed and target images. To do so, we take the mean of the intermediate features for both input and target images. Then we calculate the cosine similarity between the mean features of the perturbed and target images to measure the distance between them, which is the loss function to be used in the gradient iterations.

The loss function encourages the features of the perturbed image to be similar to those of the target image. Our attack utilizes the intermediate feature maps instead of focusing on the model's output probabilities. Thus, we chose the cosine similarity as a function due to its suitability for comparing high-dimensional feature vectors. Furthermore, the cosine similarity concentrates on the angular relationship between the two feature maps. Compared to other similarity calculations, such as Euclidean and Manhattan distances, cosine similarity is less sensitive to magnitude differences because it focuses on the angle between vectors. This property allows for a more in-depth comparison between the two feature maps. Since the cosine similarity is used to measure this similarity, a higher similarity results in a lower loss as shown in Eq. (1).

$$L(F_t, F_p) = 1 - \frac{F_t \cdot F_p}{\|F_t\|\|F_p\|} \tag{1}$$

$L(F_t, F_p)$: The loss function measuring the difference between the feature representations of the target image F_t and the perturbed image F_p.

$F_t \cdot F_p$: The dot product of the feature vectors, representing their similarity.

$\|F_t\|$and$\|F_p\|$: The magnitudes (norms) of the feature vectors, normalizing the cosine similarity.

Let M be the target ViT model and I_t and I_s be the input and target images. The optimizing perturbed patterns P is added to the input image as to generate perturbed images I_p as shown in Eq. (2). In addition, we clamp the perturbed pattern values to prevent them from becoming too large as shown in Eq. (3).

The gradient optimization can be mathematically described as:

$$\nabla_{t_i} L_i = \nabla_{t_i} \left(1 - L\left(mean\left(F_p\left(I_p\right)\right), mean(F_t(I_t))\right)\right) \tag{2}$$

$$I_p = \text{clamp}(I_s + P, -0.02, 0.02) \tag{3}$$

Algorithm 1: Feature Map ViT-specific Attack (FMViTA)

Input: Target model M, target image I_t, input images I_s, perturbed pattern P. **Output:** Perturbed images I_p.

Initialize P zeros.

for *each epoch* e **do**

  for *each input image* I_s *in* I_s **do**

    $I_p \leftarrow \text{Clamp}(I_s + P)$ Generate perturbed image

    $F_t \leftarrow M(I_t)$ Get features of target image

    $F_p \leftarrow M(I_p)$ Get features of perturbed image

    $L \leftarrow \text{Loss}(F_t, F_p)$ Calculate loss

    Update P using gradient descent: $P \leftarrow P - \alpha \nabla L$

  Return: Perturbed images I_p

IV. Experiments and Results

In this section, we first explain our experimental setup and then show the experimental results.

A. Experimental Setup

Our experiments mainly focus on pre-trained ViT (google/vit-base-patch16-224) [25], [26] that was pre-trained on ImageNet-21k [27] and fine-tuned on ImageNet [26] with a resolution of 224x224 and 1000 classes. Instead of using Adam, we use AdamW optimizer with a learning rate of 0.06 and weight decay of 0.002. The experiments were conducted on a dataset consisting of various AI-generated images for the input and target images that are classified as the ImageNet labels. We use AdamW optimizer to add the regularization

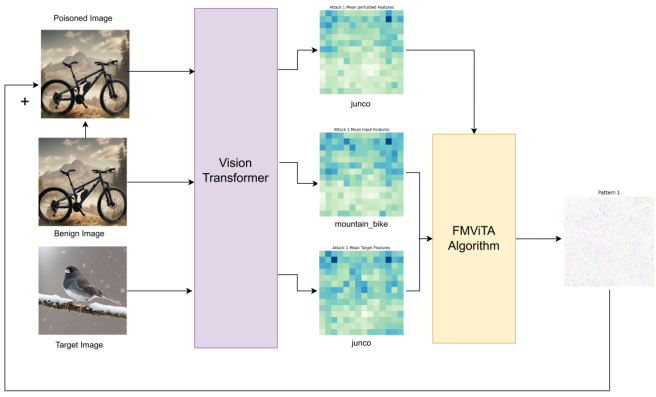

Fig. 1. The overall view of FMViTA attack ruining for Attack 1.

benefits of L2 regularization. We use AI-generated images as a dataset samples to be the target, and for the input images, we use five classes from the ImageNet dataset, which are {junco, mountain bike, terrapin, soccer ball, and goldfinch}.

Adam is an algorithm for first-order gradient-based optimization that computes adaptive learning rates for different parameters by maintaining estimates of the first and second moments of the gradients [28]. Adam combines the advantages of AdaGrad and RMSProp, with key differences in how it updates parameters and handles bias correction. However, L2 regularization and weight decay are equivalent for standard stochastic gradient descent (SGD) [29], but not for adaptive gradient algorithms like Adam. AdamW [30] modifies the popular Adam optimizer to improve its generalization performance, allowing it to compete with SGD with momentum on image classification tasks. To take advantage of AdamW we use it for the gradient-based optimization of FMViTA attack.

B. Experimental Results

We run the experiments to test the effectiveness of our attack algorithm using the same adjusted hyperparameters, such as the learning rate of 0.06, weight decay of 0.002, and 700 epochs for all five attacks. These hyperparameters were determined through an iterative process of empirical evaluation. The choice of a 0.06 learning rate suggests a balance between speed and stability for all five attacks to be run as a one-time attack; however, each individual attack can be run using a different learning rate based on the images being used. The weight decay parameter incorporated in the AdamW optimizer offers L2 regularization to address overfitting, consequently improving the generalization of the generated adversarial examples. It was set at 0.002 to provide the best balance between preventing overfitting and maintaining sufficient subtle adversarial perturbations. We decided to use 700 epochs after monitoring the convergence behaviors of the attack's loss functions.

In order to assess the effectiveness of the proposed FMViTA attack, we conducted an evaluation of the attack's capability to manipulate the source of five different input images and five corresponding target images. This paired selection allowed a more robust evaluation, and to determine how well the attack generalizes to unseen data. In Attack 1, we use a mountain bike as an input image, then after extracting the feature maps from the 12 blocks of the ViT model, we take the mean of all the maps to be in one tensor, and we do the same for the target image, which is a junco. Then we run the attack algorithm using cosine similarity as the loss function between the mean feature map of the perturbed image (the input image + perturbed pattern) and the mean feature map of the target image. We optimize the perturbed pattern using the AdamW optimizer to add the regularization benefits of L2. The goal is to make the mean feature map of the perturbed image as close as the mean feature map of the target image. The overall illustration of Attack 1 can be seen in the Fig. 1.

In Attack 2, we do it the opposite way, using a "junco" as an input image and a "mountain bike" as the target image. Then, we do the same as in Attack 1. In Attack 3 the input image was "soccer ball" and the target image was a "terrapin". In Attacks 4 and 5 "goldfinch" and "terrapin" were the input images, and "soccer ball" and "goldfinch" were the target images. All attacks' results are shown in Fig. 3.

To evaluate the attack performance, we use the attack success rate (ASR) to measure the success of the FMViTA attack. The ASR refers to the percentage of FMViTA that effectively induces a misclassification in the ViT model, and it can be represented as shown in Eq. (4).

$$ASR_{\text{FMViTA}} = \frac{N_{\text{mis}}}{N_{\text{t}}} * 100 \tag{4}$$

where: N_{mis} is the number of perturbed images from FMViTA that are misclassified by the ViT model. N_{t} is the total number of experiments.

In order to enhance the existing evaluation method, we have fixed the parameters for a group of five input images against the other five target images. Our results show that the attack achieved a success rate of 100%. However, in terms of the invisibility of the noise in perturbed images, the attack result can be better when using only one input image against one target image and adjusting parameters based on that.

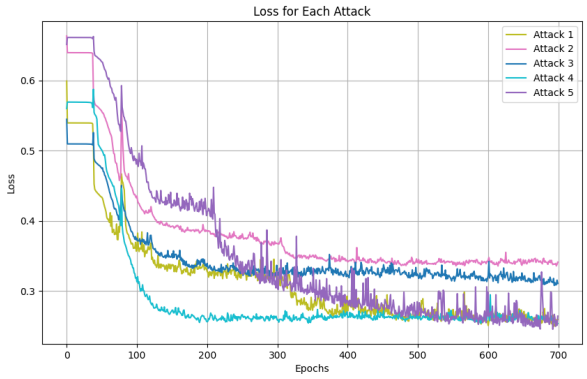

Fig. 2. The loss function results of the 5 attacks with 700 iterations.

That can be seen in Fig. 2 were losses behaved differently in each single attack iteration. Also, we found that extending the epochs did not improve the accuracy of in terms of the

invisibility of the noise in perturbed images, as if we changed the other parameters. The FMViTA attack tool will be available online with the flexibility to change the attack parameters.

Fig. 3. The results of FMViTA for a group of 5 input images against the other 5 target images.

Adversarial patterns often used in adversarial attacks, are specific inputs designed to elicit certain responses from a model. These patterns can expose the internal workings of neural networks and provide insights into their behavior under various conditions. Our patterns are typically generated through the FMViTA method to manipulate the input images intentionally.That can be seen in Fig. 4.

FMViTA method relies on feature maps, but the process of extracting features is computationally intensive, especially for long epochs and iterations in such an attack. Our optimization strategies are crucial for making the attack feasible within a reasonable timeframe. In FMViTA we extract the mean feature maps of the input and target images only once. However, it is necessary to extract the mean feature map of the perturbed images in each iteration. Fig. 5 shows the differences in mean feature maps of the input, target, and perturbed images.

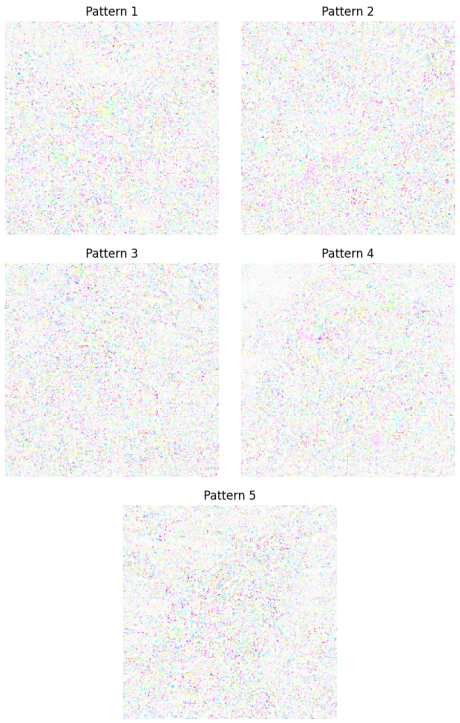

Fig. 4. The attack patterns for Attacks 1-5.

The vulnerability of ViTs to FMViTA stems from the exploitation of the intermediate feature representations within the DNN. The attack's efficacy derives from targeted manipulation of the intermediate features of the input image, leveraging gradient-based optimization, to generate perturbations that maximize the similarity between these intermediate features and the corresponding intermediate features of the target image. Thus, the success of FMViTA highlights the susceptibility of ViTs to gradient-based attacks targeting intermediate representations. Therefore, robust architectures and defenses against such sophisticated manipulation techniques are needed.

Mitigating the effectiveness of this attack approach suggests focusing on feature-space defenses. That involves analyzing the intermediate feature representations within ViTs to detect or mitigate the adversarial perturbations. One possible strategy is to apply denoising techniques to the intermediate feature maps. Recently, Yang et al. [31] have proposed the Denoising Vision Transformers (DVT) to suppress the grid-like artifacts observed in the feature maps by separating the clean features from those contaminated and then train a lightweight transformer block to predict clean features from raw ViT outputs. Another approach to mitigate such an attack is modifying the attention mechanism itself to enhance the robustness of attention weights to adversarial influence. That involves incorporating regularization terms during training or employing attention-aware denoising.

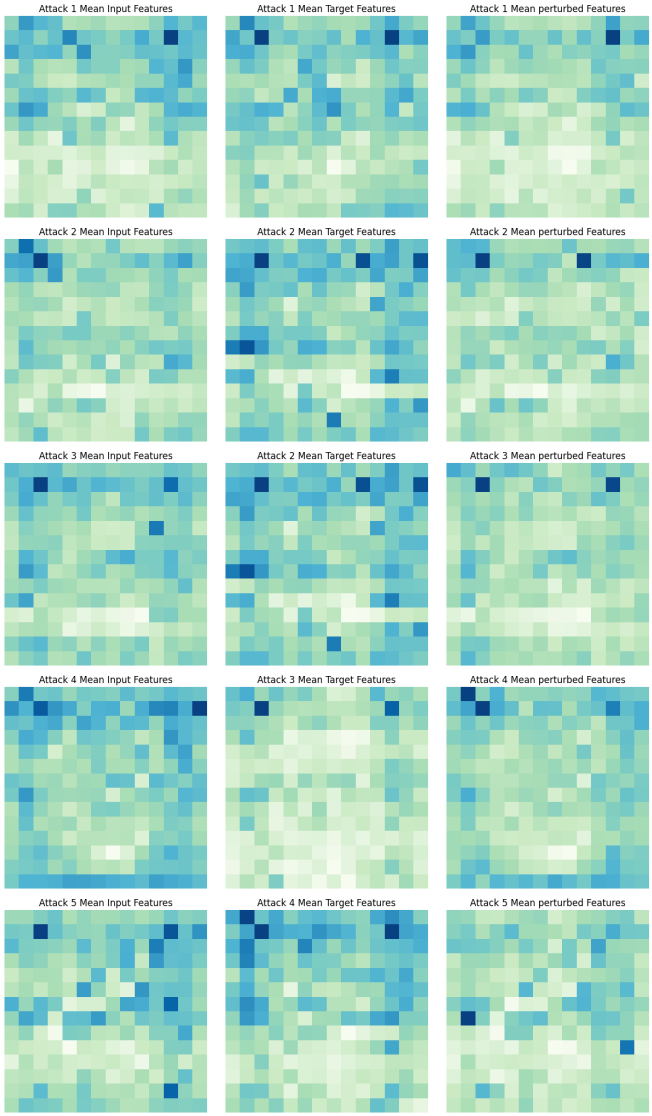

Fig. 5. The mean feature maps of the input, target, and perturbed images for Attacks 1-5.

V. Conclusion

The study found that vision transformers are vulnerable to FMViTA, which can significantly degrade their output accuracy. Therefore, developing more robust ViTs is crucial for ensuring the accuracy and reliability of ViT models. This highlights the importance of developing robust defense mechanisms to mitigate the impact of such attacks on vision transformers. However, investigating ViTs' robustness by generating adversarial attacks is a key to crafting robust defense mechanisms.

For future work, we will develop this direction of generating adversarial perturbations to be more robust to defense mechanisms. Furthermore, we will continue improving the FMViTA's performance in comparison with other state-of-the-art attacks. In addition, transferable improvements in the attack to be run in other ViT models are essential. Further, we can extend the FMViTA method to create other types of adversarial attacks, such as backdoor and poisoning attacks.

School of Electronic and Information Engineering, Liaoning Technical University, Huludao Liaoning, 125105, China

***Abstract*—Addressing issues such as the tendency for small-scale objects to be lost, incomplete segmentation of large-scale objects, and overall low segmentation accuracy in existing semantic segmentation models, an improved HRNet network model is proposed. Firstly, by introducing multi-branch deep stripe convolutions, features of multi-scale objects are adaptively extracted using convolutional kernels of different sizes, which not only enhances the model's ability to capture multi-scale objects but also strengthens its perception of the contextual environment.Secondly, to optimize the feature aggregation effect, the axial attention mechanism is adopted to aggregate image features along the x-axis and y-axis directions respectively, effectively capturing long-range dependencies within the global scope, and thus achieving precise positioning of objects of interest in the feature map.Finally, by implementing the progressive fusion-based upsampling strategy, it facilitates the complementary fusion of semantic information and detailed information between adjacent feature maps, thereby enhancing the model's capability to restore fine-grained details in images. Experimental results demonstrate that on the PASCAL VOC2012+SBD dataset, the mean Intersection over Union (mIoU) of the improved HRNet_S model in segmenting lower-resolution images is increased by 1.54% compared to the baseline method. Meanwhile, the improved HRNet_L model achieved a 3.05% increase in mIoU compared to the original model when handling higher-resolution image segmentation tasks on the Cityscapes dataset, and attained the highest segmentation accuracy in 15 out of the 19 different scale classification categories on this dataset.These results indicate that the proposed method not only exhibits high segmentation accuracy but also possesses strong adaptability to multi-scale objects.**

Keywords*—Semantic segmentation; HRNet; multi-branch deep strided convolution; axial attention mechanism; progressive fusion upsampling; multi-scale object adaptability

I. Introduction

Semantic segmentation aims to assign each pixel in an image to a specific semantic category, thereby enabling pixel-level understanding and segmentation of the image. In recent years, with the rapid development of fields such as autonomous driving and medical image processing, semantic segmentation technology has received widespread attention. Semantic segmentation models based on neural networks have become a research hotspot due to their high-precision segmentation capabilities. Although semantic segmentation technology has achieved remarkable application effects in multiple fields, current semantic segmentation methods still face many challenges due to the complex and variable nature of segmentation scenarios and the limitations of the segmentation models themselves. Firstly, the types of objects to be segmented are numerous, and there are significant differences in object scales. Existing semantic segmentation models have difficulties in accurately segmenting object edges and often encounter situations where small-scale objects are ignored or large-scale objects are segmented incompletely. Secondly, most existing models adopt an encoder-decoder architecture. To reduce computational complexity, multiple downsampling operations are performed during the encoder stage, which leads to the loss of a large amount of detailed information that is difficult for the decoder network to effectively recover through learning. Furthermore, existing models have not fully utilized the effective information in feature maps at various levels, making it difficult to strike a balance between shallow detailed information and deep semantic information. In response to the above issues, this paper proposes several improvements based on the HRNet [1] network framework. The main contributions are as follows:

- A Backbone Feature Enhancement Module (BFEM) is designed, which utilizes depth-wise strip convolutions of different scales to adaptively extract features from the backbone network's output. This generates appropriate weights for objects at each scale, addressing the issue of a single convolution kernel's difficulty in adapting to variations in object scales.
- A Flexible Upsampling Mechanism (FUSM) is proposed, which enhances the model's ability to restore image details by facilitating continuous information exchange between adjacent feature maps.
- To overcome the limitations of traditional spatial attention mechanisms in modeling long-distance dependencies, a novel Axial Attention Mechanism (AAM) is proposed. It independently generates attention maps along the length and width dimensions in the spatial dimension and sequentially applies these attention maps to the weighted processing of the input feature maps. While maintaining a lightweight design, it endows the output feature maps with remarkable directional sensitivity, effectively preserving the key positional information in the input features.
- For segmentation tasks involving input images with low resolution, the HRNet backbone network is combined with the Backbone Feature Enhancement Module, the Flexible Upsampling Module, and the Efficient Channel Attention Mechanism to construct the HRNet_S model.Furthermore, to address the challenge of segmenting high-resolution images, the Flexible Upsampling Module is further integrated with the AAM to optimize the decoder network of the HRNet model, resulting in the development of the HRNet_L model.

II. Related Works

To further elevate network performance, current research primarily focuses on three pivotal technological directions: aggregating multi-scale contextual information, enhancing global perception capabilities, and improving detail capture abilities.

In terms of aggregating multi-scale contextual information, multi-scale contextual aggregation networks based on dilated convolutions are widely employed. DeepLabv2 [2] achieves robust segmentation of objects across different scales by introducing atrous spatial pyramid pooling. DeepLabv3 [3] further designs a cascaded module utilizing dilated convolutions, bolstering the network's ability to detect convolutional features across multiple scales. PSPNet [4] harnesses the power of pyramid pooling modules to capture global contextual information for scene parsing tasks. DenseASPP [5] leverages an atrous spatial pyramid structure to extract a broader range of scale feature information. APCNet [6] introduces the Adaptive Pyramid Context Network, constructing multi-scale contextual representations through its meticulously designed Adaptive Context Module (ACM). SCTNet [7] enhances the efficiency of capturing multi-scale contextual information by learning semantic information alignment from Transformer to CNN.R-FPN [8] introduces learnable weights, enabling the network to adaptively utilize effective information from different scale feature maps, thereby improving the effectiveness of small object detection. The improved RCN model proposed by Zhu et al. utilizes the RFN module for multi-scale feature fusion, significantly enhancing the network's ability to recognize microscopic images [9].

To strengthen global perception and capture long-range dependencies, CCNet [10] incorporates a criss-cross attention module, collecting contextual information along criss-cross paths. OCNet [11] proposes an efficient interlaced sparse attention scheme, modeling pixel relationships through sparse relation matrices. DANet [12] adaptively integrates local and global feature dependencies, modeling semantic dependencies in both spatial and channel dimensions. Vision Transformer [13] utilizes a self-attention mechanism, dividing images into patches to construct pixel relationships and accurately capture long-distance dependencies. Building upon this, Swin Transformer [14] and Segformer [15] introduce multi-scale feature extraction and integration methods, enabling models to better understand the dependencies between elements. PIDNet [16] ingeniously utilizes ratio branches to analyze and preserve rich details in high-resolution feature maps, while leveraging integral branches to synthesize local and global contextual information, thereby capturing and processing complex long-range dependencies.

Regarding improving detail capture abilities, DeepLabv3+ [17] introduces early high-resolution feature maps during the decoding stage, enhancing segmentation accuracy at object boundaries. The UNet [18] network enhances high-resolution representations of feature maps by concatenating shallow feature maps with upsampled deep feature maps through skip connections. TransUNet [19] integrates a Transformer architecture into the UNet model, leveraging Transformers to encode image patches into sequences to capture global contextual information.

However, the improvements of most models in the past have often been confined to a specific area, which has somewhat restricted the potential for enhancing their performance [20], [21], [22]. After deeply analyzing the common characteristics of these successful cases, we successfully extracted three core elements for improving model performance. Based on this, we are committed to skillfully integrating these three aspects of improvement in order to achieve a significant leap in model performance. Therefore, we adopted a cascaded HRNet network as the basic building block, aiming to efficiently aggregate multi-scale contextual information. Subsequently, we introduced the Backbone Feature Enhancement Module and a finely designed attention mechanism to further strengthen the model's feature aggregation and representation capabilities. Finally, by introducing the Flexible Upsampling Mechanism, we significantly improved the model's ability to capture details. Compared to improvements in a single aspect, we conducted experiments to deeply explore the interaction mechanisms among different core elements and accordingly achieved an organic integration of various key improvements, thereby making the performance enhancement of the model more significant and comprehensive.

III. Proposed Method

A. Overall Model Architecture

The proposed improved semantic segmentation model based on HRNet is shown in Fig. 1. The network using the upper half of the figure as the model decoder is named HRNet_S, while the network using the lower half of the figure as the model decoder is named HRNet_L.

Firstly, the image is fed into the HRNet feature extraction network to initially obtain the deep semantic information and shallow detail information required by the model. The HRNet feature extraction network is primarily composed of four transition modules and four stage modules. The Transition module is primarily responsible for transforming the number of channels and performing downsampling operations. After processing by this module, the number of feature map channels between adjacent branches differs by a factor of two, and the length and width of the lower-resolution feature maps are half of those of the higher-resolution feature maps. Consequently, the feature maps in each connected Stage exhibit a cascaded pyramid structure. The Stage module is primarily composed of Basic Block modules, whose internal structure is identical to the residual connection modules in the ResNet network, aiming to further extract deeper-level features from the image. Within these modules, continuous skip connections occur between the branches of the cascaded pyramid feature maps to achieve the fusion of low-level and high-level features.

The HRNet_S network enriches the multi-scale characteristics of the lowest and second-lowest resolution feature map branches by introducing the Backbone Feature Enhancement Module (BFEM), which utilizes depth-wise strip convolutions with different kernel sizes. This process extends the semantic information depth of these two branches. Subsequently, the Flexible UpSampling Mechanism (FUSM) upsamples the four feature map branches in ascending order from low to high resolution. During the upsampling process, continuous information exchange occurs between different branches, achieving precise complementarity between semantic information and

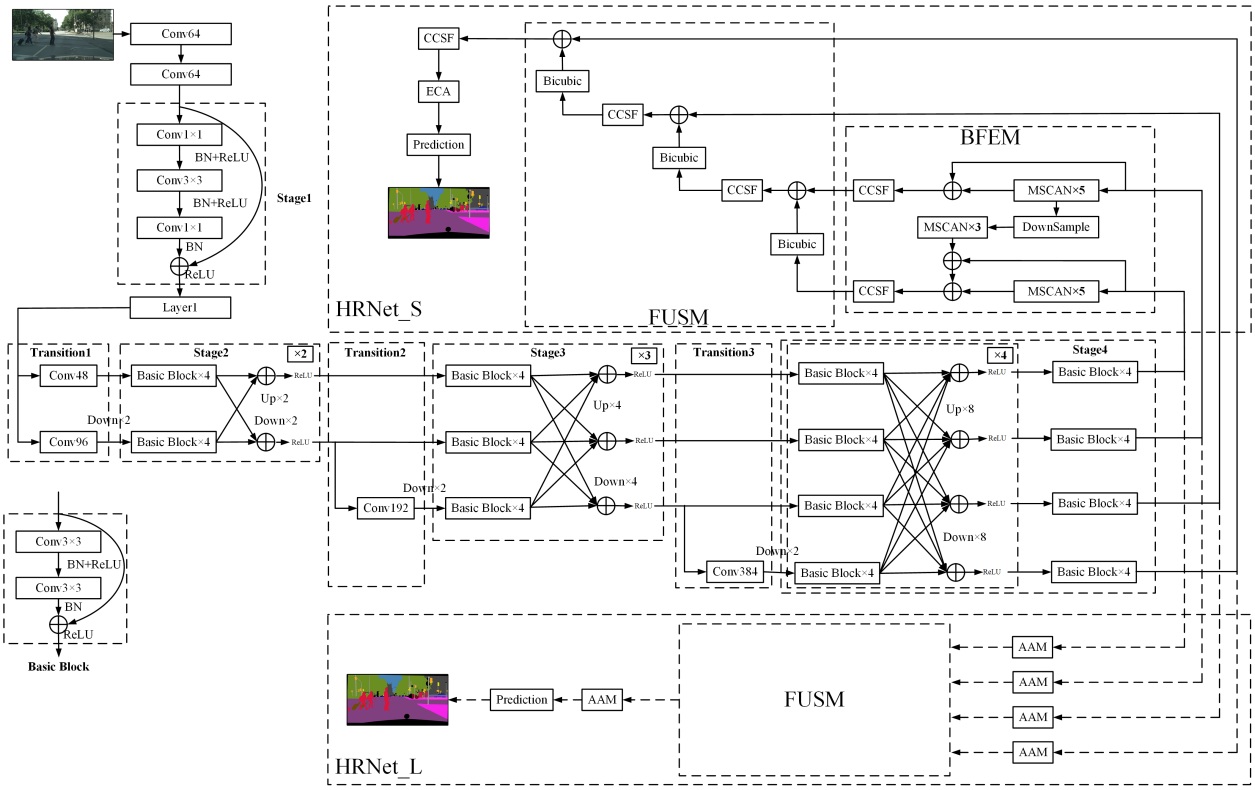

Fig. 1. Improved HRNet network architecture diagram.

detail information. Finally, the feature maps after cross-channel semantic fusion are fed into the Efficient Channel Attention (ECA) module for channel-wise weighting, enabling the network to focus on important features in a targeted manner.

In the HRNet_L network model, the feature maps output by the backbone network undergo feature aggregation along different spatial directions for each channel branch through the Axial Attention Mechanism (AAM), enhancing the model's position sensitivity to objects of interest. Immediately afterward, the feature maps of these four branches undergo upsampling in the same manner as in HRNet_S. Finally, the AAM module is utilized again to further aggregate and enhance the information in the feature maps along the spatial dimension.The HRNet_M model builds upon the HRNet_L model by adding a Cross-Channel Semantic Fusion (CCSF) module after the FUSM, while the remaining parts of the model remain consistent with the HRNet_L model.

B. Backbone Feature Enhancement Module

The structure of the Backbone Feature Enhancement Module (BFEM) is depicted in the BFEM section of Fig. 1. This module utilizes the Multi-Scale Convolutional Attention Network (MSCAN) [23] as the basic unit and strengthens the input features through step-by-step parallel connection. The final output of the sub-low-resolution feature map branch consists of two parts: one is the original feature map of the input branch, and the other is the multi-scale feature map enhanced by the original feature map after passing through five MSCAN modules. For the lowest resolution feature map branch, in addition to performing the same operations as the second-lowest resolution branch, it also concatenates with an output feature map that has undergone a $2\times$ downsampling operation and processing through three MSCAN modules. Since the concatenated branch comes from a deeper layer of the network, it contains richer and more in-depth semantic information, which is crucial for improving the accuracy of the network's category predictions. Meanwhile, the output feature maps from deeper layers have a larger receptive field, enhancing the network's ability to maintain the integrity of object segmentations and recognize large-scale objects. Finally, the semantic information from the two branches is fused through the Cross-Channel Semantic Fusion (CCSF) module. The CCSF module is composed of 1×1 convolution operations, batch normalization operations, and ReLU activation functions, enabling efficient information exchange between channels with a very low number of parameters. This operation can be represented by formula (1).

$$\mathrm{Out} = \mathrm{ReLU}\Big(\mathrm{BN}\Big(\mathrm{Conv}_{1\times1}\Big(F\Big)\Big)\Big) \tag{1}$$

Where, F represents the input feature map; Out represents the output feature map after being processed by the CCSF module.

Fig. 2(a) demonstrates the structure of the Multi-Scale Convolutional Attention (MSCA) module. Firstly, a depthwise convolution with a 5×5 kernel is employed to aggregate local information. Then, depthwise strided convolutions with sizes of 7, 11, and 21 are utilized to capture multi-scale contextual information, aiding the model in understanding contexts across

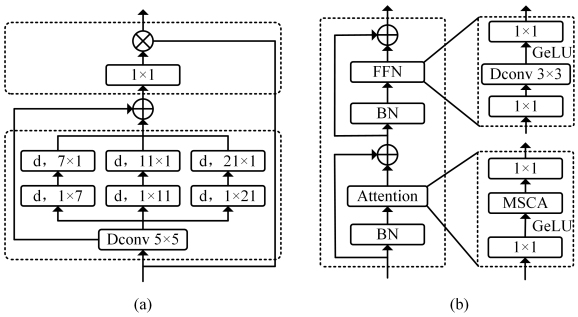

Fig. 2. (a) MSCA module and (b) MSCAN module.

different ranges [23]. Lastly, a 1×1 convolution is applied to model the relationships between different channels in the feature map, and its output is directly used to adjust the weights of the convolutional attention, achieving a weighted reconstruction of the output feature map. Compared to ordinary convolutions, the depthwise strided convolutions utilized in MSCA significantly reduce the number of model parameters. For example, a pair of 1×21 and 21×1 strided convolutions can replace a conventional 21×21 convolution, with the former requiring only 21+21=42 parameters while the latter requires 21×21=441 parameters.Mathematically, MSCA can be concisely described as a combination operation as shown in Eq. (2).

$$\begin{aligned} \text{Att} &= \text{Conv}_{1\times1}\left\{\sum_{i=0}^{3}\text{Scale}_i\Big[\text{DW-Conv}\left(F\right)\Big]\right\} \\ \text{Out} &= \text{Att}\otimes F \end{aligned} \tag{2}$$

Where: F represents the input feature map; Att denotes the attention map; DW-Conv stands for depthwise convolution; Out represents the output weighted attention feature map; $\oplus$ indicates element-wise multiplication operation in matrices; and Scale_i is the i-th branch in the MSCA diagram, where $i \in \{0, 1, 2, 3\}$.

The internal structure of MSCAN, as depicted in Fig. 2(b), primarily comprises three components: Batch Normalization (BN), Feed-Forward Neural Network (FFN), and Multi-Scale Convolutional Attention (MSCA). Among them, the FFN adopts a ResNet-like bottleneck design, aimed at reducing and expanding feature dimensions, thereby minimizing the model's parameter count and computational cost. The attention module shares a similar structure with the FFN module, with the notable difference being the replacement of the original 3×3 depthwise convolution block with the MSCA module to capture richer multi-scale contextual information. The multi-scale features and attention-weighted features output by the attention module are fused through the FFN module, generating the final feature representation.

C. Flexible Upsampling Mechanism

Upsampling operations are crucial steps indispensable for decoder networks to restore image dimensions. Traditional upsampling methods typically involve directly upsampling the deep feature maps or concatenating the upsampled deep feature maps with shallow feature maps. However, this approach has notable limitations: deep feature maps tend to lack detailed information compared to shallow feature maps, and after upsampling, there are significant differences in the distribution of semantic information between the two. This disparity and lack of information often lead to a decrease in final segmentation accuracy. To more effectively utilize the semantic and detailed information from feature maps at different scales and enhance the decoder network's ability to restore detailed information, this paper proposes a bottom-up adjacent feature map priority fusion upsampling strategy. As shown in the FUSM part of Fig. 1, this mechanism can be described by the following steps:

1) For the feature map output from the lowest resolution branch of the HRNet backbone network, a bicubic interpolation algorithm is employed for upsampling. This algorithm considers the grayscale values and their rates of change for the 16 surrounding pixels around the sampling point, generating an enlarged effect that is closer to high-resolution images, effectively preserving image details and mitigating blurring. Subsequently, the upsampled feature map is concatenated with the feature map from the next lower resolution branch along the channel dimension. Since the resolutions of the two are similar, the differences in the spatial distribution of information are relatively small. This facilitates precise alignment of key features between the feature maps, thereby promoting the retention of detailed information and reducing the introduction of noise. Following this, the concatenated feature map is processed by the CCSF module, which models the feature maps from different branches along the channel dimension, enhancing the expressive ability of important features.
2) The fused feature map is then upsampled using bicubic interpolation to match the size of the next higher resolution branch's feature map, and channel concatenation is performed with it. This process is repeated until all feature maps are upsampled to the size of the highest resolution feature map. This not only supplements the details that might be lost during the upsampling process but also enhances the semantic information in the high-resolution feature maps. Through gradual upsampling and fusion, the network can continuously interact and integrate semantic information with detailed information, thereby improving both detail recovery and category prediction accuracy. Finally, the feature map upsampled to the highest resolution will be concatenated with the feature map from the highest resolution branch, completing the entire flexible upsampling process.

Assuming F_1,F_2,F_3 and F_4 are the feature maps output by the backbone feature extraction network from the lowest to the highest resolution branches, respectively, the entire process can be expressed as Eq. (3).

$$\text{Out} = \text{CCSF}\Big(\text{Up}\Big(\text{CCSF}\Big(\text{Up}(F_1)\oplus F_2\Big)\Big)\oplus F_3\Big)\oplus F_4 \tag{3}$$

Where, $\oplus$ denotes concatenation along the channel dimension; Up represents a 2× bicubic interpolation upsampling

operation.

D. Axial Attention Mechanism

In deep learning, attention mechanisms have become a vital component, primarily comprising spatial attention and channel attention. Spatial attention mechanisms enhance focus on important regions by modeling correlations among positions on the feature map and redistributing weights to form spatial masks. In contrast, channel attention focuses on capturing the internal relationships among different channels and intelligently adjusts the importance weights of each channel's features. However, many current attention mechanisms, while fulfilling their functions, also increase the computational complexity of the model. For instance, although the Squeeze-and-Excitation (SE) [24] network can efficiently adjust weights among channels, it overlooks the significance of positional information, which is particularly crucial in tasks requiring precise spatial localization, such as semantic segmentation. The Convolutional Block Attention Module (CBAM) [25] attempts to introduce positional information in the channel dimension through global pooling, but its approach primarily relies on the multi-channel maximum and average values at each position as weight bases.This approach often captures only local information and struggles to model long-range dependencies.

To overcome this limitation, this section proposes an Axial Attention Mechanism (AAM). As shown in Fig. 3, to avoid the potential loss of positional information caused by traditional 2D global pooling, AAM decomposes the computation of spatial attention into two separate 1D feature encoding steps, performed along the length and width directions, respectively. The spatial feature vectors aggregated from these two dimensions not only contain information in their respective directions but also implicitly encode spatial position cues, which can be jointly used to efficiently integrate contextual information of spatial coordinates. The 1D pooling calculation processes along the two directions are shown in Eq. (4).

$$\begin{aligned}\text{H\_AvgPool}(F) &= \frac{1}{H}\left[\sum_{0\le j\le H} x(j,1),\cdots,\sum_{0\le j\le H} x(j,W)\right]\\ \text{W\_AvgPool}(F) &= \frac{1}{W}\left[\sum_{0\le i\le W} x(1,i),\cdots,\sum_{0\le i\le W} x(H,i)\right]\end{aligned} \tag{4}$$

Where, H_AvgPool represents the average pooling operation along the height direction, and W_AvgPool represents the average pooling operation along the width direction; H represents the height of the input image, W represents the width of the input image; F represents the input feature map, and $x(i,j)$ represents the pixel value at coordinate (i,j) in F.

Secondly, the two feature vectors rich in specific directional information are further processed to generate two attention maps. Each attention map focuses on its corresponding spatial direction and can effectively capture the long-range dependencies in that direction within the input feature map. In this way, positional information is cleverly encoded and preserved in the generated attention maps. Finally, AAM applies these two attention maps to the original input feature map through element-wise multiplication at corresponding positions, achieving the reweighting of the feature map. This operation process can be described by Eq. (5).

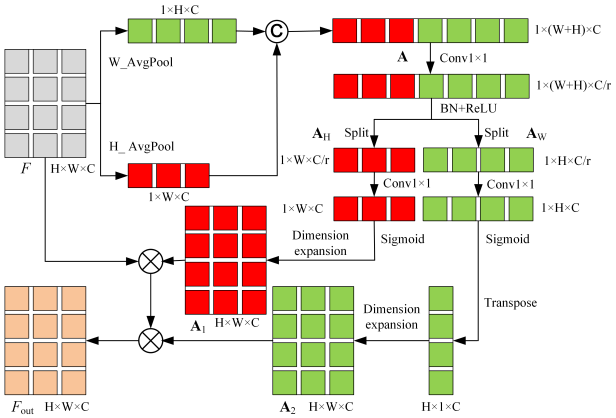

Fig. 3. Axial attention mechanism.

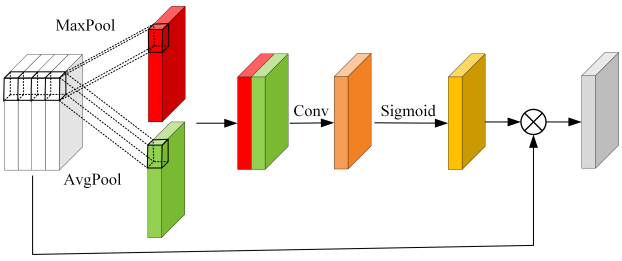

Fig. 4. Traditional spatial attention mechanism.

$$\begin{aligned}&\mathbf{A} = [\text{H\_AvgPool}(F);\text{W\_AvgPool}(F)]\\ &[\mathbf{A}_\text{H};\mathbf{A}_\text{W}]=\text{Split}\Big(\text{ReLU}\Big(\text{BN}\Big(f^{1\times1}(\mathbf{A})\Big)\Big)\Big)\\ &[\mathbf{A}_1;\mathbf{A}_2]=\text{Extend}\left[\sigma\Big(f_1^{1\times1}\Big(\mathbf{A}_\text{H}\Big)\Big);\sigma\Big(f_2^{1\times1}\Big(\mathbf{A}_\text{W}\Big)\Big)'\right]\\ &F_\text{out} = F\otimes\mathbf{A}_1\otimes\mathbf{A}_2\end{aligned} \tag{5}$$

Where, $\mathbf{A}$ represents the feature vector formed by concatenating the features from both the height and width dimensions of the input image;$\mathbf{A}_\text{H}$ and $\mathbf{A}_\text{W}$ represent the intermediate vectors obtained after performing channel dimension reduction on the features from the height and width dimensions, respectively.$\mathbf{A}_1$ and $\mathbf{A}_2$ represent the length and width directional attention matrices obtained by expanding the channel dimension and spatially expanding (replicating the single-dimensional vectors along a certain direction to match the matrix size of F) from $\mathbf{A}_\text{H}$ and $\mathbf{A}_\text{W}$, respectively.$\otimes$ denotes element-wise multiplication of corresponding positions in the matrices.

AAM not only enhances the directional sensitivity of the feature map but also retains crucial positional information, ensuring that the output results more accurately map the target regions in the image. Consequently, when performing dense prediction tasks such as semantic segmentation, AAM can significantly improve the localization accuracy of the model.

Assuming the input feature map has C channels, a height of H, and a width of W, and all convolution operations

employ 1×1 convolutional kernels. In the channel compression stage, AAM uses a compression factor r. Then, the computational complexity of the AAM attention mechanism and the traditional attention mechanism can be estimated using Eq. (6) and (7), respectively, both of which remain at the order of $O(C \cdot H \cdot W)$. Compared to traditional spatial attention mechanisms, AAM effectively captures long-range dependencies while hardly increasing computational complexity. This significant advantage makes AAM more competitive in scenarios involving high-resolution images or high real-time requirements.

$$O(\text{AAM}) = O(4 \cdot C \cdot H \cdot W) + O\Big(2 \cdot \frac{C}{\text{r}} \cdot (H+W)\Big) + O\Big(C \cdot (H+W)\Big) = O(C \cdot H \cdot W) \tag{6}$$

The computational complexity of pooling operations in both the height and width directions is $O\left(2 \cdot C \cdot H \cdot W\right)$; the computational complexity of channel compression and recovery operations is $O\left(2 \cdot \frac{C}{\text{r}} \cdot (H+W)\right)$; the complexity of the Sigmoid function can be considered as $O\left(C \cdot (H+W)\right)$; and the complexity of the two element-wise multiplications can be considered as $O\left(2 \cdot C \cdot H \cdot W\right)$. In practical applications, $\frac{C}{\text{r}}$ can be regarded as a constant, therefore, the above results can be simplified to $O\left(C \cdot H \cdot W\right)$.

The schematic diagram of the traditional spatial attention mechanism is shown in Fig. 4, and its computational complexity can be expressed as Eq. (7).

$$O\left(\cdot\right) = O\left(6 \cdot C \cdot H \cdot W\right) = O\left(C \cdot H \cdot W\right) \tag{7}$$

The computational complexity of max pooling and average pooling is $O\left(2 \cdot C \cdot H \cdot W\right)$; the computational complexity of convolution operations is $O\left(2 \cdot C \cdot H \cdot W\right)$; the computational complexity of the Sigmoid operation is $O\left(C \cdot H \cdot W\right)$; The computational complexity of element-wise multiplication operation can be considered as $O\left(C \cdot H \cdot W\right)$.

IV. Experiment

A. Experimental Dataset

The Cityscapes dataset, jointly provided by three German institutions including Daimler AG, comprises stereo vision data from over 50 cities, featuring a total of 5000 finely annotated and 20000 coarsely annotated images of urban street scenes. In the experiments, only the 5000 finely annotated images are utilized, with 2975 for training, 500 for validation, and 1525 for testing. Each image has a resolution of 1024 pixels × 2048 pixels and is densely annotated with 19 object categories. Since the labels for the test set in the Cityscapes dataset are not publicly available, this paper evaluates the models on the validation set.

The PASCAL VOC2012+SBD dataset is an extension of the PASCAL VOC2012 dataset, obtained by merging PASCAL VOC2012 with the SBD dataset. After removing duplicate images from both datasets, this augmented dataset comprises a total of 12031 annotated images covering 20 different object categories. The images are randomly split into training and validation sets at a 9:1 ratio, with 10827 images for training and 1204 images for validation. Similarly, the models are evaluated on the validation set.

TABLE I. Experimental Hardware and Software Environment

Project Detail	Specification
CPU	16 vCPU Intel(R) Xeon(R) Platinum 8350C CPU @ 2.60GHz
GPU	NVIDIA GeForce RTX 3090 GPU(24GB) × 1
RAM	42GB
CUDA	12.2
Python type	3.8.10
Operating system	Ubuntu 18.04.5 LTS
Development framework	Torch 2.2.1

B. Experimental Environment and Parameter Settings

All networks in the experiment were implemented based on the PyTorch framework, and the hardware and software environments used during the training process are detailed in Table I. The hyperparameter settings during the training process are shown in Table II. The experiments used stochastic gradient descent with momentum for gradient updates. The learning rate decay adopted a cosine annealing schedule, with the specific calculation process described in Eq. (8).

$$lr = min\_lr + 0.5 \cdot (initial\_lr - min\_lr) \cdot \left(1 + \cos\left(\pi \cdot \frac{iter}{total\_iter}\right)\right) \tag{8}$$

Where, $initial\_lr$ represents the initial learning rate; min_lr is the minimum learning rate, which is set to 1/100 of $initial\_lr$; lr represents the current learning rate; $iter$ is the current iteration number; and $total\_iter$ represents the total number of iterations.

For models trained on the Cityscapes dataset, a combination of Focal Loss and Dice Loss was adopted as the loss function. Focal Loss can effectively address the class imbalance issue present in the Cityscapes dataset, while Dice Loss enhances the accuracy of edge prediction. Combining these two losses optimizes the training effect of the model. On the PASCAL VOC2012+SBD dataset, where the class distribution is relatively balanced, a simple CE Loss (Cross-Entropy Loss) was chosen as the loss function.To optimize the training process, bilinear interpolation was used to uniformly resize the image resolution in the Cityscapes dataset to 512 pixels × 1024 pixels, while the image resolution in the PASCAL VOC2012+SBD dataset was adjusted to 512 pixels × 512 pixels. For training all models, a transfer learning strategy was employed, where pre-trained weights on the ImageNet dataset were loaded into the backbone network, and a frozen training phase of 50 epochs was first conducted. For models trained on the PASCAL VOC2012+SBD dataset, the number of training epochs was set to 200, while for models trained on the Cityscapes dataset, the number of training epochs was set to 300.

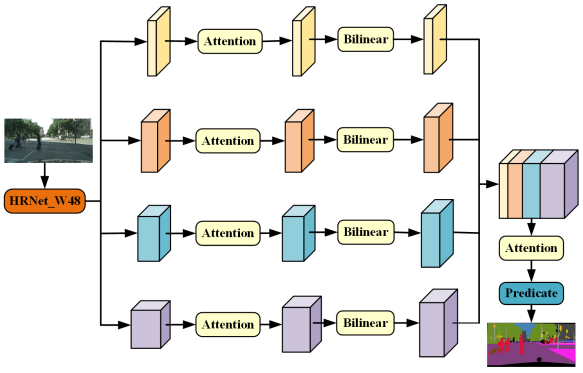

Fig. 5. Schematic diagram of attention mechanism embedding positions.

C. Experimental Results and Analysis

1) Attention selection experiment: To investigate the impact of different attention mechanisms on the segmentation performance of the model, a series of attention mechanisms were sequentially embedded into the "Attention" positions in Fig. 5 for training. These mechanisms include Strip Pooling (SP) [26], CBAM, AAM, SE, and ECA. Analyzing the experimental data in Fig. 6, it can be seen that when the test image resolution is 512 pixels×1024 pixels, the combination of the HRNet network with ECA achieves the best segmentation accuracy, with a 1.12% improvement in mean Intersection over Union (mIoU) compared to the original HRNet model. When the test image resolution is 1024 pixels×2048 pixels, the combination of HRNet with the AAM attention mechanism performs particularly well, with a 2.34% increase in mIoU compared to the original model.

ECA, AAM and CBAM, all have a positive impact on improving the segmentation accuracy of HRNet. Preliminary analysis indicates that when processing lower-resolution test images, channel attention mechanisms can significantly enhance the segmentation accuracy of the model. However, as the resolution of the test images increases, spatial attention mechanisms gradually demonstrate their unique advantage in improving model accuracy. The reason may be that when processing high-resolution images, channel attention mechanisms require deeper spatial information compression, leading to significant loss of spatial pixel information in the feature maps. Due to this information loss, channel attention weights cannot effectively measure the importance of information in the feature maps, resulting in suboptimal weighting effects on the feature maps. However, such issues do not exist when using spatial attention mechanisms.

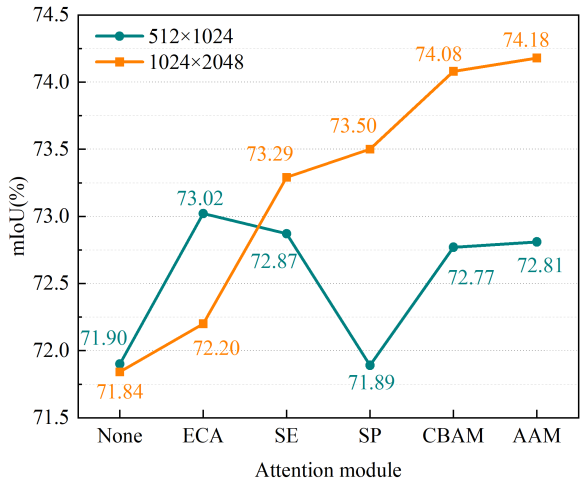

Fig. 6. Comparison of mIoU using HRNet with different attention mechanisms.

TABLE III. ABLATION EXPERIMENT RESULTS ON CITYSCAPES DATASET

BFEM	FUSM	CCSF	ECA	AAM	mIoU *(%)	mIoU ^(%)	Params /M	FLOPs */G	FLOPs ^/T
					72.34	71.79	**65.860**	**376.184**	**1.505**

[1] "*" indicates that the image resolution used during testing is 512 pixels×1024 pixels, "^" indicates that the image resolution used during testing is 1024 pixels×2048 pixels.
[2] FLOPs stands for Floating-Point Operations, referring to the total number of basic arithmetic operations (addition, subtraction, multiplication, division, etc.) required by the model during execution, which directly reflects the computational complexity of the model.
[3] G represents billion (10^9) level of operations, and T represents trillion (10^{12}) level of operations.

2) Ablation study: To validate the effectiveness of the added modules, this section sequentially adds different (combinations of) modules to the HRNet and conducts experimental verifications. The experimental results are detailed in Table III. To more intuitively demonstrate the improvement effects of each module (and their combinations) on segmentation accuracy (mIoU), the incremental data is plotted into a bar chart as shown in Fig. 7.

When the resolution of the test images is 512 pixels×1024 pixels, the impact of each module on model performance:

FUSM: After introducing this module, the model's mIoU metric improves by 0.91%, while only introducing a small increase in parameters (0.786M) and computations (8.812G). This indicates that FUSM enhances segmentation accuracy while maintaining model efficiency, particularly excelling in detail recovery.

CCSF: Adding this module on top of FUSM further boosts

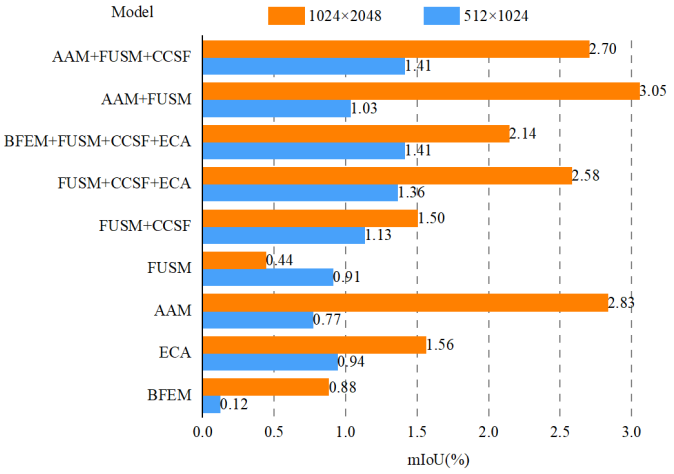

Fig. 7. The improvement in mIoU after integrating various (combinations of) modules into HRNet.

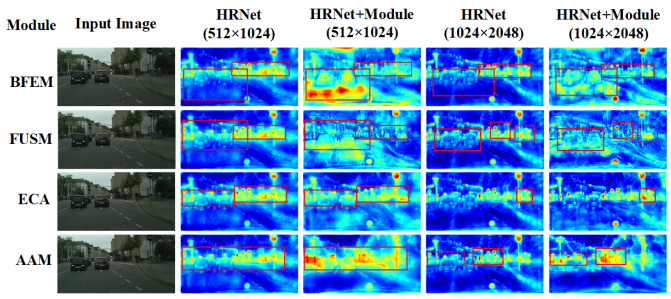

Fig. 8. Heatmap outputs before the fully connected classification layer when combining HRNet with various modules.

the mIoU metric by 0.22%. However, it significantly increases the computational cost by 34.162G. This suggests that while CCSF can improve accuracy, it comes with a relatively high computational overhead.

ECA: Incorporating this module enhances the mIoU metric by 0.27% with virtually no additional parameters or computations, demonstrating ECA's efficiency in capturing crucial information.

BFEM: Upon introduction, the mIoU metric surges to a peak of 73.75%, showcasing the module's remarkable ability to enrich multi-scale contextual information and deepen semantic understanding. However, this substantial improvement is accompanied by a notable increase in both spatial and temporal complexity of the model (an increase of 18.481M parameters and 26.734G total floating-point operations), indicating that higher computational costs are necessary to achieve this level of performance enhancement.

When the resolution of the test images is 1024 pixels$\times$2048 pixels, the impact of each module on model performance:

AAM: After introducing AAM, the mIoU significantly improves by 2.83% with only a small increase in parameters (0.268M) and almost no increase in computational complexity, demonstrating its efficient capability in processing spatial information.

FUSM: Further incorporating FUSM on top of AAM elevates the mIoU to 78.48%, achieving the optimal value. The increases in parameters and computations are relatively small, at 0.786M and 0.035T respectively, indicating that FUSM can still effectively enhance accuracy while maintaining its lightweight advantage at high resolutions.

CCSF: Adding the CCSF module to the AAM+FUSM combination unexpectedly decreases the mIoU to 74.49%, underperforming expectations, especially in high-resolution scenarios.Possible reasons for this phenomenon include: increased information redundancy or conflicts between feature maps, a high computational burden due to elevated model complexity, and complex interactions between modules that affect the model optimization process.

Fig. 8 shows heatmaps output by HRNet and its combinations with different modules, revealing the impact of each module on changes in target attention. The original HRNet heatmap primarily focuses on small targets such as bicycles and pedestrians, indicating its advantage in recognizing small-scale objects. After introducing the BFEM module, the heatmap not only continues to pay attention to small-scale targets but also starts to focus on large targets like cars and roads, suggesting that BFEM enhances the model's recognition capabilities for multi-scale targets. The addition of the FUSM module makes the temperature distribution of the heatmap more uniform and emphasizes object edges more strongly, indicating that FUSM improves the model's scene and contour perception abilities. The ECA module enables the model to more precisely focus on critical targets, contributing to enhanced feature extraction capabilities. Lastly, the AAM module clarifies the location information of objects of interest by enhancing the contrast between hot and cold regions, thereby improving the model's segmentation accuracy.

In summary, each module exhibits unique characteristics in image segmentation tasks, and their effects are significantly influenced by resolution and application scenarios. FUSM and ECA demonstrate a good balance between precision improvement and complexity control across different resolutions. While CCSF and BFEM can enhance performance, the associated increase in computational complexity cannot be overlooked. AAM is particularly efficient at high resolutions, highlighting its advantage in spatial information processing. In practical applications, the optimal combination of modules should be flexibly selected and configured based on specific requirements and environmental conditions to achieve the best balance between performance and computational efficiency.

3) Comparison with State-of-the-Art methods: To validate the performance of the proposed method in semantic segmentation, this section compares it with various state-of-the-art approaches on two standard datasets: Cityscapes and PASCAL VOC2012+SBD. The compared methods include DeepLabv3_R (based on ResNet50), DeepLabv3_X (based on Xception), PSPNet, SegFormer, SeaFormer-S, SeaFormer-B, SCTNet-S, and HRNet. The segmentation results on Cityscapes and PASCAL VOC2012+SBD datasets are presented in Tables IV and V, respectively.

Analyzing the data in Table IV, it can be observed that at a resolution of 512 pixels$\times$1024 pixels, both HRNet_S and HRNet_M achieve an optimal segmentation accuracy (mIoU)

TABLE IV. COMPARISON OF THE IMPROVED MODEL WITH STATE-OF-THE-ART METHODS ON THE CITYSCAPES DATASET

Model	mIoU *(%)	mIoU ˆ(%)	Params /M	FLOPs */G	FLOPs ˆ/T
DeepLabv3+_R[17]	70.36	71.33	**40.354**	732.532	2.930
PSPNet[4]	68.57	69.22	48.957	749.149	2.996
SegFormer[15]	72.05	72.32	47.238	**286.349**	1.145
SeaFormer-S[27]	-	70.70	-	-	**0.02**
SeaFormer-B[27]	-	72.70	-	-	0.03
SCTNet-S[7]	72.80	-	4.6	-	-
HRNet[1]	72.34	71.79	65.860	376.184	1.505
HRNet_S(ours)	**73.75**	73.93	85.647	445.939	1.784
HRNet_M(ours)	**73.75**	74.49	67.434	419.265	1.677
HRNet_L(ours)	73.37	**74.84**	66.914	385.102	1.540

TABLE V. COMPARISON OF THE IMPROVED MODEL WITH STATE-OF-THE-ART METHODS ON THE PASCAL VOC2012+SBD DATASET

Model	mIoU(%)	Params/M	FLOPs/G
DeepLabv3+_R[17]	75.68	**40.354**	366.275
DeepLabv3+_X[17]	77.82	54.714	486.773
PSPNet[4]	75.45	48.958	374.634
SegFormer[15]	**80.30**	47.239	**143.199**
HRNet[1]	77.42	65.861	188.116
HRNet_S(ours)	78.93	85.648	222.993
HRNet_M(ours)	77.62	67.435	209.674
HRNet_L(ours)	76.49	66.915	192.529

of 73.75%, surpassing the novel SegFormer model by 1.70%. Even when compared with the recent SCTNet-S model, it remains 0.95% higher. When processing images with a higher resolution of 1024 pixels×2048 pixels, the mIoU of the HRNet_L model climbs to 74.84%, outperforming SegFormer by 2.52%. Even when compared with the recent SeaFormer-B model, it remains 2.14% higher. However, in terms of parameter count and computational complexity, HRNet shows slight increases compared to SegFormer and does not have an advantage over SegFormer-B in terms of computational efficiency. Therefore, lightweight design of the model is a key focus for future research.

TABLE VI. WHEN THE TEST IMAGE RESOLUTION IS 1024 PIXELS×2048 PIXELS, THE PER-CATEGORY MIOU OF DIFFERENT MODELS ON THE CITYSCAPES DATASET (%)

Category	PSPNet	DeepLabv3+_R	SegFormer	HRNet	HRNet_L

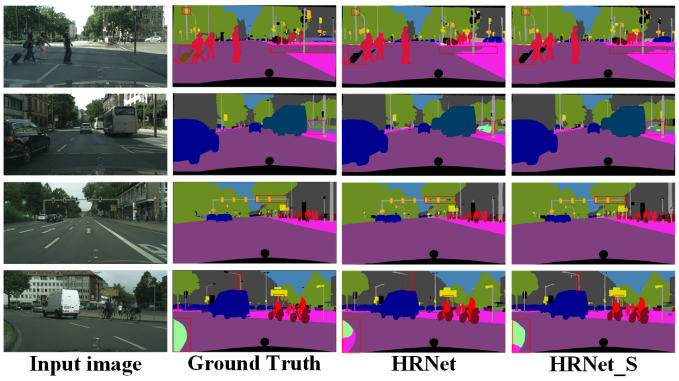

Fig. 9. The segmentation effect images of different models on the Cityscapes dataset when the test image resolution is 512 pixels×1024 pixels.

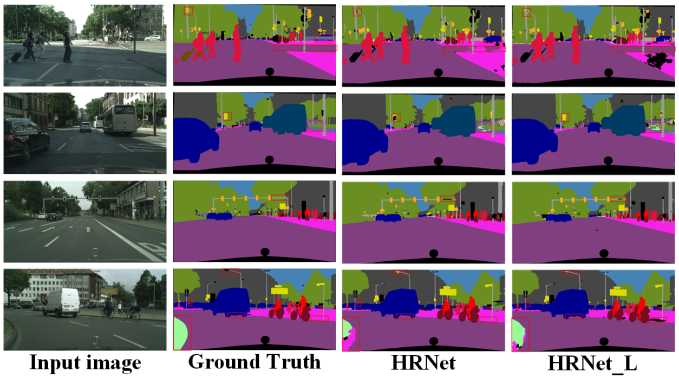

Fig. 10. The segmentation effect images of different models on the Cityscapes dataset when the test image resolution is 1024 pixels×2048 pixels.

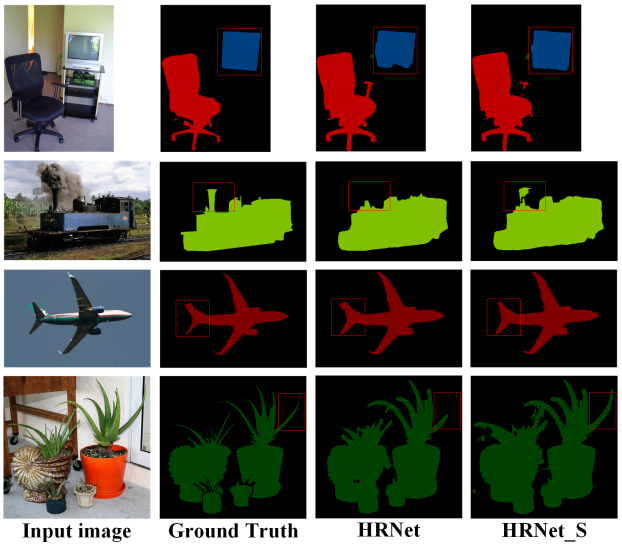

Fig. 11. Segmentation effect images of different models on the PASCAL VOC2012+SBD dataset.

As shown in Table V, on the PASCAL VOC2012+SBD dataset, for low-resolution images of 512 pixels×512 pixels, the mIoU of the HRNet_S model reaches 78.93%. Although

slightly lower in segmentation accuracy compared to the SegFormer model, HRNet_S has significantly narrowed the gap with SegFormer, demonstrating its competitiveness in low-resolution image segmentation tasks. However, from the perspective of algorithmic complexity, there is still room for further optimization of the HRNet_S model.

Combing the experimental data from Tables IV and V, from the perspectives of segmentation accuracy and model complexity, HRNet_M can be considered as a balanced choice between HRNet_S and HRNet_L. In terms of increasing computational complexity, the order is: HRNet_L, HRNet_M, HRNet_S. Additionally, the segmentation accuracy of HRNet_M also falls between that of HRNet_S and HRNet_L across different resolutions.

As shown in Table VI, which presents the category-wise mIoU data of various models on the Cityscapes dataset when tested on images with a resolution of 1024 pixels$\times$2048 pixels, it can be observed that HRNet_L significantly improves the segmentation accuracy for large-scale objects such as trucks, buses, and trains at this high resolution of 1024 pixels$\times$2048 pixels. Furthermore, HRNet_L achieves the highest accuracy in 15 out of the 19 different scale-varying categories.

To intuitively demonstrate the superiority of the proposed method in semantic segmentation tasks, this section comprehensively evaluates its segmentation effects through visual comparison experiments with the baseline method, HRNet. Fig. 9 and 10 showcase the segmentation effects of the models on Cityscapes dataset for test images with different resolutions. From these two figures, it can be observed that HRNet exhibits some shortcomings in image segmentation, particularly in road contours, traffic sign recognition, and segmentation accuracy of elongated objects such as streetlights. Additionally, it tends to confuse vegetation with terrain. However, these deficiencies are significantly improved in the proposed enhanced models, HRNet_S and HRNet_L. Fig. 11 further presents the segmentation effects of the models on the PASCAL VOC2012+SBD dataset. On this dataset, HRNet_S notably enhances the segmentation accuracy of TV and airplane wing boundaries compared to the original HRNet. Simultaneously, it exhibits more refined segmentation capabilities for complex structures such as ship funnels and vegetation leaves. This indicates that the proposed method comprehends contextual semantic information more comprehensively than the original model, validating its effectiveness in improving segmentation accuracy and detail preservation.

Based on the HRNet network, this paper introduces specific modules and successfully develops a model suitable for image segmentation across different resolutions. Specifically, the HRNet_S model demonstrates exceptional segmentation performance when dealing with lower-resolution images. However, due to its relatively high number of parameters and computational complexity, when handling higher-resolution image segmentation tasks, the significant increase in computational load becomes particularly evident, which may lead to inadequate model training and subsequently affect its final performance. Additionally, the Efficient Channel Attention Mechanism employed in HRNet_S may overly compress the valuable information in high-resolution images, adversely impacting the model's ultimate performance. In contrast, the HRNet_L model is more lightweight, thus having an advantage when dealing with higher-resolution image segmentation tasks. Its use of the AAM attention mechanism effectively aggregates valuable information in high-resolution images, which is a key factor contributing to its superior performance. However, compared to the HRNet_S model, the HRNet_L model lacks depth in semantic information, making its advantage less pronounced when handling lower-resolution image segmentation tasks.

Therefore, in practical production and life, we should select the appropriate variant of the HRNet model based on factors such as the resolution of the dataset and the application scenario, in order to achieve the best segmentation results and ensure that the model can perform optimally in image segmentation tasks across different resolutions.

V. Conclusion

Addressing the challenges faced by existing semantic segmentation networks in handling multi-scale objects, such as the tendency to lose small-scale objects, incomplete segmentation of large-scale objects, and low overall segmentation accuracy, this paper proposes an improved method based on the HRNet network. Firstly, a backbone feature enhancement module is introduced using deep stripe convolutions, which enhances the network's adaptability to multi-scale objects, overcomes the limitations of a single convolutional kernel in feature extraction, expands the model's perception range of contextual information, and enhances the network's ability to understand complex scenes. Secondly, an axial attention mechanism is employed to model the global dependency relationships within the feature maps output by the backbone network, enabling precise localization of regions of interest. Lastly, a flexible upsampling mechanism is adopted, leveraging the complementary fusion of semantic and detail information between adjacent feature maps, to effectively restore target detail information in the decoder network. Experimental results show that the proposed algorithm achieves the highest segmentation accuracy compared to other algorithms on the Cityscapes dataset. Similarly, the segmentation accuracy of the proposed algorithm on the PASCAL VOC 2012+SBD dataset is also outstanding, verifying the effectiveness of the proposed method. Further ablation studies also confirm the contributions of each improved component to enhancing the overall performance. The relevant implementation code for this paper has been uploaded to the GitHub platform (link: https://github.com/HanLeiFeng/HRNet_Series.git) for learning and exchange.

***Abstract*—The objective of this study is to address the complex task of identifying optimal locations for mountain hiking sites in the Eastern High Atlas region of Morocco, considering topographical factors. The study assesses the effectiveness of a commonly used machine learning classifier (MLC) in mapping potential mountain hiking areas, which is crucial for promoting and enhancing tourism in the area. To begin with, an extensive inventory of 120 mountain hiking sites was conducted, and precise measurements of three topographical parameters were collected at each site. Subsequently, a machine learning algorithm called Bagging was employed to develop a predictive model. The model achieved a high performance, with an area under the curve (AUC) value of 0.93. The model effectively identified favorable areas, encompassing around 24% of the study region, which were predominantly located in the western part. These areas were characterized by mountainous terrain, shorter slopes, and higher altitudes. The research findings provide valuable guidance to decision-makers, offering a roadmap to enhance the discovery of mountain hiking sites in the region.**

Keywords*—Machine learning; mountain hiking; AI-based tourism; GIS; remote sensing; tourism; bagging algorithm; decision-making

I. Introduction

Mountain hiking, also known as mountain trekking or mountaineering, is an outdoor recreational activity that involves exploring and traversing mountainous regions on foot. It typically involves escalating and descending mountains or traversing steep and rugged terrain. Mountain hiking often requires physical endurance, technical skills, and knowledge of mountaineering techniques such as navigation, rock climbing, and rope handling. Hikers engage in this activity to experience the natural beauty of mountain landscapes, challenge themselves physically and mentally, and achieve personal goals. Mountain hiking can range from leisurely day hikes on well-marked trails to multi-day expeditions that may involve camping and navigating through remote and challenging environments.

For this purpose, mountaineering has been addressed in several studies regarding its relationship with tourism, the environment, and the emotional aspects of mountaineers. The study conducted by Wang et al. [1] focuses on the contribution of mountaineering to the creation of lasting and impactful tourism experiences. By utilizing Mount Huangshan in China as a case study, the research explores how sensory perceptions, physical engagement, and emotional connections play a pivotal role in shaping the memories of tourists who engage in hiking activities within this renowned mountainous region.

On the other hand, the research conducted by Galiakbarov et al. [2] delved into the psychological and spiritual aspects of mountaineering, using calling theory to explore why individuals engage in this activity. Their research sheds light on the deeply personal motivations behind mountaineering as a purposeful and transformative experience. However, the study lacks focus on geographic and environmental factors that influence the suitability of certain regions for mountaineering, creating a gap that this research aims to address.

Several studies have also investigated the environmental aspects of mountaineering. Naseri et al. [3] examined the environmental, social, and economic dimensions of sustainable development in mountaineering tourism. Their work emphasized the need for sustainable practices to protect fragile mountain ecosystems while fostering tourism. However, geographic-specific methodologies for identifying suitable hiking sites, particularly in under-researched areas like the High Atlas of Morocco, remain limited. This gap becomes especially relevant in regions with rich biodiversity and geological formations, where tourism can play a pivotal role in both economic development and environmental conservation.

Liu et al. [4] explored the connection between leisure participation in mountaineering and environmentally responsible behavior, focusing on how emotional bonds with landscapes (place attachments) influence conservation attitudes. This emphasizes the importance of understanding not only the environmental but also the cultural and emotional factors that drive sustainable tourism development.

Similarly, Rogerson et al. [5] traced the historical evolution of mountaineering tourism in South Africa, showing how cultural and historical significance contributes to the development of special interest tourism. While these studies offer valuable insights, they do not address how modern technological tools like machine learning algorithms can assist in identifying new areas for mountain tourism based on geographical and topographical factors.

In Morocco, research on mountain hiking tourism remains scarce, particularly in the eastern High Atlas region. A notable exception is the study by Kchikach et al. [6], which focuses

on the UNESCO M'Goun Geopark in the central High Atlas. The eastern High Atlas, however, despite being known for its jagged peaks, deep gorges, and ancient rock structures, has not been extensively studied in the context of tourism development. This region holds significant potential for mountain hiking and climbing due to its unique geological formations and natural beauty, making it an ideal candidate for tourism-related research.

To address this gap, this study introduces a novel approach by leveraging machine learning algorithms, specifically Bagging, to identify potential hiking sites in the eastern High Atlas. Bagging, a robust ensemble learning method, was selected due to its ability to improve the accuracy and stability of predictions, particularly in geographic modeling tasks where data variability is high.

Furthermore, the study uses the Area Under the Curve (AUC) and Receiver Operating Characteristic (ROC) metrics to evaluate model performance, ensuring a rigorous assessment of the results. These methods are widely accepted for evaluating the accuracy of predictive models, particularly in machine learning-based geographic studies. The combination of AUC and ROC analysis with Bagging ensures a comprehensive approach to identifying suitable mountain hiking locations based on geographic data.

In addition to the technical aspects, this research has broader implications for sustainable tourism development in Morocco. By identifying suitable hiking locations, the study contributes to the sustainable management of natural resources and helps promote ecotourism in underdeveloped areas. Sustainable tourism practices, which are essential for preserving the environmental and cultural heritage of the region, can be informed by the findings of this study. As tourism continues to grow in the High Atlas, ensuring that it is developed in an environmentally responsible manner is crucial for maintaining the long-term viability of these destinations.

The implications of this research extend beyond the immediate identification of suitable hiking sites. By integrating advanced machine learning techniques into the tourism development process, this study establishes a precedent for leveraging technology to advance the tourism sector in Morocco and globally [7], [8], while also enhancing environmental conservation efforts.

The findings will not only support sustainable tourism initiatives but also contribute to the long-term preservation of the High Atlas's unique ecosystems and cultural heritage. This alignment of tourism with conservation principles can foster a more responsible tourism industry, encouraging both local communities and policymakers to prioritize sustainable practices that benefit the environment and the economy

II. Materials and Methods

A. Study Area

The upper Ziz area in the eastern High Atlas region of southeastern Morocco (Fig. 1) experiences a semi-arid climate with cold winters and dry summers, as indicated by Manaouch et al. [9]. The average annual precipitation ranges from 119 to 377 mm, and temperatures vary between 10.2 and 19.2°C, as documented by Manaouch et al. [10]. The elevation ranges from 1023 to 3687 meters above sea level, with slopes ranging from 0 to 66°C, as noted by Manaouch et al. [11].

This region boasts numerous mountain hiking sites that showcase its unique geological and geomorphological features. These sites provide opportunities for tourism, offering insights into the region's geological history. Among these sites, the Gorges of Ziz are particularly remarkable. Carved by the Ziz river over millennia, these limestone gorges feature towering cliffs and winding canyons, creating a breathtaking landscape. Their geological significance and picturesque beauty make them a magnet for geologists and nature enthusiasts alike.

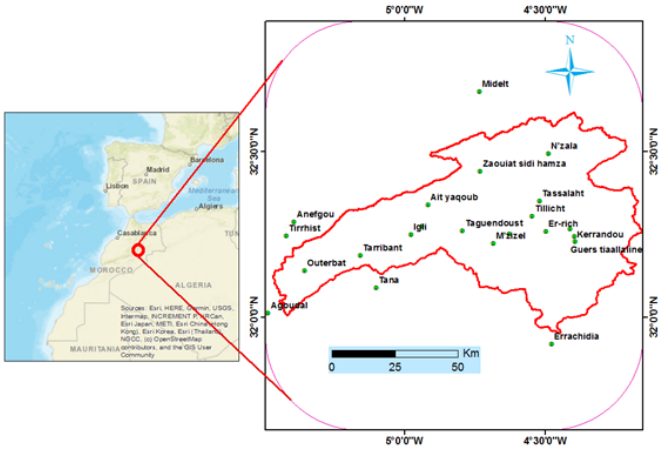

Fig. 1. Location of the eastern high atlas of upper Ziz in Morocco.

B. Data Used and Mountain Hiking Sites Inventory

Accurate identification and selection of mountain hiking sites require a thorough analysis of the phenomenon and its underlying factors [12]. This study conducted extensive field visits in the eastern High Atlas of upper Ziz, SE Morocco, identifying and modeling a total of 120 mountain hiking sites. An equal number of non-mountain hiking sites were also considered to ensure a balanced approach (Fig. 2).

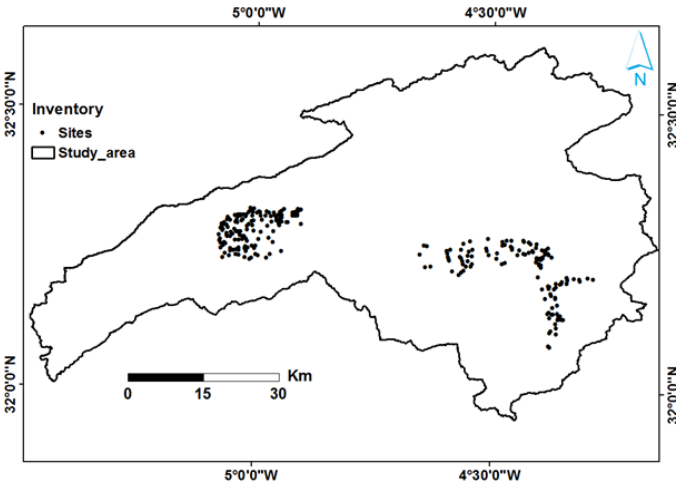

Fig. 2. Mountain hiking sites inventory map.

The study incorporated three conditioning factors (slope, length of slope, and elevation) as independent variables influencing the suitability of areas for mountain hiking sites. These variables were measured for the 240 selected sites. The dataset was divided into training data (70%) and validation data (30%) following established spatial modeling conventions.

Data processing was performed using ArcGIS 10.5 and SPSS Statistics 26 software, which enabled the transformation of geospatial data into a tabular format. The dataset was prepared for analysis by importing data, defining attributes, executing geoprocessing tools, configuring parameters, and performing geoprocessing operations. Model validation was conducted using the Area Under the Curve (AUC) of the receiver operating characteristic (ROC), a common method in geospatial modeling studies to assess and validate model reliability [10].

C. Mountain Hiking Sites (MHS)

Mountain hiking sites (MHS) are of paramount importance in various fields such as environmental education, recreation, and sports [13]. These sites not only offer opportunities for exploration and the appreciation of natural landscapes but also serve as key locations for ecological studies, conservation efforts, and physical fitness activities [14]. Canyons, cliffs, and other geological formations are significant not just for their scenic beauty but also for the insight they provide into the Earth's geological history, making them valuable for scientific research and outdoor education [15].

In addition to their value in education and conservation, MHS contribute to local economies by supporting activities such as mountaineering, hiking, and outdoor excursions, which often require the development of infrastructure such as trails, shelters, and conservation measures. These efforts foster sustainable practices and environmental stewardship while providing recreational opportunities [16].

Fig. 3. Mountainous hiking sites and mountain hikers encountered in the upper Ziz.

While mountain hiking sites are frequently associated with tourism, their broader significance spans disciplines like environmental science, geography, and physical education [17]. In particular, these sites are ideal for studying geomorphological processes, fostering a deeper understanding of natural erosion and sedimentation patterns [18]. Mountain hiking activities, especially in regions like the upper Ziz valley, support not only recreation but also health and well-being through physical fitness and mental restoration [19].

Fig. 3 provides visual examples of mountain hiking sites and hikers along the Ziz valley, showcasing their versatility and value across multiple domains.

III. Methodology

Fig. 4 depicts a flowchart that outlines the sequential procedure employed to evaluate the suitability of mountain hiking locations utilizing an advanced machine learning algorithm. The methodology begins with gathering data from diverse sources, including Google Earth images, field surveys, geological maps, Landsat 8 OLI images, and previous studies. By consolidating this information, a comprehensive database is created, serving as the foundation for the analysis.

Key mountain hiking conditioning factors (MHCFs) such as slope, length of slope, and elevation are identified and incorporated into the study. These factors are crucial in determining the suitability of hiking locations. An inventory map is developed, detailing 240 sites that serve as reference points for the evaluation process. The MHCFs undergo geoprocessing, which involves manipulating spatial data to derive meaningful insights. This step ensures that the data is in a suitable format for further analysis. The processed data is stored in a centralized database, facilitating convenient access and management.

To build and validate the machine learning model, the data is split into training and testing sets, with 70% allocated for training and 30% for testing. This division is essential for developing a robust and reliable model. The process also includes calculating frequency ratios, normalizing data, examining spatial relationships, and preparing data layers, all of which ensure the data is ready for analysis.

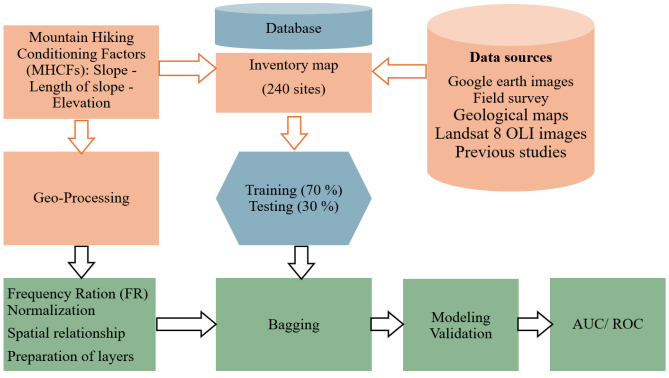

Fig. 4. Flowchart of the modeling strategy used.

The final step involves evaluating the model's performance using AUC (Area Under the Curve) and ROC (Receiver Operating Characteristic) metrics. These metrics provide a measure of the model's accuracy and effectiveness, ensuring the methodology yields reliable results for assessing mountain hiking locations. The subsequent sections offer a comprehensive and detailed explanation of this methodology, providing a deeper understanding of the approach.

A. Mountain Hiking Conditioning Factors (MHCFs)

Topographic factors such as slope, slope length, and elevation significantly impact the suitability of mountainous areas for hiking. These factors influence the characteristics and spatial distribution of land formations. The following sections discuss each factor in detail and provide visual maps representing them.

1) Elevation: Elevation is a crucial attribute in mountain hiking site identification as it helps differentiate various landforms. Mountain hiking sites may vary significantly in elevation, influencing the climate, vegetation, and geological processes of the area. Surveying techniques, satellite-based systems (e.g. GPS), and remote sensing methods like LiDAR or radar are commonly used to measure elevation. Fig. 5 shows the elevation map of the study area.

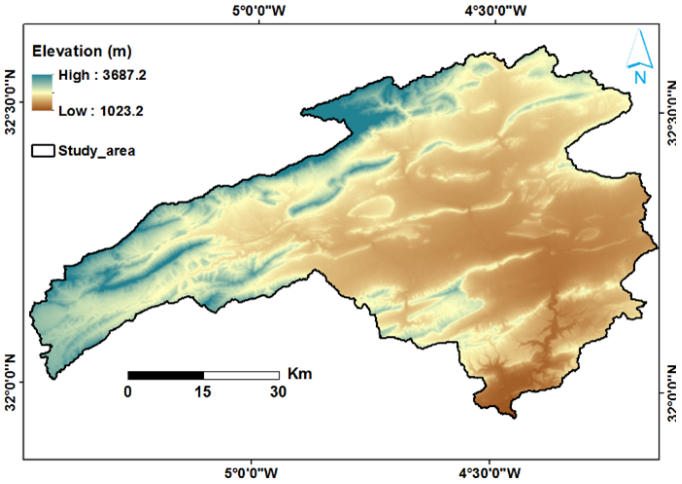

Fig. 5. MHCF map: Elevation.

2) Slope: Slope refers to the steepness or inclination of a landform's surface, a key factor in evaluating hiking site suitability. The slope is calculated in ArcGIS using the variation in elevation between adjacent cells within a Digital Elevation Model (DEM) raster dataset. The formula for calculating slope is:

$$\text{Slope } (\%) = \left(\frac{\text{rise}}{\text{run}}\right) \times 100 \tag{1}$$

Where:

- *rise* represents the change in elevation between cells.
- *run* represents the horizontal distance between the cells.

Fig. 6 illustrates the slope map derived from the DEM.

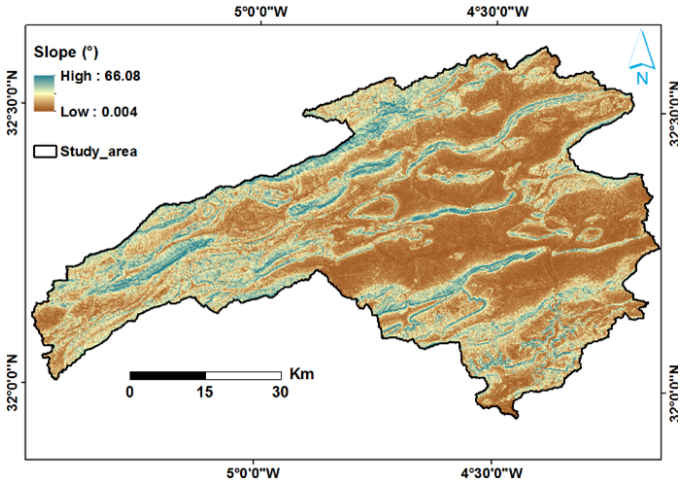

Fig. 6. MHCF map: Slope.

3) Length of Slope (LS): The length of the slope (LS) helps characterize landforms within mountain hiking sites. LS is derived from the DEM using ArcGIS 10.5 software based on the methodology developed by Bizuwerk et al. [20], following Wischmeier and Smith's formula:

$$\text{LS} = \left(\frac{L}{22.13}\right)^{m} \times \left(65.41 \sin^2(S) + 4.56 \sin(S) + 0.065\right) \tag{2}$$

where,

- L is the slope length.
- S is the slope gradient (expressed as a percentage).
- m is a constant value that varies depending on the range of slope gradients.

The resulting LS map is shown in Fig. 7.

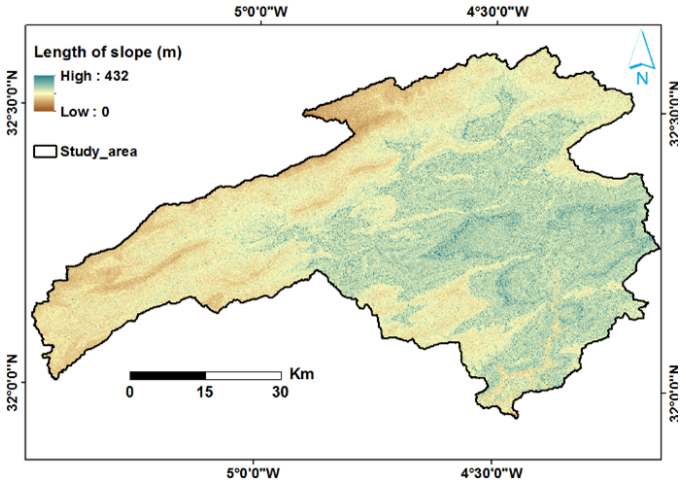

Fig. 7. MHCF map: Length of slope.

B. Machine Learning Algorithm and Frequency Ratio (FR)

1) Bagging algorithm: The Bagging algorithm (Bootstrap Aggregating) comprises two main steps, as described by Breiman et al. [21]. In the first step, multiple training datasets are created by resampling from the original data, a process known as bootstrapping. This involves randomly selecting observations from the original dataset with replacement, allowing some observations to be repeated while others may be omitted. This resampling technique helps to reduce variance and improve the stability of the model.

In the second step, multiple models are constructed using these bootstrapped training datasets. Each model is trained independently, allowing them to capture different aspects of the data. The final predictions are then obtained by aggregating the results of these individual models, typically through averaging for regression tasks or majority voting for classification tasks. This aggregation process tends to produce a more robust and accurate model than any single constituent model.

Bagging has been widely applied in geospatial modeling tasks, where the inherent variability in spatial data can significantly impact model performance. For instance, studies like [22] and [23] have demonstrated the effectiveness of Bagging in enhancing predictive accuracy for various geospatial phenomena.

This model was chosen for this study due to its ability to reduce variance and enhance model stability, particularly in geographic modeling tasks, where data variability can significantly impact predictive performance. While Random Forest is another popular ensemble method frequently applied in geospatial analysis [24], [25], it is a variant of Bagging that focuses on constructing multiple decision trees. In contrast, Bagging can be applied with a variety of base learners, offering greater flexibility. Random Forest incorporates random feature selection at each split, which can be advantageous for certain types of data but may lead to higher bias when modeling complex spatial patterns.

Support Vector Machines (SVM) are also widely used in geographic information system (GIS) modeling due to their strong performance in high-dimensional spaces [26]. However, SVM can be sensitive to noise in the data and may require extensive parameter tuning, especially in cases where the data distribution is complex and non-linear. Bagging, by aggregating the predictions of multiple base models, mitigates the risk of overfitting and noise sensitivity, providing a more balanced approach to spatial data modeling.

2) Frequency Ratio (FR): The goal of analyzing the mountain hiking conditioning factors is to carefully assess how different geographic parameters relate to the presence of mountain hiking sites. To do this, we use the frequency ratio method, which allows us to measure how often hiking sites appear in different classes of geographic factors (such as elevation, slope, or land use) compared to how much area those classes cover. As explained by Manaouch et al. [23], this method helps determine the likelihood of finding a hiking site in specific geographic conditions.

The frequency ratio technique works by comparing two percentages: the percentage of mountain hiking sites located in a certain class and the percentage of the total area that this class occupies. A higher frequency ratio means there is a greater chance of finding a hiking site in that specific geographic class, as noted by Samanta et al. [27].

The frequency ratio for a particular class is calculated using the following equation:

$$FR_i = \frac{\left(\frac{N_i}{N}\right)}{\left(\frac{S_i}{S}\right)} \tag{3}$$

Where:

- N_i is the number of mountain hiking sites within the ith class of a geographic factor (e.g., a specific elevation range or slope category).
- N is the total number of mountain hiking sites in the study area.
- S_i is the area of the ith class of the geographic factor.
- S is the total area of the study region.

This formula helps us understand whether certain geographic conditions are more favorable for mountain hiking. For example, if a specific elevation range covers 20% of the study area but contains 50% of the hiking sites, the frequency ratio will be higher, indicating that this elevation is particularly suitable for hiking.

The frequency ratio equation is used to compute FR_i for each class of a conditioning factor, helping us evaluate how well different geographic conditions align with the locations of hiking sites.

C. Performance and Model Validation

The model's performance was evaluated using the Area Under the Curve (AUC) of the receiver operating characteristic (ROC) analysis. This analysis provides a comprehensive measure of the model's ability to distinguish between suitable and unsuitable mountain hiking areas. The AUC value ranges from 0 to 1, where a value of 0.5 indicates no discriminative power and a value of 1 signifies perfect discrimination.

For this study, the AUC/ROC analysis involved 120 mountain hiking sites and the classified map of potential hiking areas. True Positive (TP), True Negative (TN), False Positive (FP), and False Negative (FN) rates were calculated, which serve as critical metrics in evaluating the model's predictive accuracy. These metrics were derived using the following equations:

$$TPR = \frac{TP}{TP + FN} \tag{4}$$

$$FPR = \frac{FP}{FP + TN} \tag{5}$$

In this context, the True Positive Rate (TPR), also known as sensitivity or recall, reflects the proportion of actual positives that were correctly identified by the model. Conversely, the False Positive Rate (FPR) quantifies the proportion of actual negatives that were incorrectly classified as positives. By

analyzing these rates, we can better understand the trade-offs between sensitivity and specificity, which is crucial for applications where the consequences of false positives and false negatives differ significantly.

TABLE I. DATA LABELING FOR ROC ANALYSIS

Actual Label	Predicted Positive	Predicted Negative
Positive	TP	FN
Negative	FP	TN

Table I summarizes the data labeling used for the ROC analysis, indicating how actual labels correspond to predicted outcomes. This structured approach enables a clearer evaluation of the model's performance across different thresholds.

The resulting AUC value of approximately 0.93 indicates that the Bagging classifier performed exceptionally well in accurately identifying and distinguishing potential mountain hiking sites. Such validation not only affirms the reliability of the model but also enhances confidence among stakeholders in utilizing these findings for informed decision-making regarding tourism development.

Furthermore, the ROC curve, which graphically represents the TPR against the FPR at various threshold settings, provides an intuitive visualization of the model's performance. Analyzing the shape and area under this curve can reveal insights into the model's robustness, assisting in the selection of the optimal threshold that balances sensitivity and specificity according to the specific context of mountain hiking site selection.

D. Mountain Hiking Sites and Conditioning Factors

Table II presents the calculated frequency ratio values for the three conditioning factors, each consisting of multiple classes. To facilitate analysis, these values have been normalized using the normalize filter method, which transforms them into a range of 0.1 to 0.9. A normalized value closer to 1 indicates a stronger association between mountain hiking sites and the corresponding factor, while a value closer to 0 indicates a weaker association. The spatial relationship between the conditioning factors and mountain hiking sites is assessed through the frequency ratio calculation, and the results are presented in Table II for all factors.

E. Mountain Hiking Suitability Map

Fig. 8 illustrates the mountain hiking suitability map generated by the Bagging classifier. The map highlights that the northern and western regions exhibit higher suitability for potential mountain hiking sites compared to other areas. To gain a deeper understanding of the factors influencing the suitability or unsuitability of different areas and to explore the underlying reasons for these variations, we collaborated with local experts who possess substantial knowledge of the region.

Additionally, we validated our findings by cross-referencing them with images obtained from Google Earth. Fig. 10 provides the corresponding percentages of the area covered by each suitability class in the generated map.

TABLE II. SPATIAL RELATIONSHIP BETWEEN SLOPE AND MOUNTAIN CLIMBING SITES POINTS USING FREQUENCY RATIO (FR)

RCF	Class	Frequency Ratio FRi	Frequency Ratio FRn
Slope	1	0.045	0.1
	2	0.3	0.12
	3	0.74	0.15
	4	1.43	0.21
	5	9.58	0.9
Elevation	1	0.1	0.1
	2	0.2	0.1
	3	0.69	0.13
	4	0	0.1
	5	0.2	0.1
	6	0	0.1
	7	7.6	0.55
	8	4.17	0.34
	9	0	0.1
Length of slope	1	0	0.1
	2	0	0.1
	3	0.16	0.11
	4	0.5	0.24
	5	2.02	0.81

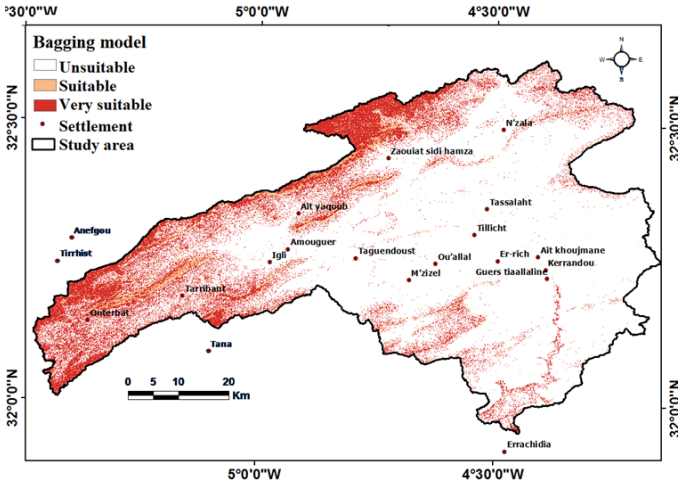

Fig. 8. Generated mountain hiking suitability map using Bagging.

F. Model's Performance

The effectiveness of the Bagging classifier was evaluated using the AUC/ROC method, which is widely recognized for its robustness in assessing model performance in binary classification tasks. During the training phase, the classifier demonstrated impressive performance, achieving an average accuracy rate of 97.29%. This high accuracy reflects the model's capability to learn from the training data effectively and underscores its potential in identifying suitable mountain hiking sites.

However, during the validation phase, significant fluctuations in the classifier's performance were observed, as depicted in Fig. 9. These fluctuations can be attributed to several factors, including variability in the validation dataset, potential overfitting during the training phase, and the inherent complexity of the mountain hiking suitability classification task. Understanding these fluctuations is crucial, as they highlight the necessity for careful model tuning and validation to ensure reliable outcomes in real-world applications.

The obtained AUC value of 0.935 indicates that the Bagging classifier successfully modeled the suitability mapping of mountain hiking sites in the upper Ziz region. An AUC value above 0.9 is generally considered excellent, suggesting that the model has a high probability of distinguishing between suitable and unsuitable hiking areas. This level of performance is particularly encouraging, as it implies that the classifier can reliably inform decisions regarding the identification of potential hiking locations.

Fig. 9 illustrates the prediction rate curve for the mountain hiking suitability map produced by the Bagging classifier. The curve visually represents the relationship between the true positive rate (TPR) and the false positive rate (FPR) across various threshold settings. Analyzing this curve allows for a deeper understanding of the trade-offs involved in selecting an optimal threshold, ensuring that the final suitability map meets the specific objectives of identifying suitable hiking sites.

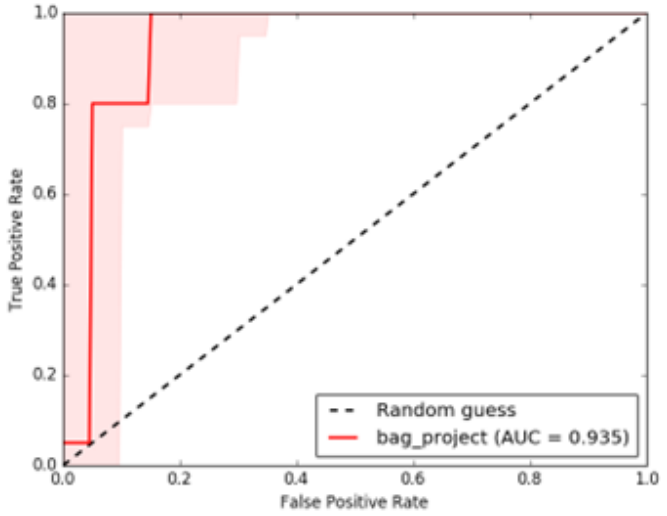

Fig. 9. Prediction rate curve for mountain hiking suitability map produced by Bagging.

IV. Discussion

A. Analysis of Precision

The performance of machine learning models (MLMs) can vary depending on the specific algorithm employed. In the case of Bagging, its performance was assessed using the 10-fold cross-validation method during the training phase, resulting in a high level of performance with an AUC value of 0.97.

However, during the validation phase, the performance of Bagging decreased to 93%, as depicted in Fig. 9. It is generally observed that algorithms with higher AUC values tend to exhibit more accurate and efficient prediction capabilities, as emphasized by Su et al. [28]. Considering the current AUC value of Bagging, it can be inferred that Bagging performs relatively lower compared to the results reported by Manaouch et al. [23] in predicting potential reforestation areas. Nevertheless, it is important to note that Bagging still demonstrates a favorable level of accuracy and efficiency, as evidenced by its AUC value of 0.93.

In evaluating the model's accuracy, it is essential to consider other factors that influence the suitability of regions for mountain hiking beyond the quantitative metrics provided by the model. For instance, cultural aspects, such as local traditions and community engagement in outdoor activities, can significantly impact the attractiveness of certain hiking locations. Furthermore, the presence of infrastructure, including access roads, trail maintenance, and proximity to amenities (like parking and rest areas), plays a crucial role in determining the feasibility and safety of hiking sites. Areas that may have high ecological or aesthetic value but lack necessary infrastructure may be less suitable for hiking compared to less pristine areas that are well-supported by facilities.

B. Distribution of Suitable Mountainous Hiking Areas

The data attributes collected from the upper Ziz region underwent preprocessing using the pre-trained Bagging classifier. During this preprocessing stage, mountain hiking suitability indices were computed for each pixel within the study area. The "Natural breaks" algorithm was employed to classify these suitability indices, resulting in the creation of three distinct classes: unsuitable, suitable, and very suitable. This process led to the generation of a mountain hiking suitability map, as depicted in Fig. 8.

The findings indicate that approximately 24% of the entire study area comprises very suitable areas for potential mountain hiking sites, as shown in Fig. 10. According to the Bagging model, the southern parts of the region are deemed unsuitable for mountain hiking sites, while the mountainous regions situated to the west and north exhibit a high level of suitability. Additionally, the Bagging model reveals that areas classified as very suitable for mountain hiking sites are dispersed along the Ziz wadi, located to the south of the upper Ziz region.

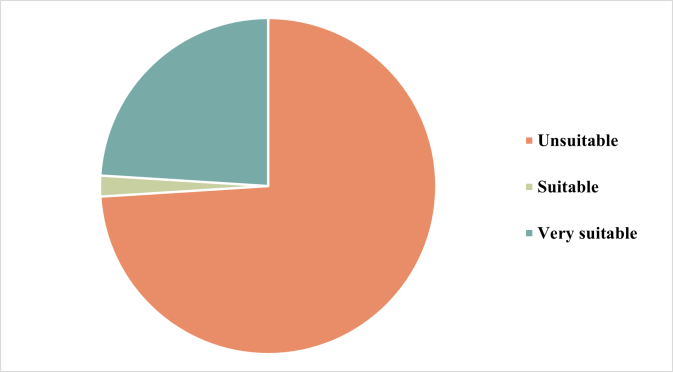

Fig. 10. Percentage of mountain hiking suitability classes' areas for Bagging model.

Despite these promising results, there are several limitations to this study that must be acknowledged. One significant limitation is the potential quality of the data used in the analysis. Incomplete or inaccurate data could adversely affect the model's predictive capabilities. Furthermore, the scope of topographical features included in the analysis may not encompass all relevant variables that could influence hiking suitability, such as microclimate variations, vegetation types, or the impact of human activities on the landscape. A broader

dataset could enhance the model's accuracy and provide a more comprehensive understanding of the factors affecting hiking suitability.

V. Conclusion and Future Work

The integration of topographical data and the Bagging algorithm has demonstrated significant potential in enhancing tourism through the identification of suitable mountain hiking sites. By utilizing the Bagging classifier, which incorporates critical topographical features such as slope, length of slope, and elevation, and validating the resulting map using the AUC/ROC metric, valuable insights can be gained to identify potential mountain hiking sites in the eastern High Atlas of the upper Ziz in Southeast Morocco. The findings indicate that approximately 24% of the study area comprises very suitable areas for potential mountain hiking sites, primarily located in the northern and western regions, as well as around the Ziz wadi, particularly in the downstream part of the study area.

The application of the AUC/ROC evaluation metric in this study provides a robust measure of the algorithm's ability to differentiate between suitable and unsuitable mountain hiking sites, achieving an impressive score of approximately 93%. This indicates that the Bagging algorithm performed exceptionally well in accurately identifying and distinguishing potential mountain hiking sites. Such validation approaches not only ensure the reliability and accuracy of the generated map but also empower decision-makers and stakeholders in the tourism industry to confidently identify and prioritize areas for tourism development.

Furthermore, the findings of this study underscore the importance of employing machine learning techniques in environmental and tourism planning. By systematically analyzing the spatial relationships among various topographical factors, stakeholders can make informed decisions that promote sustainable tourism practices while preserving natural landscapes.

Future research could explore the integration of additional ecological and socio-economic data to refine the suitability assessments further. Incorporating factors such as ecological diversity and human accessibility, including proximity to transport links and local amenities, can significantly enhance the accuracy of suitability models. Additionally, collaborating with local communities is crucial for validating findings. Engaging with residents can provide insights into cultural significance, traditional knowledge, and existing infrastructure, which are essential for a comprehensive understanding of the area's tourism potential.

Moreover, applying similar methodologies in other geographical areas could contribute to a broader understanding of potential hiking sites, ultimately supporting the growth of ecotourism on a larger scale. Future studies should also consider the impacts of climate change on hiking site suitability, ensuring that long-term strategies for tourism development are both adaptable and sustainable.

Overall, this study not only contributes to the literature on tourism but also offers practical applications for enhancing the visitor experience in mountain environments, fostering both environmental conservation and local economic development.

Acknowledgment

This research project was supported by funding from the CNRST (National Center for Scientific and Technical Research) under the Moroccan project titled "Al-Khawarizmi program in AI and its Applications", (Alkhawarizmi/2020/32).

The authors would like to express their gratitude to Mohamed Manaouch for providing the necessary facilities and data for this study. Additionally, the authors would like to extend their thanks to Mr. N. Khan for his invaluable assistance during the validation phase

Pioneering Granularity: Advancing Native Language Identification in Ultra-Short EAP Texts

Zhendong Du, Kenji Hashimoto
Graduate School of Information, Production and Systems
Waseda University, Fukuoka, Japan 808-0135

***Abstract*—This study addresses the challenge of Native Language Identification (NLI) in ultra-short English for Academic Purposes (EAP) texts by proposing an innovative two-stage recognition method. Conventional views suggest that ultra-short texts lack sufficient linguistic features for effective NLI. However, we have found that even in such brief texts, subtle linguistic cues—such as syntactic structures, lexical choices, and grammatical errors—can still reveal the author's native language background. Our approach involves fine-tuning the granularity of first language (L1) labels and refining deep learning models to more accurately capture the subtle differences in second language (L2) English texts written by individuals from similar cultural backgrounds. To validate the effectiveness of this method, we designed and conducted a series of scientific experiments using advanced Natural Language Processing (NLP) techniques. The results demonstrate that models adjusted for granular L1 distinctions exhibit greater sensitivity and accuracy in identifying language variations caused by nuanced cultural differences. Furthermore, this method is not only applicable to ultra-short texts but can also be extended to texts of varying lengths, offering new perspectives and tools for handling diverse language inputs. By integrating in-depth linguistic analysis with advanced computational techniques, our research opens up new possibilities for enhancing the performance and adaptability of NLI models in complex linguistic environments. It also provides fresh insights for future efforts aimed at optimizing the capture of linguistic features.**

***Keywords*—Native language identification; English for academic purposes; natural language processing**

I. Introduction

NLI is a technique used to determine an author's native language by evaluating their written text. This method plays a crucial role in L2 writing research [1]. Traditionally, it has been assumed that effective NLI requires longer texts [2], as extended content provides a broader range of stylistic and linguistic features, making it easier to infer the author's native language with greater accuracy. This belief stems from the linguistic diversity and variability seen across different languages, as individuals' written expressions are shaped by their unique cultural and educational backgrounds [3]. However, these influences are often difficult to capture in shorter texts, leading to the widespread misconception that extremely short texts are unsuitable for NLI.

This assumption, however, overlooks certain fundamental aspects of linguistics. Even in very short texts, specific linguistic features—such as grammatical structures, lexical choices, and common errors—can reveal clues about the author's native language. For instance, writers from different language backgrounds often follow identifiable patterns when using prepositions, articles, or complex sentence structures [4]. These patterns may still be present even in short text segments. Moreover, mistakes such as misusing certain tenses or irregular verb forms can provide valuable insights for NLI.

In many practical applications, it is common to encounter texts at the sentence level or even shorter [5]. This reality has driven the exploration of NLI techniques capable of handling ultra-short texts, particularly in the context of EAP. In EAP writing, each word choice and grammatical structure may reflect the author's linguistic habits and native language influences [6]. Thus, even brief texts, such as titles, abstracts, or notes, can contain enough information to facilitate effective NLI.

Recognizing that traditional NLI approaches often overlook the subtle linguistic cues in ultra-short texts, this study proposes an innovative two-stage NLI method. By fine-tuning the granularity of NLI classification labels, we enhance the system's ability to analyze very short texts. This approach challenges conventional wisdom and proves particularly useful for academic English, enabling accurate identification of subtle differences in expression that arise from cultural and linguistic background variations.

Moreover, our method emphasizes the importance of linguistic analysis to uncover and utilize nuanced differences, such as slight variations in grammatical structures or lexical preferences. These aspects are often neglected in traditional NLI methodologies. To validate the effectiveness of our approach, we conducted a series of targeted experiments using advanced machine learning models. The results demonstrate that our method not only excels in identifying native languages from ultra-short texts but also offers more precise language analysis for applications like academic writing assistants and Grammatical Error Correction (GEC) tools. These applications can provide more tailored writing suggestions and GEC by accurately identifying the author's native language, ultimately improving both the quality and efficiency of writing. This study's success paves the way for further integration of linguistic research and natural language processing technologies.

II. Related Work

A. Overview

NLI aims to infer an author's native language based on the text written in a target language. This task holds significant importance in the field of NLP due to its various applications. For instance, NLI can be leveraged to improve language teaching methods, enhance the quality of machine translation, and bolster security monitoring capabilities. By understanding an

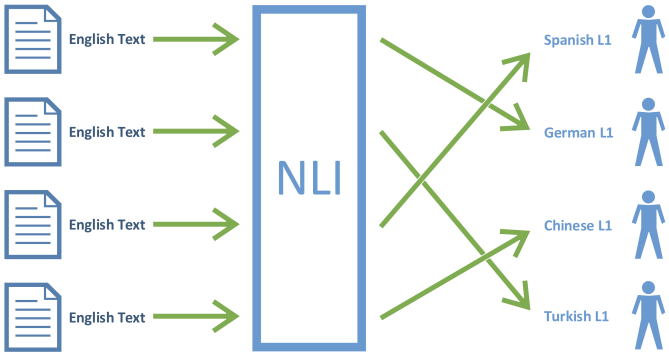

Fig. 1. The general concept of an NLI system is depicted in this figure. Image adapted from [7].

author's native language, we can more accurately identify their linguistic habits and potential errors [8], thereby providing valuable support for downstream tasks [9]. Fig. 1 illustrates the concept of NLI.

B. English NLI

English NLI is the most extensively studied area within NLI. This prominence is due to the widespread use and influence of English as the primary international language. In English NLI, researchers focus on extracting linguistic features from English texts that reflect the author's native language characteristics. Most existing studies have concentrated on long texts, such as essays [10], articles [11], and speeches [12]. These long texts provide a wealth of data, enabling models to capture the linguistic habits and preferences of speakers from different native language backgrounds. Common analytical dimensions include lexical usage frequency [13], syntactic structures [14], and pragmatic features [15].

Academic English NLI is a specialized subfield of NLI, aiming to infer the author's native language background through the analysis of academic English texts. Due to the relatively uniform style and conventions of academic English, extracting native language features poses a greater challenge [16]. Nevertheless, authors from different native language backgrounds exhibit variations in lexical choices [17], syntactic complexity [18], and argumentation styles within academic writing. Some studies utilize corpora comprising academic papers, research reports, and students' academic writings to analyze features such as discipline-specific terminology [20], the frequency of passive voice usage [21], and the overall text organization structure [22].

C. Short Text NLI

It is important to note that current research primarily focuses on NLI for long texts [23], while there is skepticism regarding the feasibility of effective NLI for very short texts, such as at the sentence level. This skepticism stems from the limited linguistic features available in ultra-short texts, making it challenging for models to capture stable native language traits [24]. Despite this, NLI for short texts is essential for specific NLP downstream tasks, such as English GEC or writing assistance tools. Unfortunately, due to the prevailing view that NLI has a minimum text length requirement, researchers have not yet explored this area adequately.

We argue that the conclusion regarding the limitations of NLI for short texts arises because prior studies did not consider different approaches for varying text lengths. Long texts, such as paragraphs, contain a wealth of linguistic features, and methods developed for them are often inappropriately applied to sentence-level texts. Hence, the current state of research in this area requires further investigation and reevaluation.

III. Goal

This study aims to address the gap in NLI research for very short texts by proposing a systematic and scientific solution. To ensure the quantifiability of the research, the focus is specifically on EAP, with the text length constrained to the sentence level.

IV. Method

NLI is a typical text classification task where the core challenge lies in enabling the NLI system to effectively learn to balance different classification labels [25]. Traditional classification methods often struggle when the NLI system is presented with sentence-level texts that have minimal distinguishing features. However, even at the sentence level, there are usually subtle differences present [26]; the key challenge is how to identify and leverage these differences.

A recent study explored this by extracting sentences from academic papers and translating them into different languages using a specific method [27]. These sentences were then translated back into English by English L2 speakers whose native languages matched the target language. The researchers found that texts produced by L2 speakers from similar cultural backgrounds exhibited certain similarities, which were evident in aspects such as grammatical errors and linguistic style. Fig. 2 illustrates part of the study's findings, showing the distribution of grammatical errors. Some researchers may view these results as reinforcing the idea that such linguistic similarities make sentence-level NLI even less feasible. However, we take an opposing stance.

We propose that, by dynamically adjusting the granularity of classification labels during the training of an NLI system, and allowing the system to learn the features of English texts in stages, it becomes possible to capture those subtle features more effectively. This approach may enhance the system's ability to identify nuanced linguistic characteristics that are otherwise overlooked in conventional classification methods.

Fig. 2 reveals some intriguing patterns in the distribution of grammatical error types among certain L2 learners. Notably, learners from China, Japan, and South Korea exhibit highly similar distributions of grammatical errors. According to the original authors, this similarity can be attributed to the cultural and linguistic ties shared by these three countries, which result in analogous challenges in learning English as a second language.

Our proposed approach involves training the model to first learn the shared linguistic features present in English texts produced by L2 learners from these three countries. Following this, the model will focus on the subtle, unique characteristics

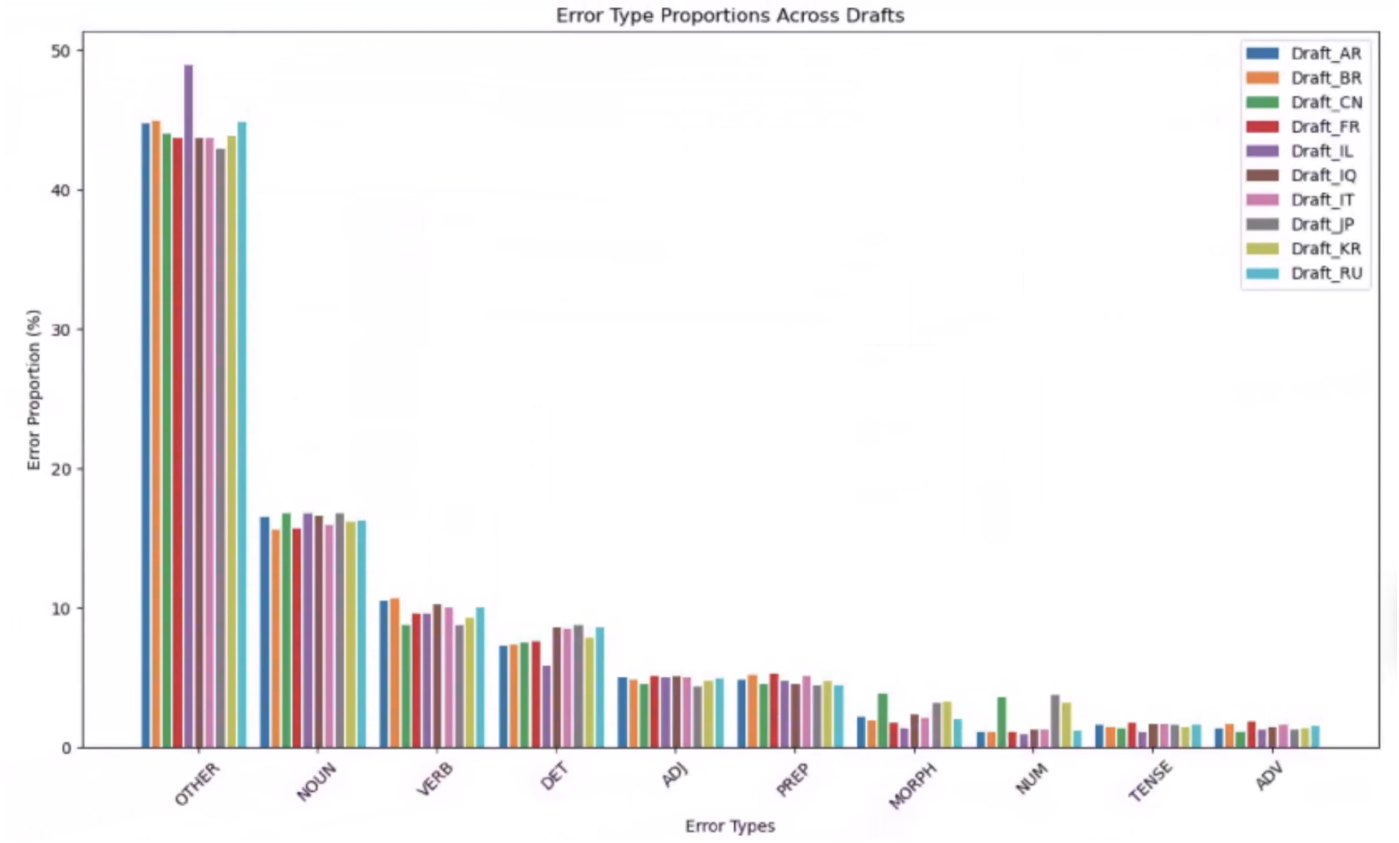

Fig. 2. Distribution of grammatical error types across different L2 transcribed texts. Different colors represent the native languages of various L2 speakers. Image adapted from [27].

of English usage specific to each country. Although similar patterns of error distribution may exist among L2 learners from other countries, our study is constrained by the availability of existing research data. Therefore, we have chosen to focus on learners from China, Japan, and South Korea. The specific methodology is detailed in Fig. 3.

V. Experiment

A. Data

In our study, we have selected the validation set of the TCNAEC [27] dataset as the training data and the test set as the testing data. To the best of our knowledge, there are currently no other publicly available datasets that meet the specific requirements of our task. While there are some English datasets consisting of paragraph collections that can be segmented into sentences, they lack the necessary labeled test data. Specifically, our task requires both the training and testing datasets to include English texts produced by L2 speakers from China, Japan, and South Korea. TCNAEC is the only dataset that satisfies this condition. It comprises 10 categories labeled as AR (Argentina), BR (Brazil), CN (China), FR (France), IL (Israel), IQ (Iraq), IT (Italy), JP (Japan), KR (South Korea), and RU (Russia), with each label containing 1,000 validation entries and 1,000 test entries.

B. Model

In this study, we selected the RoBERTa-large [28] model as the pre-trained foundation for our experiments. RoBERTa-large was chosen due to its robust text classification capabilities, which makes it well-suited to validate the proposed approach. The experiment was divided into two phases, each with distinct objectives and configurations.

In the first experiment, we followed the conventional method where data, balanced across original labels, was input into the model. This model is referred to as RoBERTa-10[1]. For the second experiment, we implemented our proposed method, where the three labels—CN, JA, and KR—were initially merged into a single label, CJK. This produced an intermediary model, referred to as NLI Model 1. Subsequently, using the same settings as in the first experiment, the data was reclassified into CN, JA, and KR labels, resulting in NLI Model 2, named RoBERTa-8to10[2].

The two experiments employed distinct hyperparameter configurations across different phases of training. In the first experiment, parameters were set according to configuration two (shown in Table II). For the second experiment, the first phase used configuration one (Table I), while the second phase used configuration two. The rationale behind using different parameter configurations for each phase was to address the

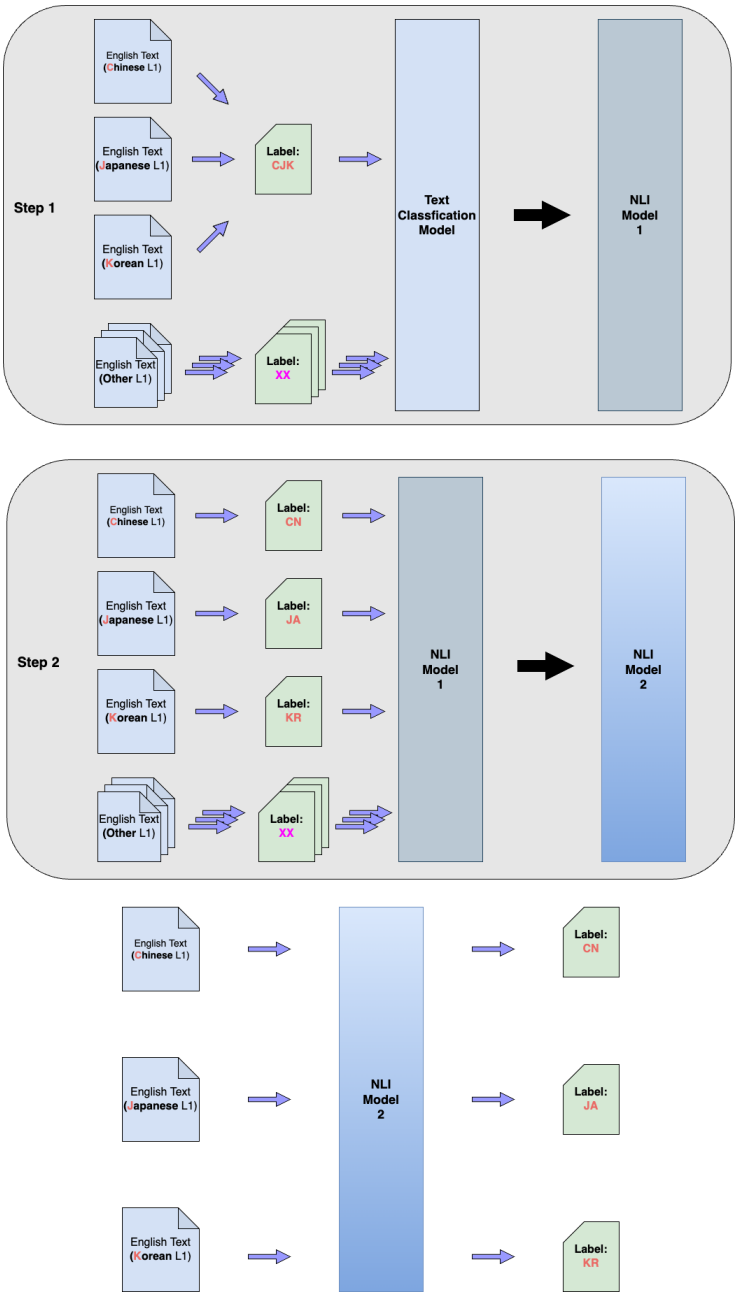

Fig. 3. Method details.

Step 1 Consolidates English text from Chinese, Japanese, and Korean L1 into the ***CJK*** label and feeds it, along with other labels, into a Text Classification Model to create **NLI Model 1**.

Step 2 Re-divides the ***CJK*** label into ***CN***, ***JA***, ***KR*** labels, which, alongside other labels, are fed into **NLI Model 1** to generate **NLI Model 2**. **NLI Model 2** can then more accurately identify and categorize English text from Chinese, Japanese, and Korean L1.

varying demands of the tasks and differences in the distribution of data labels.

Step 1: Establishing Baseline Classification Capabilities: The objective of the first phase was to establish NLI Model 1, which was designed to handle tasks involving broader categorical distinctions. Specifically, the model's primary goal was to classify English text originating from Chinese, Japanese, and Korean into the unified CJK label, alongside other distinct labels. This strategy aimed to capture key distinguishing features across broader language groups while ignoring minor linguistic variations, thereby forming a foundational understanding and classification ability for the main language groups.

To accommodate this requirement, we opted for a relatively large batch size (32) and a high learning rate (0.0001) to facilitate rapid convergence in the early stages of training. A cosine learning rate scheduler with restarts was employed to help the model effectively navigate potential local minima during training. Additionally, we adjusted the class weights to reflect label imbalances, particularly assigning a lower weight (0.333) to the CJK class to prevent the model from dispropor-

tionately favoring this category, which combined texts from three different languages.

Step 2: Enhancing Language Recognition Precision: In the second phase, the focus shifted towards more fine-grained language recognition. The objective of RoBERTa-8to10 in this phase was to differentiate between CN, JA, and KR labels, building on the language recognition capabilities developed in the first phase. To capture the nuanced differences between these languages, we adopted a smaller batch size (16) and a lower learning rate (0.00005), encouraging the model to become more sensitive to subtle details and achieve higher accuracy. To further prevent overfitting and ensure better generalization across fine-grained categories, we increased the dropout rate to 0.5.

By employing this step, targeted training strategy with parameter adjustments tailored to each phase's needs, RoBERTa-8to10 was able to improve classification accuracy and sensitivity when distinguishing between Chinese, Japanese, and Korean texts. This approach successfully met the distinct objectives of each phase.

VI. RESULTS

A. Analysis

We compared the classification performance of two models, RoBERTa-10 and RoBERTa-8to10, through metric evaluations (Table III) and confusion matrix analyses (Fig. 4) to explore the impact of a phased classification strategy on model performance.

TABLE III. MODEL PERFORMANCE METRICS

Model	Metric	CN	JP	KR
RoBERTa-10	Precision	28.02	35.29	10.12
	Recall	**78.60**	1.20	2.50
	$F_{0.5}$	32.16	5.28	6.29
	Average $F_{0.5}$		14.58	
RoBERTa-8to10	Precision	**33.06**	**42.37**	**16.85**
	Recall	59.50	**2.50**	**16.80**
	$F_{0.5}$	**36.28**	**10.11**	**16.84**
	Average $F_{0.5}$		**21.08**	

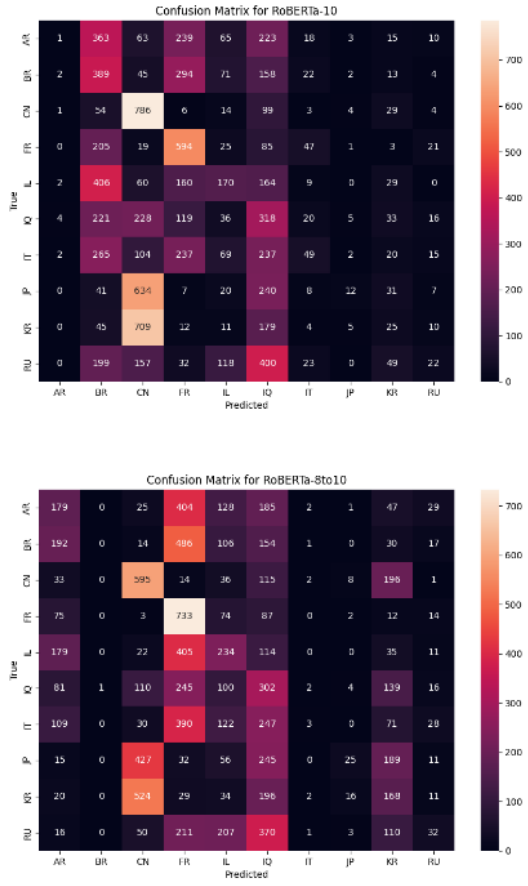

Fig. 4. Confusion matrix for models.

In the RoBERTa-10 model, all 10 labels were used simultaneously for training and prediction. The metric evaluations show that the model achieved a relatively high recall rate (78.60) for the CN label, but its precision was low (0.2802), resulting in a relatively low $F_{0.5}$ (32.16). This suggests that although the model successfully captured a significant portion of CN-labeled samples, its accuracy was insufficient, with a high number of misclassifications. The confusion matrix further confirmed this: while 786 CN samples were correctly classified, a considerable number of samples were misclassified as JP or KR. For the JP and KR labels, the recall rates were extremely low, with only a small number of samples correctly classified, and most were misclassified as CN. This indicates that the model struggled significantly in distinguishing between

these three labels.

In contrast, the RoBERTa-8to10 model employed a phased classification strategy. First, the CN, JP, and KR labels, which were prone to confusion, were merged into a new CJK label. This CJK label, along with the remaining seven labels, was used for initial model training. In the second phase, samples predicted as CJK were further subdivided. Metric evaluations showed an improvement in precision for the CN label to 33.06, with a corresponding increase in the $F_{0.5}$ score to 36.28, despite a slight drop in recall (0.5950). This indicates that the model effectively reduced misclassifications while maintaining a good ability to identify CN-labeled samples. For the JP and KR labels, both precision and $F_{0.5}$ scores saw significant improvements, particularly for the JP label, where precision increased from 35.29 to 42.37. The confusion matrix revealed that the number of correctly classified JP samples doubled to 25, while the number of correctly classified KR samples surged to 168. This highlights the effectiveness of the phased classification strategy in enhancing the model's ability to differentiate between these confusing labels [29].

In summary, the RoBERTa-8to10 model demonstrated substantial improvements in classification performance for the CN, JP, and KR labels. By merging the easily confused labels in the initial phase, the phased classification strategy reduced the complexity of the initial classification task. In the subsequent fine-tuning phase, the model was able to better learn the subtle differences between these labels, leading to enhanced precision and reliability. These results validate the advantages of a phased classification approach in multi-label classification tasks and provide an effective solution for addressing similar classification challenges.

B. Discussion and Future Work

In this work, we have demonstrated the effectiveness of the proposed method, showing that the phased classification strategy has significant advantages in handling multi-label classification tasks with easily confused labels. Due to limitations in data volume and the available types of data, our current exploration is restricted to English texts written by native speakers of Chinese, Japanese, and Korean. The linguistic and cultural similarities among these three languages make the classification task more challenging, but also provide an ideal testing ground for our model.

Looking ahead, we aim to address the issue of data scarcity. By collecting and constructing larger, more diverse datasets, we hope to validate our approach across a broader range of languages and cultural contexts. This would not only improve the generalization capabilities of the model but also allow us to explore the application of the phased classification strategy to more complex groupings and finer-grained labels.

Additionally, while this study focuses on sentence-level text classification, our approach is theoretically applicable to longer texts as well. For example, texts at the paragraph or full-article level contain richer contextual and semantic information [30], which could enable the model to more accurately capture linguistic features and distinctions. Thus, we plan to extend our method to longer texts in future research, with the expectation of achieving even better classification performance.

VII. Conclusion

In this study, we focus on NLI for ultra-short EAP texts and propose an innovative methodological strategy. This strategy primarily involves the phase-wise adjustment of L1 label granularity to fine-tune deep learning models, thereby more accurately capturing the subtle linguistic features of L2 English texts from similar cultural backgrounds. The core of this method integrates in-depth grammatical analysis with advanced computational techniques, combining traditional linguistic knowledge with modern machine learning technologies to enhance model performance and adaptability in complex linguistic environments. To validate our approach, we designed a series of scientific experiments that clearly demonstrate the effectiveness of the proposed method by comparing model performance before and after the experiments. The results show that the granularity-adjusted models are more sensitive to and can better identify linguistic variations caused by subtle cultural differences, thereby significantly improving the accuracy of NLI. Moreover, we conducted multiple rounds of verification to ensure the reliability and repeatability of the results. Through exhaustive data analysis, we not only proved the effectiveness of our method but also explored its potential for future research. The analysis indicates that this strategy is applicable not only to ultra-short texts but can also be effectively applied to texts of varying lengths, offering new perspectives and tools for managing diverse linguistic inputs. Our research further reveals that further optimization of the label granularity adjustment strategy could allow for more precise capture of linguistic features, providing new directions and possibilities for future research.

Feature Creation to Enhance Explainability and Predictability of ML Models Using XAI

Waseem Ahmed

Jeddah, Saudi Arabia

***Abstract*—Bringing more transparency to the decision making process in fields deploying ML tools is important in various fields. ML tools need to be designed in such a way that they are more understandable and explainable to end users while bringing trust. The field of XAI, although a mature area of research, is increasingly being seen as a solution to address these missing aspects of ML systems. In this paper, we focus on transparency issues when using ML tools in the decision making process in general, and specifically while recruiting candidates to high-profile positions. In the field of software development, it is important to correctly identify and differentiate highly skilled developers from developers who are adept at only performing regular and mundane programming jobs. If AI is used in the decision process, HR recruiting agents need to justify to their managers why certain candidates were selected and why some were rejected. Online Judges (OJ) are increasingly being used for developer recruitment across various levels attracting thousands of candidates. Automating this decision-making process using ML tools can bring speed while mitigating bias in the selection process. However, the raw and huge dataset available on the OJs need to be well curated and enhanced to make the decision process accurate and explainable. To address this, we built and subsequently enhanced a ML regressor model and the underlying dataset using XAI tools. We evaluated the model to show how XAI can be actively and iteratively used during pre-deployment stage to improve the quality of the dataset and to improve the prediction accuracy of the regression model. We show how these iterative changes helped improve the r2-score of the GradientRegressor model used in our experiments from 0.3507 to 0.9834 (an improvement of 63.27%). We also show how the explainability of LIME and SHAP tools were increased using these steps. A unique contribution of this work is the application of XAI to a very niche area in recruitment, i.e. in the evaluation of performance of users on OJs in software developer recruitment.**

***Keywords*—XAI; ML; AI; Recruitment**

I. Introduction

The use of classification and regression models based on Machine Learning and Deep learning techniques in various domains is now common and ubiquitous. Advances in the field have brought faster diagnosis to patients undergoing life critical treatments in the medical domain, has made autonomous driverless vehicles possible and has revolutionized the commercial and financial world through prediction and recommendation systems. Although these systems are becoming increasingly pervasive in many domains, their adoption has become challenging in areas where trust, accountability and transparency of the decision making process is important and crucial to the users and other stakeholders of the application. One of the main reasons is that most of these ML models are closed *black-boxes* - they lack interpretability and explainability. ML models exist on both side of the spectrum. Models based on linear and logistic regression and classification are simple to understand and decisions made by them are easily explainable; but they lack accuracy and performance. On the other hand, there are ML models built on deep learning technologies which have great accuracy and performance but are not interpretable and decisions made by them are not explainable.

Besides this, there are other inherent problems in these systems. For example, they are trained on existing datasets and tested on an unseen dataset. However, this unseen data is, in reality, not really unseen but available to the developers at development and pre-deployment time. If there is a problem in the data or the data is biased in some way, the model is trained on this incorrect data and decisions it subsequently makes would be biased. And because these systems are trained on a specific data structure, they cannot be generalized or easily extended to systems where structure of data may be different or unknown.

In the early days of AI, systems were knowledge based [1] built on strong formalisms, rules and symbolic representations and thus decisions taken by them could, in most cases, be explained in detail. AI systems today, that are based on subsymbolic representations are skill based [1]. The focus of these systems in largely on performance and lesser on explainability. But for a ML system to be adopted in a life-critical or similar domains the system has to be considered trustworthy and transparent by the domain expert or the end user.

The field of Explainable AI (XAI) has been addressing the issue of bringing more transparency, understandability and explainability to these closed ML models [2], [3], [4], [5]. Bringing trust and explainability to ML systems while eliminating bias in decision making is critical in fields like Human Resources [6].

Systems based on ML are increasingly being used in the business world in decision making, which is sometimes leading to the decision making process being less transparent. Managers may not have the necessary skills to understand the decision making skills of the underlying black-box ML models used to make the decision (prediction or classification) and the XAI system should help them communicate with their team in a natural and more understandable way. XAI also seeks to addresses this concern to ensure that relationships between managers and other decision makers in such domains, which

are based on trust and transparency, are upheld. Ideally, if these systems are deployed in areas like HR, they should be able to bring accountability and address the big issue of eliminating bias during recruitment [7]. Providing a detailed justification when recruiting for a high-profile job may take a legal form and if aided with ML models, and a human understandable explanation will be sought as to why a candidate was accepted or rejected. Making algorithmic decision-making more accountable has been made a part of the Right to Explanation in the European Union General Data Protection Regulation (GDPR) [8].

Recently, HR recruitment in the software industry is increasingly being done using Online Judges through hackathons and online contests [9]. They are increasingly being used by companies to facilitate recruitment at different levels of skills ranging from software developers for various IT projects [10] to freshers in campus recruitment drives. Indeed, there are dedicated OJs primarily used to support the recruitment process like *CodeEval*, *Codility*, *HackerRank*, *HackerEarth* and *Qualified*. Data on these OJs is automatically generated with zero human intervention and is thus devoid of biases related to ethnicity, sex and color, thus, presenting a great opportunity to fields like recruitment where such discrimination is to be avoided.

In this research we show how XAI tools can be better used to bring more understandability and explainability to the recruitment process using OJs. Specifically, we show how XAI tools can be used for two main purposes during pre-deployment:

1) to understand and improve the performance of the ML model.
2) to improve the structure of the underlying dataset such that it contributes to increase the understandability and explainability of the ML model.

We designed and conducted iterative experiments to address both of the above aspects. Our experiences from these experiments are shared in the paper.

The rest of the paper is organized as follows. Section II provides a background on Online Judges (OJs) and XAI in the ML pipeline. Section III describes the first setup of the experiment. Section IV describes how domain knowledge is used to improvise both the model and the dataset. Observations and analysis using XAI on the extended and modified dataset are given in Section V. Related work is given in Section VI followed by the Conclusion section.

II. Related Work

Explainable Artificial Intelligence has drawn a lot of attention recently with lots of survey papers presented in literature on the topic [2], [4], [11], [3] and has drawn a lot of citations. It's importance and significance can be seen by DARPA's increasing interest in the field [12], [13]. Also, there are various domain specific papers that highlight the use and importance of XAI in critical fields like pathology, cancer detection, AI aided Alzheimer's Disease detection and bioinformatics [1], [14], [15], [5], [16]. It has also been used in non life-critical fields like Credit Risk Analysis [17] and in Human Resources in predicting employee attrition and implementing effective employee retention strategies [6]. Although the field of XAI has drawn a lot of attention recently creating new tracks within conferences and workshops and initiating new research initiatives and groups [2], it is not new. Researchers have been working in the field since many decades as detailed in [2].

AI and XAI have recently been used by HR in an increasing number of companies attempting to automate the recruitment process. ML has been used for screening resumes to shortlisting candidates, to analyzing employee churn, implementing strategies to improve employee retention, to identifying training and development needs, and in designing personalized development programs for employees. Some of these approaches have been evaluated by researchers and external agencies for their applicability. For example, [18] has applied the Design Thinking approach to evaluate the explainability aspect of a recruitment system by presenting counterfactuals generated by XAI systems [18]. A group of handpicked volunteers were selected for their experiment. However, their system is pretty basic and considers just two generic personas for evaluation and a relatively small data set.

XAI has also been adopted in fields closely related to software development. For example, in the software development process [19], in defect monitoring and prioritization [20], in software analytics [21] and during software maintenance [22]. There has been ongoing research in predicting developer performance with and without using AI and XAI principles. For example, the work done by [23] closely reflects our work in predicting developer performance without using XAI tools or techniques. Another similarity with our work is that it uses data from Codeforces for analysis. They train four different neural network models and obtain the best results for LSTM with Attention. This work differs from ours in many ways. Firstly, the dataset they use comprises of just 100 users. The paper does not explain how these 100 users were selected from about 140k registered users. The dataset seems too small to be representative of the different categories of users on Codeforces. Secondly, predictability of these users in terms of their behavior between contests is relatively consistent. Also, The paper does not consider temperamental performances of users in contests. Also, in their research, they consider past performances of users in both contests and practice sessions after the contest to predict rating after the contest while we use just contest data.

The work done in this paper differs from other previous works in two main aspects. First, we use XAI to both understand and improve the performance and explainability of the ML model. Second, we apply it to a system to predict developer performance in OJs. To the best of our knowledge, no work exists in this field. Moreover, the research work presented in this paper has a very narrow focus, i.e. evaluation of developer performance prediction during software development which may be in the form of a hackathon session created primarily for recruitment.

III. Background

A. Online Judges

Online Judge (OJ) platforms like SPOJ, EulerProject, Codeforces [24], Codechef, Topcoder, HackerEarth, etc. are being used by a wide spectrum of developers across the world

today to practice, sharpen and showcase their developmental skills. They are being used as development platforms, as crowd-sourcing platforms to hunt for solutions to industrial and science-driven challenges, as online compilers, in education, in workforce development and training, and more recently in recruitment [10] and by coaches in Universities to train and pick the best candidates to participate in the prestigious ICPC Challenge drawing more than 50,000 students from over 3000 Universities worldwide [25].

Most of them regularly hold online rated contests of fixed time durations in which thousands of users across the globe participate. Contestants are expected to solve a certain number of problems in each contest and are awarded *ranks*, *ratings* and *positions* after every contest and these are reflected on the OJ's leaderboard. These are described below in more detail.

1) Problems and verdicts: Each rated contest on an OJs presents contestants with problems at various difficulty levels ranging from elementary (easy) to hard (complex) [26]. In the context of this paper, we denote the difficulty level of a problem with θ ranging from 1 to 5 where θ=1 represents the difficulty level of the easiest problem in the contest and $\theta = 5$ represents the difficulty level of the hardest problem in the contest. Each problem is accompanied by a clear, and unambiguous description statement, sample inputs with their corresponding expected outputs, and time, memory and resource constraints under which the solution to the problem is to be executed to be successfully accepted by the OJ. Simple problems can be implemented with the use of simple logic and simple data structures while hard problems require the use of more sophisticated algorithms and efficient data structures in producing complete and correct solutions in addition to optimization to meet the specified performance and resource constraints.

For each submission made by a user, the OJ returns a verdict which can take one of the values specified in the first column of Table I.

2) Rating and divisions: When users participate in rated contests, they see a positive or negative change in rating that reflects their ability to solve the problems (tasks) in that contest relative to the previous contests. According to the rating, the contestants are split into multiple divisions based on their current rating. Division 1 on Codeforces consists of users who have the highest rankings (1900+), and problems in rated contests at this Division are generally the hardest to solve.

B. XAI Phases in a ML Pipeline

Consider a typical ML Pipeline indicated in Fig. 1 showing the two main phases where the use of XAI tools and techniques can be productive. The first phase is the *Understanding phase*, which subsumes the pre-deployment phases and comprises of Feature Engineering, Model Training and Model Testing. The second phase, is the *Explaining phase*, which subsumes the later two or more post-deployment phases.

The level of detail in the XAI generated explanations vary between the phases. For example, the explanation in the *Understanding* phase can be technical and given in semantics and formalism used by statisticians, mathematicians and informaticians. The first phase involves XAI tools being used

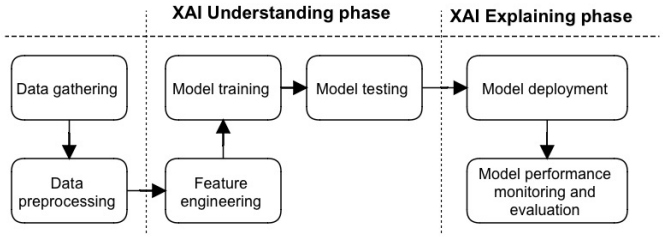

Fig. 1. A typical ML pipeline indicating XAI phases.

by the developer to improve the model during the training and testing stages and ensure that it works as intended [4] when it is deployed in the real-world. In the *Explaining phase*, however, the preferred way of explanation would be in Natural Language and/or intuitive and simple-to-understand visualizations. This phase would involve XAI tools being used by domain experts (a physician or a recruiting agent, for example) and end-users (a patient or a candidate for a job, for example) to interpret and better understand the reasons behind the decisions taken by the ML model deployed in real-life applications [4].

IV. ML Model with Traditional Stats

1) Data collection: For this research, we used *Codeforces* as the choice of OJ as they have easily accessible and large repositories and have a well documented API to access these repositories. First, user profiles of all 143,853 registered users on Codeforces was obtained using the Codeforces API. Next, for each of these users, details of all submissions made by these users to Codeforces was fetched for this study. This included more than 72 million submissions made to Codeforces. Submissions made to rated contests during its specified duration, submissions made to problems for practice, submissions that were successfully accepted or not, and those made in all accepted languages by the judge (including C/C++, Java, Ruby, Rust, Python, PHP, Kotlin, etc.) were included for analysis. The data obtained was largely clean except for missing entries for features that were not relevant to this research.

Features describing each user submission are shown in Table II. To this set of features, two new features - Experience based on time (exp_time) and experience based on the count of rated contests participated by the user (exp_contests) - were calculated and added for each submission entry. *exp_time* was calculated in days as the difference between the current date and the date of registration of the user on Codeforces. *exp_contests* involved more steps. First, to classify contests as rated contest hosted by Codeforces, details of all contests had to be obtained. Next, *contestId* for all Codeforces' rated contests were shortlisted and used to filter user's submissions based on the *problem.contestId* field to only include submissions made to rated contests. Next, using the *author.participantType* field, only submissions made by the user to the contest as a *Participant* were filtered. From this truncated submission list for each user, his *exp_contests* was then obtained.

Next, the nominal variable, *verdict*, in each submission, was converted to a numeric variable $0 \leq score \leq 1$ based on the verdict obtained against the test suite (*testset*) , where $score = 0$ implies that no submission has been made and

TABLE I. OJ RESPONSES TO USER SUBMISSIONS BASED ON QUALITY SUB-CHARACTERISTICS

OJ Verdict	Status of submission's execution	A	B	C
Wrong Answer (*WA*)	wrong output or some requirements not satisfied	X	X	-
Time Limit Exceeded (*TLE*)	exceeded maximal specified processing time limit	-	-	X
Memory Limit Exceeded (*MLE*)	exceeded specified RAM utilization limit (stack or heap)	-	-	X
Runtime Error (*RTE*)	runtime error occurred during execution	-	-	X
Accepted (*AC*)	passed all tests without exceeding resource or time limits	Y	Y	Y

Y - Satisfied, X - Not satisfied A-correct, B-complete, C-meets all specified performance and resource constraints

TABLE II. FEATURES DESCRIBING EACH SUBMISSIONS

#	Feature name	Datatype	#	Feature name	Datatype	#	Feature name	Datatype
1	id	int64	10	timeConsumedMillis	int64	19	author.members	object
2	user	object	11	memoryConsumedBytes	int64	20	author.participantType	object
3	contestId	int64	12	points	float64	21	author.ghost	bool
4	creationTimeSeconds	int64	13	problem.contestId	int64	22	author.startTimeSeconds	float64
5	relativeTimeSeconds	int64	14	problem.index	object	23	problem.points	float64
6	programmingLanguage	object	15	problem.name	object	24	problem.rating	float64
7	verdict	object	16	problem.type	object	25	author.room	float64
8	testset	object	17	problem.tags	object	26	author.teamId	float64
9	passedTestCount	int64	18	author.contestId	int64	27	author.teamName	object

$score = 1$ indicates an *AC*. Concept of *score*, and calculations related to *score* have been elaborated in [27].

A. ML Model Setup

In this experiment, we trained and tested seven ML regression models using traditional developer stats directly provided by OJs and use it to predict the *score* of developer in an unseen contest in a problem (E) at difficulty level $\theta = 5$ which was used as the target variable, Y. Traditional stats used as input features to the ML regression models were as follows: X = [*'rank'*, *'maxRank'*, *'rating'*, *'maxRating'*, *'position'*, *'exp_years*', '*exp_contests*'], The statistical distribution of features in X are given in Table III.

We decided to use symbolic ML representations in this experiments to better assess and study the explainability of a regression model as using subsymbolic models such as Deep Neural Networks or ensembles of simpler regression models will require the deciphering and subsequent understanding of the underlying complex black-box models which still remains a challenge [2].

The seven ML regression models were successfully trained and tested based on data of 143,853 registered users. The RMSE values and the prediction accuracy obtained using the seven ML regression models are given in Table IV. As the purpose of this research was not primarily to improve the prediction of a regression model by tuning the hyperparameters of the model, but to study the effect of features in improving the explainability of a model, we decided to use just one among the seven models. Among the seven ML regression models used, the *GradientBoost* regressor provided the least *RMSE* and the best *score* in our first experiments and was, thus, retained as the model of choice in this research.

The next section explains the evaluation of LIME and SHAP [28], two popular model-agnostic XAI tools that can be easily applied to comprehend ML models based on symbolic representations.

TABLE III. STATISTICS OF TRADITIONAL STATS

Feature	mean	std	min	max
rating	1074.4	454.9	-53.0	3757.0
maxRating	1130.3	473.7	227.0	3979.0
rank	1.0	1.8	0.0	10.0
maxRank	1.2	1.9	0.0	10.0
position	71927.0	41526.9	1.0	143853.0
exp_time	773.2	755.2	4.0	5234.0
exp_contests	12.6	23.7	0.0	816.0

TABLE IV. MODEL PREDICTION USING TRADITIONAL DEVELOPER STATS

ML Model used	RMSE values	accuracy
Elastic	0.1409	0.3106
Gradient Boost	0.1367	0.3507
Lasso	0.1408	0.3118
Linear	0.1407	0.3129
Random Forest	0.1442	0.2780
Ridge	0.1407	0.3129
XGBoost	0.1436	0.2837

B. LIME Analysis

LIME explains a prediction of a machine learning model, in our case the GradientBoost Regressor model, for a query point by finding important predictors and fitting a simple interpretable model. We applied LIME on our model and tested its behavior with ten randomly chosen query points, specifying five as the number of most important predictors to report. Based on these parameters, LIME was applied to our testset; LIME internally generated a synthetic data set, fitted a simple interpretable model of important predictors to it, and then used it to explain the predictions around the specified externally supplied ten selected query points. The explanations generated by LIME for the 10 query points and for our ML regression model are given in Table V.

It can be seen that *position* is consistently being used in all 10 explanations as the feature contributing the most to the prediction. It appears that LIME has identified four crisp categories of positions which are then used in the explanation. The second most important feature appears to be *maxRating* which also appears to have been divided into four separate

TABLE V. LIME EXPLAINABILITY

	Feature contribution 1	Feature contribution 2	Feature contribution 3	Feature contribution 4	Feature contribution 5
1	60871.00 ¡ position ¡= 93407.50	929.00 ¡ maxRating ¡= 1184.00	exp_contests ¿ 17.00	rank ¡= 0.00	870.00 ¡ rating ¡= 1107.00
2	position ¿ 93407.50	maxRating ¡= 929.00	maxRank ¡= 0.00	exp_contests ¡= 2.00	exp_time ¡= 295.00
3	30101.50 ¡ position ¡= 60871.00	1184.00 ¡ maxRating ¡= 1480.50	exp_time ¿ 1139.00	1107.00 ¡ rating ¡= 1422.00	0.00 ¡ maxRank ¡= 3.00
4	30101.50 ¡ position ¡= 60871.00	1184.00 ¡ maxRating ¡= 1480.50	exp_time ¿ 1139.00	0.00 ¡ maxRank ¡= 3.00	0.00 ¡ rank ¡= 3.00
5	position ¡= 30101.50	maxRating ¿ 1480.50	rating ¿ 1422.00	exp_contests ¿ 17.00	exp_time ¿ 1139.00
6	30101.50 ¡ position ¡= 60871.00	exp_time ¿ 1139.00	1184.00 ¡ maxRating ¡= 1480.50	1107.00 ¡ rating ¡= 1422.00	0.00 ¡ rank ¡= 3.00
7	60871.00 ¡ position ¡= 93407.50	929.00 ¡ maxRating ¡= 1184.00	2.00 ¡ exp_contests ¡= 6.00	maxRank ¡= 0.00	870.00 ¡ rating ¡= 1107.00
8	30101.50 ¡ position ¡= 60871.00	1184.00 ¡ maxRating ¡= 1480.50	295.00 ¡ exp_time ¡= 604.00	6.00 ¡ exp_contests ¡= 17.00	1107.00 ¡ rating ¡= 1422.00
9	60871.00 ¡ position ¡= 93407.50	929.00 ¡ maxRating ¡= 1184.00	exp_contests ¿ 17.00	295.00 ¡ exp_time ¡= 604.00	870.00 ¡ rating ¡= 1107.00
10	position ¿ 93407.50	929.00 ¡ maxRating ¡= 1184.00	maxRank ¡= 0.00	rating ¡= 870.00	2.00 ¡ exp_contests ¡= 6.00

categories and are used in the explanation. The exception to this is the 6th datapoint where LIME uses *exp_time* to provide the explanation. For the third and next important features there is a variation between the importance of features in prediction. For example, an XAI output generated in Natural Language to explain the first point may be as follows:

"*Since the user was placed between positions 60871 and 93497.50, and had a rating between 929 and 1184, and had participated in more than 17 contests and ranked at the lowest level, and had a rating between 870 and 1107, ...*"

Similarly, for the second point the explanation would have read as follows:

Since the user was placed at a position higher than 93497.50, and had a rating lower than or equal to 929, and had always been ranked at the lowest level, and participated in no more than 2 rated contests, and made his debut on Codeforces 295 days back , ...

Although this is easily understandable from the domain expert point of view, such explanations involving wide and deep decision trees and which have mathematics at their core, may overwhelm a typical end user even when provided in Natural Language.

To identify the feature importance in explanations, we executed LIME on 3000 separate data points and collated the results as shown in Table VI. Each row in the table shows details of one the six traditional stats, as specified below the table. The columns specify the feature importance. For example, *rating* (Feature 4) is the most important feature used in explaining 2925 of the 3000 points (97.5%) and is used as the second most important feature used to explain 75 of the total 3000 points (2.5%). Another important feature is *maxRating* (Feature 1) which was used as the most important feature to explain 75 of the 3000 data points (2.5%) and the second most important feature in explaining 2558 of the 3000 (85.26%) points. However, we see that the numbers are widely distributed among other features in the table cells. Such distribution of numbers in the table implies that the decision tree used in the explanation by LIME can get very wide clouding the explanation in NL when explaining multiple data points.

A metric that could capture this information could be represented as a k-tuple where k is the number of features used. In this experiment we have used $k = 5$ so we have a 5-tuple as follows: $< 97.5, 85.26, 37.2, 24.97, 19.7 >$ where each number in the tuple indicates the percent contribution of the feature to the k-th position. In this example, we have

TABLE VI. FEATURE IMPORTANCE USING LIME

	1	**2**	**3**	**4**	**5**	%
Feature 4	**2925**	75	0	0	0	20.15
Feature 1	75	**2558**	285	52	26	20.12
Feature 0	0	105	**1116**	762	449	16.33
Feature 5	0	134	650	**749**	591	14.26
Feature 6	0	134	650	749	**591**	14.26
Feature 3	0	4	132	359	695	7.99
Feature 2	0	1	84	296	645	6.89

features = [rating, maxRating, rank, maxRank, position, exp_time, exp_contests]

Feature 4 being used 97.5% of the time as the first feature in explaining a data point and Feature 1 being used 85.26% of the time as the second feature in explaining a data point. In an ideal case (a fully and consistently explainable model), each number in the k-tuple should be 100.

An ideal matrix for XAI would be a left diagonal sparse matrix of size $k \times k$, where k is the parameter to LIME specifying the number of features to include in the explanation.

C. SHAP Analysis

SHAP, like LIME, is model-agnostic and can be applied to explain models based on symbolic representations. It stands for SHapley Additive exPlanations and attempts to explain the prediction of an instance by computing the contribution of each feature to the prediction. We applied SHAP to our regression model and to evaluate its explainability on our dataset. Fig. 2 shows the SHAP plot for the seven traditional stats (listed below the figure). Similar to LIME, SHAP also ranked *position* as its most important feature followed by *maxRating*. But we can see that *exp_contests*, *rating*, and *exp_time* are also highly used.

Having a plot shape which is top-heavy, like an exaggerated overgrown mushroom, helps improve the explainability of an XAI tool. Carefully assembling and curating a good dataset can bring such a shape to the plot and increase its explainability.

V. ADDING DOMAIN KNOWLEDGE TO DATASET

Based on lessons learnt from the previous experiment, we decided to incorporate some domain knowledge directly into the dataset. This first involved basic feature engineering to identify and eliminate unimportant features. Next, having studied different OJ environments, their rated contests and user behavior during contests over the past several years, we decided to include features that implicitly incorporated domain knowledge into the dataset. The next subsections give a few illustrative examples of domain knowledge missing from the

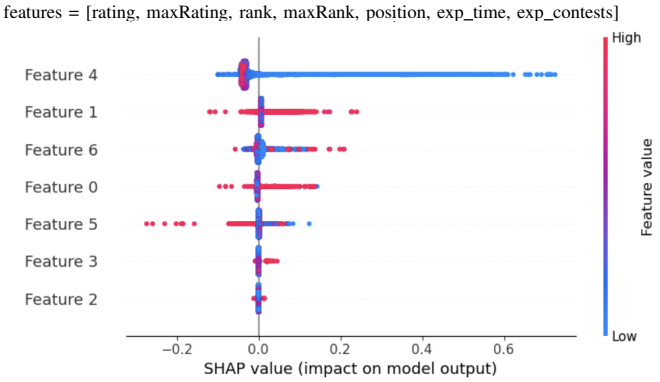

Fig. 2. SHAP Plot showing feature importance for traditional stats.

previous dataset because of which both the predictability of the model and the XAI aspect of the model were affected. This involved introducing new features, deriving new features from existing features, identifying outliers based on these newly generated features, classifying and segregating classes of submissions, we created a new dataset comprising of more than 40 new features in addition to the previous seven traditional stats used in the previous experiment. By including this domain knowledge into the dataset as additional features, and appropriately segregating and curating data, and training the ML regression model on this dataset, we show that the predictability and explainability of the trained model can be substantially increased.

A. Explaining Rank, Rating and Positional Related Inconsistencies

Rank, *rating* and *position* on an OJ may not give a complete picture of the ability and skills of a developer. For example, a low *rank* and *rating* on the OJ does not necessarily imply that the developer has poor programming ability. This is because every new user registering on an OJ, is assigned a default low *rank*, *rating* and *position* regardless of his programming experience or capability. It will take regular participation in rated contests on the OJ and consistently good performances in them for a developer to rise up the leaderboard and to be assigned a high *rank*, *rating* or *position* by the OJ. The rating algorithm used by Codeforces is a variation of the Elo rating [29] used in sports. Understanding the Elo rating system will help explain why an old user on the OJ with good *rating* can fall down the leaderboard with a few bad consecutive performances in contests. This knowledge is not explicitly built into the previous dataset. Identifying and explaining such instances will be challenging to an XAI tool in the existing case. For example, how could an XAI tool explain the situation of a newly registered user on the OJ consistently and successfully solving the difficult problems in contests?

1) Correction mechanism: By associating user submission history to user performances, could help generate better and more reasonable XAI outputs.

B. Upsets *in Contests*

Similar to contests in sports, seeing upsets happen in rated contests is not uncommon. As illustration of upsets, consider the two examples given in Fig. 4. The first example shows the five most recent performances of an average programmer. We can see that he had successfully solved only two easy problems while consistently attempting to solve the third one ($\theta = 3$). However, in the unseen contest he was able to successfully solve the first four problems ($score = 1$) and obtain a high score in problem E (at $\theta = 5$). The second example, shows the performances of a good programmer in the last five most recent contests.We can see that he consistently obtained high scores in all the five problems. But in the unseen contest, however, he performs very badly, not able to successfully solve even the two most easy problems. How could such datapoints be presented by XAI tools?

1) A possible XAI explanation in natural language: "This average user has caused an upset by solving the most difficult problems in the contest."

2) Correction mechanism: These *upsets* or erratic and temperamental performances [27] by contestants can be seen as outliers or stray occurrences in the dataset. Correctly identifying and labelling such *upsets* in the dataset or eliminating them altogether will help improve the accuracy of the model and increase the explainability aspect of the model.

C. Divisions: Different Playing Fields

The *problem.index* field in the *submissions* table (Feature no. 14 in Table II) indicates the problem index (A..E) and hence specifies the problem's difficulty level ($1 \leq \theta \leq 5$). Closer inspection of the dataset reveals a strange trend - higher ranked and rated contestants have difficulty in successfully solving problems D and E, while many lower ranked and rated contestants regularly seem to be successfully solving problem E. Domain knowledge says that all E's are not equal. Users on Codeforces are classified into four divisions based on their rating. Higher rated contestants play (participate) in the highest *Division* (*Division* 1). Rated contests are held separately for each *Division*. While users from higher *Divisions* can register and participate in contests targeted for lower *Divisions*, they are not counted towards their rating. Problems in all rated contests, regardless of *Division*, are indexed from *A* to *E*. This implies that a problem indexed as *E* in a contest at a lower *Division* could be presented as index *A* in a contest at a higher *Division*. This muddles the concept of problem difficulty (θ) and brings inconsistency in the predictability of the regression model. How could such datapoints be presented by XAI tools?

1) A possible XAI explanation in natural language: "This user is from a lower Division and thus could solve problem E which, in reality, may not be too difficult to solve"

2) Correction mechanism: Classifying and segregating submissions based on contestant *rating* into Divisions and possibly training and testing separate ML regression models based on Divisions. This mechanism will ensure the XAI outputs are more natural and understandable.

D. Oscillations Between Divisions

Oscillations between Divisions is an extension of the previous explanation of Divisions. Consider a developer whose current rating is close to the boundary of the next higher Division. A good performance in a rated contest in his existing

(a) Good programmer in good health (b) Good programmer in poor health

(c) Average programmer in good health (d) Average programmer in poor health

(e) A healthy programmer showing consistently good growth (f) A programmer showing a chronic health condition

Fig. 3. Sample health cards showing developer health over a 7-contest window ($w = 7$).

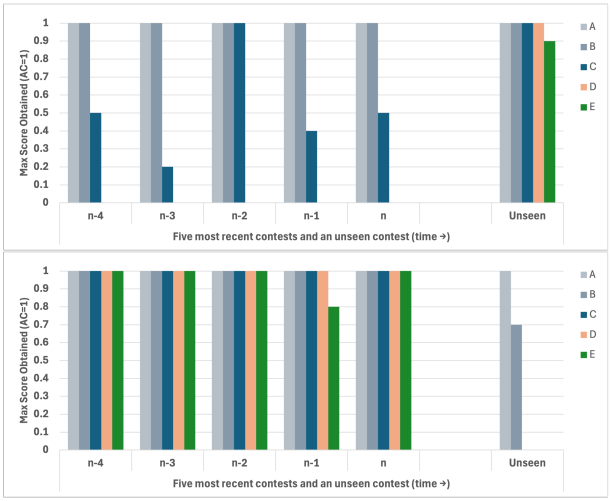

Fig. 4. Upsets in contests.

Division will increase his rating and will subsequently place him in the next higher Division. Similarly, a poor performance by a user in a contest whose rating is close to the boundary of the lower Division, may be placed in the lower Division after the contest. A situation may occur when the ratings fluctuate at the Division boundary causing a user to consistently solve problems D and E when placed in the lower division, and afterward fail to solve problems D and E when placed in the higher Division and vice versa. We refer to this as phenomenon as *oscillations between Divisions*. This common but strange behavior negatively impacts the prediction of a ML model and can be difficult to explain by an XAI tool. How could such datapoints be presented to end user of an XAI tool?

1) A possible XAI explanation in natural language: "*This user's currently rating is at the Division boundary and he is, thus, demonstrating this oscillating behavior.*"

2) Correction mechanism: Specifying a boundary threshold (δ) and segregating users from the dataset whose rating falls within this threshold ($\pm\delta$) at the Division boundary. This mechanism will ensure the XAI outputs are more natural and understandable.

E. Joint Contests

OJs frequently organize joint contests between two different Divisions with problem being identified using the same problem index. However, the rating change calculations differ between divisions. This is not very explicit in the dataset and such contests will have to be identified and marked as such in the dataset.

1) A possible XAI explanation in natural language: "*This user's participation is probably in a joint contest between Divisions and thus has not been able to solve problem E in the higher Division level.*"

2) Correction mechanism: Manually identifying and tagging joint contests as such, will help generate better XAI outputs which are more natural and understandable.

F. Health Card and Development History

Similar to clinical history of a patient [16] and player stats which show past performances and record of a soccer player, a development history could record the history of a developer. This history could provide various insights into a developer's behavior over time. This could be semantically arranged and structured to provide a valuable source of information for XAI applications . Unfortunately, there is currently no standard way of documenting this history - past achievements related to code development, role and contribution to open-source projects, awards obtained in hackathons and programing contests, etc. remain disparate entities and connected together only on the CV of a developer if a job change is desired or to a social media page.

A performance in a single recruitment contest or a hackathon cannot be used as the sole criteria by HR to recruit a candidate. There may be cases of false positive or false negatives.

1) A bad programmer being classified as good - An average candidate may perform extremely well in such a contest if he is lucky enough to get a problem previously 'seen' by him or that he has worked on
2) A good programmer being classified as bad - A good programmer who may not perform well in such a contest because of health-related or personal reasons on that particular day.

However, a record of the developer's recent history augmented with the performance in the recruitment contest can aid HR in better decision making.

1) Reflection of developer health: A health card of a developer provides an clear insight into the health, maturity level and growth of a developer. Fig. 3 shows examples of five health cards. Each health card shows a windows into scores obtained by contestants in their last seven rated contests ($w = 7$) with the rightmost contest being the most recent contest that the user participated in. Each contest has five problems (A..E) at varying difficulty levels (θ) with A being at the lowest level of difficulty ($\theta = 1$) and E at relatively the highest level of difficulty ($\theta = 5$) among the five problems. Good developers are identified by their capability of successfully and consistently solving all five problems with an AC ($score \sim 1$). Average developers are able to solve the first few problems ($\theta \leq 3$) consistently with a $score = 1$, but have difficulty successfully solving problems at the higher level of difficulty ($\theta \geq 4$) and usually end up obtaining $0 \leq score < 0.7$ for these problems.

As can be seen from Fig. 3(a), the first user appears to be good developer as demonstrated by his consistently and (almost) successfully solving all five problems in all his seven past contests. His *rank*, *position* and *rating* on the OJ will continue to remain stable with minor fluctuations. On the other hand, the health card of the second user shown in Fig. 3(b) shows a different trend. The user appears to have a history of solving all five problems in contests. However, his performance in the more recent contests seems to have deteriorated. We refer to this performance deterioration as a sign of *poor health* of the developer. The term *poor health* is not absolute but relative to a developers's past performances. In this example, the user has successfully solved a few problems. But based on his demonstrated capability of solving all problems in the past, we say that his health is *poor*. Because of his poor recent performances, his *rank*, *position* and *rating* will take a beating and fall to levels that may not reflect the developer's actual capability.

Likewise, we have the health cards of two average programmers. Fig. 3(c) shows the health card of a healthy average programmer. We label him *healthy* as his health card shows a consistent performance with the developer consistently solving the first few problems in the most recent seven contests. The *rank*, *position* and *rating* of this developer on the OJ will continue to remain stable with minor fluctuations. On the other hand, the average programmer's health card in Fig. 3(d) shows a deteriorating performance - although he had a history of demonstrated capability in solving problems A and B in a few recent contests, he has consistently failed to successfully solve these problems in the more recent contests. Similar to the effect of deteriorating health of a good developer, the *rank*, *position* and *rating* on this developer on the OJ will drop to levels that do not rightly indicate the capability of this developer.

This *poor health* that we refer to in this paper is similar to the *loss of form* of a player referred to in sports. There is a high probability that a developer in poor health may not be able to perform his best in a recruitment hackathon or a contest much like an *out-of-form* player's performance in a game because of an injury, illness or some personal issue. This developer, as such, should not be evaluated by a single contest in his current poor form.

The health card in Fig. 3(e) shows a developer in good health and demonstrating good and steady growth. We see that his capability as a developer has matured over the last few contests. A few contests back, he was only able to solve problems at $\theta \leq 2$ but has grown in his capability as a developer to successfully solve problems at $\theta \leq 4$ while able to attempt problems at 5.

These health cards in the figure show contests over a window size of $w = 7$. Larger window sizes will give more meaningful and deeper insights into the growth, consistency and maturity of a programmer over a longer time period.

2) Structure of a developer's health card: A health card reflects the performance of a user in each of the rated contests that he has attempted on the OJ. A contest is defined as $C = \{c_1, c_2, ..., c_n\}$ where each c_i gives a summary of the performance of the developer in the contest *i*. The size of the set, $|C|$, gives the contest experience or the number of rated contests the developer has participated in on the OJ. For the scope of this paper, each contest has five problems (A..E) at increasing level of difficulty, with A being at the easiest level ($\theta = 1$) and E at the most difficult level ($\theta = 5$).

Each c in turn consists of sets of 5-tuples represented formally as $c = \{s_1, s_2, ...s_m\}$. where each s is a 5-tuple representing values associated with the five problems (A..E) in the contest. The size of the *set, m*, is contextual and can be varied based on the user need. For example, s_1 could be used to

represent the final verdict awarded by the OJ for the contest where verdicts are assigned representative scores between 0 and 1.0 where 0 indicates that the user has made no submission to the problem in the contest and 1.0 represents an AC with other verdicts (WA, RTE, TLE, MLE, etc.) falling within this range. Similarly, s_2 could be used to record attempts made for each problem in a contest. Other stats that could be stored are numbers of WAs for each problem, number of TLEs obtained for each problem, etc.

For example, consider the following representation of data of a programmer for contest *j*.

$$c_j = \{score_j, attempts_j, wa_j, tle_j, rte_j ...\}$$

where each $c_j \epsilon C$ represents a rated contest that a user has participated in on the OJ. It could contain various details about the performance of the user in problems in the contest at difficulty levels $1 \leq \theta \leq 5$ as 5-tuples. Some of the important statistics that could be included in c_j are given below. *score* is a 5-tuple that gives the maximum score that a user has been able to attain among all attempts that were submitted to the OJ during the contest. Consider the example below:

$$score_j = (1.0, 1.0, 1.0, 1.0, 0)$$

In this contest, the user has been able to successfully solve the first four problems (A..D) but did not solve problem E. The 5-tuple *score* does not indicate the number of attempts (shots) that were taken. The 5-tuple *attempts* indicates the total number of submissions, both successful and unsuccessful, that the user made to the OJ during the contest. Consider the example below

$$attempts_j = (1.0, 1.0, 1.0, 8.0, 0)$$

The user made one submission each to problem A..C, made eight attempts to solve problem D and no attempts at solving problem E. This 5-tuple gives an indication to the ability of a developer to understand the given problem statement. The verdicts returned by the OJ for each of the submissions and for each of the problems are captured in their respective 5-tuples. Consider the 5-tuple for wa_j below

$$wa_j = (1.0, 1.0, 1.0, 1.0, 0)$$

This indicates that the user has made one wrong submission for each of the problems A..D. The 0 for problem could mean two things - either he obtained no WA for problem E for any of the submissions made or he obtained no WA because he made no submission to problem E. This can be better understood from $attempts_j$. Similarly, we have the 5-tuples tle_j and rte_j, which give an indication to the submissions which were awarded TLE and RTE for each of the five problems.

For contestants who have participated in many contests, the size of set C can get large. Also, if we decide to store a large set of data for each contest, the size of the encoding vector can become fairly large. Although this could be seen as a limitation, it adds more explainability to the model. However, this limitation can be overcome by constraining the size of set *C*. The set *C* could be seen in two forms:

1) The set *C* contains the complete history of the developer on the OJ where $|C|$ gives the total sum of rated contests that the developer has participated in. Although this set can get large, this provides insights into the growth and maturity of a developer since his registration on the OJ.
2) The set *C* contains only a window to the most recent *w* contests and provides a glimpse to the health or most recent form of a developer. This can be see in Fig. 3 (Health chart) with where $w = 7$.

[Explain the significance of the two sets] EAI can add transparency and a clearer explanation and justification to the decision making process by presenting the health chart of the developer in a visually intuitive form while additionally providing the set *C*. This will also help in increasing trust in the system.

VI. Enhancing XAI with Derived Data

The main objective of this research was to bring more explainability to the ML models by focusing more on the data aspect rather than just enhancing the performance of ML models though hyper-parameter tuning. This was achieved by enhancing data quality through carefully creating and adding new features to the dataset and by creatively mitigating the effect of noise and outliers using knowledge of the domain.

One of the major changes made to the dataset used in the previous experiment was to incorporate developer history. This proved to be a double-edged sword - it increased the performance of the model while providing more meaningful data to enhance the explainability of the XAI tools. The resultant dataset considerably improved the r2-score of the GradientRegressor model from 0.3507 to 0.9834 (63.27%) which was a substantial improvement.

Additionally, the health chart of a user can be easily extracted from the dataset to add more human-understandable explanation to the XAI generated output.

A. LIME - Results and Discussion

Similar to the previous experiment, we applied LIME to the GradientBoost Regressor model trained on the enhanced dataset and tested its behavior with ten randomly chosen query points, specifying five as the number of most important predictors to report. For these parameters, LIME internally generated a synthetic data set, fitted a simple interpretable model of important predictors to it, and then used it to explain the predictions around the specified externally supplied ten selected query points. The explanations generated by LIME for the 10 query points and for our ML regression model in this experiment are given in Table VII.

Compared to the explanations in the previous experiment, we note that one feature is consistently and dominantly used in all 10 explanations as the feature contributing the most to the prediction and using the same decision. This is reflected in the second and third most important features used in the explanation of the query points with no exceptions. When

generating an explanation for this in Natural Language, the XAI output would be consistent across most, if not all, data points. For example, explanations for the first two data points could read as as follows:

1) "*Since the user could not successfully solve problems B, E and C even though he made feeble attempts to solving problems E and C in the last five contests he participated in .....*"
2) "*Since the user could not successfully solve problems B, E, C and A and made no attempt to solve problem D in the last five contests he participated in.....*"

Compared to the possible explanations that could be generated in the previous experiments, these are more understandable and consistently presented to the end user. A caveat - in the dataset for Codeforces, and generally in most OJs, a large majority of registered participants are not able to successfully solve most problems. This explains the apparent bias visible in the choice of query points in Table VII.

To further identify the feature importance in explanations, we executed LIME on 3000 separate data points and collated the results as shown in Table VIII.

The table has been limited to show just twenty of the total features used in this experiment. Each row in the table shows details of one feature. The columns specify the feature importance. In this experiment, Feature 16 was the most important feature used in explaining all of the 3000 points (100%). The second and thirst most important features were Feature 19 and Feature 17, respectively, which were used to explain all of the 3000 data points (100%). However, we see that the numbers are evenly distributed among other four features in the table cells for the fourth and fifth most important feature. This distribution of numbers in the table differs from the numbers seen in the previous experiment. We can be infer from the features and the range selected that the decision trees used in the explanations may not be very wide which will aid the visual explanation generated by LIME when explaining multiple data points.

In this experiment 5-tuple used to capture the explainability of the model read as follows: $< 100, 100, 99.13, 24.8, 21.8 >$. This is a substantial improvement over the previous 5-tuple which was $< 97.5, 85.26, 37.2, 24.97, 19.7 >$. Comparing the two, we can observe that each feature contribution to the explanation has improved.

Also, and as pointed out earlier, an ideal matrix for XAI would be a left diagonal sparse matrix of size $k \times k$, where k is the parameter to LIME specifying the number of features to include in the explanation. Wee see that this matrix is a left diagonal matrix at $k = 3$ which was not the case in the previous experiment.

B. SHAP: Results and Discussion

We applied SHAP to evaluate the GradientBoost Regressor model trained on the enhanced dataset for explainability. Fig. 5 show the SHAP plot for twenty of the total features present in the dataset. Similar to LIME, SHAP also ranked Feature 16 as the most important feature followed by Feature 19 followed by Features 17, 18 and 15.

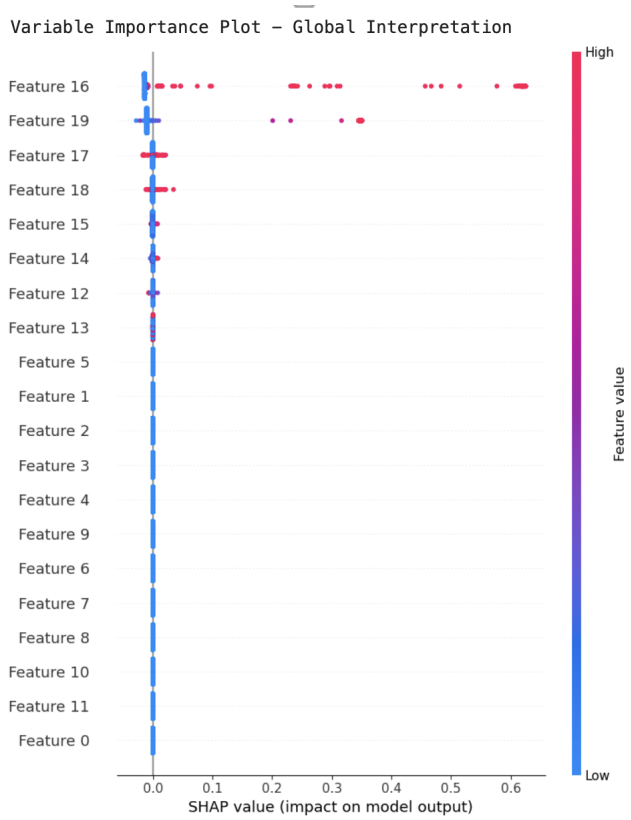

Fig. 5. SHAP values for ML model using the enhanced dataset.

As pointed out earlier, and ideal SHAP plot shape would be a top-heavy one, like an exaggerated overgrown mushroom. The SHAP plot obtained in this experiment appeared to be just that - this greatly aids in improving the explainability aspect of the XAI tool. This was a result of carefully assembling and curating the dataset to bring such a shape to the SHAP plot and, subsequently, to increase its explainability.

VII. Conclusion

Bringing more transparency to the decision making process in fields deploying ML tools is important in various fields. This implies that ML tools need to be designed in such a way that they are more understandable and explainable to the end users while also increasing trust in them. The field of XAI, although a mature area of research, is increasingly being seen as a solution to address these missing aspects of ML systems.

The focus of this work was on improving the transparency of the decision making process in recruitment of software developers using Online Judges. As the field of software development attracts talent at various levels for the high-paying lucrative jobs that is has, it is important to correctly identify and differentiate highly skilled developers from developers who are adept at only performing regular and mundane programming jobs. Also, HR recruiting agents needs to report back to their managers and justify why certain candidates were selected and why some were rejected.

To address this, we built a regressor model that can help differentiate developers based on their ability, while identifying

TABLE VII. LIME EXPLAINABILITY

	Feature contribution 1	Feature contribution 2	Feature contribution 3	Feature contribution 4	Feature contribution 5

Feature 1	0	0	0	0	0	0
Feature 2	0	0	0	0	0	0
Feature 3	0	0	0	0	0	0
Feature 4	0	0	0	0	0	0
Feature 5	0	0	0	0	0	0
Feature 6	0	0	0	0	0	0
Feature 7	0	0	0	0	0	0
Feature 8	0	0	0	0	0	0
Feature 9	0	0	0	0	0	0
Feature 10	0	0	0	0	0	0
Feature 11	0	0	0	0	0	0

and ignoring their erratic (temperamental) performances during contests. We showed how both the ML model and the underlying dataset used in training and testing the model can impact the explainability of the model. The underlying dataset that was readily available from the OJ, was enhanced by adding more features and creating new derived features based on our knowledge of the domain. This was done to add more explainability to the model and to increase its predictability and performance accuracy. We also showed how XAI can be actively and iteratively used during pre-deployment to improve the quality of the dataset and to improve the prediction accuracy of the regression model. These iterative changes helped improve the r2-score of our GradientRegressor model from 0.3507 to 0.9834 (63.27%) which was a substantial improvement. We also showed how the consistency and explainability of LIME and SHAP, the XAI tools used in this research, increased over the iterations.

We believe that the work presented in this paper, has great applicability to areas other than developer recruitment. For example, it could be used by project managers to suggest focussed training regimes for developers in their team, to recruit developers for specialized domains, by coaches at Universities to better select their programming team, and in academia where students' performance in programming courses need be predicted to take early remedial action.

***Abstract*—Ransomware is a prevalent and highly destructive type of malware that has increasingly targeted cloud storage systems, leading to significant data loss and financial damage. Conventional security mechanisms, such as firewalls, antivirus software, and backups, have proven inadequate in preventing ransomware attacks, highlighting the need for more robust solutions. This paper proposes the use of Secret Sharing Schemes (SSS) as a defense mechanism to safeguard cloud storage systems from ransomware threats. Secret sharing works by splitting data into several encrypted shares, which are stored across different locations. This ensures that even if some shares are compromised, the original data remains recoverable, providing both security and redundancy. We conducted a comprehensive review of existing secret sharing schemes and evaluated their suitability for cloud storage protection. Building on this analysis, we proposed a novel framework that integrates secret sharing with cloud storage systems to enhance their resilience against ransomware attacks. The framework was tested through simulations and theoretical evaluations, which demonstrated its effectiveness in preventing data loss, even in the event of partial compromise. Our findings show that secret sharing can significantly improve the reliability and security of cloud storage systems, minimizing the impact of ransomware by allowing data to be reconstructed without paying a ransom. The proposed solution also offers scalability and flexibility, making it adaptable to different cloud storage environments. This research provides a valuable contribution to the field of cloud security, offering a new layer of protection against the growing threat of ransomware.**

***Keywords*—Ransomware; secret sharing; cloud storage; data leakage; reliability**

I. Introduction

Cyber attacks in the form of ransomware have now become one of the most frequent and most vicious types of cybercrime [1]. These attacks usually involve software that secretly encrypts a person's files, and hence becomes inaccessible until a certain amount of money is paid to the attackers for the decryption key [2], [3]. The rise of ransomware is attributed to the fact that the attackers can demand and receive payments in cryptocurrencies and continued expansion of digitalization in different industries. WannaCry and NotPetya attacks are some of the most infamous ransomware attacks that have shown the extent of the damage that can be caused to critical infrastructure, healthcare, finance, and everyday users [4].

In our research article Cloud storage services have revolutionized data management by offering scalable, accessible, and cost-effective solutions for storing vast amounts of information. Organizations and individuals alike benefit from the convenience and flexibility provided by cloud storage. However, this dependence on cloud services also presents significant security challenges. As more sensitive and critical data is stored in the cloud, it becomes an attractive target for cybercriminals. The centralized nature of cloud storage makes it vulnerable to various attacks, including data breaches, insider threats, and ransomware.

A. Motivation

The more frequent and complex ransomware attacks on the cloud storage systems clearly show that protect measures are insufficient. The conventional security measures including antivirus, firewall and data backup may not be effective in dealing with the modern day hackers. Ransomware can spread through the system and encrypt data within a short time; thus, organizations have no choice but to pay the ransom or lose their data.

Thus, secret sharing schemes may be considered as a rather effective approach to increasing cloud storage security. These cryptographic techniques include: this is a method of dividing a secret, for instance, a piece of data into several parts and spread out. Some of these shares are adequate to reconstruct the original data and, thus, the system offers both security and redundancy. Thus, using secret sharing schemes in cloud storage, data can be protected from ransomware attacks since even if some shares are stolen, the original data is still restorable.

B. Objectives

The purpose of this paper is to analyze how secret sharing schemes can help in combating ransomware attacks in cloud storage systems, which are explained followings:

1) Review Existing Secret Sharing Schemes: It is an analysis of many types of schemes for secret sharing and assess how suitable they are for the cloud storage security.

2) Propose a Novel Framework: Propose a design of an architecture that incorporates secret sharing techniques with cloud storage to strengthen the protection against ransomware threats. This framework will describe the steps of partitioning the data, encrypting the data, distributing the data and recovery of the data.

3) Evaluate Effectiveness: Evaluate the preparedness of work and acquire robust information based on simulations and theoretical investigation of the proposed framework about how well it will perform and how easily it can be penetrated by ransomware attacks while not compromising significantly on system throughput.

C. Contributions

The contributions of this paper are threefold:

1) Comprehensive Review: In this paper, we present a detailed analysis of the SSSs, their relevance in cloud storage security, and the most appropriate ones for combating ransomware.

2) Novel Framework: This paper proposes a new approach that incorporates secret sharing techniques to fortify the security of cloud storage. This framework outlines the measures to follow in order to incorporate SSS with ordinary cloud storage systems and guidelines for the same.

3) Evaluation and Analysis: To assess the efficacy of the proposed framework we have carried out a number of simulation and theoretical exercises. Thus, the proposed framework can be considered as an effective means of countering ransomware threats in cloud storage systems.

D. Structure of the Paper

The remainder of this paper is organized as follows: Section II presents the related work in the areas of ransomware protection and secret sharing techniques. Section III presents the definitions. The system proposed in this paper is described in Section IV, which includes the architecture and the way the framework will be implemented. Sections V and VI, respectively explains the experiment setup and the results of the experiment which prove that the framework is useful and efficient. Section VII looks at the security, usability and the major constraints of the proposed framework. Section VIII presents the discussions. Lastly, Section IX offers the summary of the research and the recommendations for further studies.

Thus, this paper focuses on the problem of ransomware in the cloud storage context and offers a new idea to overcome this issue using the secret sharing technique. The following framework is presented as a viable way of mitigating the current and future risks of ransomware attacks and thus maintaining the security of data stored in the cloud services.

E. Preliminaries

We used mathematical symbols throughout the paper, which is explained below in Table I.

TABLE I. PRELIMINARIES: SYMBOLS AND DESCRIPTIONS

Symbols	Description
S	Secret to be shared
n	Total number of shares
t	Threshold
x	Share index
$f(x)$	Polynomial used in Shamir's Secret Sharing scheme
a_0	Constant term in the polynomial (the secret)
a_i	Coefficients of the polynomial
K	Encryption key size
T	Threshold value for secret reconstruction
R	Ransom amount
P	Polynomial interpolation (Lagrange interpolation)

II. RELATED WORK

A. Ransomware in Cloud Environments

Ransomware attacks have become more complex in recent years as attackers look for ways to circumvent existing protection mechanisms. Ransomware is now attacking cloud environments because of the large storage capacity and shared data repositories that they offer. Kharraz et al. [5] and Scaife et al. [6] for instance have described the evolution of ransomware in which more targeted attacks are now being conducted on valuable data in the cloud storage. Some of the defense mechanisms that have been suggested to protect cloud storage from ransomware include:Some of these are anomaly detection systems, data encryption, and backup solutions. For instance, investigated the possibilities of applying machine learning to identify the ransomware activity in cloud settings [7], which was based on the anomalous behavior of file reading and writing processes. However, these methods can only help to detect and contain ransomware attacks and cannot prevent initial infiltration and guarantee data restoration without paying the criminals.

B. Secret Sharing Schemes

Secret sharing is a technique in which a secret is split up and given to a number of people who are then able to reconstruct the original secret only if they hold a certain number of shares. The concept was suggested for the first time by Shamir and Blakley in 1979 [8] and both, though independently, presented methods of secret sharing.

SSS scheme by Shamir that employs polynomial interpolation is quite popular and secure due to its ease of implementation. In SSS, a secret is divided into n shares and a threshold t is set and any t shares can reconstruct the original secret while less than t shares give no information about the secret [9]. This feature makes SSS suitable in applications that need to have high security and are also tolerant to faults.

The application of the Chinese Remainder Theorem (CRT) has also been made in secret sharing. The schemes based on CRT, described by Asmuth and Bloom (1983), are another way to accomplish the secret division process by using the characteristics of the modular arithmetic. These schemes are beneficial regarding computational overhead but can be difficult to implement as opposed to SSS.

C. Integration of Cryptographic Techniques with Cloud Storage

Many cryptographic approaches have been applied to the cloud storage to increase the level of data protection. Gentry [10] has worked on homomorphic encryption which enables computation on encrypted data without decrypting it, thus enabling secure data in clouds. Likewise, Attribute Based Encryption (ABE) also have a feature of access control which means that the owner of the data can determine who should be able to decrypt it depending on the attributes that have been assigned to the users.

Even though there have been numerous developments in cryptographic methods, the precise implementation of secret sharing techniques for combating ransomware in cloud storage is not well-researched. Chou and Wei [11] provided a research

on the use of secret sharing for secure cloud storage with emphasis on data confidentiality and data integrity. However, their work did not capture the threat of ransomware and the difficulties that follow in the wake of the attack regarding data retrieval.

D. Existing Solutions and Gaps

The current approaches to combating ransomware in cloud storage are mainly based on the detection and mitigation measures rather than prevention and the building of resistance. For instance, Scaife et al. [12] presented CryptoDrop which is a system that analyzes for the existence of ransomware by checking on the file operations. Although they are useful in identifying ransomware activity, they do not prevent the encryption of data as soon as the ransomware gains entry into the organization's system resulting into data loss and ransom demands.

However, the conventional backup systems though critical may not be adequate for advanced ransomware attacks that specifically go after the backup data and its storage. This paper provides a new perspective on how to improve the reliability of cloud storage through the integration of secret sharing schemes. This means that since shares can be stored in different locations, even if some of the shares are violated, the original data can still be reconstructed from the remaining shares.

In conclusion, although there has been progress in the identification of ransomware and improvement of cloud storage security, there is still a gap in the development of efficient and effective methods of protection. cryptographic solution that can be used to protect the cloud storage against ransomware attacks is the secret sharing schemes. Due to the self-healing property of secret sharing, it is possible to design framework that not only prevent data to be completely lost but also to be retrieved when attacked.

This paper contributes to the current literature through proposing a new framework that enhances the application of secret sharing schemes in cloud storage to combat ransomware attacks. The following sections will elaborate the proposed framework, the way through which it has been applied, and the findings of the experiment that proves the efficiency of the proposed framework as a strong defence mechanism for cloud storage settings.

III. Definition: Secret Sharing for Ransomware Defense

Let S represent the sensitive data that needs protection within a cloud storage system. Secret Sharing Schemes (SSS) aim to protect S by splitting it into n distinct shares such that the original data S can only be reconstructed when a threshold $t \leq n$ number of shares is available [13], [14]. This approach ensures that even if fewer than t shares are compromised, the attacker gains no knowledge about the original data, making the system resilient against ransomware [15].

1) General Secret Sharing Scheme: A secret sharing scheme defines two key algorithms:
1. Share Generation: $\text{Gen}(S, t, n) \rightarrow \{S_1, S_2, \ldots, S_n\}$.

The algorithm takes the secret S, the threshold t, and the total number of shares n as inputs and outputs n shares $S_1, S_2, \ldots, S_n$.

2. Secret Reconstruction: $\text{Recon}(\{S_i\}_{i \in \mathcal{I}}) \rightarrow S$.

This algorithm takes any subset of at least t shares as input and reconstructs the secret S. For any subset smaller than t, no information about S is revealed.

2) Security Against Ransomware: Let k represent the number of shares an adversary manages to compromise. The key security property of secret sharing is that, for any $k < t$, the adversary gains no useful information about S. This property can be formalized as follows:

$$I(S; \{S_1, S_2, \ldots, S_k\}) = 0 \quad \text{for} \quad k < t \tag{1}$$

Where $I(S; \cdot)$ denotes the mutual information between the secret S and the compromised shares. This ensures perfect secrecy for any number of compromised shares less than t.

3) Attack Probability and Security: To quantify the security provided by secret sharing, let $P_{\text{comp}}(t, n, k)$ represent the probability that an adversary can compromise k out of n shares, where $k \geq t$. Assuming that the probability of compromising any single share is p, the probability of an attack being successful (i.e., compromising at least t shares) is given by:

$$P_{\text{attack}}(t, n, p) = \sum_{k=t}^{n} \binom{n}{k} p^k (1-p)^{n-k} \tag{2}$$

This probability decreases exponentially with increasing t, highlighting the robustness of the system. The function $\binom{n}{k}$ represents the binomial coefficient, capturing the number of ways the attacker can choose k shares from n.

4) Threshold and Ransomware Mitigation: The threshold t in a secret sharing scheme plays a critical role in ransomware defense. By setting an appropriate threshold, we can guarantee that ransomware attackers must compromise at least t shares before they can attempt to reconstruct the secret. Given the difficulty of breaching multiple cloud locations simultaneously, this provides a significant defense against ransomware.

The choice of t involves a trade-off between security and efficiency:

High t: Increases security but requires more shares for reconstruction, which can increase system overhead.

Low t: Reduces overhead but makes it easier for attackers to reconstruct the secret if they can breach multiple locations.

The optimal threshold t_{opt} can be determined by minimizing the following cost function:

$$\text{Cost}(t) = \alpha \cdot P_{\text{attack}}(t, n, p) + \beta \cdot C_{\text{recon}}(t) \tag{3}$$

Where: - α and β are weight factors, - $P_{\text{attack}}(t, n, p)$ is the probability of a successful attack given threshold t, - $C_{\text{recon}}(t)$ is the computational cost of reconstructing the secret using t shares.

5) Ransomware Impact and Share Distribution: A key advantage of secret sharing in ransomware scenarios is the ability to disperse shares across multiple cloud storage providers or geographical locations. This means that even if a ransomware attack compromises one or more locations, it remains highly unlikely that the attacker will obtain enough shares to reconstruct S.

Let M denote the number of distinct storage locations. Assuming that the probability of breaching any location is independent, the overall probability $P_{\text{location breach}}(k, M, p)$ of an attacker compromising k shares stored in different locations can be modeled as:

$$P_{\text{location breach}}(k, M, p) = \binom{M}{k} p^k (1-p)^{M-k} \tag{4}$$

This model further reduces the attack success probability, making the system more secure as the number of distinct storage locations increases.

6) Ransom Demands and Economic Impact: In ransomware attacks, the ransom demand is often proportional to the amount of data encrypted. Let $R(S)$ represent the ransom demand as a function of the secret S, which can be modeled as:

$$R(S) = \gamma \cdot \text{value}(S) \tag{5}$$

Where γ is a constant scaling factor representing the attacker's valuation of the data. Secret sharing reduces the expected financial impact $E[R_{\text{effective}}]$ by minimizing the likelihood of the data being compromised:

$$E[R_{\text{effective}}] = P_{\text{attack}}(t, n, p) \cdot R(S) \tag{6}$$

Since $P_{\text{attack}}(t, n, p)$ decreases with t, the ransom demand and the overall financial impact are significantly reduced through secret sharing.

A mathematical framework is provided by secret sharing for defending against ransomware attacks in cloud storage systems. Secret sharing spans the range of handling shared data by splitting it up into multiple shares, which are distributed to different locations, thereby improving the resistance of cloud infrastructures to unavailability. An optimal threshold is selected, and we provide strong theoretical guarantees of security by offering probabilistic analysis of attack success rates, minimizing the probability of data compromise while ensuring a low, and possibly zero, financial impact of ransomware.

IV. Proposed Scheme

A. Proposed Model

This paper presents the combined architecture of the Shamir's Secret Sharing scheme with cloud storage to ensure the security and protection of data from ransomware attacks. The framework divides a secret S into n shares using a polynomial $f(x) = S + a_1 x + a_2 x^2 + \cdots + a_{t-1} x^{t-1} \pmod p$, where p is a prime number larger than S and $a_1, a_2, \ldots, a_{t-1}$ are randomly chosen coefficients from the finite field Z_p. Each share is generated by evaluating the polynomial at n different non-zero points $x_1, x_2, \ldots, x_n$, resulting in shares $(x_i, f(x_i))$. These shares are then encrypted using symmetric encryption (e.g. AES) with unique keys K_i to form $\text{EncShare}_i = \text{Encrypt}(\text{Share}_i, K_i)$. The encrypted shares are divided into several cloud storage services for enhanced security and the purpose of having a backup. In case of a ransomware attack, the necessary t shares are retrieved, decrypted, and the secret S is reconstructed using Lagrange interpolation: $S = \sum_{j=1}^{t} y_j \prod_{1 \le k \le t, k \ne j} \frac{x_k}{x_k - x_j} \pmod p$. This way, the secret can be reconstructed only when the required threshold t shares are present which helps to prevent data loss and unauthorized access. The proposed model in detail is illustrated in Fig. 1.

B. Secret Sharing Scheme Selection

The following is a detailed procedure of the "Secret Sharing Scheme Selection" using Shamir's Secret Sharing (SSS) scheme. For share storage, Shamir's Secret Sharing (SSS) is preferred since it allows the splitting of a secret S into shares and distributing them to participants or storage locations in a secure manner.

1) Setup: Let the prime number be p and let $p > S$. This prime number sets the finite Field Z_p on which computations will be carried out.

2) Polynomial Construction: Generate a random polynomial $f(x)$ of degree $t-1$ where t is the number of shares needed to get the secret S;

$$f(x) = S + a_1 x + a_2 x^2 + \cdots + a_{t-1} x^{t-1} \pmod p \tag{7}$$

$a_1, a_2, \ldots, a_{t-1}$ are randomly chosen coefficients from Z_p.

3) Share Generation: Determine the n shares by plugging in n different non-zero points $x_1, x_2, \ldots, x_n$ in Z_p and evaluating them with the polynomial $f(x)$;

$$\text{Share}_i = (x_i, f(x_i)) \quad \text{for} \quad i = 1, 2, \ldots, n \tag{8}$$

A share Share_i contains a point x_i and the value of the polynomial at this point, $f(x_i)$.

4) Distribution: It may be expected that each share Share_i is encrypted with the help of a symmetric encryption algorithm, for example, AES, with a unique encryption key K_i;

$$\text{EncShare}_i = \text{Encrypt}(\text{Share}_i, K_i) \tag{9}$$

This step also enhance the security since the share which might be intercept by the third party cannot be easily deciphered without the key.

5) Storage and Management: The shares EncShare_i should be divided and stored in different locations or among multiple participants in order to avoid one party to get the entire secret S.

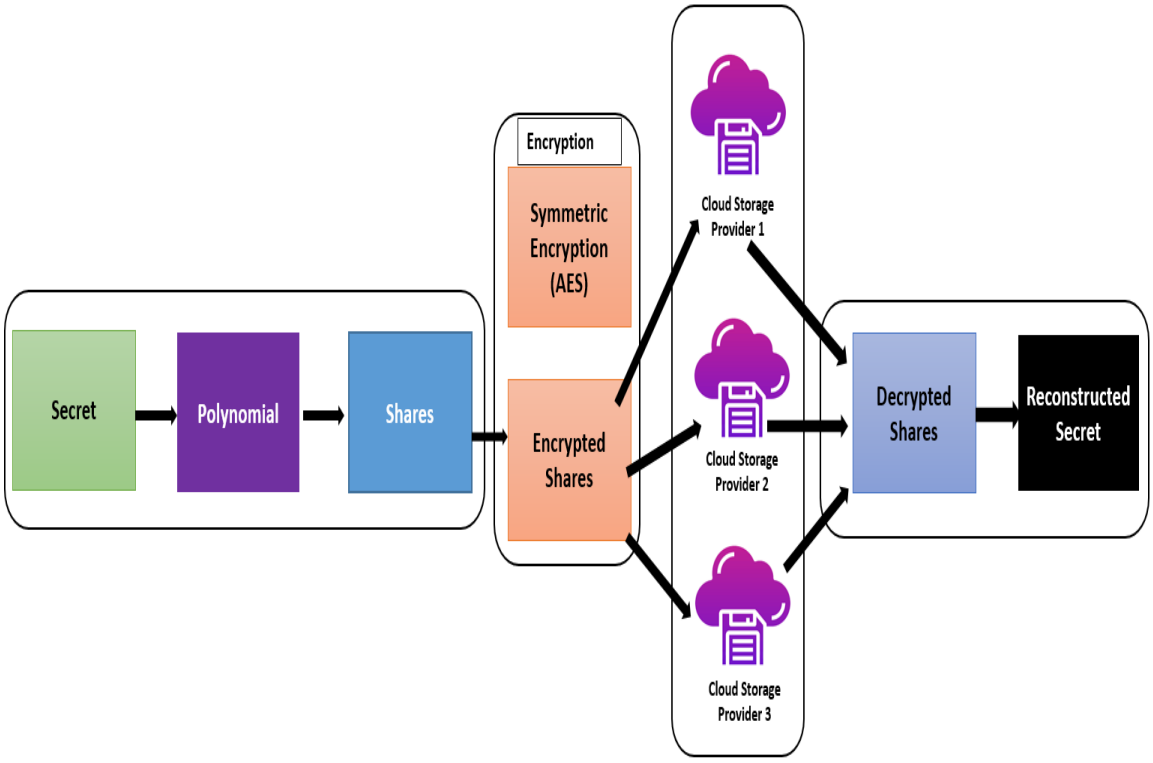

Fig. 1. Proposed model.

C. Advantages of Shamir's Secret Sharing

Security: The scheme allows any set of t or more shares to compute the secret S, while set of less than t shares will not give any information concerning S.

Flexibility: It also affords the user the chance to set the threshold, t, and the number of shares needed n, which enables it to be flexible depending on the security frequencies and recovery needs.

Efficiency: The polynomial interpolation is adopted in secret reconstruction (Lagrange interpolation) which is efficient in computation; thus it can be applied in numerous cases.

With the choice of Shamir's Secret Sharing scheme, the framework provides the data protection from unauthorized access of data, which is vital for improving the security of cloud storage and countering the ransomware attacks.

V. Experimental Setup

To implement this experiment, it is necessary to set up a network of servers or virtual machines that are capable of mimicking various CSPs while having enough CPU, memory, and storage power. Python with the help of libraries like PyCrypto or OpenSSL can be used for encryption of shares using Shamir's Secret Sharing scheme and AES encryption algorithm. The setup entails producing different datasets for the purpose of determining the scalability and performance when dealing with large files, as well as the encryption parameters such as the key size and mode to determine their effects on the security and performance. Approaches to allocating shares among simulated providers are investigated, assessing the time required and resistance to partial captures. The key factors for assessment include security, which will be measured by the provided confidentiality and shares integrity during the distribution and recovery processes; the performance parameters include encryption/decryption rate, share generation, and reconstruction duration; resource utilization is also of concern. Scalability tests check the framework's capacity in terms of share and threshold t parameters increase. A detailed documentation of the entire process in the experimental workflow has been done in the setup, implementation, execution, and analysis of the framework to help in identifying the framework's strengths, weaknesses, and opportunities that may be useful in future research and applications of the framework for combating ransomware threats in cloud environments.

VI. Results and Performance Analysis

We introduce an experimental setup meant to test the proposed secret sharing-based framework against different datasets (small, medium, and large). The number of shares, encryption key size, threshold, and ransom value were integrated as key performance metrics to evaluate. We simulate the framework under different dataset sizes and show the results of the simulation to demonstrate the scalability and flexibility of the design. Finally, these results demonstrate the efficacy of the proposed framework in defending against ransomware attacks.

The simulation results are presented in Table II, the parameters are compared where on small, slow, and large datasets. The security measures can be seen to scale with dataset size, and these parameters: number of shares, encryption key size,

and threshold for secret reconstruction are all provided in the table. This tabulated form makes the performance of the framework easier to understand and offers a structured and quantifiable way to compare different scenarios.

The Table II, presents how dataset size affects several critical security parameters in a cloud-based cryptographic scheme. The table is divided into five columns: The choices I made for data set size (small, medium, large), number of shares, encryption key size (in bits), threshold, and ransom amount (in dollars). For small datasets, they generate 8 shares on a 256-bit encryption key with a 5-share threshold to reconstruction and a $10,000 ransom amount. It takes a 128-bit key, 7 shares for threshold, $15k ransom, Medium datasets produce 12 shares. For 20 shares, a 192-bit key, 10 shares threshold, and a ransom amount of $20,000 we get large datasets. They present a table showing how the security measures and the economic impact scale concerning the size of the dataset, revealing that at larger dataset sizes methods based on standard cryptographic schemes are required.

TABLE II. ACHIEVED PARAMETERS

Dataset Size	Number of Shares	Encryption Key Size (bits)	Threshold	Ransom Amount ($)
Small	8	256	5	10000
Medium	12	128	7	15000
Large	20	192	10	20000

The provided Fig. 2, present a comparison of major security aspects in the context of the dataset size (small, medium, and large) of a cloud-based cryptographic model. The first chart depicts the number of shares produced, and it is observed that the number of shares increases linearly in proportion to the size of the dataset, where the relationship is given by the equation $n_s = k \cdot \text{dataset size}$, where k is a constant. In the case of small data the number of shares is approximately 8, for medium data category it is approximately 12 and for large data it is 20, showing a linear trend. The second graph depicts the encryption key size where the small size of datasets uses the biggest keys that are 250 units, the moderate size datasets use approximately 150 units and the large size datasets use approximately 200 units. This can be depicted by the formula $K = a \cdot \text{dataset size} + b$ where a and b are constants that factor in the minimum levels of security that need to be met and the specific characteristics of the datasets respectively. The third chart refers to the threshold of secret reconstruction, which depends on the size of the dataset, where the relationship is defined by the formula $T = c \cdot \text{dataset size} + d$. Small datasets have a threshold of 5, medium datasets 7, and large datasets 10 meaning that for this security scheme more shares are required for large datasets in order to counter threshold attacks. Last but not the least, the ransom amount which is represented by $R = e \cdot \text{dataset size} + f$ shows the possible monetary damage of a breach. A small dataset is expected to have a ransom of about $10,000, medium datasets about $15,000 and large datasets up to $20,000 increasing in a typical exponential manner with size to imply that larger datasets contain valuable, sensitive information. Altogether, these findings reveal the interdependencies between the size of datasets, cryptographic security measures, and economic impacts, which calls for a purchasable and scalable security solution for protecting data at various scales in the context of cloud computing.

A. Performance Analysis

In Table III, Ransomware attacks have become a significant threat to cloud storage systems, data infrastructures, and modern organizations. In response, several advanced security models have been proposed, including Secret Sharing Schemes (SSS), Homomorphic Encryption, Attribute-Based Encryption (ABE), and Backup Solutions, each with its distinct advantages and limitations when it comes to defending against ransomware. A thorough understanding of these defense mechanisms requires familiarity with their primary defense mechanism, security levels, data recoverability, computation complexity, resistance to ransomware, scalability, implementation complexity, real-time protection, and key weaknesses. While all these methods solve the problem of ransomware from different angles, some focus on data accessibility, others on data encryption, and the third one addresses data access control. For instance, the Secret Sharing Scheme (SSS) for its part represents a strong cryptographic method to split up secret and sensitive data into many parts, which we call "shares". Then, the shares are distributed across different locations or storage systems, and the recovery of data is possible only when a threshold of shares is available. The idea here is so-called "threshold cryptography", which means that if some of the shares are violated in a ransomware attack, the original data cannot be fully decrypted or held hostage without the required threshold. What makes SSS most powerful is its secrecy: if less than the required number of shares is captured, no information about the original data is revealed. As a result, it's very effective in implementing distributed cloud storage where data security is critical. SSS also has great data recoverability, as the system is intrinsically compromised against partial data breaches with strong guarantees that data will not be damaged, and can always be recovered, even following a ransomware attack. In addition, since SSS is decentralized, it is resistant to a large set of attacks ranging from ransomware down to SYN attacks. She wrote that even if ransomware encrypts some of the shares, the remaining shares will still allow the data to be reconstructed, eliminating the need to pay a ransom.

On the other hand, Homomorphic Encryption offers a different kind of protection, primarily focused on securing data during computation. In homomorphic encryption, data remains encrypted while operations are performed on it, meaning that sensitive data never needs to be decrypted during processing. This characteristic is beneficial for protecting data from unauthorized access during computation, especially in cloud environments where data might be processed by third-party servers. Homomorphic encryption ensures that even if a server is compromised, the data remains encrypted, preventing ransomware from directly accessing the plaintext. However, homomorphic encryption is not specifically designed to handle ransomware attacks, as its primary focus is on securing data during computation rather than when it is stored or accessed. This means that if ransomware encrypts or locks access to the ciphertext, homomorphic encryption does not inherently provide a mechanism for data recovery. The computational complexity of homomorphic encryption is also a significant challenge. Fully homomorphic encryption (FHE), which allows for arbitrary computations on encrypted data, is known for its resource-intensive nature, requiring considerable processing power and time to perform even basic operations. This makes it less practical for large-scale systems or real-time applica-

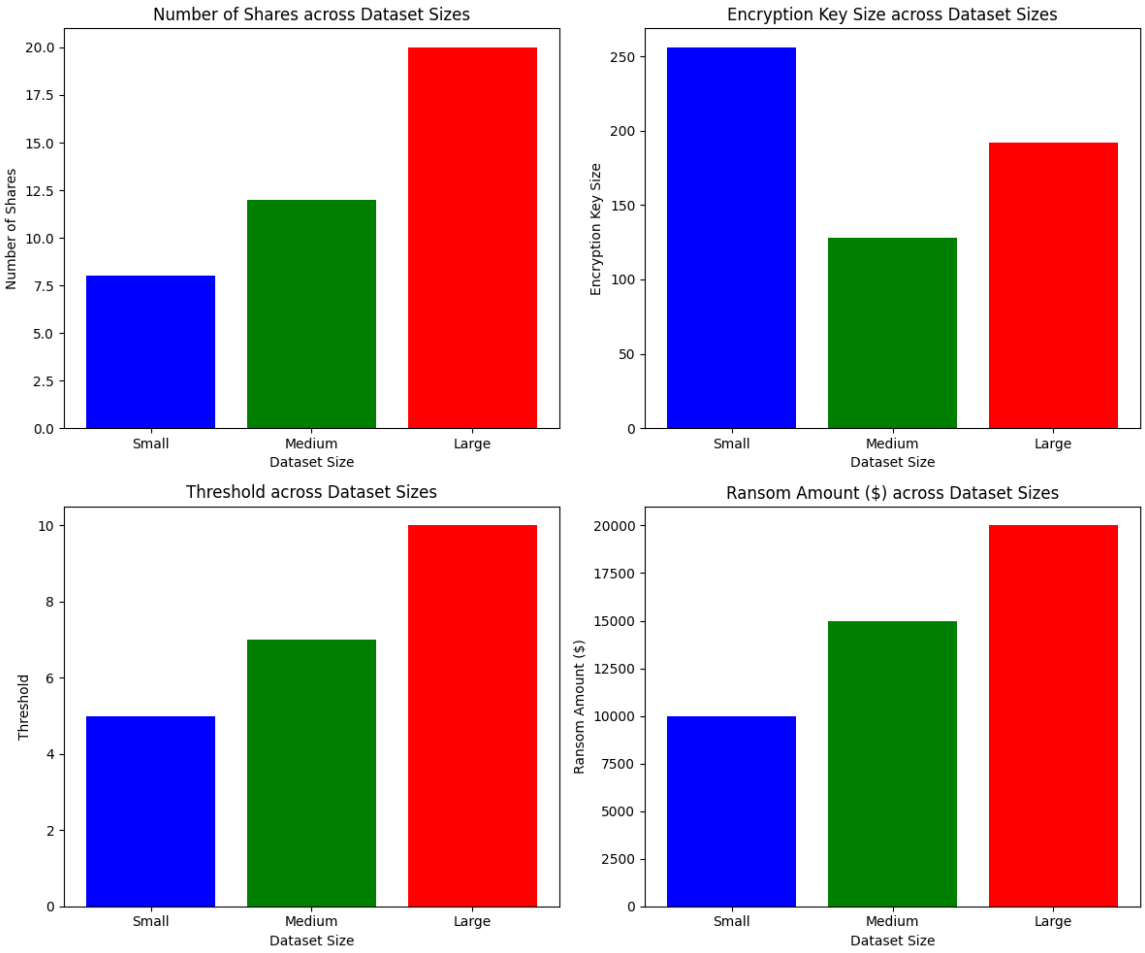

Fig. 2. Comparison of key security parameters based on dataset size (Small, Medium, Large). The graphs show the relationship between dataset size and (1) the number of shares, (2) encryption key size, (3) threshold for secret reconstruction, and (4) potential ransom amounts. As dataset size increases, more shares and higher thresholds are required, while ransom demands and encryption key sizes adjust accordingly.

tions, limiting its scalability. Although homomorphic encryption offers high security during computation, its resistance to ransomware is limited because it does not address the problem of data being encrypted or locked by ransomware outside of the computation process.

Attribute-Based Encryption (ABE) focuses on access control, granting data access based on user attributes, such as roles in a healthcare system (e.g., doctor, nurse). This fine-grained control makes ABE suitable for environments requiring strict access policies. However, ABE's security hinges on effective key and attribute management; if these systems are compromised, the overall security is weakened, making it vulnerable to ransomware attacks. While ABE controls access, it does not protect against ransomware encrypting data if it gains access to the system. Data recoverability is good if key management is intact, but recovery becomes difficult if keys or attributes are compromised. ABE has moderate computational complexity, being more efficient than homomorphic encryption but still more resource-intensive than simple symmetric methods. Overall, ABE offers moderate resistance to ransomware, limiting access but remaining susceptible to attacks on key management systems.

Backup solutions are a traditional and widely-used method for mitigating ransomware effects. By regularly creating and securely storing copies of important data, organizations can recover from ransomware attacks without paying ransoms. However, modern ransomware often targets backup files, complicating recovery. To enhance security, advanced strategies like air-gapped, immutable, and versioned backups have been developed, but these do not prevent attacks. Backup solutions are computationally simple, but their effectiveness hinges on the frequency and security of backups. Their data recoverability ranges from moderate to high, but if backups are compromised, recovery becomes difficult. Overall, backup solutions provide low to medium resistance to ransomware, serving primarily as a reactive measure rather than a proactive defense.

In terms of scalability, SSS is highly adaptable, allowing for flexible data reconstruction thresholds suitable for various deployments. Homomorphic encryption and ABE are moderately scalable; however, their complexity increases with the system's size and user attributes. Backup solutions are also highly scalable but require diligent management for frequent and secure backups. Regarding implementation complexity, SSS and homomorphic encryption are relatively complex,

needing cryptographic expertise. ABE is moderately complex due to its attribute and access policy management, while backup solutions are the simplest but demand regular maintenance.For real-time protection against ransomware, SSS offers moderate capabilities by pre-splitting data, while backup solutions provide low protection, serving primarily as a recovery method. SSS incurs significant storage overhead, and homomorphic encryption is computationally intensive, resulting in slower performance. ABE depends heavily on key management, and backup solutions are vulnerable to ransomware targeting backup files.

All of these, in conclusion, are ransomware defense mechanisms organizations choose to best fit their specific needs. High security and scalability are offered by SSS, ideal for data-sensitive environments but require a lot of resources. Although homomorphic encryption protects data when computation is done with it, it is not effective against a ransomware attack on the data as it is. Fine-grained access control is provided by ABE on the condition that secure key management exists. It is a common and simple backup solution that, well, is growing ever more susceptible to attacks on its backup files. They also understand the strengths and weaknesses of each method and therefore, organizations can mix it and create a balanced ransomware defense strategy, which is balanced by security, complexity, and recoverability.

VII. Security Analysis

1. Shamir's Secret Sharing (SSS) Scheme

Theorem 1: Shamir's Secret Sharing scheme ensures that any subset of t or more shares can reconstruct the secret S, while fewer than t shares reveal no information about S.

Proof: Polynomial Construction: The secret S is encoded into a polynomial $f(x) = a_0+a_1x+a_2x^2+\ldots+a_{t-1}x^{t-1}$ over a finite field F_p, where $a_0 = S$ and a_i (for $i = 1, \ldots, t-1$) are randomly chosen coefficients. Share Generation: Shares $(x_i, f(x_i))$ are distributed among participants. Any subset of t or more shares can reconstruct $f(x)$ using Lagrange interpolation. Security Guarantee: The security of Shamir's Secret Sharing against ransomware attacks lies in the computational complexity of reconstructing S without at least t shares, leveraging the properties of irreducible polynomials and the Chinese Remainder Theorem (CRT).

2. Encryption Key Size and Brute-Force Resistance

Theorem 2: The strength of encryption against ransomware attacks increases exponentially with the size of the encryption key n in bits.

Proof: Let n be the size of the encryption key in bits. The total number of possible keys N for an n-bit key is given by the formula:

$$N = 2^n. \tag{10}$$

1. Exponential Growth of Key Space: As n increases, the number of possible keys N grows exponentially. This means that even a small increase in the key size leads to a significant increase in the key space.

For a 128-bit key:

$$N = 2^{128} \approx 3.4 \times 10^{38} \quad \text{(about 340 undecillion keys).} \tag{11}$$

For a 256-bit key:

$$N = 2^{256} \approx 1.1 \times 10^{77} \quad \text{(about 115 quindecillion keys).} \tag{12}$$

2. Computational Effort for Brute-Force Attacks: To perform a brute-force attack, an adversary must try every possible key until the correct one is found. The expected time $T(n)$ required for a brute-force attack can be modeled as:

$$T(n) = k \cdot 2^{n-1} \tag{13}$$

where k is a constant that represents the time taken to test each key. The factor of 2^{n-1} reflects that, on average, half of the keys need to be tested before finding the correct one.

Assuming a hypothetical scenario where a powerful computer can test 10^{12} keys per second, we can calculate the time required to break various key sizes.

For a 128-bit key:

$$\begin{aligned} T(128) &= k \cdot 2^{127} \\ &\approx \frac{3.4 \times 10^{38}}{10^{12}} \\ &\approx 3.4 \times 10^{26} \text{ seconds} \\ &\approx 1.08 \times 10^{19} \text{ years.} \end{aligned} \tag{14}$$

For a 256-bit key:

$$\begin{aligned} T(256) &= k \cdot 2^{255} \\ &\approx \frac{1.1 \times 10^{77}}{10^{12}} \\ &\approx 1.1 \times 10^{65} \text{ seconds} \\ &\approx 3.5 \times 10^{57} \text{ years.} \end{aligned} \tag{15}$$

3. Cryptographic Resilience: Larger key sizes provide better cryptographic resilience. As the key size n increases, the effective key space N expands exponentially, making it computationally infeasible for adversaries to decrypt the data through brute-force methods.

Increasing the encryption key size n leads to an exponential increase in the number of possible keys $N = 2^n$. This exponential growth significantly raises the computational effort required for brute-force attacks, thus enhancing the strength of encryption against ransomware attacks. In practical terms, key sizes of 256 bits or larger are considered highly secure, as they provide a level of protection that is currently beyond the reach of even the most advanced computing resources.

3. Threshold and Access Control in Ransomware Scenario

Theorem 3: Setting a higher threshold t in secret sharing schemes enhances security against ransomware attacks by minimizing the risk of unauthorized data decryption.

TABLE III. COMPARISON OF RANSOMWARE DEFENSE MECHANISMS

Feature	Secret Sharing Scheme (SSS)	Homomorphic Encryption	Attribute-Based Encryption (ABE)	Backup Solutions
Primary Defense Mechanism	Data split into shares, requiring a threshold for reconstruction	Computations on encrypted data without decryption	Access control based on user attributes	Regular data backups to restore after an attack
Security Level	High (Perfect secrecy, no information leak with less than t shares)	High (Data never decrypted)	Medium (Depends on key management)	Medium (Vulnerable if backup also attacked)
Data Recoverability	Excellent (Recoverable from remaining shares if some are lost)	Good (Can operate on encrypted data but may not prevent initial data loss)	Good (Access control limits exposure)	Moderate (Depends on backup recency)
Computational Complexity	Moderate to High (Depends on share generation and reconstruction)	High (Intensive computations for large datasets)	Moderate (Key generation and access policies)	Low (Relatively simple but limited to restore phase)
Resistance to Ransomware	High (Threshold-based recovery without paying ransom)	High (Data is never decrypted)	Moderate (Depends on access policies and key management)	Low to Medium (Attackers can target backup files)
Scalability	High (Threshold can be adjusted based on storage size)	Moderate (Depends on encryption size)	Moderate (Attributes increase complexity)	High (Easy to scale but vulnerable to large-scale attacks)
Implementation Complexity	Moderate to High (Requires share management and multi-storage nodes)	High (Complex mathematical operations)	Moderate (Requires careful attribute policy management)	Low (Simple but not ransomware-resistant by itself)
Real-Time Protection	Moderate (Shares distributed beforehand, not real-time)	Low (Does not prevent attack, only secures data)	Moderate (Access control at the time of use)	Low (Data is encrypted but might be vulnerable during the interval before backup)
Key Weakness	Storage overhead and share management complexity	High computational cost and slower performance	Key management and complexity of policy enforcement	Backup files can also be targeted by ransomware

Proof: Let S be the secret to be shared among n participants using a (t, n)-threshold secret sharing scheme. The scheme divides S into n shares such that any subset of at least t shares can reconstruct the secret, while any subset of fewer than t shares provides no information about the secret.

Access Control Mechanism: Specifically, it is required that the adversary should have at least t shares to be able to decrypt the secret S. If the adversary needs to reconstruct S, then their task becomes more difficult: for the threshold to increase t they must obtain a greater subset of shares. It makes the access control mechanism much more difficult for unauthorized entities to break into the system.

Mathematical Basis: The security of a (t, n)-threshold scheme is grounded in the following combinatorial and probabilistic argument:

The number of ways for an adversary to obtain exactly k shares out of n participants is given by the binomial coefficient:

$$\binom{n}{k} = \frac{n!}{k!(n-k)!} \tag{16}$$

For $k < t$, the adversary holds fewer than t shares, and by the properties of the secret sharing scheme, these shares reveal no information about the secret. The probability $P_{\text{compromise}}$ that an adversary can randomly access at least t shares (i.e., the minimum number required to decrypt S) is given by:

$$P_{\text{compromise}} = \frac{\binom{n}{t}}{\binom{n}{n}} = \frac{\binom{n}{t}}{1} = \binom{n}{t} \tag{17}$$

where $\binom{n}{t}$ is the number of combinations of selecting t shares from n total shares. As the threshold t increases, the number of possible combinations $\binom{n}{t}$ decreases, making it exponentially harder for the adversary to compromise the secret.

By increasing the threshold t, the probability that an adversary can obtain the required number of shares for decryption is reduced exponentially. This strengthens the overall security of the system, especially against ransomware attacks, where unauthorized decryption of data is a primary concern.

4. Economic Dynamics and Mitigation Strategies

Theorem 4: In a cloud storage system using a (t, n)-threshold secret sharing scheme, the probability of successful decryption of encrypted data by a ransomware attack decreases exponentially as the threshold t increases, thereby enhancing security and mitigating financial and operational impact.

Proof: Let S be the sensitive data stored in a cloud storage system, which is divided into n shares using a (t, n)-threshold secret sharing scheme. The secret S can only be reconstructed if an adversary gains access to at least t shares, where $t \leq n$.

1. Probability of Successful Attack: Assume an adversary compromises m shares, where $m < t$, through a ransomware attack. Since fewer than t shares are insufficient to reconstruct S, the adversary gains no information about the secret, making the probability of a successful decryption:

$$P_{\text{decrypt}} = 0 \quad \text{for} \quad m < t. \tag{18}$$

If the adversary compromises at least t shares, the probability of successful decryption increases. The probability P_{success} that the adversary compromises at least t shares from the n total shares is given by:

$$P_{\text{success}} = \frac{\binom{n}{m}}{\binom{n}{t}} \quad \text{for} \quad m \geq t, \tag{19}$$

where $\binom{n}{m}$ is the number of ways the adversary can select m shares from n, and $\binom{n}{t}$ represents the threshold for reconstruction. This probability diminishes rapidly as t increases, making a successful attack less likely.

2. Economic Impact of Ransomware: The economic cost of ransomware can be modeled as a function of the probability of successful decryption. Let C_r represent the cost of paying the ransom if the data is compromised, and C_s represent the cost of securely implementing the secret sharing scheme. The total expected cost $E(C_{\text{total}})$ is the weighted sum of the probabilities of successful and unsuccessful decryption:

$$E(C_{\text{total}}) = P_{\text{success}} \cdot C_r + (1 - P_{\text{success}}) \cdot C_s. \quad (20)$$

Since P_{success} decreases exponentially with increasing t, the cost of implementing the secret sharing scheme C_s becomes more favorable compared to paying the ransom, making secret sharing an effective economic defense strategy against ransomware.

3. Threshold and Security: To further enhance security, increasing the threshold t not only reduces P_{success} but also increases the adversary's difficulty in reconstructing S. The exponential decrease in the probability of a successful attack as t increases can be formalized using the binomial distribution:

$$P_{\text{success}}(t) = \sum_{k=t}^{n} \binom{n}{k} p^k (1-p)^{n-k}, \quad (21)$$

where p is the probability that an adversary gains access to a single share. As t increases, $P_{\text{success}}(t)$ tends to zero, ensuring that the adversary's likelihood of success diminishes exponentially.

By using secret sharing with a high threshold t, the probability of successful decryption by a ransomware attack is minimized. The overall economic impact is mitigated as the cost of secure implementation C_s becomes a better option than the ransom payment C_r. This proves that secret sharing is a mathematically sound and economically viable defense mechanism against ransomware in cloud storage systems.

VIII. Discussion

The rising prevalence of ransomware attacks has exposed the vulnerabilities inherent in cloud storage systems, necessitating new and improved defense mechanisms. Traditional security measures, such as encryption, firewalls, and data backups, have proven insufficient in combating sophisticated ransomware attacks that can infiltrate, encrypt, and destroy data rapidly. However, in this paper, we propose the use of Secret Sharing Schemes (SSS) as a powerful means to achieve augmented cloud storage security, narrowing the gaps.

A. Efficacy of Secret Sharing Schemes in Combating Ransomware

The results of our study indicate that using Shamir's Secret Sharing (SSS) scheme, we can include an additional layer of security to cloud storage systems, by dividing sensitive data into multiple pieces. This way guarantees that, in the case of compromise of some shares due to ransomware, the entire dataset will not be compromised, assuming that the minimum threshold of shares is preserved. This is a very useful feature that greatly reduces the chances of complete data loss and limits to a large degree how much leverage attackers can use via ransom demands. The main virtue of the secret-sharing technique is based on its self-healing properties. In contrast to traditional encryption schemes, where it is possible to compromise the whole dataset once the decryption key is stolen, secret sharing solves this problem: an attacker cannot read the secret without stealing more than one of the shares under his control placed at distinct locations. Consequently, original data is much more difficult to reconstruct making ransomware attacks successful and less probable. We show, using our framework, that secret sharing can not only protect data but also maintain system availability and reliability during an attack.

B. Advantages Over Traditional Security Mechanisms

A main advantage of the proposed framework arises from the fact that it prevents a single point of failure. Encrypted or backup-based systems are those traditionally used where even encrypted backup systems can be crippled by the ransomware that corrupts the backup backups or steals the encryption keys. By spreading the data over multiple storage nodes, secret sharing dices one data up; even if some shares are compromised, an attacker won't have access to the whole picture. Secret sharing, moreover, leads to increased redundancy, and thus data recovery. Traditional backup mechanisms may also restore data but typically take time to do so, leaving organizations without access to their data and engaging in downtime or negotiations with attackers. But with secret sharing, the data can be combined quickly from available shares, making sure business operations can continue nearly seamlessly.

C. Challenges and Limitations

The framework gives a great deal of security benefits, but, as with everything, limitations exist as well. The greatest challenge is that the process of generating and storing multiple shares of data is computationally intensive and consumes resources. However, the overhead may prevent the scalability of the framework in terms of both time and computational resources when implemented for cloud storage systems handling large masses of data. Furthermore, secret sharing is useful for data loss prevention but does not stop the ransomware from getting into the system. As a result, the proposed framework should be complemented by other detection mechanisms such as anomaly detection and real-time monitoring. This is made more complex by the increased complexity of managing share distribution across multiple cloud providers or storage nodes.

IX. Conclusion and Implications and Future Work

One of the major cybersecurity threats in cloud storage systems is ransomware which needs an effective defense mechanism. We propose in this paper a framework that exploits the secret sharing scheme as a strong countermeasure. To enhance data security, the framework divides data into shares and distributes them across different locations. The redundancy of the shares would mean that if an attack happens data can be retrieved without succumbing to ransom demands. The results of this study demonstrate that secret sharing can effectively provide high levels of ransomware resilience for cloud storage infrastructures. Furthermore, the self-healing property of the cryptographic security offered by the Shamir Secret Sharing

(SSS) scheme guarantees data confidentiality, even if there is a partial loss of shares. As such, this model can be a foundation solution to allow cloud service providers to improve their data protection strategies for protecting against increasingly sophisticated ransomware attacks.

A. Implications and Future Work

This research results show that utilizing secret sharing schemes with cloud storage is a promising approach to counteract ransomware attacks. Nevertheless, the proposed solution comes along with certain shortcomings, in particular, concerning computational overhead and resource costs. However, these limitations could limit its scalability to resource-constrained environments. The next steps in future research should be optimizing the framework efficiently to reduce the computational load without losing security. Future work might also consider possible combinations with other cryptographic techniques (such as homomorphic encryption or more advanced multi-factor authentication systems) to further increase the effectiveness of the framework. Further, it addresses the feasibility of integrating correct real-time ransomware detection and response mechanisms with secret sharing schemes to be able to come up with a complete solution for future cloud storage systems. Lastly, secret sharing is adopted as a defense mechanism which is a major advancement in cloud storage security and serves as a solid starting point to further adopt this revolutionary use of secret sharing for enhancements. This approach could be an important part of future secure and resilient cloud infrastructures with further refinement.

ACKNOWLEDGMENT

We would like to express our sincere gratitude to all the reviewers for their invaluable guidance, support, and insightful feedback throughout this research. We are also thankful to our collaborators for their collaboration and encouragement, which enriched the quality of this work. We gratefully acknowledge the financial support provided for this research, as well as the access to facilities and resources.

Core Scheduler Task Duplication for Multicore Multiprocessor System

Aya A. Eladgham, Nesreen I. Ziedan, Ibrahim Ziedan
Computer and Systems Engineering Department-Faculty of Engineering, Zagazig University, Egypt

***Abstract*—The increasing complexity of multi-core multiprocessor systems presents significant challenges in task scheduling. The scheduling of tasks across multiple cores remains a significant challenge due to its NP-complete nature, especially with the increasing complexity of multi-core / multi-processors architectures. This paper focuses on Multi-Core Oriented (MCO) scheduling algorithms, which specifically target multi-core multi-processor systems. This paper proposes a novel scheduling algorithm, Core Scheduler Task Duplication (CSD), specifically designed for multi-core multi-processors environment. The CSD algorithm combines static and dynamic task prioritization to enhance processor utilization and performance. The proposed algorithm clusters related tasks to the same cores to improve efficiency and reduce execution time. By leveraging task duplication, the proposed algorithm improves processor utilization and reduces task waiting times. To evaluate the CSD algorithm's performance, the algorithm was implemented and compared against the Modified Critical Path (MCP) scheduling algorithm. A series of experimental tests were conducted on diverse task sets, varying in size and complexity. Simulation results demonstrate that CSD outperforms existing compared approaches in task scheduling and processor utilization, making it a promising solution for multi-core systems.**

***Keywords*—MultiCore; multiprocessor; DAG scheduling; dynamic priority; task duplication; clustering; MCP**

I. Introduction

With the increasing demand of high-performance and low energy consumption processing, which is a basic requirement in many applications such as image and video processing [1] [2] [3] [4], climate modeling [5] [6] [7], artificial intelligence [8] [9] [10]. Parallel processing is needed to speed up applications performance by splitting its overall job into smaller tasks [11] [12] [13], execute and complete its work across multiple processors. There is an increasing interest in addressing issues related to multi-core chips. The shift to multi-core has emerged because of reaching the physical limits of single core chips, especially clock speed bottleneck [14] [15]. In the last few decades, multi-core processors have evolved from just two cores in a single CPU to multiple cores [11] [12]. It is challenging to find a computer with single-core CPU, as even low-power CPUs are now designed with two or more core per chip [16]. Intel already launches Intel® Xeon® 6 server processor, code-named Sierra Forest with up to 144 cores [17].

In traditional multiple processors, scheduling problem appears to solve the contention between concurrent parts of programs, or arrange programs execution to guarantee enhancement in the overall performance [13]. In multi-core processors the scheduling problem gets worse with the presence of many cores, where a program can be seen as a set of tasks which can run serially or parallelly. The relationship among these tasks may or may not include precedence constrains [11] [12]. Precedence constrains indicates when one task begins or ends in relation to another task [13]. If precedence constrains exist, a Directed Acyclic Graph (DAG) is used to build a task model [12] [13] [18].

The presence and use of multi-core processors is more popular than the traditional multiple processors. In multi-core processors, the scheduling problem is magnified, which is a non-deterministic polynomial (NP-complete) problem [19] [20]. Most of the traditional parallel processing algorithms are designed to handle one-core processors or designed for multi-core processor, but it does not fit multi-core multi-processors [18]. The primary goal of all these algorithms is to try to reduce the program execution time. The DAG based Heuristic algorithms, which can be divided into four categories, which are List based task scheduling algorithms [21] [22] [23] [24] [25] [26], Task Duplication-based scheduling algorithms [27] [28] [29], Cluster based scheduling algorithms [21] [30] [31], and Multi-Core Oriented scheduling algorithms (MCO), which specialize in the types that deal with multi-core multi-processors machines.

Multi-Core Oriented scheduling algorithms are the focus in this paper. Despite the many advantages and the ongoing manufacturing of multi-core multi-processors systems [17]. MCO scheduling algorithms are not independent types, but they apply concepts and methods from previous types targeting multi-core multi-processors systems (MCMP). This paper introduces some attempts.

The utilization of multi-core processor architecture is growing more common in the realm of high-powered computing. This is considered one of the reasons for the emergence of the MCO scheduling algorithms. Some examples of MCO scheduling algorithms are weighted Earliest Finish Time (wEFT) [32], the Priority Queue Task Duplication scheduling algorithm (PQTD) and Genetic-based Scheduling Algorithm on Multicore (GSAM) [33].

The wEFT [32] algorithm is designed for multi-core processor systems, where it assigns the task with minimum earliest completion time to a certain processor core. wEFT performs well when compared with existing task scheduling algorithms, but wEFT is not the best in average waiting time of the tasks. The PQTD is proposed in [18] for multi-core processors. PQTD uses priority queue and task duplication concepts to map the generated task model to processors. As mentioned in [18] The PQTD algorithm has better performance and better processor utilization compared to TDS [34], and CPFD [35].

The GSAM [33] is try to take advantage of multi-core multi-processors and provided solution for the scheduling problem based on genetic approach. The algorithm is repeatedly executed until it reaches a fixed number of iterations. The GSAM algorithm inherits some defects form GA and multi-cores, such as high computation and time consumption. In addition, GSAM suffers from high power need in multi-core architectures. Existing GA based scheduling algorithms have some disadvantages such as high complexity, high power consumption, poor efficiency, poor processors utilization, etc. [36] [37] [15]. The GA and multi core algorithms are intended for some specific applications and are not suitable for other applications.

The proposed scheduling algorithm combines the qualities of multi-core processors algorithms and multi-processors. The proposed algorithm deals with fine grain task graph applications. It overcomes some problems and combines some of the advantages found in others. It increases the processor utilization and tries to cluster the related tasks to run in the same processor cores to improve the performance. The proposed algorithm first uses static priority for level categorization, and then dynamic priority for tasks in each level while assigning tasks. The proposed algorithm Core Scheduler task Duplication, which is CSD.

The remainder of this paper is organized as follows. The proposed scheduling algorithm is presented in Section II. Section III introduces an application example illustrating the proposed scheduling algorithms steps. Section IV provides the simulation results and discussions. Finally, the conclusion is provided in the last section.

II. The Proposed CSD Scheduling Algorithm Design

A. Task Mode

The properties associated with any parallel program such as processing time, data dependencies, communication cost, and synchronization requirements must be known before scheduling. The parallel program is represented by node and edge DAG [13].The DAG task model G = {T, E, C, W} where the set of nodes T is a set of n tasks, where n is the total number of tasks. E is a set of edges in the DAG between two vertices (nodes) Ti, and Tj,where $0 \leq$ i,j $\leq$ n. Cij is as set of communication time between two tasks, where $0 \leq$ i,j $\leq$ n. W is a set of processing time of each task. Fig. 1 is an example of DAG with four tasks numbered. from T1 to T4, T1 has processing time equal to 2 unit of time. T1 and T2 are connected with an edge with communication weight equal to 1 unit of time.

B. Assumptions and Constraints

Some restrictions are necessary to explain the CSD scheduling algorithm, which are as follows:

- CSD targets a machine with a set of n homogenous Processing Elements (PE), where each PE contains a set of m homogenous cores idiomatically called (n) multiprocessor (m) multi-cores system. The core j inside Processing Element i is called (PEi-ci).

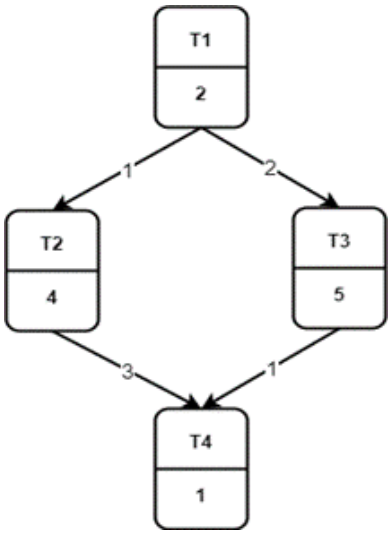

Fig. 1. Example of Directed Acyclic Graph (DAG).

- The processors are fully connected, where link contention and routing strategies used for communication are neglected.
- The communication delay Cij between two cores in the same processor element is negligible (Cij $\approx$ 0), while it takes cij units of time if the two cores belong to different processor elements.
- Any task cannot be started until all its predecessors are completed.
- Assignment procedure will be initiated if either any core is free or the task has been completed, which leads to a free core.
- Transition from any level to another is not allowed until the assignment of all tasks at this level are completed.

C. CSD Scheduling Algorithm Procedure

CSD scheduling algorithm is formalized in this section.

Input:

- A DAG describes tasks workloads, their weights, communication cost between any tasks, and precedence relation.
- The number of PE and how many cores each one contains.

Output: Gantt chart illustrates the list of all tasks allocated to each core ordered by their starting, finishing, and execution time. Gantt chart also indicated Idle periods for every core.

Steps: Fig. 2 shows the steps of CSD algorithm, while the part concerned with selecting task from unassigned level list is illustrated in Fig. 3. These steps are listed as follows:

1) Arrange the given M cores of each processing elements PE lexicographically in a queue.

2) Build the static task queue, where this queue is divided into static priority levels starting from Level1 (L1) to Levelm (Lm). Tasks belonging to any level Li only depend on the tasks belonging to the previous level Li-1. Tasks arranged at this point have no order. Only the tasks belonging to the same level are stacked together with no priority. Each level is rearranged during the assignment procedure step and accordingly the priorities of the tasks are changed during the successive stages of CSD algorithm within the same level. Because of this change, the task static priorities turn to dynamic priorities.
3) Collect and compute all the following characteristics for each task before the assignment procedure:
   - weight of the task i, $0 \leq i \leq n$ (Wi),
   - list of the predecessors of the task, i.e. parents (predi),
   - successors of the task, i.e. children (succi),
   - the task should be duplicated or not and how many times it should be duplicated (D) according to Eq. (1).

$$\min(\#ofPEs, ceil(\frac{\#ofchildren}{\#ofcores})) \quad (1)$$

   As the number of tasks in the same level increases, the congestion problem emerges and worsens with the duplication according to the (1). This problem was resolved using Eq. (2).

$$\min(\#ofPEs, floor(\frac{\#ofchildren}{\#ofcores})/\#oftasks) \quad (2)$$

   - The task found in critical path (CP) in the DAG, which is the longest path in the DAG or not,
   - degree of the CP, which is number of tasks in the CP, the more tasks the higher the degree (DCP), and located on more than one CP.
   - Select the tasks that can be duplicated if possible and mark it as duplicated task. The selection process satisfies the inequality: # of children $>$ # of cores.
   - Any task chosen for duplication is indeed duplicated in the task queue many times as Eq. (1) or Eq. (2).
4) Assign previously arranged tasks to cores: this step is called assignment procedure, which assigns the tasks to cores and is carried out periodically in every time slot. The procedure is divided into two phases. The first phase is called **core phase** and deals with the cores. Meanwhile the second phase is called **task phase** and deals with the selection of the task to be performed. Each phase is explained as follows.
   Core phase: Roll over all free cores to see if they can start any selected task from the next phase. It should be noted that the list of free cores changes every time slot, where the algorithm picks all free cores. The CSD algorithm determines, which core suitable for the priority based ordered tasks.
   Task phase: Priorities change at this phase based on a number of criteria to choose the task, which has the highest priority. These priorities change periodically with each start of task selection. CSD considers all the tasks in the same level and rearrange them again, then choose the task that will be executed if:
   • One of its predecessors is completed, and none of its duplicated is running in the same processing element PE. If a tie occurs, then go to the next step.
   • When CSD algorithm reaches this step, there is more than one choice, which are:
   First: There is only one task in CP,
   Second: There are two or more tasks in CP.
   Third: no task in CP.
   For the first case the algorithm chooses this task to be scheduled. For the second and third track, the algorithm calculates the longest path of Ti where the task is on (LPi). The LPi can be calculated using Eq. (3):

$$LPi = longestpathbefore + longestpathafter - Wi \quad (3)$$

   for each task, if two or more tasks have the same LPi length, then the algorithm calculates Forest Cost of task i (FCi). FCi is the number of edges in the following subgraph for this task. If tie occurs again then the algorithm moves to the next action.
   - Choose the task with greater number of children if tie occurs then.
   - Choose the one with lower weight, if tie occurs then.
   - Choose task with small index.

   After selecting the task, the CSD determines if the task is duplicated and how many times. CSD has to decide whether to start all the duplicated tasks all at the same time at available free cores and remove the exceeded copies from task queue. The other choice for CSD is to start the duplicated task any time as there are free cores.
   Repeat step 4 till each free core from core phase gains a task. Consequently, the same steps are repeated and moved from one level to another until the assignment procedure is completed for all tasks.

III. An Application Example

The following example illustrates how CSD algorithm works.

Assume that the DAG shown in Fig. 4 is given. The objective is to schedule this DAG to 2 PE with 2 cores each. The DAG has 10 nodes, 14 edges, and with CP equal to 13. In the Fig. 4, CP is shown with thick arrows.

1) Arrange the PE, with its cores in processor queue as shown in Fig. 5.
2) Arrange tasks in static levels as shown in Fig. 5.
3) collect all the information about each task in advance as Shown in Table I.
4) Assignment procedure:
   - L1 has only one node (entry node) which is marked as duplicated (2-times) on different cores (PE0-c0), and (PE1-c0).

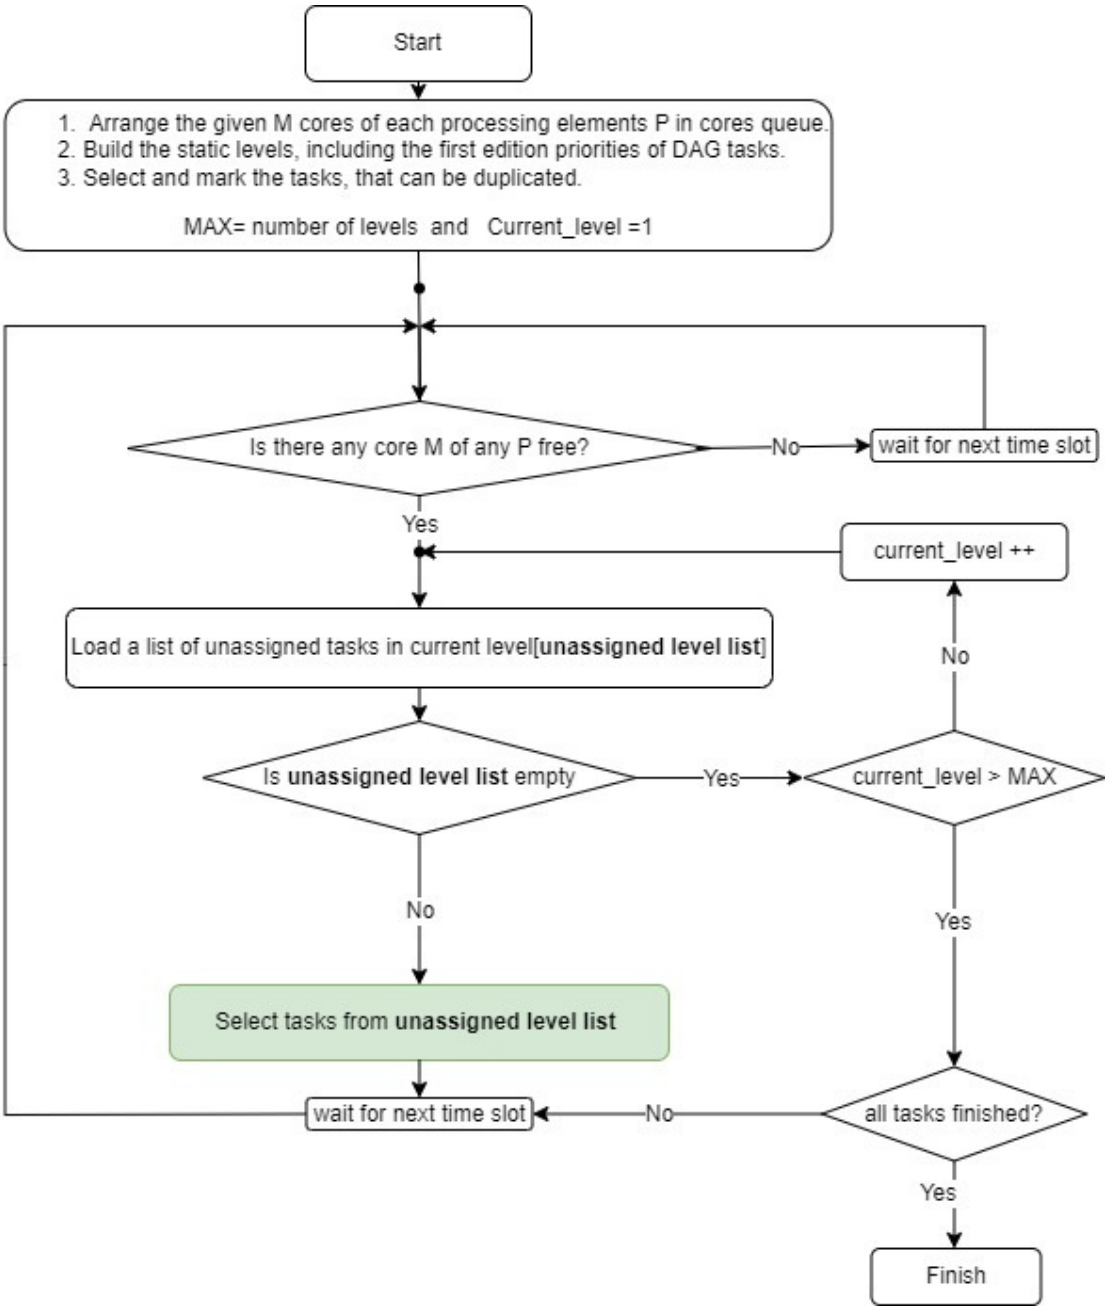

Fig. 2. CSD Scheduling algorithm flowchart.

- The assignment procedure suspended till T1 finished.
- CSD algorithm dynamically rearranges tasks in L2 to get ready_list1, followed by ready_list2: Ready_list1: T2, T3, T4, T5
  Ready_list2: T2, T3, T4, T5
  Final arrangement in this step: T3, T2, T4, T5
- CSD algorithm assigns T3 to (PE0-c0). At the same time slot, it assigns T2 to (PE0-c1), T4 to (PE1-c0), and T5 to (PE1-c1). T4 is marked as duplicated, but there are no free cores available for duplication. At this moment all cores are busy, so CSD waits until one becomes free. The beginning of time slot 4 (PE0-c0), and (PE1-c0) will be free.
- At this moment when L2 is finished CSD algorithm goes to L3, but there are no tasks ready. Therefore, the algorithm waits until the next time slot.
- The algorithm rearranges tasks in L3 until it reaches the final arrangement according to the illustrated criteria in the algorithm procedure. The Final arrangement became T6, T7, T8.
- The algorithm assigns T6 to (PE0-c0).
- T7 is assigned to any of the following (PE0-c1) or (PE1-c0) or (PE1-c1), where (PE0-c1)

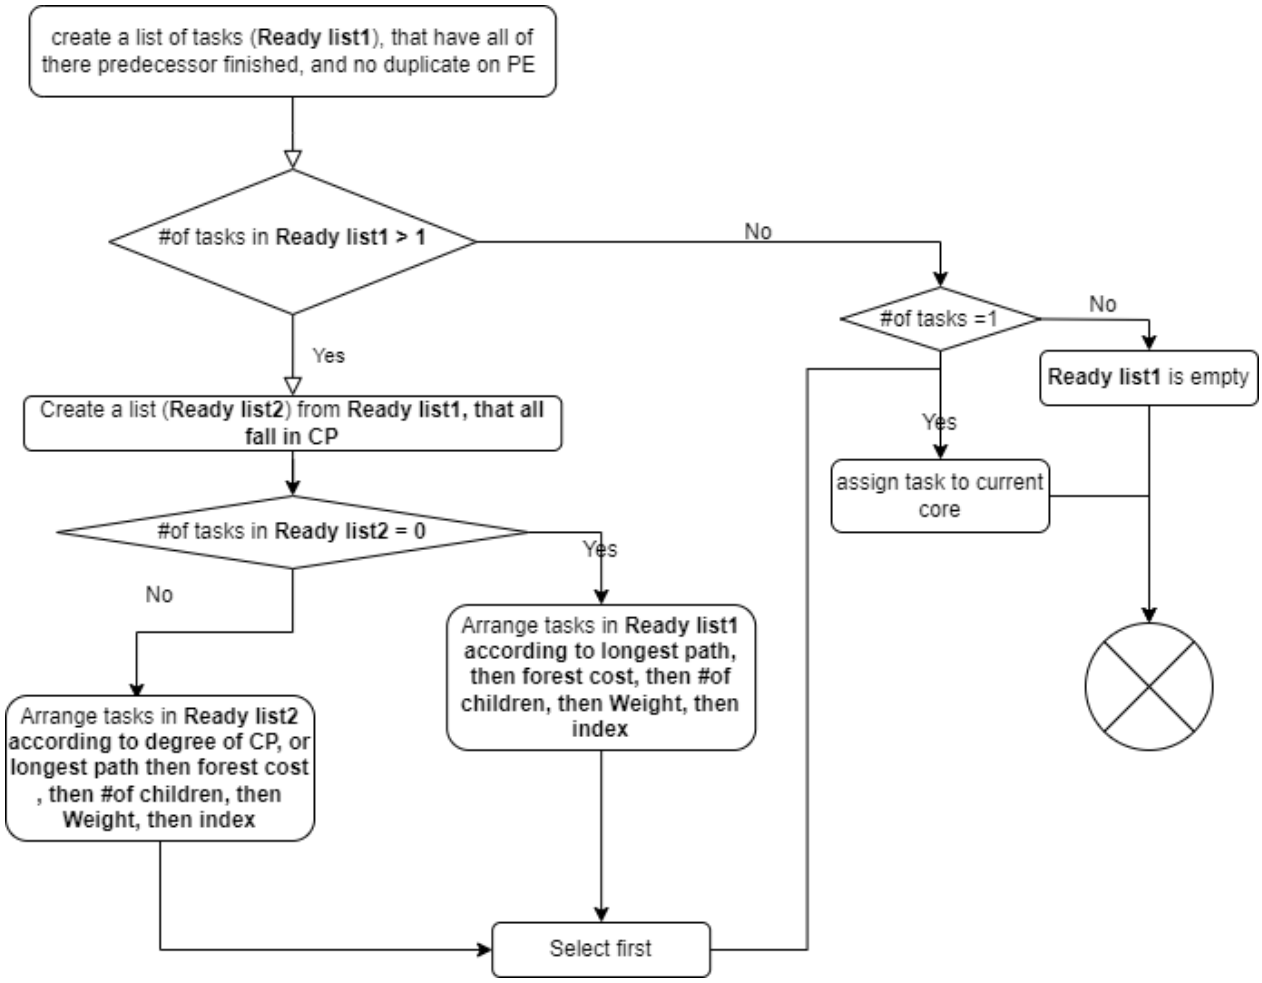

Fig. 3. Task selection flowchart.

TABLE I. TASK CHARACTERISTICS

	T1	T6
ID	1	6
Wi	1	2
Duplicated	yes	no
D	2	2
predi	2	2
succi	–	2
found in CP or not	yes	yes
DCP	5	5

starts after 2 time slots from time slot 4, and (PE1-c0) or (PE1-c1) start immediately, so assign T7 to (PE1-c0).

- T8 has similar situations as T7, so the algorithm assigns T8 to (PE1-c1).
- (PE0-c1) is free, and L3 is finished, but T9 cannot start until T6 is finished, so the algorithm waits.
- When T6, T7, and T8 are also finished, then all cores are free. However, the most suitable core is (PE0-c0), so the algorithm assigns T9 to (PE0-c0).
- T10 cannot start until all predecessors are finished (T9, T7, and T8). Once finished, all cores become free. Either PE0 or PE1 starts the execution of T10 at the beginning of the 8th time slot, so all cores have the same chance to execute it, so the algorithm assigns T10 to (PE0-c0).
- The output of the previous steps represented in Gantt chart shown in Fig. 6. The Gantt chart represents the Schedule Length (SL). SL is the total duration or makespan of the schedule, which emphasizes all the tasks is completed.

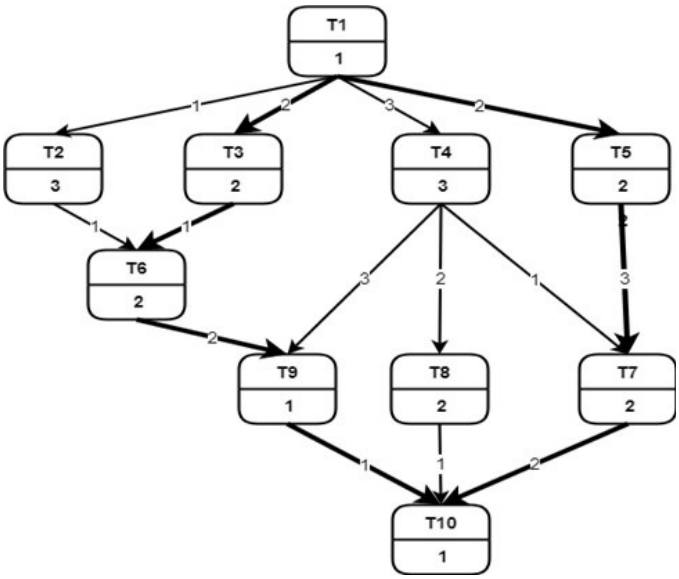

Fig. 4. A sample DAG from [18].

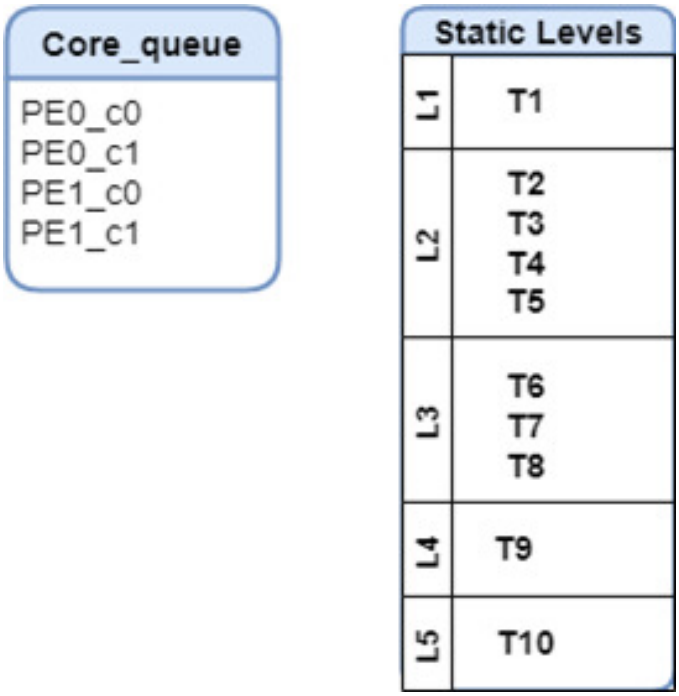

Fig. 5. Arrangement of core queue, and static task levels.

IV. Simulation and Results

The performance of the proposed scheduling algorithm is evaluated using randomly generated task graphs or task graphs modeled from actual application programs from Standard Task Graph set, which is presented in [38].

1) The first task graph t50_rand1 is composed of 50 tasks and 985 edges with computation to communication ratio (CCR) equal 0.1.
2) t100_rand2 composed of 100 tasks and 3943 edges with CCR equal 0.02.

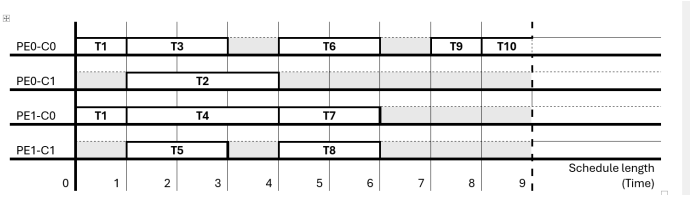

Fig. 6. The schedule generated by CSD algorithm.

3) and robot control application with 88 tasks and 131 edges with CCR equal 0.85 and 5.

The CSD scheduling algorithm simulation is conducted using Python running several times with various processing elements / cores settings. Fig. 7 presents the simulation results of the CSD scheduling algorithm with varying numbers of Processing Elements (PEs), each containing only one core. The x-axis represents the number of PEs, while the y-axis indicates the Schedule Length (SL). The figure also compares the performance of different versions of the CSD scheduling algorithm with the Modified Critical Path (MCP) scheduling algorithm. The difference between the multiple versions of CSD is when to duplicate the chosen task to be duplicated and how many times:

- If duplication occurs during the first copy assignment process at the same level according to (1) Version CSD (once_nolvl) is generated.
- If duplication occurs any time according to (1) Version CSD (any_nolvl) is generated.
- If duplication occurs during the first copy assignment process at the same level according to (2) Version CSD (once_lvl) is generated.
- If duplication occurs any time according to (2) Version CSD (any_lvl) is generated.
- CSD (none) is generated when no duplication occurs.

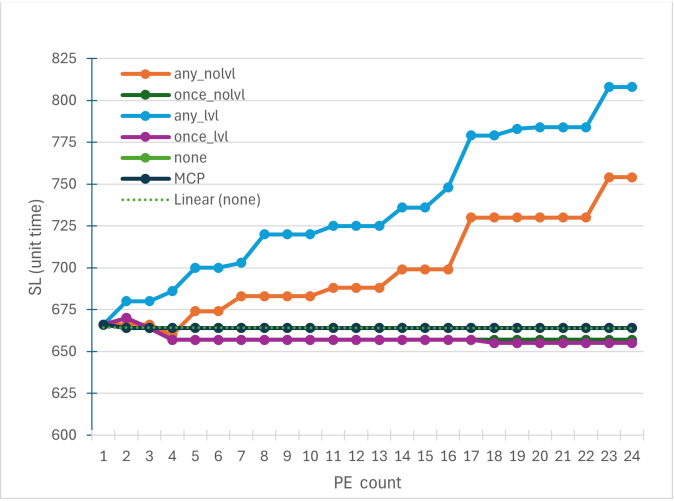

Fig. 7. Scheduling for t50_rand1 DAG.

As seen in Fig. 7 the SL is improved with the CSD (once_lvl and once_nolvl) versions compared to other algo-

rithms. CSD (once_lvl) outperforms CSD (once_nolvl) when the number of tasks in the same level increases. The performance of CSD (none) algorithm coincides with MCP algorithm. Both CSD (none) and MCP algorithms outperform all the reset versions of CSD. While the CSD (any_nolvl) and (any_lvl) deviated too far as it exhausted the free cores in duplication while there are already tasks to begin execution. This scenario is reflected in a significant increase in SL. CSD(Any_nolvl) and CSD(any_lvl) and the results are ignored. Fig. 8 illustrates SL for t100_rand2, which is like t50_rand1. It is noticeable that there is an improvement of CSD (once_lvl) over MCP, as the number of parallel paths increase. Fig. 9 illustrates the average SL output behavior with robot control application generated with CCR equal 0.85 and 5. Robot control DAG in contrast to other DAGs shows a significant improvement performance of MCP over all version of the proposed CSD. This is due to the decrease in parallel paths, which is the primary motivation and cause for duplication.

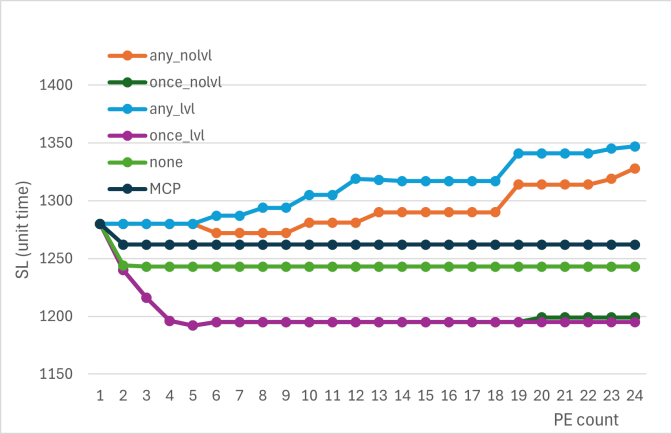

Fig. 8. Scheduling for t100_rand2 DAG.

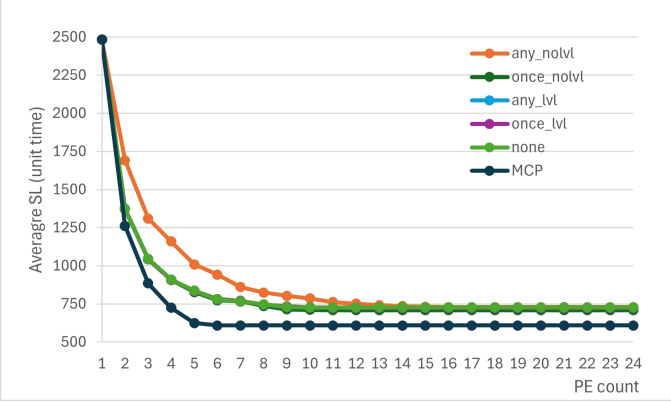

Fig. 9. Average SL for robot control with (0.85,5) CCR.

The CSD scheduling algorithm is simulated again with one PE only that has varying number of cores. Fig. 10 shows the SL with robot control DAG described before. The chosen DAG indicates almost the same response as robot task graph when applying this PE/Cores configuration. The comparisons here are between the versions of CSD and the optimal SL. Optimal SL is the length of CP without communication. The primary goal of the CSD algorithm is to reduce SL by clustering the tasks related to others and give higher priority to CP tasks. CSD algorithm closely approach the optimal demonstrating its effectiveness in finding near-optimal SL.

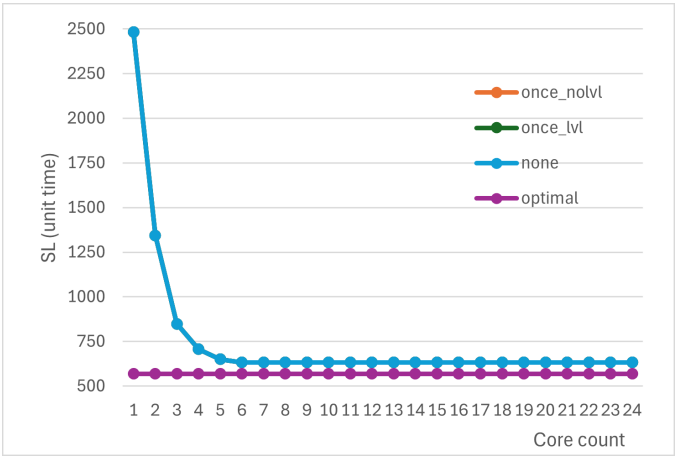

Fig. 10. Scheduling for robot control 88 tasks DAG.

Fig. 11 shows the result when the CSD algorithm is simulated with different number of PEs that have varying number of cores. Given that the total number of processing units (i.e. PE or core) is fixed and equal to 24. xxx shows the average SL for CSD versions on all the task graphs with different CCR. CSD algorithm produces schedule close to optimal as the number of cores increase.

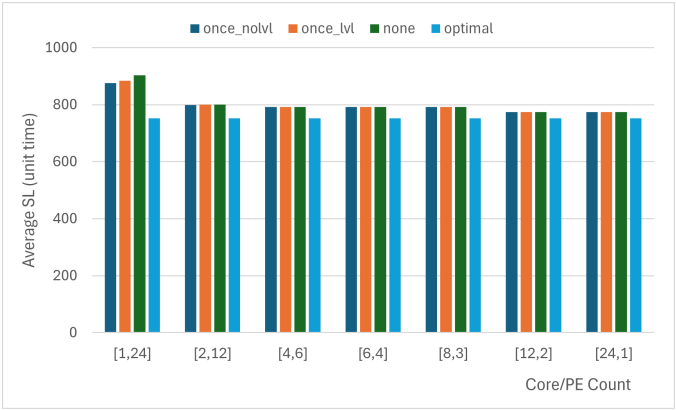

Fig. 11. Average SL for all task graphs.

V. Conclusion

This paper proposed multiple versions of a scheduling algorithm called CSD. Each version introduces enhancements and modifications that change with the workload behavior. CSD in its primitive version with no duplication matches MCP in the case the used architecture has only one core with different PEs. When comparing the (once_nolvl) version of CSD with MCP, the proposed algorithm outperforms MCP in SL, throughput and processors utilization. The results indicate that no single algorithm outperforms others in all scenarios. Instead, the effectiveness of a scheduling algorithm is dependent on factors

such as the nature of workload and architecture of multi-processor/multi-core system.

Enhancing Skin Cancer Detection with Transfer Learning and Vision Transformers

Istiak Ahmad, Bassma Saleh Alsulami, Fahad Alqurashi
Department of Computer Science-Faculty of Computing and Information Technology,
King Abdulaziz University, Jeddah 21589, Saudi Arabia

***Abstract*—Early and accurate detection of skin cancer is critical for effective treatment. This research aims to enhance skin cancer multi-class classification using transfer learning and Vision Transformers (ViTs), addressing the challenges of imbalanced medical imaging data. We introduced data augmentation techniques to the HAM10000 dataset to enhance the diversity of the training and implemented 13 pre-trained transfer learning models. These included DenseNet (121, 169, and 201), ResNet (50V2, 101V2, and 152V2), VGG (16 and 19), NasNet (mobile and large), InceptionV3, MobileNetV2, and InceptionResNetV2, as well as two Vision Transformer architectures (ViT and deepViT). After fine-tuning these models, DenseNet121 achieved the highest accuracy of 94%, while deepViT reached 92%, highlighting the effectiveness of these approaches in skin cancer detection. Future work will focus on refining these models, exploring hybrid approaches that combine convolutional neural networks and transformers, and expanding the framework to other cancer types to advance automated diagnostic tools in dermatology.**

***Keywords*—Medical imaging; skin cancer; multi-class classification; detection; deep learning; transfer learning; vision transformer**

I. Introduction

Skin cancer [1] typically starts in the skin cells when skin cells are damaged, usually from too much exposure to the sun's ultraviolet (UV) rays. The three main types of skin cancer are basal cell carcinoma, squamous cell carcinoma, and melanoma, where melanoma is the most serious. People with fair skin, a history of sunburns, prolonged sun exposure, a family history of skin cancer, or a weakened immune system are at the highest risk. Symptoms of skin cancer include the appearance of new or unusual skin growths, changes in the size, shape, or colour of moles, and persistent non-healing sores. According to the American Cancer Society [2], in 2024, there are estimated to be 100,640 new cases of melanoma skin cancer (59,170 male and 41,740 female) and an estimated 8,290 deaths (5,430 male and 2,860 female). The National Cancer Institute [3] reported that the relative survival rate for skin cancer over the five years from 2014 to 2020 is 94.1%. Early skin cancer detection is crucial, as it significantly enhances the likelihood of effective therapy and survival.

Artificial intelligence plays a pivotal role in enhancing sustainability across various sectors, including education [4], transportation [5], cybersecurity [6], [7], social media [8], [9] and healthcare. Notably, the field of healthcare has experienced remarkable advancements, particularly in the early detection of cancer, with AI's contributions proving to be increasingly impactful. The prompt identification of skin cancer enables using less invasive treatment approaches, reducing the risk of severe consequences and improving the patient's prognosis. The process of developing an early skin cancer detection system involves integrating cutting-edge imaging technology with advanced deep-learning algorithms. These appliances have the capability to accurately analyse skin lesions, detecting distinguishing patterns that may signify the presence of cancer. Computer-aided diagnosis (CAD) is a vital component of these systems, providing dermatologists with a valuable tool. CAD systems enhance diagnostic accuracy by analyzing visual data from skin images and distinguishing between benign and malignant tumours. CAD systems are essential for improving skin cancer's early and accurate diagnosis [10], improving patient outcomes by providing reliable views, and eliminating diagnostic errors. Skin cancer detection encounters challenges, including limited, diverse datasets, which hinder model generalization and class imbalance, leading to biased predictions. The visual similarity between benign and malignant lesions complicates detection, while the "black box" nature of AI models raises interpretability issues. Overcoming these hurdles is essential for enhancing skin cancer detection technologies. Transfer learning and Vision Transformers (ViTs) enhance model performance and generalization to overcome challenges with skin cancer detection. Transfer learning utilizes pre-trained models on extensive datasets to improve accuracy, even when skin cancer data is limited, and to address the issue of imbalanced classes. Vision Transformers (ViTs) improve the distinction between visually similar benign and malignant tumours by analyzing complex patterns and establishing connections across long distances in images.

A. The Aim and Objectives

The aim of this research is to develop and evaluate a robust multiclass skin cancer detection system by leveraging transfer learning, Vision Transformers, and advanced data augmentation techniques to achieve high accuracy. The research contributions are as follows:

- Applied refined data augmentation techniques to address challenges of limited and imbalanced datasets, significantly improving model robustness and generalization.
- Conducted a comprehensive analysis of 13 transfer learning models, underlining their comparative performance and demonstrating significant improvements in skin cancer detection accuracy.
- Implemented two Vision Transformer models, effectively leveraging their ability to capture intricate patterns in skin lesion images, enhancing detection accuracy.

The remainder of the paper is organised as follows: Section II discusses the literature review and research gaps. Section III discusses the proposed research methodology. Section IV discusses the research outcomes for transfer learning models and vision transformers models. Section V compares the overall research outputs with existing research and discusses research challenges and limitations. Finally, Section VI concludes by stating the future direction.

II. Literature Review

Kondaveeti et al. [11] proposed pre-trained models, such as ResNet50, MobileNet, Xception, and InceptionV3 for 7 types of skin cancer detection. They achieved the highest 90% accuracy, 89% weighted average precision, and 90% recall for ResNet50 on the HAM10000 dataset. Naik et al. [12] proposed MobileNetV2 for skin cancer detection and achieved 93.11% accuracy. Fraiwan and Faouri [13] used 13 transfer learning models to detect 7 types of skin cancer. They achieved the highest 82.9% accuracy for the DenseNet201 model. Swetha et al. [14] compared several transfer learning models, such as ResNet50, ResNet152, ResNet101, VGG16, VGG19, MobileNet, and Xception for multiclass skin cancer detection and obtained 83.69% categorical accuracy. Vishnu et al. [15] presented augmentation techniques and ensemble models by integrating InceptionV3 and DenseNet201 weights and outputs for six types of skin cancer detection. They achieved 89% accuracy with a validation loss of 0.44. Kaveti et al. [16] proposed a ResNet101 model for multiclass skin cancer detection using the HAM1000 dataset and got an accuracy of 92% for seven skin cancer categories. Arshed et al. [17] employed a pre-trained vision transformer model for seven types of skin cancer detection and achieved 92.14% accuracy. Tuncer et al. [18] presented lightweight CNN-based techniques for detecting benign and malignant types of skin cancer. They achieved 92.12% accuracy using the HAM10000 dataset. Yang et al. [19] proposed attention-weighted transformers for skin cancer detection using the HAM10000 dataset and achieved 93.75% accuracy. Ashfaq and Ahmad [20] implemented InceptionResNetV2, VGG16, ResNet50, EfficientNetB3, and vision transformer B32 for multiclass skin cancer classification. Among these models, EfficientNetB3 obtained the highest accuracy of 86% with precision 85%, recall 79%, and F1-score 81%. Sanchez et al. [21] proposed EfficientNet (B0, B1, B2, and B3) and ViT (base 16, base 32, large 16 and large 32) models and obtained the highest accuracy of 85% by fine-tuning the number of epochs and learning rate.

Despite considerable progress in skin cancer detection, key gaps remain that align with this study's objectives. Existing research has explored data augmentation to address imbalanced datasets; however, more refined techniques are needed to further enhance model robustness. This study addresses the scarcity of comprehensive comparisons of multiple transfer learning models' performances by evaluating 13 models, thereby providing a clearer insight into their effectiveness. Moreover, Vision Transformers (ViTs) have shown promise, but their potential to capture detailed patterns in skin lesion images remains underexplored. This research advances the field by implementing and testing two ViT models, demonstrating their capability to enhance detection accuracy.

III. Methodology and Design

Fig. 1 presents the proposed research methodology for developing and evaluating models for cancer detection using transfer learning and vision transformer techniques. The methodology is divided into several key steps. The first step includes dataset collection from the HAM10000 dataset. We have conducted several exploratory data analyses, including analysing the distribution of classes and disease distribution across genders, to acquire an understanding of the dataset. We have discovered that the dataset is imbalanced, which can lead to bias and overfitting issues. Data augmentation techniques are implemented to resolve these issues and improve model generalization. The more details of the dataset distribution are discussed in Section III-A. This study implemented several transfer learning models (see Section III-B) and vision transformer models (see Section III-C) for cancer detection. Finally, the models are evaluated using evaluation metrics (see Section III-D).

Algorithm 1 shows the process of our proposed methodology. Initially, we read all the images from the directory and saved them with the corresponding labels (line numbers 23 and 24). After that, image preprocessing is employed to remove noise from the image, and image augmentation techniques are applied to balance the number of images for each class (lines 25 and 26). The function AUGMENTEDPIPELINE discusses the applied augmentation techniques in this study (line numbers 1 to 11). Following this, the dataset is split into training, validation, and testing sets equally (line number 27). Then, the Keras transfer learning pre-trained model is loaded as a base model and added to a fully connected layer (FCmodel) (line numbers 29 and 30). The detailed architecture of a fully connected layer is given from lines numbers 12 to 22. Furthermore, the FCmodel, Adam optimizer, and entropy loss function are passed as parameters to the compiler (line number 31). Similarly, PyTorch vision transformer modes (DeepViT and ViT) are loaded as transformer models (line number 33). To calculate the training time of the proposed method, a timer is started in line number 34. Sequentially, the compiled model, validation, and training set are passed to train the model (line number 35). After training the model, the model and training history are saved in h5 format (line number 36). Line number 37 provides the model execution time. Finally, we evaluate our proposed method by passing the testing set, saved model, and training history through several evaluation metrics.

A. Dataset

This study used the HAM10000 (Human Against Machine with 10000 training images) [22] dataset, which was presented by the International Skin Imaging Collaboration (ISIC) for skin cancer detection in 2018 [23]. This dataset contains 10,015 dermatoscopic images for seven types of cancer, including Actinic keratoses and intraepithelial carcinoma (akiec), basal cell carcinoma (bcc), benign keratosis-like lesions (bkl), dermatofibroma (df), melanoma (mel), melanocytic nevi (nv) and vascular lesions (vasc). Fig. 2 presents the distribution of seven types of skin cancer derived from the HAM10000 dataset. The image IDs, along with the corresponding patient details, such as age, sex, and lesion localization, are as follows: akiec (ISIC_0027930, 60, male, and scalp), bcc (ISIC_0026343, 70, male, and face), bkl (ISIC_0028233, 55, male, and

face), df (ISIC_0028880, 55, male, and lower extremity), nv (ISIC_0028888, 50, male, and trunk), mel (ISIC_0029241, 70, male, and face), and vasc (ISIC_0027790, 50, female, and face).

Table I provides a comprehensive overview of the HAM10000 dataset, demonstrating the distribution of images across different classes and dataset splits. Each class includes a specific number of original and augmented images, as well as their distribution across training, validation, and test sets. As the original dataset is imbalanced, we implemented data augmentation techniques such as horizontal and vertical flipping, cropping, rotation, adjusting brightness and contrast, applying Gaussian blur, and adding Gaussian noise to address the class imbalance and improve the model's generalization capability.

TABLE I. DISTRIBUTION OF ORIGINAL, AUGMENTED, AND SPLIT DATASET IMAGES ACROSS SEVEN DIAGNOSTIC CLASSES

Classes	Original Images	Augmented Images	Train	Valid	Test
akiec	327	6705	3747	961	1997
bcc	514	6705	3710	958	2037
bkl	1099	6705	3739	923	2043
df	115	6705	3810	898	1997
mel	1113	6705	3801	925	1979
nv	6705	6705	3751	913	2041
vasc	142	6705	3725	993	1987
Total	10015	46935	26283	6571	14081

After applying data augmentation, a uniform count of 6,705 augmented images per class was generated. We split the data into training, validation, and test sets, utilizing 26,283 images for training, 6,571 for validation, and 14,081 for testing. These splits ensure a balanced representation of each class. This detailed distribution of images allows the model to be well-trained and evaluated, with a balanced exposure to each class, thereby reducing the risk of bias and overfitting.

B. Transfer Learning Model

This study used 13 transfer learning models, such as like DenseNet (121, 169, and 201), ResNet (50V2, 101V2, and 152V2), VGG (16 and 19), InceptionV3, MobileNetV2, and NASNet (Mobile and Large). We got the highest accuracy for the DenseNet121 model. The DenseNet121 architecture, as illustrated in Fig. 3, is a robust deep learning model optimized for image classification tasks through its efficient feature extraction capabilities. The model begins with an input layer that processes images of size 224x224 with three colour

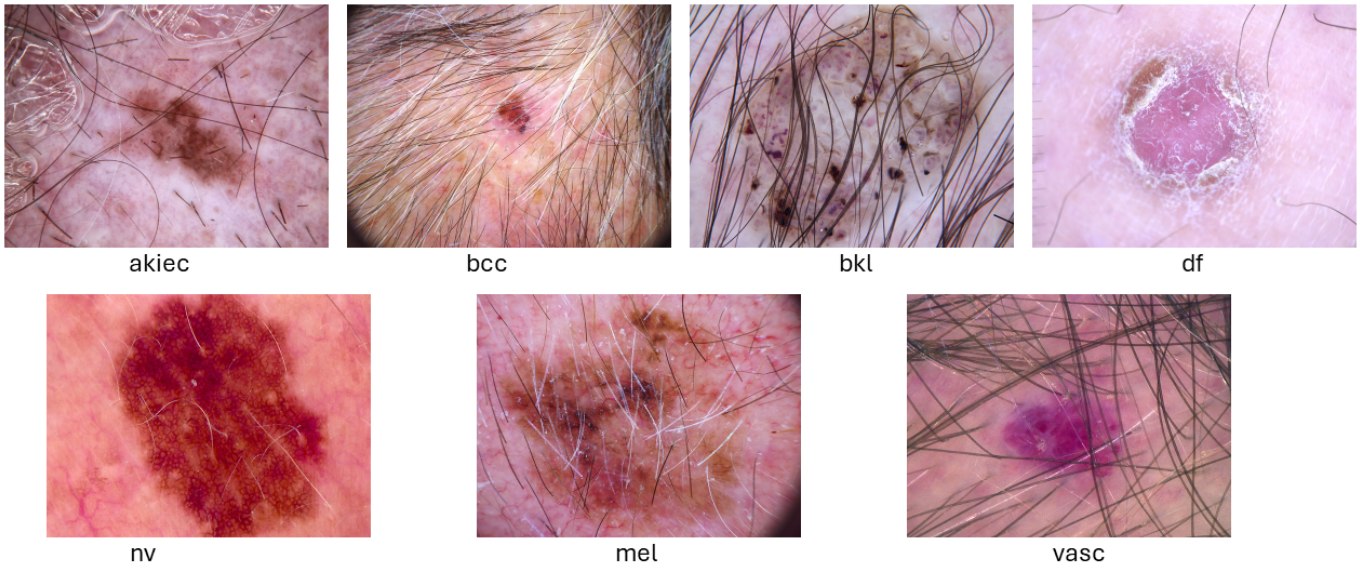

Fig. 2. Seven types of skin cancer.

channels (RGB). The next layer is an initial convolutional layer to capture fundamental features, such as edges. This layer produces a feature map with 64 channels and a spatial dimension of 56x56. The core of the model lies in its dense blocks (D1-D4), where each layer connects to all previous layers within the same block, ensuring that features are reused and information flows efficiently through the network. These dense blocks are interspersed with transition layers (T1-T3), which use 1x1 convolutions and average pooling to reduce the size of the feature maps, thereby maintaining computational efficiency without losing critical information. As the network progresses, the number of channels increases while the spatial dimensions decrease, refining the features extracted. The final layers include a Global Average Pooling (GAP) layer, which condenses the feature map into a vector, followed by fully connected layers that prepare the model for classification. Dropout layers are integrated to prevent overfitting, and the model concludes with a softmax activation function that outputs the probabilities for each class, making DenseNet121 both robust and accurate in image classification tasks.

C. Vision Transformer Model

Fig. 4 compares the architectures of the Vision Transformer (ViT) on the left and DeepViT on the right, highlighting key differences in their approaches to attention mechanisms and processing layers. Both models start with patch embedding and positional embedding to transform input images into a sequence of vectors, enabling the application of transformer-like attention mechanisms. In ViT, the architecture employs a standard multi-head self-attention mechanism followed by normalization and feed-forward layers. This process is repeated multiple times (xN), allowing the model to learn and refine features through self-attention across all patches. The simplicity of ViT lies in its straightforward use of self-attention without any modifications, relying on the depth of the network to capture complex patterns. However, DeepViT presents a modification known as "Re-Attention". After the initial multi-head attention, DeepViT applies normalization and a matrix transformation to refine the attention weights before they are fed into the next layers. This re-attention mechanism aims to stabilize and improve the quality of attention by reinforcing the most critical relationships between patches, potentially leading to better performance in capturing long-range dependencies.

D. Evaluation Metrics

This study used the following metrics to evaluate the performance of the classification model: A True Positive (TP) occurs when a model accurately predicts a positive class, whereas a True Negative (TN) occurs when it correctly predicts a negative class. A False Positive (FP) results when a model erroneously predicts a positive class and a False Negative (FN) happens when a model wrongly predicts a negative class as positive. These metrics were used to calculate the accuracy, precision, recall, and F1-score (see Eq. 1).

$$\begin{aligned} Accuracy &= \frac{TP + TN}{TP + TN + FP + FN} \\ Precision &= \frac{TP}{TP + FP} \\ Recall &= \frac{TP}{TP + FN} \\ F1 - score &= \frac{2 \cdot Precision \cdot Recall}{Precision + Recall} \end{aligned} \tag{1}$$

Each metric is crucial for evaluating the model's effectiveness in classifying the lesions accurately. Accuracy indicates the overall correctness of the model's predictions. Precision measures the model's ability to correctly identify positive cases, while recall assesses how well the model captures all actual positive cases. The F1-Score, a harmonic mean of precision and recall, provides a balanced measure of the model's performance.

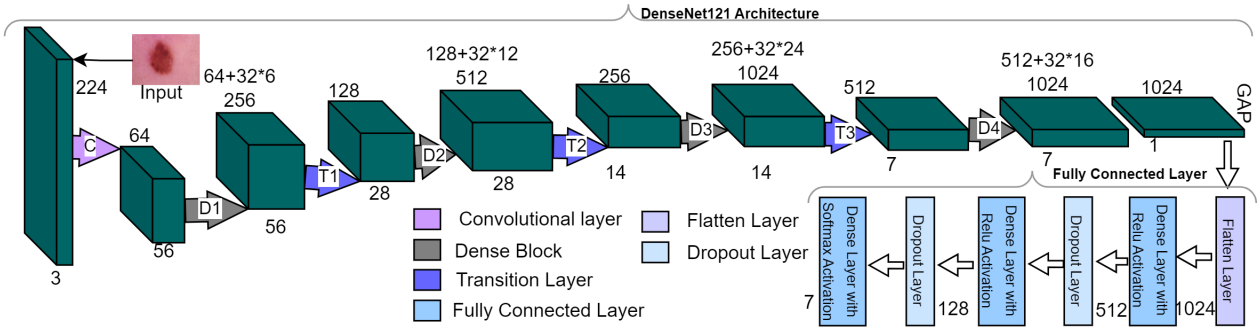

Fig. 3. DenseNet121 architecture.

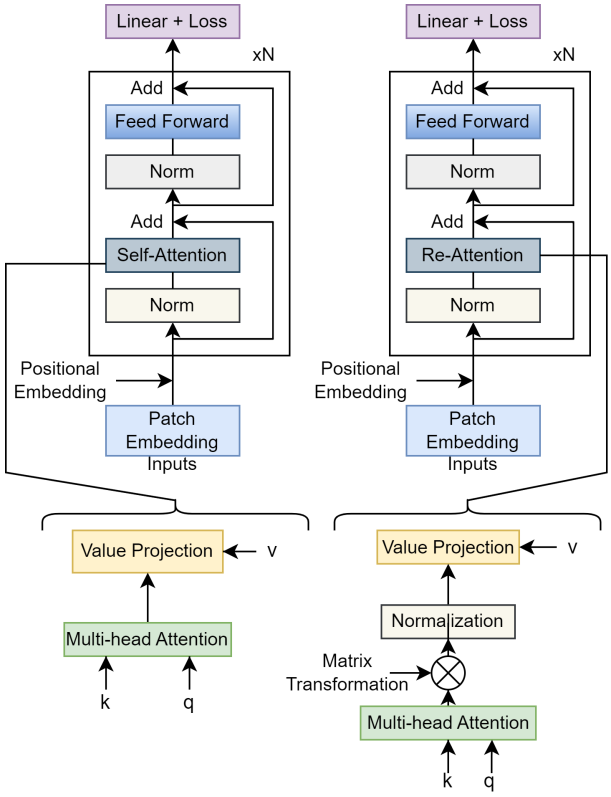

Fig. 4. Comparison between ViT (Left) and DeepViT (Right) model architecture [24].

1) Experimental Setup: The experiment was implemented on the following GPU configurations: NVIDIA GeForce RTX 4090, with 24GB memory. We employed the following parameters to train the transfer learning models: image size (224 x 224), batch size = 32, loss function: "categorical_crossentropy", optimizer: "adam", and two callback functions (ReduceLROnPlateau and EarlyStopping). For the deep vision transformer, we used the following parameters: batch size = 32, epochs = 100, learning rate = 0.00001, gamma = 0.7 and seed = 42, patch size = 32, and embedding dropout = 0.1.

TABLE II. PERFORMANCE COMPARISON OF VARIOUS DEEP LEARNING MODELS1

	Models	Ep	Time (Hour)	Acc	Pre	Re	F1-Score
Transfer Learning	DenseNet121	16	1.94	**0.94**	**0.94**	0.99	**0.94**
	DenseNet169	13	9.87	0.92	0.92	**1.00**	0.92
	DenseNet201	13	10.55	0.92	0.92	**1.00**	0.92
	ResNet50V2	16	3.95	0.92	0.93	0.98	0.93
	ResNet101V2	18	5.46	0.93	0.93	0.99	0.93
	ResNet152V2	26	11.20	0.93	**0.94**	0.99	0.93
	VGG16	12	5.47	0.89	0.91	0.97	0.90
	VGG19	12	5.2	0.87	0.88	0.97	0.87
	InceptionResNetV2	15	3.19	0.91	0.92	0.99	0.91
	InceptionV3	40	7.44	0.90	0.91	0.99	0.90

Ep = Epochs, Acc = Accuracy, Pre = Precision, Re = Recall

IV. RESULT

Table II compares the performance of various deep-learning models employed to classify skin cancers. The models report key performance metrics like accuracy (Acc), precision (Pre), recall (Re), and F1-score, along with the number of epochs (Ep) and training time in hours. For transfer learning, DenseNet121 emerges with the highest accuracy, precision, and F1-score of 0.94 with only 16 epochs and a relatively short training time of 1.94 hours. Additional variations of DenseNet, such as DenseNet169 and DenseNet201, exhibit strong performance while needing longer training durations. ResNet models exhibit impressive performance, especially ResNet152V2, which achieves an optimal trade-off between accuracy (0.93) and precision (0.94) but with the most extended training duration of 11.20 hours over 26 epochs. However, VGG models demonstrate the least accuracy, with VGG16 and VGG19 achieving accuracies of 0.89 and 0.87, respectively. The InceptionV3 and NASNet models demonstrate satisfactory performance, with NASNetLarge and InceptionV3 achieving an accuracy of 0.90. For the vision transformer, the ViT model, while requiring a significantly higher number of epochs (80) and more prolonged training time (8.92 hours), achieves an F1-score of 0.92, indicating robust performance. DeepViT slightly outperforms ViT with a higher F1-score of 0.93, albeit with a longer training time of 10.56 hours.

Fig. 5 illustrates the progression of training and validation loss, as well as accuracy measures, during best 15 epochs for a DenseNet121 model. The training loss, shown by the

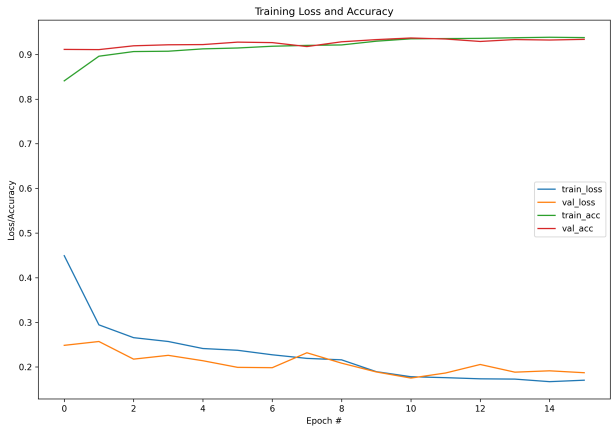

Fig. 5. Training & validation loss and accuracy (DenseNet121).

blue line, initially begins at a very large value and gradually drops, suggesting that the model is progressively learning and improving its performance as time progresses. The validation loss, shown by the orange line, has a similar trend to the training loss but consistently maintains a slightly lower value throughout all epochs. This suggests that the model possesses high generalization capabilities. The training accuracy, shown by the green line, exhibits a rapid initial rise, reaching a plateau by the third epoch, and then maintains a consistently high level for the remaining epochs. The validation accuracy, shown by the red line, has a similar pattern to the training accuracy, indicating that the model consistently performs at a high level on both the training and validation datasets.

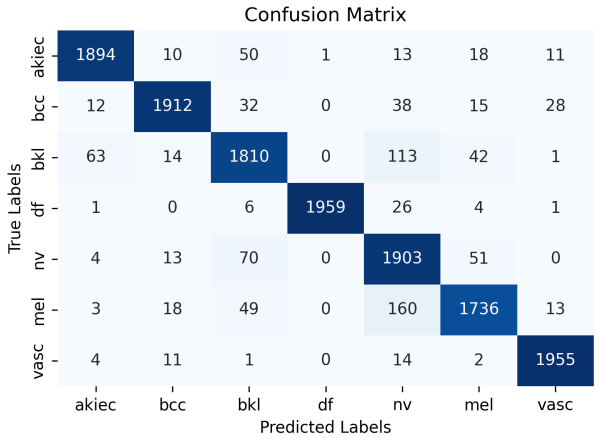

Fig. 6. Confusion matrix (DenseNet121).

Fig. 6 demonstrates the efficacy of a DenseNet121 model on a multi-class skin lesion dataset. The model has high accuracy, accurately categorizing the majority of cases in each category. For example, it accurately recognized 1894 occurrences of akiec, with the majority of misclassifications happening as bkl (50 occurrences). Similarly, the bcc category was accurately identified 1912 times, although some cases of misunderstanding resulted in misclassifications as nv (38 occurrences) and bkl (32 occurrences). The model accurately predicted 1810 cases of bkl. However, it incorrectly categorized some as mel (113) and akiec (63). The df class achieved near-perfect classification, with 1959 accurate predictions and few mistakes. The nv class achieved 1903 accurate classifications, but the model exhibited confusion in distinguishing between mel (70 occurrences) and bcc (51 cases). In the mel class, 1736 occurrences were accurately categorized, whereas 160 were mistakenly classified as nv. Ultimately, the model successfully categorized 1955 occurrences of vasc, with few mistakes. In general, the matrix demonstrates a high level of accuracy in classifying the data; however, there are a few instances where comparable classes were mistakenly identified, namely between mel and nv, as well as between akiec and bkl.

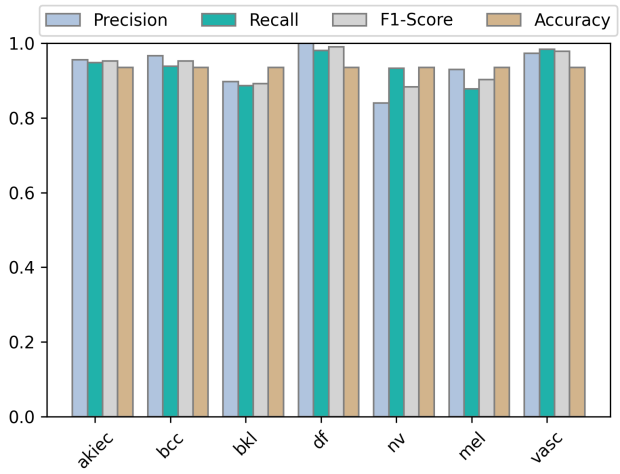

Fig. 7. Precision, recall, F1-Score, accuracy (DenseNet121).

Fig. 7 presents the performance metrics—Precision, Recall, F1-Score, and Accuracy—across different skin lesion classes (akiec, bcc, bkl, df, nv, mel, vasc) for a DenseNet121 model. The figure shows consistently high values across all metrics, demonstrating the model's strong performance across different classes, though slight variations suggest areas for potential improvement in balancing precision and recall for certain classes.

Fig. 8. Training & validation loss and accuracy (DeepViT).

Fig. 8 displays the training and validation loss and accuracy curves over the course of training for a DeepViT model, specifically focusing on the convergence and performance trends across epochs. The training loss (orange line) decreases

steadily, indicating effective learning, while the validation loss (blue line) also decreases but shows more fluctuation, suggesting variability in model performance on unseen data. The training accuracy (red line) improves rapidly and plateaus, reflecting the model's increasing ability to correctly classify training samples. The validation accuracy (green line) follows a similar trend but with smaller fluctuations. This implies that the model generalizes reasonably well but may still be prone to some overfitting, as indicated by the gap between the training and validation losses. Overall, the figure suggests that the model has learned effectively, but the slight divergence between training and validation metrics could indicate room for further tuning to improve generalization.

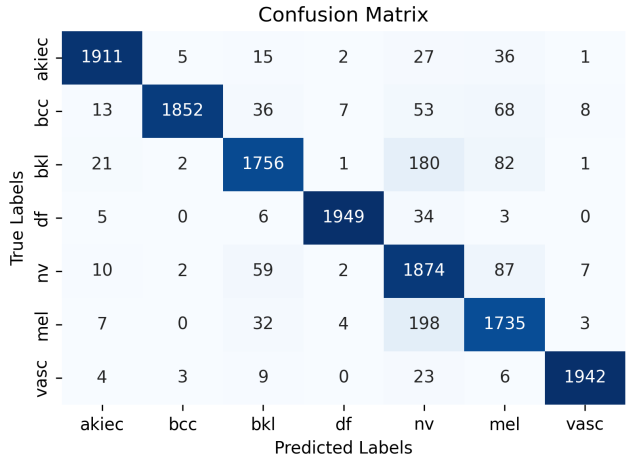

Fig. 9. Confusion matrix (DeepViT).

Fig. 9 illustrates the performance of the DeepViT transformer model in classifying various types of skin cancer. The diagonal elements represent the correctly classified instances for each class, indicating strong model performance, particularly for classes such as akiec, bcc, df, and vasc, with high true positive counts. However, some misclassifications are observed, especially in classes bkl and mel, where the model mistakenly predicts other categories. For example, 180 instances of bkl were misclassified as nv, and 82 instances of mel were also confused with nv.

Fig. 10 presents the performance metrics—Precision, Recall, F1-Score, and Accuracy—of the DeepViT transformer model across different skin cancer classes. The model shows consistently high performance across most classes, with metrics generally above 0.8, indicating effective classification. Notably, the classes akiec, bcc, and vasc exhibit near-perfect scores in all metrics, reflecting the model's strong ability to distinguish these types. These results demonstrate the potential of the DeepViT transformer in enhancing the accuracy of automated skin cancer detection, although further improvements are necessary to address the specific misclassification challenges observed in certain classes.

V. Discussion

Table III presents a comparison of the accuracy achieved by different deep-learning models for skin cancer detection. All the presented articles used the same dataset for multiclass skin

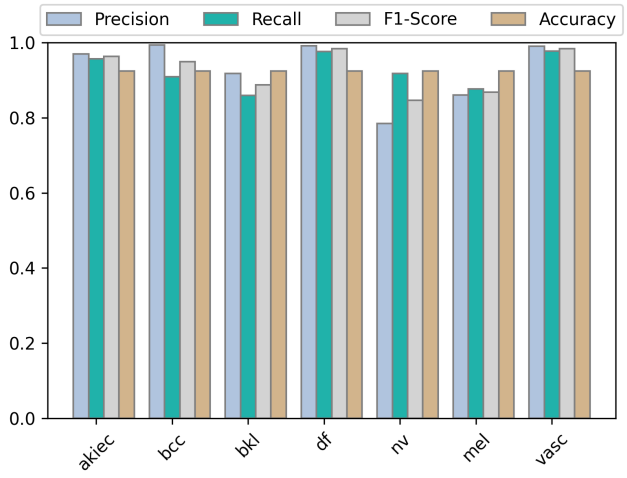

Fig. 10. Precision, recall, F1-Score, accuracy (DeepViT).

cancer classification. It places the DenseNet121 model from the current study in context with other existing methodologies, such as ResNet50, MobileNetV2, DenseNet201, Vision Transformers (ViT), EfficientNet, and others. The reported accuracy ranges from 82.9% to 93.75%. The DenseNet121 model from this study notably achieved an impressive accuracy of 94%, surpassing all the other models listed. This outstanding performance is likely a result of comprehensive data augmentation to tackle class imbalance, efficient transfer learning strategies, and the inherent strengths of the DenseNet121 architecture. These strengths include its deep layers and dense connections, which enable effective feature reuse.

TABLE III. Accuracy Comparison with Prior 7 Types of Skin Cancer Detection Studies

Ref.	Methodology	Accuracy (%)
[11], 2020	ResNet50	90
[12], 2022	MobileNetV2	93.11

VI. Conclusion

This study demonstrates the effectiveness of transfer learning and Vision Transformers (ViTs) in improving the accuracy of skin cancer detection. By addressing the challenges of imbalanced data through extensive data augmentation, we achieved notable results with DenseNet121 and deepViT models, attaining accuracies of 94% and 92%, respectively. These findings underscore the potential of these advanced models in dermatological diagnostics. However, limitations persist, such as the need for large, diverse datasets to generalize across various skin tones and cancer types. Additionally, the computational demands of training ViTs and other deep-learning models remain significant. Future work will focus on overcoming these limitations by exploring hybrid approaches

that integrate the strengths of convolutional neural networks and transformers.

Accurate Head Pose Estimation-Based SO(3) and Orientation Tokens for Driver Distraction Detection

Xiong Zhao[1], Sarina Sulaiman[2], Wong Yee Leng*[3]
Faculty of Computing, Universiti Teknologi Malaysia, 81310 Johor Bahru, Johor, Malaysia[1,2,3]
Yunnan College of Business Management, Kunming, China[1]

***Abstract*—Driver distraction is an important cause of traffic accidents. By identifying and analyzing the driver's head posture through monitor images, the driver's mental state can be effectively judged, and early warnings or reminders can be given to reduce traffic accidents. We propose a novel dual-branch network named TokenFOE that combines Convolutional Neural Networks (CNN) and Transformer. The CNN branch uses an Multilayer Perceptron (MLP) to infer the image features from the backbone, then generating a rotation matrix based on SO(3) to represent head posture. The Dimension Adaptive Transformer branch uses learnable tokens to represent the head orientation of 9 categories. Integrate the losses of both branches for training, ultimately obtaining accurate head pose estimation results. The training dataset uses 300W-LP, and the quantatitive testing datasets are AFLW-2000 and BIWI. The experiment results show that the Mean Absolute Error is improved by 21.2% and 9.4% compared to the original SOTA model on the two datasets, and the Mean Absolute Error of Vectors is improved by 19.2% and 10.2%, respectively. Based on the model output and calibrated through the camera adapter module, we present the qualitative results on the largest driver distraction detection dataset currently available, the 100-driver dataset, robust and accurate detection results were achieved for four different camera perspectives in two modalities, RGB and Near Infrared. Additionally, the ablation study shows that the model inference speed (21 to 75fps) can be used for real-time detection.**

***Keywords*—Head pose; driver distraction detection; rotation matrix; token; transformer**

I. Introduction

Distracted driving is defined as any behavior in which drivers focus their attention on activities unrelated to driving tasks [1]. The group of drivers who drive for a long time, such as long-distance bus drivers, full-time ride-hailing drivers, Taxi and truck drivers, are more prone to distraction, which is a significant safety hazard. When the driver is distracted, there is usually a phenomenon of abnormal head posture deviating from the direction of vehicle travel. Real time detection can be carried out using the existing monitoring device video in the terminal [2], and timely reminders can be given to the driver when abnormalities occur, which can effectively improve driving safety.

Face Orientation Estimation (FOE) also called Head pose estimation (HPE), is a challenging task in human-computer interaction [3], Human posture detection [4] and attention detection [5], [6]. The FOE problem can be conceptualized as a rotational dynamics challenge involving a 3D rigid body in space. To describe this 3D rotation, various mathematical techniques are available, including Euler Angles, Quaternions, Axis-Angle representations, Rotation Matrices, and Lie algebra. Each of these methods possesses unique strengths and limitations in terms of accuracy, efficiency, and ease of implementation. These advancements are attributed to the utilization of additional data sources such as facial landmark information [7], [8], [9], RGB-depth data [10], multi-task learning approaches [7], [11], and alternative parameterizations for orientation representation [11], [12], [13].

Traditional methods rely on manually extracting facial landmarks, such as the eyes, nose, and mouth, to estimate head pose. These methods are often sensitive to noise and variations in facial features. Deep learning has revolutionized FOE by enabling the direct prediction of head pose from raw images or videos. Deep learning models can learn complex patterns in facial data, leading to more robust and accurate head pose estimation, these methods use extra annotation to help FOE tasks, which usually could get good accuracy. Other methods trying to only use orientation labels, such as HopeNet [14], TriNet [11], FSA-Net [15], and TokenHPE [16], these methods also have much progress but slightly worse than aforementioned methods.

Some methods also try to use transformer architecture, such as TokenPose [17] uses a leaning token to represent a human pose, then regression the whole body key points. Following the same inspiration, TokenHPE [16] tried to use learning tokens to solve the HPE problem, they divided all the orientations into 9 or 11 regions, and every region set a token to predict.

Following these works, we introduce our work, TokenFOE, and try to estimate Head posture by a dual-branch network based SO(3) and Orientation Tokens for driver DDD (Driver Distraction Detection) task. The contributions are summarized as follows:

1) We proposed TokenFOE that adopts the dual-branch network with a joint loss that combines the CNN branch and Transformer branch, we also introduced DAT (Dimension Adaptive Transformer) architecture that could be suitable for any backbone.
2) Extensive experiments on AFLW2000 [18] and BIWI [19] show we achieved new SOTA, especially exceeding other Extra Annotation Free (EAF) methods by a wide margin.
3) To the best of our knowledge, it is the first time that SO(3) and attention mechanism are combined as a dual-branch network in a DDD task.

The paper is organized as follows: Section II introduces some related work in this field, and Section III describes in detail the

model structure of TokenFOE and provides specific important formulas, loss functions, and evaluation metrics. In Section IV, we first introduces the datasets used in this article, and then provides detailed experimental results to demonstrate the effectiveness and robustness of the method. Detailed ablation experimental results are also provided for important parameters. Finally, the limitations and conclusions of this method are discussed in Sections V and VI.

II. Related Works

Prior to the advent of deep learning, estimating facial orientation or pose from RGB images without depth information presented significant challenges. This task involved dealing with a vast representation space encompassing diverse head poses. Over the past decades, numerous methodologies have been proposed to address this challenging problem. In this section, we present a concise overview of the FOE problem.

A. Driver Distracted Detection Approaches

The accuracy of FOE has been greatly improved, and applications based on estimation results have also received more attention and research. Li et al. [20] try to review this research field use electroencephalography. Mou et al. [21] proposed a dual-channel network to try to solve the DDD problem, but it just tested on an early simulated small dataset, and the model's true generalization performance is difficult to verify, with few types of distraction detection. 100-driver [22] is a large-scale, diverse posture-based distracted diver dataset, with more than 470K images taken by 4 cameras observing 100 drivers over 79 hours from 5 vehicles. Gebert P. et al. use an attention module integrated into the network for adaptive feature extraction. Li et al. introduced an efficient system based on a Transformer to detect driving behavior.

B. Extra Information-utilized HPE Approaches

PRNet [23] predicts 2D UV position maps that encode 3D points and utilizes the connectivity of the Basel Face Model (BFM) mesh to construct face models. Research [24] approach combines coarse and fine regression outputs within a deep neural network framework. Meanwhile, SynergyNet [7] explores a synergistic learning process that leverages both 3D Morphable Models (3DMM) and 3D facial landmarks to predict the entire 3D facial geometry, achieving highly accurate results. In contrast, [25] proposes a method that does not require training with head pose labels, instead relying on matching key points between a reconstructed 3D face model and the 2D input image. However, all prediction methods that rely on key points are significantly influenced by the quality of the input image.

Unlike traditional methods that rely on pre-labeled head poses for training, method [25] estimates pose by aligning a reconstructed 3D face model with the 2D input image, bypassing the need for explicit pose labels. However, this approach has a limitation: its accuracy can be affected by variations in image quality, as it depends on precise keypoint detection.

C. Extra Annotation Free HPE Approaches

TokenHPE [16] was a Transformer-based method that is critically aware of minority relationships among facial parts. This approach specifically focuses on learning the intricate relationships between different facial components. To achieve this, they introduce several orientation tokens that are designed to explicitly encode the fundamental orientation regions of the face. Furthermore, they devise a novel token-guided multi-loss function that serves as a guide for the orientation tokens, enabling them to learn the desired regional similarities and relationships. This approach not only enhances the accuracy of head pose estimation but also provides a deeper understanding of the intricate facial geometry. 6dRepNet [13] tackles unconstrained head pose estimation. It overcomes the limitations of prior methods by using a continuous 6D rotation matrix representation for ground truth data. This allows it to learn the full range of head rotations, unlike previous approaches restricted to narrow angles. Additionally, a geodesic distance-based loss function ensures learned rotations adhere to real-world 3D rotation space geometry, boosting accuracy and robustness. LwPosr [26] utilizes a combination of depthwise separable convolutional and transformer encoder layers for efficient and fine-grained head pose prediction.

Overall, these methods have explored various technological routes in the field of FOE and achieved some good results. If new methods want to further improve performance or enhance generalization, they face significant challenges.

III. Method

As shown in Fig. 1, estimating the driver's head posture in the monitored image can help solve DDBR problem.

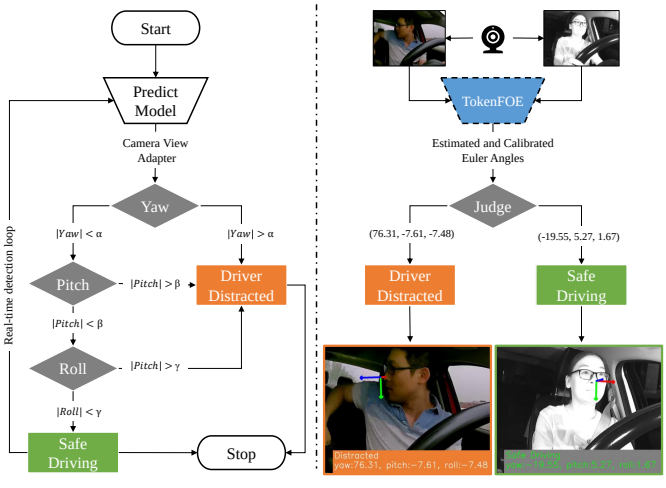

Fig. 1. Left: Overview of proposed driver distraction detection workflow. Right: One RGB and one Near Infrared (NIR) sample of detected results using TokenFOE.

In this section, we first introduce the overview of TokenFOE, then describe every part, including the representation methods of rotation, Gram-Schmidt process, MLP structure, Dimension Adaptive Transformer, and evaluation metric.

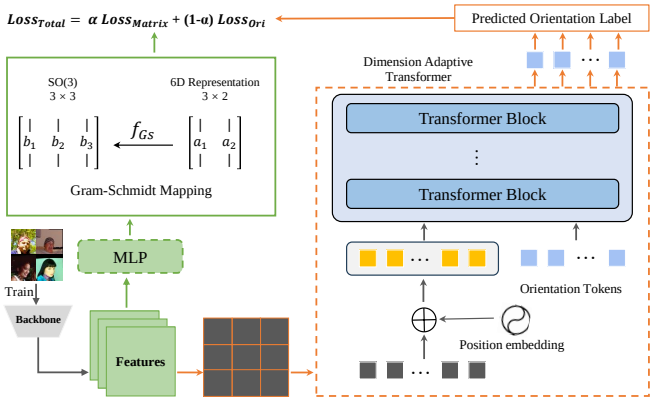

Fig. 2. The pipeline of proposed TokenFOE, a CNN and Transformer fusion dual-branch network based SO(3) and orientation tokens. The main module MLP (*Sec. III-C*), Gram-Schmidt Process (*sec. III-D*) and Dimension Adaptive Transformer (*sec. III-E*) will described respectively.

A. Pipeline of TokenFOE

1) Dual branch architecture: The whole pipeline of TokenFOE is refer to Fig. 2, which first pre-processes the input image (Section IV-B1), then using a pre-trained CNN model to extract image features. The extracted image features are processed in two separate paths. One path is connected to the MLP to predict a 6d representation, follow a Gram-Schimidt process mapped it into a 3×3 rotation matrix belonging SO(3), while the other path adopts the Vit approach to divide features into 14×14 patches, overlay them with position embedding, and send them together with orientation tokens to the transformer block for attention calculation. The calculated results are generated through an fully connected (FC) layer to generate a set of predictions, which are the class of orientation. The calculation results of the two losses are fused using a hyper-parameter α to obtain the final output.

B. Head Orientation and Representation of Rotation

1) Head orientation partitioning: According different orientation euler angles, we could divided head posture to several region. In this work, we followed TokenHPE [16] divided all posture into 9 classes, the illustration refer to Fig. 3.

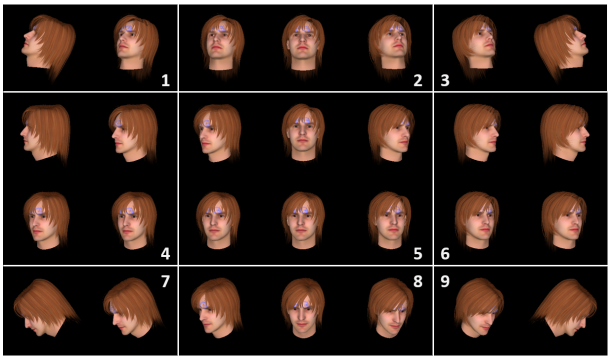

Fig. 3. According the neighbor image similarities, we divided head posture into 9 classes as the schematic diagram.

2) Rotation matrix: There are several methods available to represent a 3D rotation, such as Euler angles, Rotation matrix, Axis-angle, Quaternion, or Lie algebra. Among these, Euler angles are commonly used and intuitive. They decompose a 3D rotation into rotations along the three orthogonal coordinate axes of the object, known as Yaw, Pitch, and Roll. Axis-angle representation and Rotation matrix are closely related and can be converted into each other. If v is a vector in $\mathbb{R}^3$ and k is a unit vector describing an axis of rotation about which v rotates by an angle θ according to the right-hand rule. As we know, an object rotation θ degrees by axis x, y, z could described by followed Eq. 1 and Eq. 2 where the $c_\theta = cos(\theta), s_\theta = sin(\theta), \xi = 1 - cos(\theta)$.

$$R_{(\theta)} = \begin{bmatrix} 1 & 0 & 0 \\ 0 & c_\theta & -s_\theta \\ 0 & s_\theta & c_\theta \end{bmatrix} \begin{bmatrix} c_\theta & 0 & s_\theta \\ 0 & 1 & 0 \\ -s_\theta & 0 & c_\theta \end{bmatrix} \begin{bmatrix} c_\theta & -s_\theta & 0 \\ s_\theta & c_\theta & 0 \\ 0 & 0 & 1 \end{bmatrix} \quad (1)$$

$$R = \begin{bmatrix} c_\theta + u_x^2\xi & u_x u_y \xi - u_z s_\theta & u_x u_z \xi + u_y s_\theta \\ u_y u_z \xi + u_z s_\theta & c_\theta + u_y^2 \xi & u_y u_z \xi - u_x s_\theta \\ u_z u_x \xi - u_y s_\theta & u_z u_y \xi + u_x s_\theta & c_\theta + u_z^2 \xi \end{bmatrix} \quad (2)$$

C. MLP Architecture

MLP is a classic artificial neural network model. It consists of an input layer, several hidden layers, and an output layer. In this work, we ultimately chose a single hidden layer MLP module instead of FC according to the ablation study result, with the dimension of the hidden layer set to 768. When using the default RepVgg_b2g4 as the backbone, the complete workflow is shown in Fig. 4.

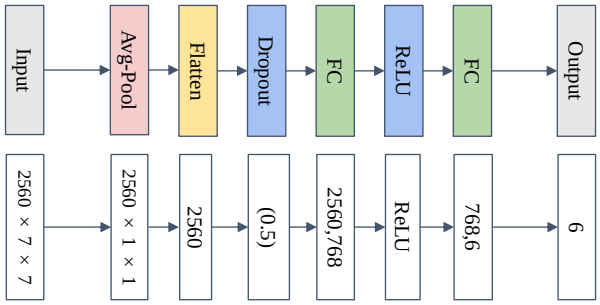

Fig. 4. Upper: MLP architecture with one hidden layer. Lower: the example tensor dimension when use RepVgg_b2g4 as backbone.

D. Gram-Schmidt Process

A set of nonzero vectors $\mu_1, \mu_2, ..., \mu_n$ is called orthogonal if $\mu_i \cdot \mu_j \neq 0$ whenever $i \neq j$. It is orthonormal if it is orthogonal and in addition $\mu_i \cdot \mu_i = 1$ for all $i = 1, 2, 3, ..., n$. We can use the Gram-Schmidt Process to perform orthogonal transformations on the predicted rotation matrix, that is means we could convert the HPE problem to estimate the satisfied rotation matrix.

According TriNet [27] indicated, we could use map function f_{Gs} (refer to Eq. 3) to map the output into $\hat{R}$, furthermore, predict 6 elements could get the best precision and guarantee

the representation space continuity than predict five or nine elements.

$$\hat{R} = f_{Gs}(\begin{bmatrix} | & | \\ a_1 & a_2 \\ | & | \end{bmatrix}) = \begin{bmatrix} | & | & | \\ b_1 & b_2 & b_3 \\ | & | & | \end{bmatrix} \tag{3}$$

The calculate method of the f_{Gs} is using Eq. 4 and Eq. 5.

$$b_i = \begin{bmatrix} N(a_1) & i=1 \\ N(a_2 - (b_1 \cdot a_2)b_1) & i=2 \\ b_1 \times b_2 & i=3 \end{bmatrix}^T \tag{4}$$

$N(\cdot)$ denotes a Normalization function.

$$N(u_i) = \frac{u_i}{\|u_i\|} \tag{5}$$

E. Dimension Adaptive Transformer

ViT [28] is a typical model and also is the first successful vision transformer model. In ViT, an input image undergoes a process of being segmented into smaller patches to avoid the exponential increase in computational complexity caused by too many patches, e.g. the default input image size is $224 \times 224 \times 3$, the author divides the image into $16 \times 16 \times 3$ patches, and maps each patch to a 768 dimensional 1D vector. The total number of patches is $14 \times 14 = 196$.

1) Dimension adaptive layer: In TokenFOE, the object processed by the transformer block is not the original image data, but the features output by the backbones. Different backbones output different feature dimensions and orders, for example, the output of resnet50 is $2048 \times 7 \times 7$, the output of RepVgg_b2g4 is $2560 \times 7 \times 7$, and the output of Swin_base_224 is $7 \times 7 \times 1024$. To be compatible with different feature dimensions without losing information, we introduce a DDT(Dimension Adaptive Transformer), as shown in Fig. 5. The input features undergo dimension adaptation while keeping the number of patches constant, and then are uniformly mapped to 128 dimensions as input for the transformer block. This operation allows our model to match the output of any backbone.

2) Transformer block: Given the 1D token embedding sequence $T = \{[visual], [euler\ angles]\}$ as input, the Transformer encoder learns pose feature representation by stacking M blocks. Each block contains a Multi-head Self-attention (MSA) module and a Multilayer Perceptron (MLP) module. In addition, layer norm (LN) is adopted before every module. Self-attention (SA) can be formulated as Eq. 6.

$$SA(T^{l-1}) = softmax(\frac{T^{l-1}W_Q(T^{l-1}W_K)^T}{\sqrt{d_h}})(T^{l-1}W_V) \tag{6}$$

where $W_Q, W_K, W_V \in R^{d \times d}$ are the learnable parameters of three linear projection layers, T_{l-1} is the output of the $(l-1)_{th}$ layer, d is the dimension of tokens, and $d_h = d \cdot MSA$ is an extension of SA with h self-attention operations which are called "heads". In MSA (Refer to Eq. 7), d_h is typically set to d/h.

$$MSA(T) = [SA_1(T); SA_2(T); ...; SA(h)(T)]W_p \tag{7}$$

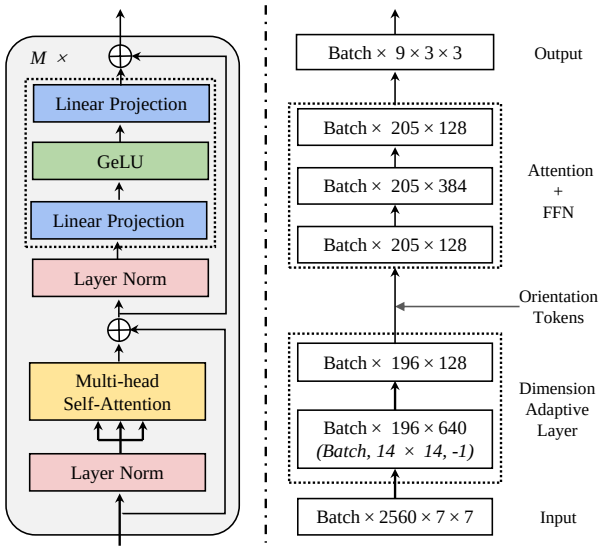

Fig. 5. Left: The architecture of Transformer block that consist of transformer branch. Right: The pipeline and example of dimension adaptive calculation process when use RepVgg_b2g4 as backbone.

Given that spatial relationships are essential for accurate HPE, positional embedding, pos, is added to the visual tokens to reserve spatial relationships, which can be expressed as Eq. 8:

$$[Visual] = \{v_1 + pos, v_2 + pos, ..., v_n + pos\} \tag{8}$$

where, n is the number of patches. Then, we obtain n×1D vectors symbolically presented by [visual] tokens. The position embedding use Eq. 9 followed [29].

$$PE = \begin{cases} \sin(pos/10000^{2i/d_{model}}) & (pos, 2i) \\ \cos(pos/10000^{2i/d_{model}}) & (pos, 2i+1) \end{cases} \tag{9}$$

F. Evaluation Metric

1) Loss function: As we know, for any $R \in SO(3)$ must satisfy $R^T = R^{-1}$, $detR = \pm 1$. Given a specified image x^i from the test data set, there is only one correct rotation matrix converted from the label we called R_{gt}, The model could predict a rotation matrix $\hat{R}$, we want the $\hat{R}$ as closely as possible of R_{gt}, the limitation is $\hat{R} = R_{gt}$, then $\hat{R}R_{gt}^T = I$, I is an identity matrix. we use the Eq. 10 as the loss function followed paper [13].

$$\mathbb{L}_{pose} = \arccos\left(\frac{1}{2}(tr(\hat{R}_i R_{gt_i}^T) - 1)\right) \tag{10}$$

When $R_{gt_i} = \hat{R}_i$, the $\mathbb{L}_{pose}$ equal zero. If the result is not equal to zero, It means our model predicts an incorrect rotation matrix, we could use the result to penalty our model by back propagation algorithm. The final loss function is calculated by Eq. 11, α is a hyper-parameters combine the two branches.

$$Loss_{Total} = \alpha Loss_{matrix} + (1-\alpha)Loss_{ori} \tag{11}$$

2) Evaluate: MAE is a standard metric for HPE, it is defined as Eq. 12.

$$MAE = \frac{1}{N}\sum_{i=1}^{N}(|x_i - \hat{x}_i|) \tag{12}$$

where N is the number of face images and x_i and $\hat{x}_i$ represent the ground truth and predicted pose parameters, respectively.

MAEV is defined as Eq. 13. where N is the number of face images in the dataset and v_i and $\hat{v}_i$ are the vector of ground truth and the predicted result.

$$MAEV = \frac{1}{N}\sum_{i=1}^{N} cos^{-1}\left(\frac{v_i \cdot \hat{v}_i}{|v_i||\hat{v}_i|}\right) \tag{13}$$

IV. Experiments

A. Datasets

We follow the methodologies employed in [13], [15], [11] and utilize well-established public face datasets for training and testing. Specifically, we use the widely recognized 300W-LP [8] as the training set, AFLW-2000 [18] and BIWI [19] for quantitative testing, 100-Driver [22] for DDD task.

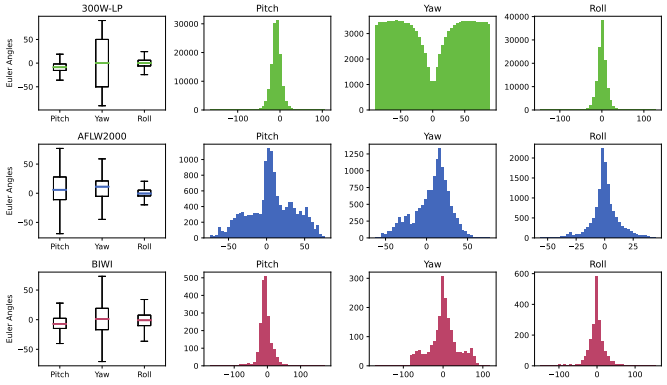

Fig. 6. Box and Hist plots of Training and Testing datasets, statistic by Euler angles. Green(300W-LP [8]), Blue(BIWI [19]) and Red(AFLW2000 [18]).

1) Training: The 300W-LP [8] dataset comprises over 60,000 face samples collected from multiple databases, the statistic results shown in the first line of Fig. 6. We convert ground truth Euler angle into rotation matrices for training.

2) Quantitative testing: AFLW-2000 [18] consists of the first 2000 images from the AFLW dataset. This dataset is annotated with ground truth 3D faces and corresponding 21 landmarks. It offers a diverse range of samples with varying lighting conditions and occlusion levels, providing a robust evaluation environment for our model. BIWI [19] includes more than 15K images of 20 individuals. The head pose range covers about ±75° yaw and ±60° pitch. The statistic data is shown as Fig. 6.

3) Driver distracted detection: 100-Driver [22] is the largest DDD dataset with more than 470K images taken by 4 cameras, observing 100 drivers, over 79 hours from 5 vehicles and including different vehicles, drivers, camera view, and modalities.

B. Model Settings

1) Pre-processing: First, we resize all the images into 300×300 pixels, then random crop to 224×224 pixels as input, we don't use any other augment method. The model uses the pre-trained RepVgg_b2g4 provided by TIMM framework [30] as the backbone, it's one of powerful and popular CNN models. We use Top-Down mode and employ MTCNN [31] to deal with the face location detection task.

2) Hyper-parameters settings: The training and testing environment is Ubuntu 22.04, Python 3.10, cuda 12.6, Pytorch 1.13, and a Nvidia 2080Ti with 11G GPU memory. The core parameters of the training are: the batch size is 64, use the Adam optimizer, the total epochs is 30, and the initial Leaning Rate is set to 1e-4, which is reduced halve when 8^{th}, $16^{th}$and 24^{th} Epoch. All the weights in our model are random initialization and the hyper-parameters α are set to 0.6 by the ablation study result.

C. Experimental Results

Fig. 7 shows that the accuracy on AFLW2000 and BIWI consistently increases with the training progress. There are three periodic low points at 9^{th}, 17^{th} and 27^{th} epoch, respectively, just accompanied by three times decrease in learning rate. The plot also shows an increasing trend until the 30^{th} Epoch, but the growth limit has not been explored yet.

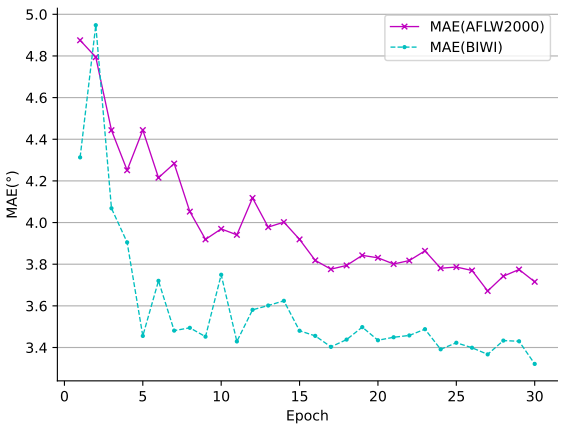

Fig. 7. Per epoch MAE plots tested on AFLW-2000 [18] and BIWI [19].

Follow the old SOTA method, TokenHPE [16], we also show the MAEV scores compared with other popular EAF methods, Refer to Fig. 8, our score exceeds others by a wide margin, specifically, improved by 19.2% on AFLW2000.

HPE is a classical problem that has been studied in many papers. According to literature [16], the methods are divided into two categories: pure HPE and using additional annotated data. Taking SynergyNet [7] as an example, facial key points are used for training. In fact, the coordinate of upper key points already contains head orientation information, which can greatly improve accuracy. As can be seen from Table I, this type of method generally has higher accuracy. Among all methods that do not use additional annotation information, our method has the highest accuracy. We achieved four new SOTA on AFLW-2000 and BIWI. Because TokenHPE [16] is

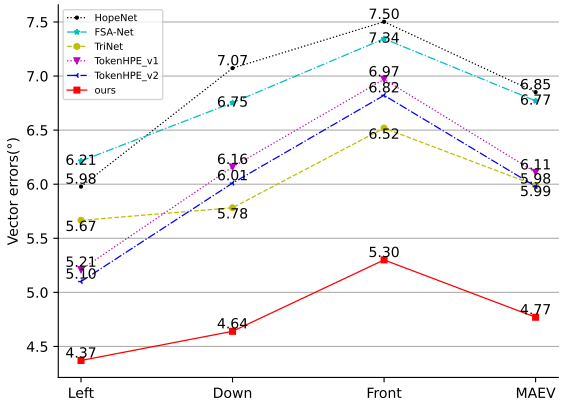

Fig. 8. Comparison with other methods on AFLW-2000 measured by MAEV. Our accuracy exceeds other EAF methods by a wide margin. The lower the better, best viewed in color.

the most familiar with our method, we conducted a careful comparison with it (indicated by underline), using downward arrows(↓) and percentages(%) to indicate the specific values of accuracy improvement.

We conducted extensive ablation experiments to investigate the impact of each module on overall performance.

Table II shows the impact of different backbones on model performance. The results show that the backbone has a significant impact on the final performance. Combining the training and inference speed experimental results in Table III, a trade-off between performance and speed can be made according to specific needs.

TABLE II. ABLATION STUDY OF DIFFERENT BACKBONE. THE OVERALL PERFORMANCE OF THE CNN MODEL IS BETTER THAN THAT OF THE TRANSFORMER MODEL

Backbone	Type	MAE(AFLW2000)	MAE(BIWI)
Swin_base_224	Transformer	5.03	3.44
ResNet50	CNN	4.40	3.69
RepVgg_b2g4	CNN	3.67	3.37

The MLP structure also has a significant impact on accuracy. We compared and tested FC, single hidden layer MLP with different dimensions, and double hidden-layer MLP, and found that the single-layer MLP with dimension 768 had the best performance. All the data refer to Table IV.

TABLE III. ABLATION STUDY RESULTS OF TRAINING AND INFERENCE SPEED. 'M' AND 'MS' ABBREVIATION FOR MINUTES AND MILLISECONDS, RESPECTIVELY

Model	Backbone	Image Size (C,H,W)	Training (M/epoch)	Inference (ms/image)
TokenFOE	Swin_base_224	3,224,224	29	33.9
TokenFOE	ResNet50	3,224,224	13	13.3
TokenFOE	RepVgg_b2g4	3,224,224	31	48.7

TABLE IV. ABLATION STUDY RESULTS OF DIFFERENT MLP ARCHITECTURES. SINGLE HIDDEN LAYER ARE THE BEST MODULE THAN FC AND TWO HIDDEN LAYER ARCHITECTURE

Module	Hidden Layers	Hidden Dimensions	MAE(AFLW2000)
FC	0	-	3.77
MLP	1	128	4.05
MLP	1	256	4.03
MLP	1	512	3.76
MLP	1	768	3.67
MLP	1	1024	3.95
MLP	2	1024,256	4.26

In the end, we tested different loss weights refer to Fig. 9, that is say the different values of α. According to our design, the Transformer branch performs classification tasks, which can improve the overall model accuracy(improved about 11.2%) but is not suitable for independent work. When α is set to 1, means only the CNN branch worked.

So far, our method can accurately estimate the head pose angle, but there is still a problem when facing DDD tasks. The training images are all based on the front profile view as the initial position, and the output Euler angles are also the deviation values relative to this initial position.

However, in the DDD task, the cameras may be arranged in different positions, and due to the influence of the view angle, completely different Euler angles will be output for the same driver posture. This article simply sets up a Camera Adapter layer to solve it. Through cluster analysis for 100-driver [22],

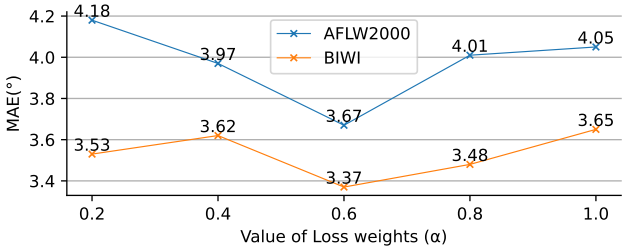

Fig. 9. Ablation study results of model architectures. $Loss_{Matrix}$ is more important than $Loss_{Ori}$.

it was determined that Pitch and Roll directions greater than $\pm 15°$, Yaw direction greater than $50°$, or yaw less than $-75°$ with an absolute value greater than $25°$ are Distracted. Fig. 10 shows the visual detection results of different camera views, modalities, lighting, vehicles, and drivers, further demonstrating the effectiveness and robustness of this method.

V. Limitation and Discussion

In this section, we will discuss the limitations of our method in this article.

First, TokenFOE adopts a dual-branch structure to calculate two sets of Lose separately, which theoretically enhances the model's expressive power. However, compared to CNN, especially lightweight CNN models represented by Mobile-net [36], the computational complexity and resource consumption of the transformer model have significantly increased, which is not cost-effective from an efficiency perspective. The advantage of the transformer scheme is that the model performs better when training with large amounts of data. If we want to deploy the model to a vehicle terminal device for terminal inference, maybe need to fine-tune the model, such as using a lighter backbone and reducing the number of parameters appropriately.

Second, sleeping and yawning is also an important sign of fatigue and distraction, our method can only detect head posture, making it difficult to make quick judgments in such scenarios (refer to Fig. 11).

VI. Conclusion

We proposed a novel dual-branch network named TokenFOE, that combines CNN and Transformer, one is the classic CNN path, and the other is a transformer model based on a self-attention mechanism, the dimension adaptive algorithm suitable uses any pre-trained backbone for the feature extractor.

We train the model on 300W-LP, quantitative test on AFLW-2000 and BIWI. The experiment results show that the MAE score is improved by 21.2% and 9.4% compared to the original SOTA model, and the MAEV score is improved by 19.2% and 10.2%, respectively. Based on the model output and calibrated through the camera adapter module, we present the visualization results on the largest DDD dataset currently available, the 100-driver [22] dataset. Robust and accurate detection results were achieved for four different camera perspectives in daytime (RGB) and Night time(NIR). Additionally, the ablation study shows that the model inference speed (21 to 75fps) can be used for real-time detection.

The main limitation of this method is that the heavy model leads to high training and inference costs, and the computational overhead of the self-attention part is too high. In theory, more tasks can be completed by adding a small number of additional tokens, such as key points. In addition to further improving accuracy and reducing costs, the fusion of multi-task and multi-modality is also a future research direction.

Conflict of Interest

The authors declare no conflict of interest.

Authors' Contributions

Xiong Zhao conceived the main idea, conducted the experiments and wrote the manuscript. Sarina Sulaiman guided the research direction. Wong Yee Leng analyze the results and proposed improvement suggestions. All authors had reviewed and approved the final version.

Predicting the Most Suitable Delivery Method for Pregnant Women by Using the KGC Ensemble Algorithm in Machine Learning

Pusarla Sindhu, Parasana Sankara Rao
Department of Computer Science and Engineering
GITAM (Deemed to be)University, Visakhapatnam-530045, India

***Abstract*—Maternal and neonatal mortality rates pose a significant challenge in healthcare systems worldwide. Predicting the childbirth approach is essential for safeguarding the mother's and child's well-being. Currently, it is dependent on the judgment of the attending obstetrician. However, selecting the incorrect delivery method can cause serious health complications both in mother and child over short-time and long-time. This research harnesses machine learning algorithms' capability to automate the delivery method prediction process. This research studied two different stackings implemented in machine learning, leveraging a dataset of 6157 electronic health records and a minimal feature set. Stack1 consisted of k-nearest neighbors, decision trees, random forest, and support vector machine methods, yielding an F1-score of 95.67%. Stack 2 consisted of Gradient Boosting, k-nearest neighbors, and CatBoost methods, which yielded 98.84%. This highlights the superior effectiveness of its integrated methodologies. This research enables obstetricians to ascertain the delivery method promptly and initiate essential measures to ensure the mother's and baby's safety and well-being.**

Keywords*—Delivery method; stacking; neonatal mortality; KGC ensemble algorithm

I. Introduction

Maternal and neonatal mortality can be significantly reduced by carefully selecting the most appropriate delivery method based on the mother's health, pregnancy complications, and fetal conditions [1]. Mode of childbirth has become a significant issue for obstetricians, health authorities, and mothers. Over the current years, there has been a global rise in cesarean delivery rates, contrary to the World Health Organization's guidelines advocating for rates below 15% [2]. However, determining an appropriate cesarean delivery rate and the impact it has on maternal and infant well-being remains a topic of debate within the obstetrics community [3]. Progressive medicalization can be attributed partly to the ever-rising rates of cesarean sections [4].

Medical technology advancements such as elective or planned Caesarean, emergency cesarean section, forceps delivery, and vacuum extraction have resulted in a safer experience during childbirth. In a cesarean delivery, also known as a C-section, surgeons perform a laparotomy (an abdominal incision in the mother) followed by a hysterotomy (an incision in the uterus) to facilitate the birth of the baby [5]. Broadly, experts classify cesarean sections into three categories: elective or planned, emergency, and cesarean on demand [6].

Obstetricians opt for cesarean delivery or C-section if the fetus inside the mother's womb is in an unusual position, has very little amniotic liquid, possessing multiple fetuses or many other reasons. Choosing the wrong delivery technique may impose immediate and long-term health complications on both mother and child. Seeking the help of technology can help obstetricians make decisions accurately. Machine learning can guide the obstetrician in predicting the probable chances of the type of delivery, which can educate the mother on a safer mode of birth.

The elective cesarean is a prepared delivery when maternal or fetal indications arise in the antepartum period opted before the ongoing labor. On the other hand, medical professionals perform an emergency cesarean when they observe symptoms that emerge during labor, requiring immediate medical intervention. Healthcare providers perform a cesarean on demand when women specifically request it, as indicated by its name. Cesarean delivery is performed for patients in conditions like when the mother possesses more than one fetus when the baby is in a breech position, when the mother has severe health conditions like diabetes or pre-eclampsia, when labor does not progress any further, when elderly primigravida or dystocia or maternal HIV occurs, C-sections can be a life savior. Assisted deliveries like forceps and vacuum extraction can provide extra support during childbirth for the protection of both mother and baby. Forceps provide traction on the baby's head and vacuum extraction using suction to assist delivery.

A well-chosen birthing technique-whether vaginal birth, cesarean section, or other interventions can help avoid potential risks, ensuring safer childbirth outcomes. The gynecologist chooses the delivery method by evaluating various obstetric characteristics like the number of fetuses and the medical history of the pregnant woman, such as diabetes and blood pressure. Personalized care, guided by healthcare professionals, ensures that the delivery method aligns with maternal and fetal needs, reducing the likelihood of complications and improving overall survival rates for mothers and newborns.The gynecologist selects the delivery method by evaluating various biological factors of the mother, such as age, medical history, and other relevant health conditions.

In this research, the proposed algorithm is an ensemble of K-Nearest Neighbors (KNN), CatBoost (CB), and Gradient Boosting (GB). The algorithms have been wisely chosen for their complementary strengths. KNN is helpful for less noisy datasets because of its simplicity and interoperability,

while CatBoost handles categorical data efficiently, even on imbalanced datasets.GB excels in capturing complex relationships and delivering high predictive accuracy. The stack of these classifiers offers flexibility to explore a diverse learning approach to optimize model performance with hyperparameter tuning.

This research focuses on tackling the existing literature gap by developing a predictive model that integrates multiple clinical features to define the mode of childbirth. The approach utilizes a stacked ensemble of ML algorithms to optimize performance through hyperparameter tuning, providing more accurate predictions. The novelty of this study lies in diverse classifiers, which significantly enhance the model's performance metrics.

The main contributions of this research include

- A detailed literature survey on the type of algorithms used in the recent studies.
- Model can handle large datasets with more features accurately.
- The study employs three classifier algorithms stacked to ensure more precise and reliable decisions.

The paper is structured as follows: Section II provides a review of related literature, Section III presents the methods and materials used, Section IV describes the experimental process Section V analyzes the results obtained, and finally, Section VI concludes the study and suggests potential future research directions.

II. Literature Survey

Recent studies have witnessed the growing importance of machine learning by various authors for pregnancy outcomes and optimizing medical decisions.Fernández et al. [3] investigated algorithms like support vector machines(SVM), Random forest(RF), and the Multilayer Perceptron (MLP) to forecast the delivery type among three classes, namely C-section, euthocic vaginal, and instrumental deliveries. HGSORF, which applies the Henry Gas Solubility Optimization algorithm with Random Forest was designed to predict C-sections, demonstrating the potential of decision-making [7]. Khan et al. [8] investigated how machine learning techniques transform gynecological healthcare, aiming to enhance diagnostics and the challenges faced. Lestari et al. [9] conducted a comprehensive review on anticipating pregnancy-related complications. Tiruneh et al. [10] organized a broad review to compare Pre-Eclampsia Prediction using regression models and machine learning algorithms.

Islam et al. [11] performed a systematic review on ML uses to predict pregnancy outcomes, identifying gaps in the existing approaches and proposing a research agenda for future work.Kolasa et al. [12] have done a diverse review of the usage of ML algorithms in health care. Mas-Cabo et al. [13] studied algorithms like Multilayer Perceptron(MLP) and Artificial Neural Network(ANN) to forecast anticipated labor in women with early labor symptoms through the analysis of electrohysterogram (EHG) signals of the uterus. ANN was employed to estimate the success of labor induction, analyzing the uterine EHG signals [14]. The authors achieved different objectives with ML, such as classifying placenta cells [15], developing pregnancy disorder in the first-trimester prediction [16], and evaluating cesarean delivery risk in term nulliparous.

XGBoost (Extreme Gradient Boosting) has been extensively used to solve predictive modeling tasks by constructing a series of decision trees to rectify previous errors and avoid overfitting. To illustrate, Sultan [17] experimented with different algorithms to identify the most suited algorithm to classify cesarean section deliveries. Xi [18] worked towards predicting the large gestational age neonates in parturients exposed to radiation using machine learning.Yu [19] evaluated using machine learning algorithms for preterm birth forecast in singleton pregnancies through time-series data [20].

Stacking has been popular machine learning, widely used in various applications like the detection of thyroid diseases [21], software bug prediction [22] predicting childbirth approach, preterm birth prediction [23] used for various applications. Islam et al. [4] focused on the features suited best for the prediction of the delivery technique using algorithms like RF, SVM, Decision Tree (DT), K-Nearest Neighbors (KNN), and stacking classifier (SC). Yang and Shami [24] explored hyperparameter optimization across most machine learning algorithms, emphasizing its critical role in enhancing predictive performance.

III. Methods and Materials

In this study, we assessed the appropriateness of utilizing various ML algorithms for anticipating the mode of childbirth across six classifications: CES Programmed(Elective Cesarean), Emergency Cesarean, Eutocic delivery, Forceps delivery, vacuum extraction, and Epistiomy.

The dataset comprised instances of women presented for childbirth at four public hospitals across three distinct autonomous regions in Spain in 2014 [25]. One hundred and sixty-one personal health and medical features were recorded from each mother and the fetus; few details were gathered in antepartum and remaining in intrapartum.

A. Dataset Description

The Target variable Type of birth was noted as the significant result of the labor. The Target Variable has been classified as one of the classes CES Programmed, Elective Cesarean, Eutocic delivery, Forceps delivery, vacuum extraction, and Epistiomy. Medical circumstances surrounding the mother and fetus were given utmost priority in deciding the type of delivery technique for their well-being.

B. Data Preprocessing

This process is crucial for ensuring the accuracy and effectiveness of the models built using the data and preprocessing, including data reduction, preparation, and balancing techniques. The dataset contained 6157 data records with 161 attributes. Data reduction is a crucial preprocessing approach that can decrease the size and complexity of a dataset while preserving its essential information. It involves removing or merging redundant or irrelevant features, removing noise and outliers, and transforming the data into a more convenient representation.

Data reduction aims to make the dataset more manageable and accessible without sacrificing important patterns or relationships. Dimensionality reduction helps machine learning algorithms function more effectively and predict better. We discarded features with minimal or no impact (e.g. OLIGOAMNIOS, Isoimmunization, MIOMECTOMY, and many more). Other aspects, such as the sex of the fetus and fetal admission to the ICU, are only identifiable after the delivery process. Islam and his colleagues conducted structured interviews with 111 features to obtain information on their relevance [4]. The weighted average score, which ranges from 1 to 5, was calculated across 111 features by averaging each score and considering their assigned weight. The importance or significance of the feature can determine the weight. Thirty-two features scored above 1.5 on average, while 79 scored below 1.5. Setting a threshold of 1.5, the initial set comprised 32 features, with the remaining 79 considered less significant. Table I contains the 32 attributes of the dataset selected after preprocessing.

Data reduction was achieved by removing 18 duplicate records from the dataset. We replaced missing values for the numerical features with their mean, and the mode was substituted for categorical features. Data preparation involves initializing input data to make it suitable for effective analysis by algorithms. The MinMaxScaler transforms the dataset's features, allowing each feature to have an equal impact on the predictive capability by scaling to an interval of 0 to 1. Subsequently, the normalize function applies L2 normalization, which modifies the feature vectors to have a unit norm, improving the model's capacity to handle different magnitudes across the data.

The dataset suffered from a strong inequality between the superior class Eutocic and the minority class Epistiomy. To mitigate overfitting and prevent the model from favoring the majority class excessively in terms of accuracy and frequency over the minority class, random oversampling was employed to balance the class distribution until achieving a 1:1 ratio. Random oversampling duplicates the samples from the minority class and introduces them to the superior class to achieve a balanced representation of majority and minority samples in the dataset.

C. Algorithms

1) K-Nearest Neighbors: This non-parametric algorithm assigns labels or predicts values depending on the majority class of its closest neighbors in the feature domain.

2) Gradient Boosting: This machine learning ensemble technique constructs predictive models by merging weak learners, which are decision trees, into a strong ensemble model.

3) CatBoost: Categorical boosting, also known as CatBoost, stands out for its efficient handling of categorical features. This algorithm automatically handles categorical variables without extensive preprocessing, making it convenient for real-world datasets with common categorical features.

IV. Methodology

The algorithms were created, trained, and evaluated using Jupyter Notebook, a scientific program development and open-source development platform implemented in Python utilizing the Scikit-learn package. From the data, 80% is randomly utilized for the trained model, and the remaining 20% is employed for testing and evaluating each model.

A. Experimental Setup

Each algorithm is tuned for the hyperparameters using Grid search with five-fold cross-validation and accuracy as the performance metric for tuning the hyperparameters. Through an exploratory research approach, the hyperparameters have been selected after testing over a broad range of configurations. This gives the flexibility in identifying optimal parameters based on the dataset's performance rather than predetermined theoretical values.

1) K-Nearest Neighbors: Several configurations of the KNN algorithm were used as it doesn't build the model explicitly during training. A general rule doesn't exist that predicts the optimal value of the parameters, which in turn is dependent on the dataset characteristics and must be found empirically. A grid search is employed as a tuning technique to identify the optimal values of the hyperparameters. Grid Search has been applied to the K-Nearest Neighbors (KNN) algorithm, tuning the hyperparameters across the following ranges: the number of neighbors (n_neighbors) from 1 to 20, the weighting metrics ("uniform" and "distance"), and the distance metrics ("Euclidean", "Manhattan", "Minkowski").

- n_neighbors: This parameter dictates the number of neighboring data points examined during prediction, influencing the model's decision boundary flexibility. A smaller "n_neighbors" value can make the model more susceptible to noise, potentially causing overfitting. Conversely, a larger "n_neighbors" value can make the model too generalized, possibly overlooking local patterns in the data.
- metric: This parameter defines the distance metric used to measure the distance between points in the feature space. Various distance metrics lead to varied notions of proximity between points, which can affect the performance of the K-nearest neighbors algorithm.
- distance: The weights parameter steers the decision of data point classification in KNeighborsClassifier. Exploring various weight configurations can boost the model's effectiveness, mainly when working with imbalanced datasets or fluctuating feature significance.

The best parameters the classifier finds with grid search for this algorithm are {"n_neighbors": 5, "metric": "manhattan", "weights": "uniform"}.

2) Gradient Boosting: Grid Search has been applied to the algorithm, tuning the hyperparameters across the following ranges considering the number of estimators from 10 to 200, learning rate from 0.01 to 1.0, and maximum depth of trees from 1 to 20.

- n_estimators (Number of Estimators): This parameter dictates the number of boosting trees built in the ensemble. A higher number of trees generally leads to a more expressive model, potentially capturing intricate patterns in the data.

TABLE I. FEATURES OF THE DATASET

Feature	Description	Type
AGE	Age of the individual	Numerical
ALCOHOL	Alcohol consumption during pregnancy	Categorical
AMNIOCENTESIS	A medical procedure involving the extraction of amniotic fluid for various diagnostic purposes, such as genetic testing.	Categorical
AMNIOTIC LIQUID	Characteristics of amniotic fluid	Categorical
ANESTHESIA	Administration of anesthesia during childbirth or related medical procedures.	Categorical
ART	Presence of assisted reproductive technology in the conception of the pregnancy.	Categorical
ART MODE	Methods to Assisted Reproductive Technology	Categorical
BMI	Body Mass Index of the individual	Numerical
CARDIOTOCOGRAPHY	Monitoring the fetal heartbeat and uterine contractions during labor.	Categorical
COMORBIDITY	Presence of one or more additional disorders or diseases alongside the pregnancy	Categorical
COMPLICATIONS	Medical issues or difficulties during pregnancy or childbirth.	Categorical
EPISIOTOMY	A surgical incision made during childbirth to widen the opening of the vagina.	Categorical
FETAL INTRAPARTUM PH	Measurement of the acidity or alkalinity of the fetal blood during labor.	Categorical
GESTATIONAL AGE	The age of the fetus in weeks, calculated from the beginning to end of the menstrual period.	Numerical
HEIGHT	Height of the individual	Numerical
INDUCTION	Method of labor induction	Categorical
KG INCREASED PREGNANCY	Increase in weight during pregnancy	Numerical
MATERNAL EDUCATION	Level of education of the mother	Categorical
MISCARRIAGES	Number of miscarriages	Numerical
NUMBER OF PREV CESAREAN	Number of previous cesarean deliveries	Numerical
OBSTETRIC RISK	Risk factors associated with pregnancy	Categorical
OXYTOCIN	Use of oxytocin during labor	Categorical
PARITY	The count of a woman giving birth to a fetus crossing the gestational age of 24 weeks or more.	Numerical
PREINDUCTION	Usage of medical interventions to initiate labor before it starts spontaneously.	Categorical
PREVIOUS CESAREAN	Indication of whether the mother had a cesarean section in a previous pregnancy.	Categorical
PREVIOUS PRETERM PREGNANCIES	Number of previous preterm pregnancies	Numerical
PREVIOUS TERM PREGNANCIES	Number of previous full-term pregnancies	Numerical
ROBSON GROUP	Robson classification group	Categorical
SMOKING	Smoking status during pregnancy	Categorical
START ANTENATAL CARE	Timing of initiation of medical care and attention during pregnancy.	Categorical
SUBSTANCE ABUSE	History of harmful substances (e.g., drugs or alcohol) during pregnancy.	Categorical
WEIGHT	Weight of the individual	Numerical

- learning_rate (Learning Rate): The learning rate controls the contribution of each tree to the final prediction. A higher learning rate speeds convergence but risks overshooting, while a lower rate requires more iterations but enhances generalization.
- max_depth (Maximum Depth of Trees): This parameter determines the maximum depth allowed for each tree in the ensemble. Deeper trees can capture more detailed data features but may also result in overfitting as they learn the noise in the training data.

The hyperparameters by the grid search for this algorithm are "n_estimators": 90, "learning_rate": 0.5, "max_depth": 10.

3) CatBoost: A systematic exploration of different parameter combinations was conducted to optimize the training of CatBoost models involving varying key hyperparameter ranges, namely, the number of estimators ("n_estimators") from 10 to 200, the depth ("depth") from 1 to 16, and the learning rate ("learning_rate") from 0.01 to 1.0.

- n_estimators (Number of Estimators): This defines the number of trees (boosting iterations) to be built during training. Increasing the number of estimators can lead to a more complex model, potentially improving performance, but it may also increase training time and the risk of overfitting
- learning_rate (Learning Rate): The learning rate controls the step size at each iteration during the gradient descent optimization process. It adjusts the model weights in response to the error gradient.
- max_depth (Maximum Depth of Trees): This parameter sets the maximum depth allowed for each tree in the ensemble. Deeper trees can capture more complex relationships in the data but may also lead to overfitting.

The hyperparameters by the grid search for this algorithm are "n_estimators": 100, "learning_rate": 0.5, "max_depth": 10.

4) Stacking: An ensemble learning method combines to generate a new training set for a meta-classifier based on the predictions of multiple classifiers. Each classifier is trained on the entire training set individually, and the meta-classifier is learned from the predictions made by the base models. Fig. 1 illustrates the stacking classifier's architecture. The initial training data (X) had 6157 samples and 2 features. Three M different models (M = 3) are trained on X, and their predictions (y) are combined to generate a data set X^2 for the level 2 model. A strong SC was proposed in which KNN, GB, and CB with the hyperparameters were the base classifiers.

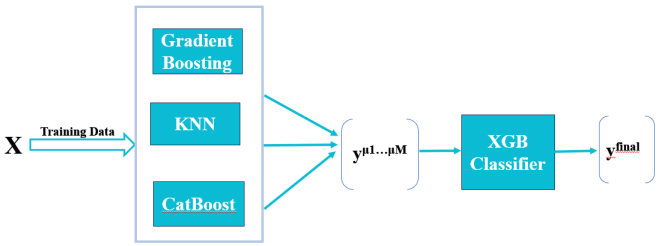

Fig. 1. Proposed KGC ensemble architecture.

5) Proposed Algorithm: KGC Ensemble Algorithm: A KGC ensemble algorithm has been developed using the stacking of KNN, GB, and CatBoost algorithms with the hyperparameters found in the GridSearch. This algorithm excels beyond the standard ML algorithms with default parameters (Stack 1). The primary goal of the stacking is to minimize data variance and optimize its suitability for machine learning models.

K-Nearest Neighbors (KNN) starts the process by classifying data points based on the proximity to other points in the dataset. In KNN, each data item is assigned to the class frequency among k nearest numbers where k is predetermined.

$$h(x) = \text{majority\_label}\left(\{y_i \mid x_i \in N_k(x)\}\right)$$

where:

- x is the data point to classify,
- $N_k(x)$ represents the k-nearest neighbors of x,
- and *majority_label* denotes the most frequent label among these neighbors.

The algorithm classifies based on the majority class contribution among neighbors, effectively performing similarity-based classification.

Further, the dataset undergoes similar training under Gradient Boosting (GB). GB builds an ensemble of decision trees that sequentially trains every tree to rectify the errors of its predecessor. The process continuously minimizes a loss function, making the model more accurate. Prediction is a weighted sum of the predictions of all trees, and the function h can be expressed as:

$$h(x) = \sum w_i f_i(x)$$

where:

- $f_i(x)$ are the individual decision trees,
- and w_i are the weights assigned to each tree's prediction.

Finally, CatBoost, an advanced boosting algorithm, is applied. CatBoost builds an ensemble of trees, similar to GB, but uses ordered boosting and permutation techniques to ensure unbiased and robust learning. The hypothesis function h in CatBoost can be represented as:

$$h(x) = \sum \alpha_i T_i(x)$$

where:

- $T_i(x)$ are the individual trees,
- and α_i are the weights assigned to each tree's output.

The ensemble of these models KNN, GB, and CatBoost-work to improve the overall performance, reduce variance, and provide a robust solution for classification tasks. The pseudocode of the ensemble is shown in Algorithm 1.

Algorithm 1 KGC Ensemble Algorithm:

Input: Initial training dataset $D_s = \{(x_i, y_i)\}_{i=1}^{k}$
Output: An ensemble classifier H
$B_1, B_2, \ldots, B_L$: Base classifiers
M: Meta classifier
p_{il}: Predicted values output by base classifiers B_i for data sample x_i
Step 1: for $l \leftarrow 1, 2, \ldots, L$ do
Train base classifier B_l on D_s to obtain h_l
Step 2: for each data sample x_i in D_s do
for $l \leftarrow 1, 2, \ldots, L$ do
$p_{il} = h_l(x_i)$ *(Predict using base model h_l)*
Step 3: Form the new dataset D_{new} by augmenting D_s with the predictions p_{il}
$D_{\text{new}} = \{(x_i, p_{i1}, p_{i2}, \ldots, p_{iL}, y_i)\}_{i=1}^{k}$
Step 4: Train the meta classifier M on D_{new}
return $H(x) = M(x, h_1(x), h_2(x), \ldots, h_L(x))$

6) Performance evaluation of algorithms: The following metrics are evaluated at each stage of the experimentation.

- Precision: Precision calculates the number of predictions made for a class that belongs to the class.
- Recall: Recall calculates the number of estimates made for a class amongst all the cases of that class present in the dataset
- F1-Score: The F1-score is the weighted average of precision and recall, typically ranging from 0 to 1.

V. Results and Discussion

Two stack ensembles are constructed to evaluate the performance of the different model configurations. The first stack consisted of the classifiers DT, KNN, RF, and SVM balanced using the sampling technique ADASYN. In contrast, the second stack contained KNN, GB, and Catboost, each tuned with the optimized hyperparameters with the random oversampling technique. The experimental setup involved comparing the predictive performance of both stacks on the same validation dataset, with results being analyzed to assess the overall effectiveness of the ensemble.

Results provided by the proposed stack showcase an excellent predictive capability to classify the type of delivery method correctly. Even though the individual methods performed well, the proposed algorithm combines the pitfalls of each method and showcases good results compared to the individual models. Fig. 2 represents the stack's performance comprising the models SVM, DT, KNN, and RF balanced using the ADASYN balancing technique, and the metrics of the proposed KGC Ensemble balanced using random oversampling are depicted in Fig. 3.

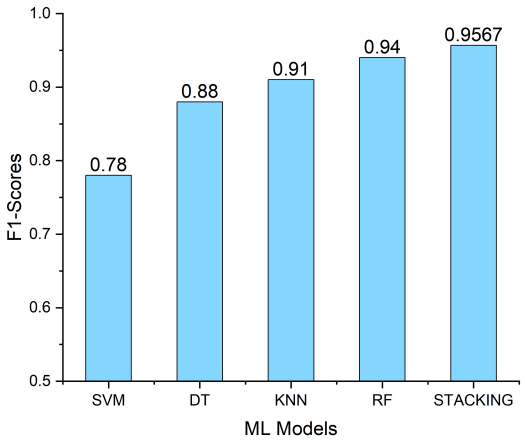

Fig. 2. Metrics of ADASYN sampling.

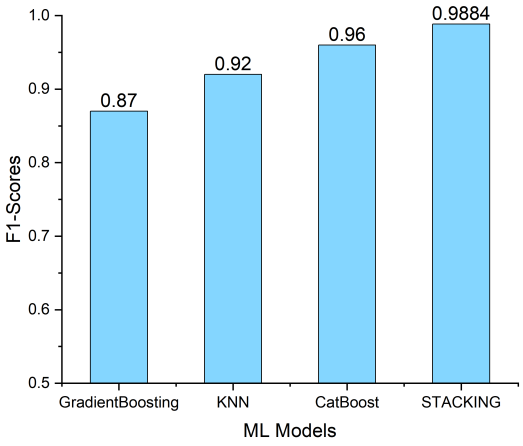

Fig. 3. Metrics of random oversampling.

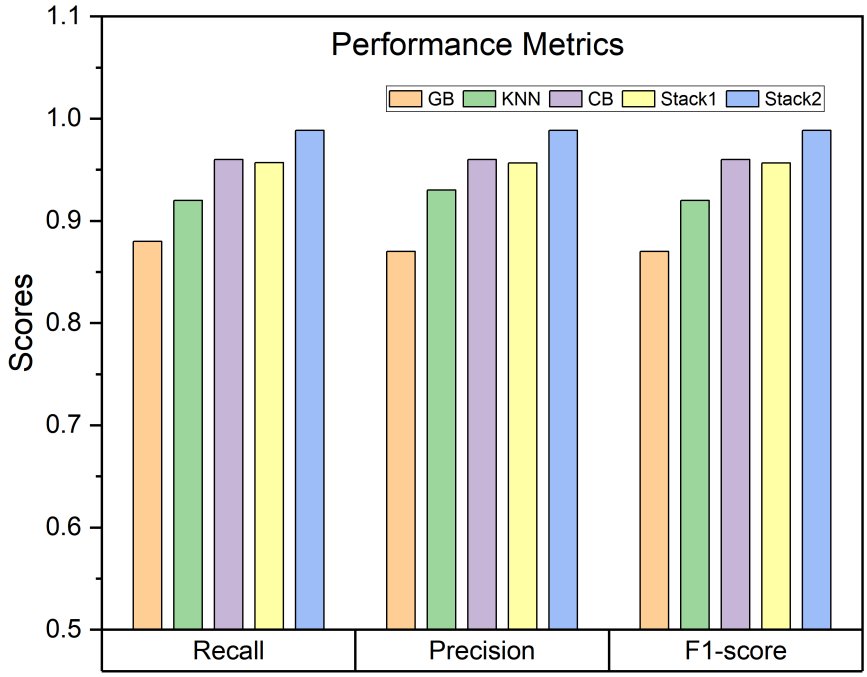

Fig. 4. Comparison of the results obtained by each stack.

Developing decision support systems is complex and aims to maximize performance measures like precision and recall to reduce false positives and negatives. While high and balanced values are ideal, clinical criteria, which can vary between hospitals, should determine which measure to prioritize. Therefore, hospital systems should be flexible, allowing clinicians to adapt protocols and prioritize specific performance measures, such as cesarean, vaginal, and assisted vaginal delivery decisions. The overall performance metrics of both stacks are represented in Table II with numerical values and in Fig. 4 through bar plots.

This study's findings exceed previous works aimed at predicting delivery methods and assessing cesarean risks, considering antepartum and intrapartum factors. In [3], a cohort of 25,038 patients with single pregnancies from the Service of

TABLE II. PERFORMANCE METRICS FOR DIFFERENT MODELS

Model	Recall	Precision	F1-Score
GradientBoosting	0.88	0.87	0.87
KNN	0.92	0.93	0.92
CatBoost	0.96	0.96	0.96
STACK1	0.957	0.9567	0.9567
STACK2	0.9885	0.9886	0.9884

Obstetrics and Gynaecology of the University Clinical Hospital evaluated the feasibility of using algorithms, namely, SVM, RF, and MultiLayer Perceptron, to predict the delivery method among cesarean, eutocic and assisted vaginal deliveries. The algorithms displayed an accuracy of 87%-90%. The study by Sultan et al. [17] and by Hasan et al. [26] on a sample containing 692 cesarean and 5465 non-cesarean samples collected from 4 hospitals in Spain worked on cesarean prediction. The SVC, XGB, and RF ensemble has achieved an F1-score of 96%. Concerning [27], a cohort of 13527 was prospectively assessed to predict cesarean deliveries. 32 classifiers were assessed, and the Quadratic discriminant analysis achieved an accuracy and F1-score of 97.9%.

The proposed KGC ensemble model consisting of KNN, Gradient Boosting, and CatBoost achieved a high F1 score of 98.84%, demonstrating its strong predictive capability. Gradient Boosting and CatBoost enhance the model's ability to handle complex, nonlinear relationships, while KNN adds the advantage of capturing local data patterns. The blend strikes a balance between bias and variance, in turn improving the model's generalization. However, the ensemble has challenges, including increased computational complexity and longer training times. Moreover, the decision-making process becomes less interpretable due to the complexity of Gradient Boosting and CatBoost, making it harder to understand how the model arrives at its predictions than KNN.

VI. CONCLUSION

An alarming increase in cesarean section rates surpassing WHO recommended levels poses significant medical, financial, and organizational challenges. Typically in low-risk pregnancies and non-elective cesarean sections, the possibility of vaginal or c-section deliveries relies on medical conditions and initiatives taken. Machine learning can act as a driving force and aid obstetricians in predicting the best feasible delivery mode based on the medical conditions, ensuring the mother's and newborn's safety. Machine learning can assist obstetricians working night shifts and in varying localities by providing real-time, data-driven insights and recommendations on the optimal delivery mode, accounting for factors such as limited staff availability, resource constraints, and patient demographics.

This research has proposed an optimized KGC classifier combining the algorithms of GB, KNN, and CatBoost along with a random oversampling balanced dataset to increase the predictive capability of the delivery mode. The performance of the proposed classifier has been tested against different performance metrics such as F-measure, recall and precision. Our proposed KGC classifier has achieved an F1-score of 98.84%, outperforming stack1 composed of KNN, DT, SVM, and RF.

In addition,KGC algorithm provides better results compared to previous studies. Hence we can conclude an optimized and random oversampled-balanced KGC classifier can reliably predict the C-section and vaginal classes.While our research has provided valuable insights,it is important to understand the dataset was limited to 6157 records. To further validate the model's robustness, future work is aimed to target the larger datasets with more intrapartum details. Incorporating such demographic variables in future studies could enhance the predictive power and applicability of the model. Further , our classifier can be applied to skin cancer, Parkinson's, gestational diabetes and socio-demographic data. In the future, we would like to work with deep learning algorithms for better predictive capabilities to implement a possible computer decision support system model to be built for the benefit of obstetricians and pregnant women.

***Abstract*—Vision Transformers (ViTs) have become increasingly popular in various vision tasks. However, it also becomes challenging to adapt them to applications where computation resources are very limited. To this end, we propose a novel multi-path hybrid architecture and develop a series of lightweight ViT (MH-LViT) models to balance well performance and complexity. Specifically, a triple-path architecture is exploited to facilitate feature representation learning that divides and shuffles image features in channels following a feature scale balancing strategy. In the first path ViTs are utilized to extract global features while in the second path CNNs are introduced to focus more on local features extraction. The third path completes the representation learning with a residual connection. Based on the developed lightweight models, a novel knowledge distillation framework IntPNKD (Normalized Knowledge Distillation with Intermediate Layer Prediction Alignment) is proposed to enhance their representation ability, and in the meanwhile, an additional Mixup regularization term is introduced to further improve their generalization ability. Experimental results on benchmark datasets show that, with the multi-path architecture, the developed lightweight models perform well by utilizing existing CNN and ViT components, and with the proposed model enhancement training methods, the resultant models outperform notably their competitors. For example, on dataset miniImageNet, our MH-LViT_M3 improves the top-1 accuracy by 4.43% and runs 4x faster on GPU, compared with EdgeViT-S; on dataset CIFA10, our MH-LViT_M1 improves the top-1 accuracy by 1.24% and the enhanced version MH-LViT_M1* by 2.28%, compared to the recent model EfficientViT_M1.**

***Keywords*—Multi-path hybrid; lightweight ViT; normalized knowledge distillation; Mixup regularization**

I. Introduction

In recent years, Vision transformers (ViTs) [1] have received increasing attention in many visual tasks, achieving remarkable results in tasks such as image classification [1], [2], [3], target detection [4], [5], [6], [7] and semantic segmentation [8], [9], [10], [11], [12], [13]. However, the computational overhead of the self-attention mechanism makes ViTs less efficient than Convolutional Neural Networks (CNNs) [14] on memory and computationally constrained devices. The huge model size and computational cost make it challenging to adapt them to real-time applications. Therefore, researchers tend to build lightweight and efficient ViT models.

Some approaches aim to build lightweight versions of ViT models by reducing the number of feature channels or self-attentive heads. Nevertheless, such approaches usually lead to significant performance degradation. The author in [15] successfully improves the performance of existing tiny ViTs by introducing a plugin that groups and shuffles feature channels. Alternatively, some researchers have attempted to improve model performance through specific designs, such as combining computationally expensive self-attention with efficient convolutional operations to create hybrid efficient ViTs [16], [17], [18], [19], [20]. Among them, MobileViT [16] combines the image-specific inductive bias of CNNs and the global information processing capability of ViTs to encode both local and global information efficiently. EdgeViT [19] combines the attention mechanism and CNNs through the implementation of local-global-local (LGL) blocks. Nevertheless, most of these methods serially stack self-attention and convolutional layers, and the extraction of global features often compromises previously extracted local features, failing to take full advantage of global and local features. To overcome this problem, several studies have begun to explore the application of parallel structures in feature extraction. The parallel structure allows the self-attention and convolutional layers to work simultaneously and extracts global and local features independently, and then fuses them in some way. This structure can maintain the integrity of local features while combining global features to achieve a more comprehensive feature representation. For example, TransXNet [20] efficiently extracts and fuses global and local features by combining self-attention and convolution in parallel to achieve excellent performance.

Therefore, this paper adopts a parallel structure approach to extract both global and local features, fully exploiting the diversity of features to enhance the model performance. Unlike previous parallel structures, we have added an additional residual branch to enhance the learning ability of feature representation, without explicitly increasing parameters or computational overhead. Specifically, we exploit a feature scale balancing strategy to divide input features into three parts. The first one is fed into the Transformer branch to extract global features, the second one is fed into the CNN branch to extract local features, and the last one is directly used to form the Residual branch. Subsequently, the feature fusion module is employed to shuffle extracted features and balance their chances to be processed in different branches. Based on this, we conclude that the tiny model has strong features representation ability. To further release their representation potential, we propose a new knowledge distillation framework, IntPNKD (Normalized Knowledge Distillation with Intermediate Layer Prediction Alignment), to effectively improve the inference performance without additional inference cost. In addition to the standard knowledge distillation procedure of NKD (Normalized Knowledge Distillation) [21], IntPNKD aligns the predictions made respectively on intermediate feature maps of the teacher and the student. In the meanwhile, an image mixing regularizer

is introduced to further enhance the generalization ability of the resultant model. The main contributions of this paper are summarized as follows:

- We propose a multi-path hybrid architecture to design lightweight ViT model (MH-LViT), where a triple-branch architecture (transformer, CNN, and residual) is employed to extract efficiently local and global features, and the features extracted by multiple branches are further shuffled and re-assigned with a feature fusion module.
- We propose a new knowledge distillation framework IntPNKD to improve the representation ability of MH-LViT, which is further enhanced by introducing an image mixing regularization term. The achieved performance improvement costs nothing in inference.
- We develop a series MH-LViT models with various sizes that are tested on multiple benchmark datasets. The experimental results show that our models balance well the efficiency and the accuracy.

II. Related Work

A. Efficient Vision Transformers

In order to reduce the number of parameters and the computational overhead, a series of works on efficient vision transformers have been proposed, which cover a wide range of interesting ideas such as lightweight module design, model compression, token compression, hybrid model design, and so on. Window-based Self-Attention ViT proposed in Swin [4] reduces the computation cost of each transformer block by dividing the feature map into windows and restricting the attention operation within a local window. In this way, the length of input sequence fed into Transformer is reduced, leading to improved efficiency. Wang et al. [22] proposed a spatial-reduction attention (SRA) to reduce the computation cost of self-attention, by downsampling the spatial resolution dimensions of the input Query and Key branches via a lightweight depthwise convolution. Token merging [23] achieves parameter compression by merging tokens with large semantic similarity. CVT [24] and LeViT [17] insert some convolutional layers into Transformer layers, to downsample feature maps and perform local information fusion, where the Transformer layers are used to capture the global information from deep features. Liu et al. [25] proposed a cascade group attention module that uses only three or four attention heads, to increase the diversity of features while reducing computational redundancy in multi-head attention.

B. Efficient Convolutional Neural Networks

Actually, before the arrival of ViT, models based on Convolutional Neural Networks (CNNs) faced the same challenge to deploy them to devices with limited computational resources. To fix this, a series of elegant work have been proposed. MobileNets [26], [27] leverage depthwise separable convolutions to reduce the computation complexity. ShuffleNet [28] utilizes pointwise group convolution and performs channel shuffle operations to reduce the computation cost. IDConv[20] reduces the computation overhead by utilizing dynamic deep convolutions and adaptive average pooling. Overall, efficient CNNs work well in a variety of scenarios which inspires us to develop a novel model that combines efficient CNNs and ViT in some way, to extract effectively both global and local features.

C. Knowledge Distillation

Knowledge distillation (KD) has attracted wide attention in the field of model compression, which typically transfers knowledge from a teacher (model) to a student (model) to improve the latter's performance. This framework, originally proposed by Hinton et al. [29], utilizes both the hard labels of ground truth and the soft ones provided by the teacher to guide the learning process of the student. Recently, there have emerged studies [30], [21] focused on KD in ViT. For instance, DeiT [30] introduces a novel distillation procedure which relies on a distillation token ensuring that the student learns from the teacher through attention, to achieve efficient transformers with competitive top-1 accuracy on ImageNet. MixSKD [31] is a self-knowledge distillation framework that enables the network to learn cross-image knowledge by modeling supervisory signals from mixup images. The most relevant work on knowledge distillation to ours is NKD [21], which uses cross-entropy to align respectively the probability distributions of target class and non-target classes. We build our KD framework on NKD and introduce Middle Feature Prediction Alignment into it for better knowledge transfer.

III. Preliminaries

A. EfficientViT

Unlike the classic ViT [1], EfficientViT [25] adopts a sandwich layout and a cascade group attention. Specifically, the cascade group self-attention layer Φ_i^A is sandwiched between two FFN (Feed Forward Network) layers each of them is denoted with Φ_i^F. The operation of the i-th block can be formulated as:

$$X_{i+1} = \Phi_i^{\mathrm{F}}(\Phi_i^{\mathrm{A}}(\Phi_i^{\mathrm{F}}(X_i))), \tag{1}$$

where X_i is the input feature of the i-th block. In the the cascade group self-attention layer Φ_i^A, the input feature X_i is divided into J parts which are fed into J attention heads, where the output of each head is added to the subsequent heads to enrich the feature information. Formally, the operation of the j-th attention head can be expressed as:

$$\mathring{X}_i^j = \begin{cases} \mathrm{Attn}(X_i^j), & if\ j = 0, \\ \mathrm{Attn}(X_i^j + \mathrm{Attn}(\mathring{X}_i^{j-1})), & if\ j \geq 1, \end{cases} \tag{2}$$

where, X_i^j denotes the j-th split of input X_i and $\mathring{X}_i^j$ is its corresponding attention output. Then J attention outputs are concatenated:

$$\hat{X}_i = \Phi_i^A(X_i) = \mathrm{concat}[\{\tilde{X}_i^j\}_{j=1}^J], \tag{3}$$

where, $\hat{X}_i$ is the output of the i-th cascade group attention layer.

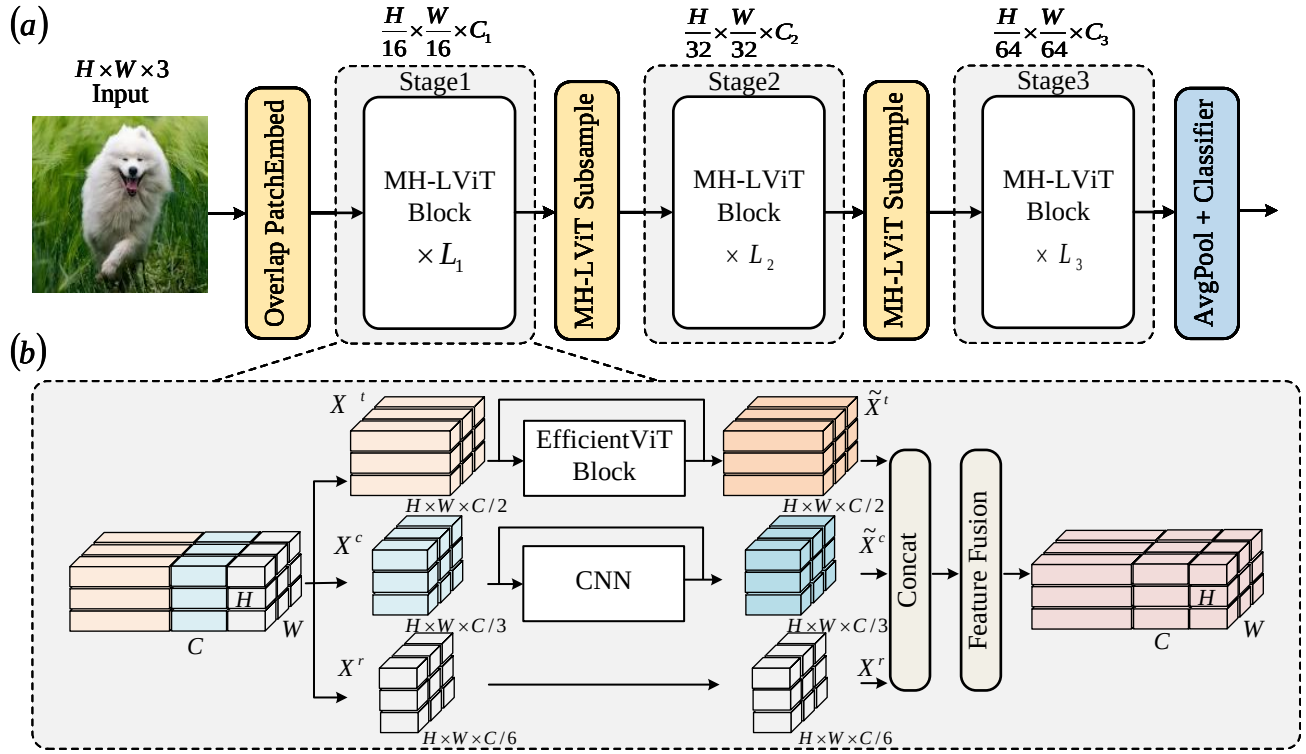

Fig. 1. Architecture of MH-LViT: (a) Overall architecture of MH-LViT; (b) Multi-Path branch block.

B. Normalized Knowledge Distillation

Normalized Knowledge Distillation (NKD) [21] is an improvement version of the decoupled knowledge distillation (DKD) [32] that normalizes the non-target logits and utilizes Cross-Entropy (CE) instead of Kullback-Leibler (KL) divergence to align the target and non-target class distributions respectively. In particular, the loss of NKD can be formulated as follows:

$$L_{NKD} = -T_t log(S_t) - \gamma \cdot \lambda^2 \cdot \sum_{k \neq t} \mathcal{N}(T_k^{\lambda}) log(\mathcal{N}(S_k^{\lambda})), \quad (4)$$

where, the index t denotes the target class, T_k (S_k) denotes the output probabilities of teacher (student) model corresponding to the k-th class, λ is the KD temperature [29], γ is the hyper-parameter to balance the two items in the loss, and $\mathcal{N}(*)$ denote the normalization operation.

C. Mixup

Mixup [33] generates a mixed image (x_{ab}, y_{ab}) by linearly combining a pair of original images $\{x_a, y_a; x_b, y_b\} \in D$, where D denote a data set, x_a (x_b) denotes the image a (b) and y_a (y_b) is its corresponding label. The mixed image and its corresponding label are formulated as follows:

$$\begin{aligned} x_{ab} &= \lambda x_a + (1-\lambda) x_b, \\ y_{ab} &= \lambda y_a + (1-\lambda) y_b, \end{aligned} \quad (5)$$

where, the combination is controlled by the mixing factor λ sampled from the beta distribution.

IV. Methods

A. Overview

We propose a new multi-path hybrid architecture to design lightweight ViT model MH-LViT. The overall architecture of MH-ViT is shown in Fig. 1(a). The model adopts a hierarchical architecture, that effectively reduces the resolution of feature maps during the forward propagation process, while gradually increases the number of channels for feature map. Specifically, MH-LViT contains three stages, each of which consists of L MH-LViT blocks. In order to reduce the amount of parameters and computation overhead, we divide the input features by channels in the ratio of $3:2:1$ via the feature scale balancing strategy, and then learn images' representation in parallel through three paths, i.e. Transformer, CNN and Residual. By introducing the multi-hybrid structure, the model can capture global information and local details at the same time, to understand well the images for latter computer vision (CV) tasks. In addition, a new type of knowledge distillation and a mixup regularization are exploited to further improve the inference performance without any additional inference cost.

B. Lightweight Model Design

1) Multi-Path branch: As shown in Fig. 1(b), the MH-LViT Block is mainly composed of a three-branch architecture

and a feature fusion module. In particular, the three branches includes an efficient Transformer (EfficientViT Block), a lightweight CNN (IDConv) and a residual connection. Formally, the operations in MH-LViT Block can be written as follows:

$$X_i^t, X_i^c, X_i^r = \text{Split}(X_i),\ X_i^t : X_i^c : X_i^r = 3:2:1; \quad (6)$$

$$\tilde{X}_i^t = \text{EfficientViTBlock}(X_i^t); \quad (7)$$

$$\tilde{X}_i^c = \text{IDConv}(X_i^c); \quad (8)$$

$$\tilde{X}_i = \text{Concat}(\tilde{X}_i^t, \tilde{X}_i^c, X_i^r); \quad (9)$$

$$X_{i+1} = \text{FF}(\tilde{X}_i). \quad (10)$$

Here, with a little notation abuse, X_i denotes the input feature of the i-th MH-LViT block and X_{i+1} the corresponding output. $Split(\cdot)$ denotes the operation to divide the input feature into three splits with the specified ratio and : denotes the ratio of the number of channels.

2) Transformer branch: It is particularly important to capture effective global information of images for CV tasks. To this end, we introduce the cutting-edge EfficientViT [25] to our model to extract global features. EfficientViT not only inherits powerful capabilities of the vanilla ViT model, but also significantly improves the computational efficiency via a sandwich layout and a cascade group attention. In addition, the depthwise convolution (DWConv) is used for information fusion before the final FFN layer of the block. The part of input features X_i^t is fed into the EfficientViT branch, to learn the representations of images base on the global information. The processing of X_i^t in an EfficientViT Block can be expressed as follows:

$$\tilde{X}_i^t = \text{FFN}(\text{DW}((\Phi_i^A(\text{FFN}(\text{DW}(X_i^t)))))), \quad (11)$$

where, $DW(\cdot)$ denotes the depthwise convolution and other notations denote the same operation as indicated before.

3) CNN branch: In order to inject inductive bias for local feature extraction, this paper introduces IDConv (Input-dependent Depthwise Convolution) [20] to extract image local information. IDConv can dynamically generate convolution kernels, which enhances the adaptability and characterization of CNN for different data features. Firstly, the spatial dimension of input features $X_i^c \in C/3{\times}H{\times}W$ is compressed to K^2 by using adaptive pooling, to aggregate the spatial context information. Subsequently, two consecutive $1{\times}1$ convolutional layers are utilized to generate the attention map $A' \in (G{\times}C/3){\times}K^2$, where G represents the number of attention groups. Then, A' is reshaped to $G{\times}C/3{\times}K^2$, where a softmax operation is applied in the G-dimension to generate the attention weights $A \in G{\times}C/3{\times}K^2$. Finally, the attention weight A is element-wise multiplied with a set of learnable parameters $P \in G{\times}C/3{\times}K^2$ and summed along the G-dimension to obtain the input-dependent deep convolution kernel $W \in C/3{\times}K^2$. This whole process can be expressed as follows:

$$A_i' = \text{Conv}(\text{Conv}(\text{AdaptivePool}(X_i^c))); \quad (12)$$

$$A_i = \text{Softmax}(\text{Reshape}(A_i')); \quad (13)$$

$$W_i = \sum_{g=1}^{G} (P_i)_g (A_i)_g; \quad (14)$$

$$\tilde{X}_i^c = W_i X_i^c. \quad (15)$$

4) Residual branch: As we know, in CV models, the information of original features may be weakened or lost when a series of transformation operations have been performed on them. To further enrich the feature representation and to ensure that the model can make full use of the original information, we preserve part of original features, i.e. X_i^r, and do not perform any transforming or processing on these features. In this way, we include both processed and unprocessed raw features to enhance the learning ability of feature representation, without explicit increasing in parameters or computation overhead.

5) Fusion module: For the features extracted through multiple paths, we introduce a feature fusion module to shuffle them, to let features in each branch get the chance to be fed into other branches. The feature fusion module mainly implements channel shuffle, aiming to shuffle the limited interaction between branches by shuffling features from different branches. This mixes the features from different branches, thereby achieving information fusion. Specifically, the global features extracted through Transformer Branch, the local features through CNN Branch, and the features for residual connection are first concatenated and then input into the fusion module, where a channel shuffle operation is utilized to shuffle inputs. In particular, the input feature tensor $\tilde{X}_i$ is grouped into a certain number of groups by the channel-dimension, and then the channels within each group are rearranged to obtain the shuffled tensor $X_i^{shuffle}$. Finally, $X_i^{shuffle}$ is restored to the original shape to obtain the fused feature tensor X_{i+1}. This module effectively mixes the features extracted from different branches, to avoid features in one branch are locked within this branch. Formally, the operations in FF module can be written as follows:

$$\tilde{X}_i^{group} = \text{Split}_{\text{group}}(\tilde{X}_i); \quad (16)$$

$$\tilde{X}_i^{shuffle} = \text{Shuffle}(\tilde{X}_i^{group}); \quad (17)$$

$$X_{i+1} = \text{Reshape}(\tilde{X}_i^{shuffle}). \quad (18)$$

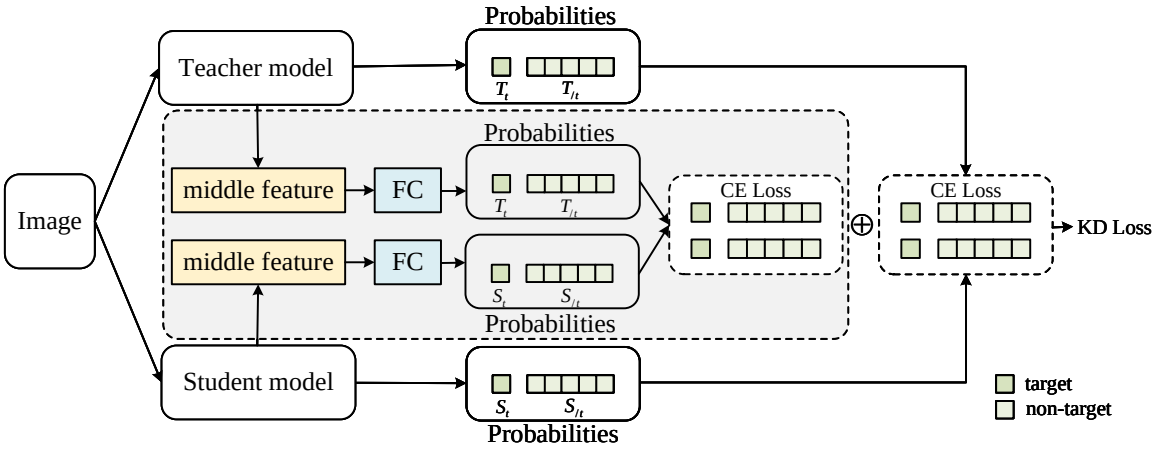

Fig. 2. Illustration of IntPNKD (Normalized knowledge distillation with intermediate layer prediction alignment).

C. Lightweight Model Enhancements

1) IntPNKD: Limited to its lightweight, the developed tiny model inevitably sacrifice its performance to some degree. To this end, we further propose a new distillation framework IntPNKD to improve its representation ability. Specifically, as shown in Fig. 2, IntPNKD transfers knowledge from the teacher (standard model) to the student (lightweight model), by aligning not only the output logits of two models (as vanilla NKD does) but also the predictions made on intermediate layers' feature maps. While the traditional knowledge distillation (NKD) focuses on aligning the final output logits, it may overlook important feature information encoded in the intermediate layers, which plays a critical role in the overall learning process. With the additional alignment, IntPNKD improves the effectiveness of knowledge distillation from teacher to student. Formally, let X^T_{mid} (X^S_{mid}) denote the features of the intermediate layer of teacher (student) model, $\text{FC}(\cdot)$ denote the fully connected layer and $\text{P}(\cdot)$ the softmax operation. Then the total distillation loss of IntPNKD can be written as:

$$L_{IntPNKD} = L_{NKD} + \text{KL}(\text{P}(\text{FC}(X^T_{mid})), \text{P}(\text{FC}(X^S_{mid}))). \tag{19}$$

2) Mixup regularization: Following the idea of image mixing in MixSKD [31], we introduce a regularizer L_{MR} to our case (the tiny student model), to enhance the generalization ability of the developed model. As shown in Fig. 3, we mix randomly two original images, e.g. x_a and x_b, to obtain a mixup one x_{ab}, and expect that the probability distribution output by the model on x_{ab} and the one given by mixing the logits of x_a and x_b are not too far from each other. In particular, the KL divergence is utilized to form the regularization term, to guide the model make relatively stable predictions on mixup image and original ones, leading to improved inference performance. The regularization term can be formulated as:

$$L_{MR} = \text{KL}(\text{P}^{\text{s}}(X_a, X_b), \text{P}^{\text{s}}(X_{ab})), \tag{20}$$

$$\text{P}^{\text{S}}(X_a, X_b) = \text{Softmax}(\lambda \text{S}(X_a) + (1-\lambda)\text{S}(X_b)), \tag{21}$$

$$\text{P}^{\text{S}}(X_{ab}) = \text{Softmax}(\text{S}(X_{ab})), \tag{22}$$

where, $\text{P}(\cdot)$ denotes the softmax operation, $S(\cdot)$ the logit (before softmax operation) output by the tiny student model, and λ is the mixing factor as in Eq. (5).

Combining everything together, the total loss function L used to train the lightweight model can be written as:

$$L = L_{CE} + L_{IntPNKD} + L_{MR}, \tag{23}$$

where, L_{CE} is the cross-entropy loss guided by the ground truth.

V. Experiments

In this section, we perform experiments on several benchmark datasets, to validate the effectiveness of proposed methods. We first elaborate on the implementation details of the experiments and then present the main experimental results of the proposed models and the relevant baseline models, which are discussed in depth. To further dissect the performance of proposed model, we also conduct a series of ablation studies to evaluate the practical effects of its key components.

A. Implementation Details

We conduct image classification experiments on three benchmark datasets, i.e. CIFAR10 [34], CIFAR100 [34] and miniImageNet [35]. In building the models, we used two tool libraries, i.e. PyTorch 1.11.0 [36] and Timm 0.5.4 [37]. The AdamW [38] optimizer and the cosine learning rate scheduler are used to train related models, each of which is trained 300 epochs from scratch on an Nvidia A100 GPU. For the input images, we resize and randomly crop them to 224 × 224 pixels.

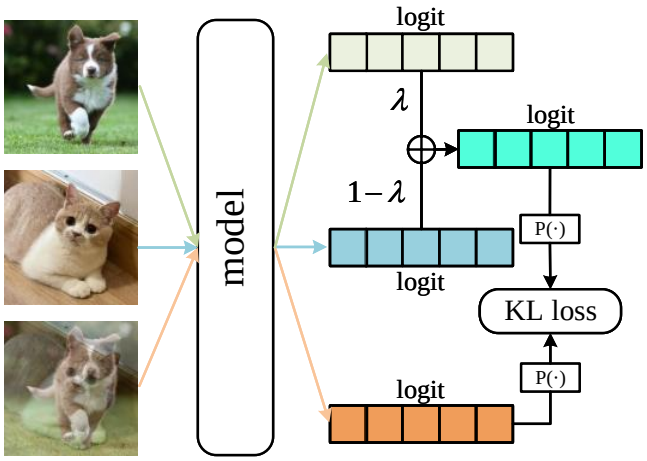

Fig. 3. Illustration of mixup regularization.

The batch size is fixed to 64, the initial learning rate is set to 1×10^{-3}, and the weight decay is 0.01. In addition, we use the same data augmentation strategies as in[30], including auto-augmentation [39] and random erasing [40]. We evaluate the model with the size, the top-1 accuracy, the throughput and Flops to get a full picture of its performance. As for KD, we utilize recently proposed CARTE-B [41] as the teacher model, which performs well with a medium model size by pre-training on ImageNet.

B. Main Results

We compare the developed MH-LViT with popular efficient models based on CNN or ViT and report the results. The results show that MH-LViT models with different sizes achieve the best accuracy and speed tradeoff across benchmark datasets in most cases.

1) Results on miniImageNet: Table I summarizes the results on the dataset miniImageNet achieved by the proposed lightweight models and multiple SOTA competitors. We first compare MH-LViT with tiny models whose size are close to it. As can be seen from the table, MH-LViT_M1 outperforms EfficientViT_M1 and EdgeViT-XXS by up to 5.57% and 6.07% respectively, with a comparable number of parameters. Compared with ShuffleNetV2 2.0x, MH-LViT_M2 improves the top-1 accuracy by 1.46% with fewer parameters and faster inference speed. Compared with EdgeViT-S, MH-LViT_M3 improves the top-1 accuracy by 1.74% and runs 4x faster on GPU. More interestingly, the enhanced version MH-LViT* outperforms all competitors in terms of accuracy. We can observe from Table I that, MH-LViT_M3* achieves 81.50% top-1accuracy on this dataset, which outperforms EdgeViT-S by up to 7.41% with a comparable number of parameters. Compared with EdgeViT-S, MH-LViT_M2* improves the top-1 accuracy by 4.19% with lower parameters and Flops. MH-ViT with various model sizes perform well on dataset miniImageNet and the results show that the multiple-path design is effective and model enhancement training strategy even goes an extra mile.

2) Results on CIFAR100: Table II shows in detail the performance of proposed models and its competitors on dataset CIFAR-100. For example, MH-LViT_M1 improves the top-1 accuracy by 2.93% compared to EfficientViT_M1. MH-LViT_M2 improves the top-1 accuracy by 2.32% and runs 3x faster on the GPU, compared to EdgeViT-XS that has a comparable number of parameters. Compared to ShuffleNetV2 2.0x that achieves the best top-1 accuracy on this dataset, MH-LViT_M2 provides a competitive top-1 accuracy but has a 1.8x throughput. MH-LViT_M2* even goes further and can beat ShuffleNetV2 2.0x with 4.01% improvement in top-1 accuracy. Compared to models with higher throughput such as EfficientViT_M3, MH-LViT_M2 improves its top-1 accuracy by 3.32% while maintaining a similar throughput. When model size goes large, MH-LViT_M3* outperforms EdgeViT-S in top-1 accuracy by 5.54% and runs 4.5x faster than it on GPU.

3) Results on CIFAR10: Table III summarizes experimental results of related models on dataset CIFA10. As what found in Tables I and II, from Table III one can find similar performance advantages of MH-LViT models over their competitors. For example, MH-LViT_M1 runs 5.2x faster than EdgeViT-XXS while improves the top-1 accuracy by 0.39%. The enhanced version MH-LViT_M1* achieves up to 96.28% top-1 accuracy on CIFA10 with 3.1M parameters. Compared with EdgeViT-XS model, MH-LViT_M2* runs 3.7x faster on the GPU with a comparable number of parameters and top-1 accuracy. MH-LViT_M3* achieves the highest top-1 accuracy of 96.75% with 12.5M parameters.

Overall, experimental results on bench mark datasets validate that the developed lightweight models with multiple-path design work well and can strike a good balance between the efficiency and the accuracy. The proposed model enhancement training strategy is effective and can provide further significant accuracy improvement without any additional inference cost.

C. Ablation Study

In this section, we validate the effectiveness of main components of MH-LViT/MH-LViT*, such as Multi-Path Branch, feature fusion module, IntPNKD, and mixup regularization, by

performing an ablation study on the dataset CIFAR100. The experimental results are summarized in Tables IV to VI.

1) Multi-Path branch: As shown in Table IV, we remove respectively the CNN Branch, the Transformer Branch, and the Residual Branch but keep the same model size as the complete one, to verify their effectiveness. As can be seen from the table, when the CNN Branch is removed, top-1 accuracy of MH-LViT_M1 decreases by 1.56%, which shows that CNNs in MH-ViT is helpful to enhance the leaning representation ability. When the Transformer Branch is removed, the top-1 accuracy decreases by 4.43%, which validates well that Transformer blocks are crucial for our model. Meanwhile, the Residual Branch also plays an auxiliary role in improving the proposed model, and when it is removed, the model accuracy decreases by 0.55%.

2) Feature fusion module: The ablation experimental result of Feature Fusion Module is also reported in Table IV, where we can observe a decrease of 0.9% in top-1 accuracy when FF module is removed from MH-LViT_M1. This result reveals the important auxiliary role of FF module in the developed model.

TABLE III. MH-LVITIMAGE CLASSIFICATION PERFORMANCE ON CIFAR10 WITH COMPARISONS TO STATE-OF-THE-ART EFFICIENT CNN AND VIT

Model	Params(M)↓	ACC_Top1 (%)↑	Throughput(images/s)↑	Flops(M)↓	Input	Epoch

MH-LViT_M3	12.5	95.78	10347	452	224	300
MH-LViT_M3*	12.5	**96.75**	10347	452	224	300
LeViT-256	18.9	94.36	6494	1059	224	300
LeViT-384	39.1	94.59	3883	2250	224	300

Feature fusion can effectively integrate the features extracted from different branches to avoid features in one branch are locked within this branch and get a chance to be processed through other branches, enabling the model to understand input images well which in turn improves the classification accuracy. This indicates that feature fusion is an important factor in improving the performance of MH-LViT.

3) Feature scale balancing strategy: In the proposed models we divide the input features by channels in a ratio of $3:2:1$ via the feature scale balancing strategy, to learn image representation in parallel through multiple paths. In this section, we vary this ratio to investigate its effects on model performance. As shown in Table V, we split the features with several typical ratios, where the baseline model EfficientViT_M1 and a double-paths scenario with the ratio of $1:1$ are also included. From the table one can observe that, compare to the baseline, the model utilizing double-paths with ratio $1:1$ improves the top-1 accuracy significantly, while the model using the ratio of $1:1:1$ is 0.4% higher than that of $1:1$, showing that multiple paths are helpful to increase model accuracy. We can also find that $2:2:1$ outperforms $1:1:1$ and among all proposed ratios, $3:2:1$ performs best which is utilized to develop the tiny models. This study suggests that a reasonable splitting ratio can facilitate feature extraction to improve model performance.

4) IntPNKD: IntPNKD is proposed to train the developed lightweight models to further improve their representation ability. In order to investigate its effect we run MH-LViT_M1* without using the IntPNKD. As shown in Table VI, the top-1 accuracy decreases by 2.58% when we give up IntPNKD, which demonstrates well its effectiveness. We also test the version with NKD by removing KD based on intermediate features prediction and its top-1 accuracy is 79.17%, which is 1.02% lower than the complete version, showing that the proposed IntPNKD is significantly helpful. By leveraging KD, the lightweight models can obtain an extra significant improvement without any model modification.

TABLE IV. ABLATION STUDY OF MH-LVIT_M1 MODEL DESIGN ON CIFAR100

Model	ACC_Top1(%)
MH-LViT_M1	76.39
MH-LViT_M1 w/o convolution path	74.83 (↓1.56)
MH-LViT_M1 w/o self-attention path	71.96 (↓4.43)
MH-LViT_M1 w/o residual path	75.84 (↓0.55)
MH-LViT_M1 w/o Fusion Module	75.49 (↓0.9)

5) Mixup regularization: As shown in Table VI, we can observe a decrease of 1.14% in top-1 accuracy by removing the mixup regularization term L_{MR} from MH-LViT_M1*. This validates well the effectiveness of introducing the regularizer based on image mixing. As like IntPNKD, Mixup Regularization can also be done without any model modification and both of them are inference-cost free inference performance improvers.

6) Visualization: To demonstrate more intuitively the advantages of proposed model, we use thermal maps to visualize the attention maps sampled from dataset miniImageNet, as shown in Fig. 4. From the figure, we can observe significant gaps among different models. Compared with its competitors, our model MH-LViT_M3 pay more attention to the key areas that include discriminative features for image classification.

In summary, the ablation experimental results fully demonstrate the effectiveness of model design elements and model enhancement training strategies, namely, the multi-path design, the feature scale balancing strategy, the feature fusion, the IntPNKD and the mixup regularization. With these components, the family models of MH-LViT achieve excellent performance on benchmark datasets.

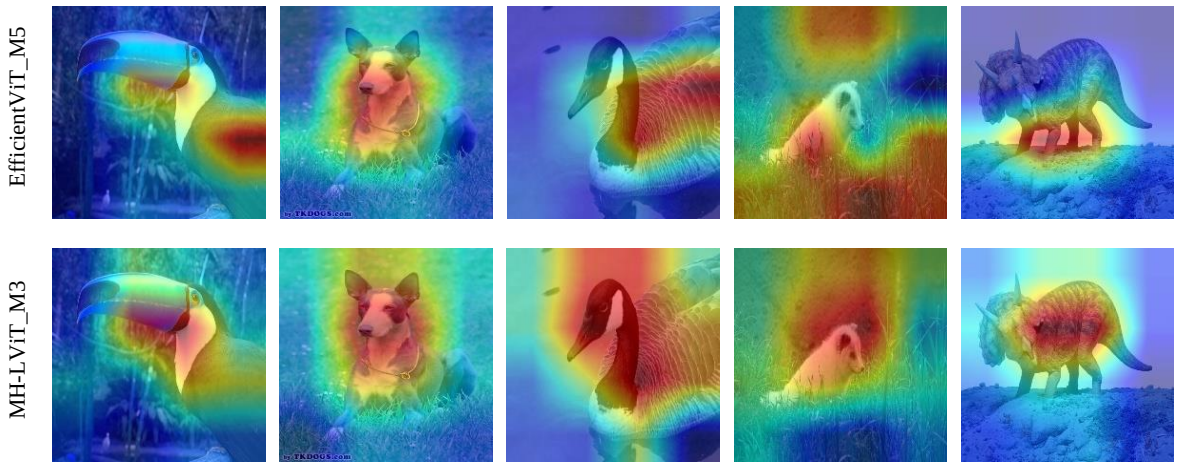

Fig. 4. Visualizations of attention maps on miniImageNet provided by MH-LViT_M3 and EfficientViT_M5.

TABLE V. ABLATION STUDY OF MH-LVIT_M1 FEATURE SCALE BALANCING STRATEGY ON CIFAR100

Channel Split Ratio	ACC_Top1(%)
1 (EfficientViT_M1)	73.46
1:1	75.23 (↑1.77)
1:1:1	75.63 (↑2.17)
2:2:1	75.97 (↑2.51)
3:2:1	76.39 (↑2.93)

TABLE VI. ABLATION STUDY OF MH-LVIT_M1 MODEL ENHANCEMENT ON CIFAR100

Model	ACC_Top1(%)
MH_LViT_M1*	80.19
MH_LViT_M1* w/o IntPNKD	77.61 (↓2.58)
MH_LViT_M1* w/o IntPA	79.17 (↓1.02)
MH_LViT_M1* w/o L_{MR}	79.05 (↓1.14)

VI. CONCLUSION

In this paper, we propose a multi-path hybrid architecture for lightweight CV model to facilitate feature representation learning and develop a series of MH-LViT models. Within the multiple paths, the global features extraction ability is leveraged by ViT Branch and the local features extraction ability is enhanced by CNN branch. A residual connection branch is further introduce to complete the feature representation and a feature fusion module is utilized to shuffle extracted features and balance their chances to be processed in different branches. In order to exploit the representation potential of developed tiny models, we propose a novel knowledge distillation framework IntPNKD that introduces an extra intermediate layer prediction alignment in addition to the standard logit alignment. Finally, an mixup regularization term is utilized to further improve the generalization ability. Experimental results on benchmark datasets show that MH-LViT models balances well complexity and performance, providing an effective solution for visual tasks in resource-constrained applications. In the multi-path branches, we only utilize existing CNNs and ViTs and deliberately designed components will release fully the potential of proposed architecture. It is also interesting to evaluate MH-LViT models on more visual tasks.

***Abstract*—This study presents an innovative deep learning approach for accurate fish species detection and classification in underwater environments. We introduce FishNet, a novel convolutional neural network architecture that combines attention mechanisms, transfer learning, and data augmentation techniques to improve fish recognition in challenging aquatic conditions. Our method was evaluated on the Fish4Knowledge dataset, achieving a mean average precision (mAP) of 92.3% for detection and 89.7% accuracy for species classification, outperforming existing state-of-the-art models. The proposed approach demonstrates robust performance across various underwater conditions, including different lighting, turbidity, and occlusion scenarios, making it suitable for real-world applications in marine biology, fisheries management, and ecological monitoring.**

***Keywords*—Deep learning; Fish4Knowledge; classification**

I. Introduction

Accurate detection and classification of fish species in their natural habitats play a vital role in managing marine ecosystems, conducting fisheries research, and conserving biodiversity. Traditional methods of monitoring fish populations, such as manual observations or physical sampling [1], [2], often require significant time and effort while potentially disturbing the aquatic environments being studied. In recent years, advances in computer vision and deep learning technologies have offered promising alternatives, enabling automated and non-invasive fish species identification [3]. However, analysing images in underwater settings presents distinct challenges. Factors such as varying light conditions, water turbidity, and complex, often cluttered, backgrounds can hinder the clarity and quality of images. Furthermore, the high diversity of fish species, including subtle differences between similar species and variations within the same species, adds another layer of complexity to the task of accurate classification [4].

Previous research has explored several deep learning approaches for detecting and classifying fish species. Techniques such as convolutional neural networks (CNNs) [3], region-based CNNs (R-CNNs) [4], and more recently, architectures based on the YOLO (You Only Look Once) framework [5], have all demonstrated significant potential. However, despite promising advancements, challenges remain, particularly in terms of enhancing accuracy, making models more robust to environmental changes, and improving computational efficiency. In this paper, we introduce FishNet, a novel deep learning model tailored specifically for the detection and classification of fish in underwater environments. FishNet introduces several key innovations to address the unique challenges of underwater image analysis: Multi-scale feature fusion: This module captures both fine-grained details, such as the specific patterns and textures of fish, as well as broader contextual information from the surrounding environment.

Attention mechanism: Our model uses an attention mechanism that helps it focus on the most distinguishing features of each fish species, improving classification accuracy [6]. Transfer learning: To improve performance, we utilize transfer learning by pre-training the model on large-scale image datasets, which helps it learn general visual features that are then fine-tuned for underwater fish species. Advanced data augmentation: To enhance the model's ability to generalize across different environments and conditions [7], we apply sophisticated data augmentation techniques, which simulate variations in underwater conditions.

We test the performance of FishNet on the Fish4Knowledge dataset, a comprehensive collection of underwater footage captured from coral reefs, and benchmark it against existing state-of-the-art models. Through these evaluations, we demonstrate that FishNet achieves superior results, outperforming previous methods in key areas such as accuracy, robustness to environmental variation, and computational efficiency.

A. Related Work

The detection and classification of fish species in underwater environments have garnered considerable attention in recent years, particularly due to the growing demand for automated, non-invasive methods to monitor marine ecosystems. Traditional fish monitoring techniques, such as manual observation and physical sampling, are not only labour-intensive and time-consuming but also potentially disruptive to aquatic habitats. Consequently, there has been an increasing focus on leveraging computer vision and deep learning technologies to address these challenges.

Early work in automated fish detection primarily relied on image processing techniques, such as thresholding, edge detection, and contour analysis, to segment fish from their backgrounds. However, these methods were limited by their sensitivity to varying underwater conditions, including changes

in illumination, water turbidity, and complex backgrounds. As a result, more recent research has shifted towards deep learning-based approaches, which offer superior performance in feature extraction and classification tasks.

Convolutional Neural Networks (CNNs) have been the most widely used deep learning architecture for fish detection and classification and other research [8]–[16]. For example, researchers in [17] demonstrated the efficacy of CNNs in automatically identifying fish species from underwater images, achieving substantial improvements over traditional methods. Their work laid the foundation for using deep learning models in this domain. Region-based CNNs (R-CNNs) further advanced this approach by combining object detection and classification within a single framework. A study by [18] applied Faster R-CNN to detect and classify fish in underwater videos, achieving higher accuracy than earlier methods. While these models marked significant progress, they were computationally expensive and exhibited limitations when dealing with complex underwater scenes characterized by occlusion, shadows, and clutter.

Recent developments in deep learning have introduced more efficient architectures for real-time object detection and classification. The You Only Look Once (YOLO) framework, proposed by [19], has been particularly influential due to its ability to perform detection and classification in a single forward pass, making it suitable for real-time applications. In the context of underwater fish species identification [20] applied YOLO to classify fish species from underwater videos, achieving promising results in terms of both accuracy and speed. Despite these advancements, YOLO-based models are still susceptible to the challenges posed by underwater environments, such as variable lighting and water turbidity, which can degrade image quality and hinder detection accuracy.

Transfer learning has emerged as a strategy to further enhance the performance of deep learning models in underwater applications. By pre-training on large-scale image datasets, models can learn general visual features that are then fine-tuned for specific tasks, such as fish classification. A study by researchers [21] successfully applied transfer learning to improve the performance of CNNs for fish species classification, particularly in scenarios with limited labelled data. Similarly, [22] demonstrated the effectiveness of transfer learning in addressing the data scarcity issue in underwater species detection, further highlighting its potential in improving model generalization.

In addition to model architecture improvements, data augmentation techniques have been employed to increase the diversity of training data and improve model robustness to underwater variations. For example, the work by [23] utilized advanced data augmentation strategies, such as random rotations, colour jittering, and noise injection, to simulate the various conditions encountered in underwater environments. These techniques helped mitigate the impact of challenging factors like water turbidity and illumination changes, thus enhancing the generalization capability of the models.

Overall, CNNs, R-CNNs, and YOLO-based architectures have made a lot of progress in finding and classifying fish species. However, there are still some problems that need to be solved, mostly related to the conditions underwater and how fast the models can run. An interesting way to improve the performance of deep learning models in this area is to use attention mechanisms, transfer learning, and advanced data augmentation techniques together.

B. Methodology

The FishNet approach combines several advanced deep learning techniques to improve fish detection and classification in underwater environments. Our method utilizes a modified ResNet-50 architecture as its backbone, enhanced with attention mechanisms and feature pyramid networks for multi-scale detection. We employed transfer learning by pre-training on ImageNet and fine-tuning on the Fish4Knowledge dataset. To increase model robustness, we applied various data augmentation techniques simulating different underwater conditions. The training process involved a two-stage approach: object detection followed by species classification. We evaluated our model's performance on the Fish4Knowledge dataset, comparing it against state-of-the-art models using metrics such as mean Average Precision (mAP) for detection and accuracy for classification.

1) Dataset: For the purpose of this research, we undertook the Fish4Knowledge Dataset, which comprises over 700, 000 fish species images annotated with respect to fish obtained from underwater video footage of corral reefs. The dataset contains 23 different species, hence it is rich in resources for both the detection as well as the classification tasks. In order to obtain a fair evaluation of the model, we partitioned the data as follows 70% of the images were used for training the system, 15% of the dataset was set aside as validation and the last 15% was used for testing the system. Each of these subsets was compartmentalized in order to create without the species uneven dispersion which prevented the results from biasing.

2) FishNet architecture: FishNet, our proposed architecture, is built upon a ResNet-101 backbone, which has been adapted with several enhancements to better handle the complexities of underwater fish detection and classification. Below are the key components of the architecture:

- Multi-scale Feature Fusion Module: We integrated a feature pyramid network (FPN) into the ResNet-101 backbone, which enables the model to capture features at multiple scales. This multi-scale feature fusion is crucial because it allows the model to detect both fine-grained details, such as the specific markings and textures that differentiate fish species, and broader contextual information, which aids in accurately localizing fish in various environments. The FPN helps the model become more robust by improving its ability to handle fish of different sizes and orientations.
- Attention Mechanism: To enhance the model's focus on the most important features for species identification, we introduced an attention mechanism inspired by Squeeze-and-Excitation Networks [24]. This mechanism applies attention both spatially and across channels. The spatial attention helps the model focus on key areas of the image that are most relevant for identifying fish, such as their body shape and fin patterns. Meanwhile, channel attention enables the model to prioritize certain feature channels that

are more discriminative for recognizing specific fish species, improving classification accuracy.

- Detection and Classification Heads: The FishNet architecture includes two separate "heads" for performing the tasks of detection and classification.
    - Detection Head: For detecting the location of fish in images, we employed an anchor-free approach that uses focal loss [25]. This method helps the model by reducing the influence of easy, well-detected examples and placing greater emphasis on harder-to-detect fish, improving overall detection accuracy.
    - Classification Head: The classification head is responsible for determining which species of fish is present within the detected bounding box. It uses a softmax classifier, paired with cross-entropy loss, to assign a probability distribution across all possible fish species and identify the correct one with high confidence. Together, these components make FishNet an efficient and robust architecture, well-suited for the task of underwater fish species detection and classification.

Fig. 1 shows A high-level flowchart of a convolutional neural network (CNN) architecture based on FishNet and intended for fish detection in underwater contexts. Underwater photos are used as input into the system to begin the process. To improve feature extraction and model correctness, Attention Mechanisms and Transfer Learning are included in the model's core. Furthermore, Data Augmentation methods like rotation and brightness modulation are used to manage difficult situations including changing illumination, turbidity, and occlusion. The last step produces reliable recognition results in a variety of aquatic environments by using the FishNet CNN for detection and classification.

3) Transfer learning: To leverage the power of transfer learning, we initialized the backbone of our model using a ResNet-101 architecture that had been pre-trained on the ImageNet dataset [13], [26]–[35]. By doing so, we transferred the learned weights from ImageNet, which allowed the model to benefit from pre-existing knowledge of general image features, such as edges and textures. This initialization serves as a strong starting point for the model, particularly when working with smaller, specialized datasets like Fish4Knowledge. After initializing with these pre-trained weights, we proceeded to train the entire network end-to-end on the Fish4Knowledge dataset. This fine-tuning process ensured that the model learned to adapt these general image features to the specific task of detecting and classifying fish species in underwater environments.

4) Data augmentation: For broad generalization across underwater conditions and to improve the model robustness [36]–[38], we augmented the data using various augmentation techniques. These manipulations introduced variance into our training data, which should make the model more robust to common challenges that show up when diving in underwater settings such as variability in lighting, water clarity and fish orientation. The augmentation methods that were used on the following data are:

Random Horizontal and Vertical Flips: This augmentation flips the image horizontally or vertically with a certain probability, since the fish can be facing different directions. This helps the model learn to detect fish in any orientation within the image.

Random rotations (±15 degrees): This technique rotates the images randomly from -15 to 15 degrees simulating fish orientation in different poses as it may appear underwater which allows the model to better generalize to those poses.

Random Brightness Contrast: We made a random change to the brightness and contrast of the images since underwater light conditions fluctuate. This way, the model can cope with different light intensities due to sunlight, water depth and turbidity.

Data Augmentation [25]: Mixup: Mixup is taking two images and combining them together while blending their pixels and labels so that the average set output is taken. This approach can reduce overfitting by the model learning smoother decision boundaries, which then leads to crisper output spike times.

Augmentations specifically designed for underwater: Additionally, we applied some augmentations to the model as per the characteristics observed in real-world underwater images. These included:

Simulated Turbidity: Adding blur and haze to the images simulating the turbid conditions offering poor visibility with loss of image quality.

Colour shifts: Also due to the colour distortion often seen with underwater lighting, we introduced random shifts in the colour spectrum to emulate how water depth and suspended pollutants affect colours. Together, these augmentation techniques significantly improved the model's ability to generalize across a wide range of underwater conditions, making it more reliable for fish species detection and classification in real-world scenarios.

5) Training details: We trained FishNet using the Adam optimizer with a learning rate of 1e-4 and a batch size of 32. When validation loss plateaued for 5 epochs, the learning rate decreased by a factor of 0.1. The training was performed on 4 NVIDIA Tesla V100 GPUs for 100 epochs [39], [40].

II. Detection and Classification Performance

In this section, we present the performance evaluation of FishNet in terms of detection accuracy, species classification, and robustness to environmental variations. The results show that FishNet achieves state-of-the-art performance across all tasks, demonstrating its effectiveness for fish detection and classification in underwater environments.

A. Detection Performance

To assess the detection capabilities of FishNet, we measured the mean average precision (mAP) at an Intersection over the Union (IoU) threshold of 0.5 on the test set [41], [42]. FishNet achieved a mAP of 92.3%, significantly outperforming two leading models: YOLOv4 and Faster R-CNN. Specifically, FishNet surpassed YOLOv4, which achieved an mAP of 88.7%, and Faster R-CNN, which obtained an mAP of 86.2%. This improvement highlights FishNet's ability to

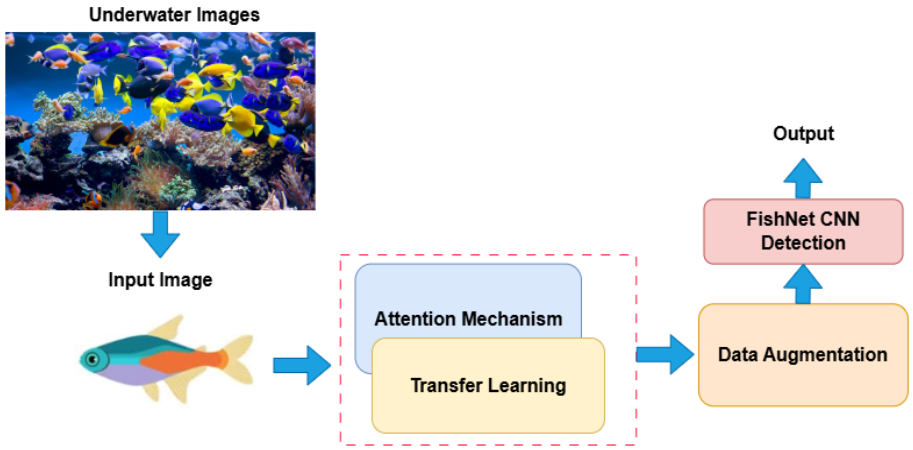

Fig. 1. The FishNet proposed model.

TABLE I. MAP IOU 0.5 COMPARISON OF EXISTING AND PROPOSED MODEL

Model	mAP IoU 0.5
YOLOv4	88.7
Faster R-CNN	86.2
FishNet (our model)	92.3

TABLE II. ACCURACY COMPARISON OF EXISTING AND PROPOSED MODEL

Model	Classification Accuracy
FishNet	89.7
CNN Ensemble [7]	85.3

accurately localize fish in underwater imagery, even in complex conditions (Table I).

The higher precision of FishNet can be attributed to the incorporation of multi-scale feature fusion and attention mechanisms, which allow the model to capture both fine-grained features and broader contextual information, leading to more accurate detections.

B. Classification Performance

For species classification, FishNet also demonstrated superior performance. On the test set, it achieved an overall accuracy of 89.7%, surpassing the previous best result of 85.3%, which was achieved by an ensemble of CNNs [23]. This notable improvement in classification accuracy indicates that FishNet effectively distinguishes between fish species, even when the inter-species differences are subtle (Table II).

The attention mechanism employed in FishNet, which emphasizes discriminative features for each species, likely contributed to this improved performance. Additionally, the separate classification head with softmax and cross-entropy loss allowed FishNet to more accurately classify fish species in diverse underwater conditions. FishNet's performance across detection and classification, its superiority over existing models. The combination of innovative architecture design, transfer learning, and advanced data augmentation techniques has enabled FishNet to set a new benchmark for fish species detection and classification in underwater environments.

III. DISCUSSION

The exceptional performance of FishNet can be attributed to several key factors, each contributing to the model's effectiveness in fish species detection and classification:

1) Multi-scale feature fusion: One of the main strengths of FishNet is its multi-scale feature fusion, which allows the model to capture details at different levels of granularity. This capability is critical for identifying fish species, as it enables the model to extract both fine-grained features (such as small distinguishing patterns or textures on a fish's body) and larger contextual information (such as the fish's position relative to its surroundings). By processing information across multiple scales, the model becomes better at both detecting fish and accurately identifying the species.

2) Attention mechanism: The incorporation of an attention mechanism further enhances FishNet's performance by enabling the model to focus on the most important and distinctive features of each fish species. This mechanism, inspired by Squeeze-and-Excitation Networks, selectively emphasizes the relevant spatial regions and feature channels, helping the model differentiate between fish species that may appear similar at first glance. As a result, this attention mechanism plays a crucial role in improving the model's classification accuracy, ensuring that subtle species-specific traits are captured effectively.

3) Transfer learning: The use of transfer learning from a pre-trained ResNet-101 backbone, initialized with weights from ImageNet, provided FishNet with a strong foundation.

Since ImageNet contains millions of diverse images, the pre-trained model comes equipped with general knowledge of visual features like edges, textures, and patterns. By fine-tuning this pre-trained model on the Fish4Knowledge dataset, FishNet was able to adapt these general features to the specific task of recognizing fish species in underwater environments. This approach greatly accelerates learning and enhances the model's accuracy, even with limited labelled data.

4) Extensive data augmentation: To improve the model's generalization and robustness, we employed a wide range of data augmentation techniques, including those tailored specifically to underwater environments. Standard augmentations, such as random flips, rotations, and brightness adjustments, helped simulate various real-world scenarios. Additionally, underwater-specific augmentations like simulated turbidity and colour shifts allowed the model to adapt to common challenges in underwater footage, such as cloudy water and lighting variations. These augmentations significantly enhanced FishNet's ability to generalize to unseen data, making it more resilient to varying environmental conditions.

5) Robustness in challenging conditions: FishNet's performance under simulated challenging conditions—such as low light, high turbidity, and partial occlusion—demonstrates its robustness and potential for real-world applications. The model performed well even under these adverse scenarios, with minimal drops in detection accuracy. This robustness is particularly important for underwater environments, where fish may often be partially obscured or captured under poor lighting conditions. FishNet's ability to handle these challenges suggests that it can be effectively deployed in diverse underwater settings, such as coral reefs, deep-sea habitats, or turbid coastal waters.

To sum up, FishNet achieved cutting-edge results in finding and classifying fish by combining multi-scale feature fusion, an attention mechanism, transfer learning, and a lot of different data-augmentation strategies. Its strong performance across various underwater conditions indicates that FishNet is a highly reliable model for marine ecosystem monitoring, fisheries research, and biodiversity conservation efforts.

IV. Conclusion

FishNet represents a significant leap forward in underwater fish detection and classification, offering a powerful tool for marine research and conservation efforts. By achieving state-of-the-art performance on the Fish4Knowledge dataset, our approach demonstrates its capability to accurately identify fish species across diverse underwater conditions. This breakthrough has far-reaching implications for marine biology, ecology, and fisheries management. The robust performance of FishNet opens up exciting new possibilities for underwater ecosystem monitoring. Marine biologists can now gather more accurate data on fish populations and behaviors, while ecologists can better understand the delicate balance of aquatic environments. For fisheries managers, FishNet provides a reliable means to assess stock levels and implement sustainable fishing practices. Looking ahead, the potential for FishNet is boundless. Future developments could expand its capabilities to encompass a broader spectrum of marine life, unlocking new insights into underwater biodiversity. By incorporating temporal data from video feeds, we could gain unprecedented understanding of fish behavior patterns and migration trends. Moreover, the development of lightweight versions of FishNet could revolutionize real-time underwater monitoring, enabling deployment on autonomous underwater vehicles or stationary sensors for continuous ecosystem observation. In conclusion, FishNet not only pushes the boundaries of deep learning in challenging underwater environments but also provides a versatile foundation for future innovations in marine science and conservation. As we continue to refine and expand this technology, we move closer to unraveling the mysteries of our oceans and safeguarding their precious ecosystems for generations to come.

***Abstract*—The voluminous number of vehicles present on principal roads together with ongoing road expansion projects are triggering serious roadblocks during peak hours in many places in Mauritius. Consequently, an innovative solution has been proposed using the strength of deep learning neural networks and cutting-edge computer vision methodologies to help reduce this problem. The idea is to create a reliable system that is adequate to measure traffic density and traffic flow on important roads of Mauritius in real-time. A dataset of 2800 frames was collected and used to train and test the YOLO models. A setup was designed for detecting, tracking and counting vehicles such as buses, cars, motorbikes, trucks and vans. Relevant traffic information from videos can also be retrieved to generate statistics for traffic density. Moreover, the system can estimate individual speed of vehicles as well as determining traffic flow on bidirectional roads. The overall mean counting accuracy was 96.1% and the overall mean classification accuracy was 94.4%. For traffic flow, the overall mean accuracy was 93.9%, while traffic density was estimated with an overall mean accuracy of 95.3%. In comparison with manual approaches used in Mauritius to understand the state of traffic, the proposed system is a modern, low-cost and effective solution that can adopted to potentially reduce traffic congestions and traffic accidents.**

***Keywords*—Computer vision; deep learning; vehicle detection and tracking; traffic accidents; traffic congestion**

I. Introduction

Traffic congestion is a persistent threat for the long-term sustainability of transport networks. Whenever travel volume surpasses the capacity of roads, reduction in normal flow of vehicles happens, causing major time delays, rise in financial losses and significant stress for drivers [1]. Unfortunately, roadblocks are a recurring issue worldwide capable of even causing motionlessness for several days as occurred in Beijing, China on August 2010 [2]. Traffic congestion is a term that can be quantified by measuring its severity, duration and extent. Severity shows the intensity of congestion, duration represents the interval that the traffic network was affected and extent being the length of road being compromised [3]. Furthermore, studies show that after drivers are stuck in traffic, they tend to be more reckless as well as being easily distracted, potentially leading to accidents [4]. Although Mauritius is known for being a paradise island, its habitants are far from being exempted from the daily struggles of traffic jam. According to reports by the Road Development Authority (RDA) in Mauritius, a significant portion of the budget allocated for road projects has been spent to decongest roads in several parts of the country [5]. In Mauritius, it is currently impossible to obtain reliable information about the state of traffic on major roads at any time. Some genuine attempts have been made to understand traffic density by placing individuals at different roads and manually counting moving vehicles. However, the growth of the transportation network has made the method extremely expensive and unsustainable. Moreover, these manual methods do come with a degree of inaccuracy due to human errors.

Frequent travel delays is costly in the long run. Thus, an automated traffic density estimation system is needed to relieve pressure on road users. As the increase in number of vehicles being purchased yearly is not coming to a halt, the concentration of vehicles on major streets during peak hours does raise a safety concern that needs to be tackled immediately. Having a reasonable but limited budget, Mauritius requires relevant and timely statistics to make optimal choices in the ongoing road decongestion program. The goals of this project are to take advantage of computer vision techniques and neural networks to understand the state of traffic from video footages. Firstly, a large number of video recordings of moving vehicles on important roads of Mauritius will be taken. The vehicles present in the frames will be meticulously labelled to form a robust dataset for training, validation and testing. After the training phase, the system shall be able to detect, track and count moving vehicles from video frames with reasonable accuracies. Then, with the help of appropriate algorithms, traffic flow, traffic density and driving speed will be estimated. Finally, an output video containing all the essential information about road traffic analysis will be generated. The system will be able to provide real-time traffic data, allowing authorities and drivers to make informed decisions on routes, reducing congestion. With the availability of real-time data, authorities can predict future traffic patterns and manage resources effectively, such as deploying traffic police or adjusting traffic signals.The system will be cheaper and more sustainable in the long run compared to manual methods.

This paper proceeds as follows. In the next Section II, we present the related works, the object detection and object tracking algorithms. The methodology is described in Section III. The implementation, testing, results and evaluation are presented in Section IV. Section V concludes the paper.

II. Literature Review

This section presents a comprehensive overview of the existing research on vehicle counting, road traffic density evaluation and vehicle speed estimation. Mandal and Adu-Gyamfi [6] built algorithms to count and track vehicles. They devel-

oped a reliable approach for vehicle counting on highways and addresses the occlusion issue of small vehicles behind trucks. CenterNet, Detectron2, YOLOv4 and EfficientDet were the four object detectors that were used. Intersection over union (IOU) tracker, Simple Online and Real-time Tracking (SORT), Feature Based Object Tracker were among the object trackers that were tested but Deep SORT was found to be the most reliable one. The combination of CenterNet and Deep SORT outperformed the rest by achieving an average counting accuracy of 95%. Zhu et al. [7] developed an enhanced Single-Shot Detector (SSD) capable of outperforming popular object detectors. ResNet achieved the best results with a classification accuracy of 96.11%, while the accuracy for Speeded-up Robust Features (SURF) was 45.74%. Consequently, a ResNet with reduced layers was picked to be the base network of the improved SSD. An overall accuracy of 90.3% was obtained for the counting and classification of vehicles. This was 3% higher than the one obtained by the traditional SSD.

Song et al. [8] developed a system to conduct vehicle detection and counting on different highways. Firstly, video frames go through the meanshift algorithm and Gaussian filters for smoothing and enhancement. Then, the results are fed to a flooding filling algorithm to identify and extract only the road surfaces. The YOLOv3 algorithm was used to locate the positions of vehicles and the Oriented FAST and Rotated BRIEF (ORB) algorithm was employed to predict driving directions. The experiments revealed that the accuracy for the counting of vehicles and driving directions were 93.% and 92.3%, respectively. Lira et al. [9] constructed a system where video footages obtained from drones were used to perform vehicle detection by using the Mixture of Gaussian (MOG2) algorithm. However, tracking of motorbikes and distant vehicles proved to be difficult. An overall accuracy of 64% was achieved for vehicle detection. Satyanarayana et al. [10] proposed a distinct approach to detect and classify vehicles from Indian roads. The CNN used was trained with 8000 images. The shapes formed by the ROIs (Regions of Interest) were used to approximate the length, width and type of vehicle. However, occurrences of closely moving two-wheelers being classified as a single vehicle of another class were observed. Also, vehicles having colours similar to roads created some difficulties for the system.

Hasan et al. [11] developed a model based on a Convolutional Neural Network (CNN) to analyze traffic density. The CNN was trained to identify five different classes ranging from "empty lanes" to "traffic not moving". One of the worrying issues of the system was overfitting. Data augmentation and batch normalization were used to reduce overfitting. The model was found to be working at an accuracy of 84.06%, with a further increase of 2.5% after batch normalization. Biswas et al. [12] constructed two automated Python algorithms for counting vehicles and for estimating traffic density. The first method was based on Single Shot Detector (SSD) while the other one made use of MobileNet SSD. SSD was able to achieve a detection accuracy of 92.9% while MobileNet only reached 79.3%. Huy and Duc [13] came up with a real-time traffic density evaluation system which locates, counts and classify vehicles using faster R-CNN (Region-Based Convolutional Neural Network) and CSRT (Channel and Spatial Reliability Tracker) algorithm. The tracker can tolerate certain unforeseeable movements and can work with intermittent frame drops. To estimate traffic density, factors such as speed of moving traffic and number of vehicles present were considered. An accuracy of about 95% on highway streets and a 5% drop on crossroads due to frequent occurrences of unpredictable movements was obtained. Bidwe et al. [14] worked on a convolutional neural network (CNN) to classify traffic images into three traffic density categories, namely, low, medium and high. The CNN was able to achieve classification accuracy of up to 99.6%. However, the system can only find density of a single image and has not been tested to calculate the overall density of a sequence of frames.

Ijeri et al. [15] came up with a traffic control system using image processing. Vehicles came from four different directions, the system determines the traffic density and picks the lane that gets green signal for an allocated time. Canny edge detection algorithm is part of the method employed to estimate traffic density. The system is found to be demanding for real-time traffic control. The overall accuracy of the system was only 45%. Mittal et al. [16] put together a traffic density estimation model intended to be used for improving green lights timings at intersections. A combination of Faster R-CNN and YOLOv5, named as EnsembleNet, was used as the object detector. The model was able to operate in low light scenarios and achieve a detection accuracy of up to 98% compared to 95.8% for YOLOv5 and 97.5% for Faster R-CNN for the same test set. Hasanah et al. [17] implemented a Smart Traffic light management system at road intersections in Indonesia. The Haar Cascade Classifier and an advanced CNN were used together to form an object detector. The algorithm can process footages of one second from CCTV cameras in 0.52s for light traffic and 1.05s for heavy traffic. The detection accuracy was 82% during calm periods but drops to 60% during rush hours.

Fedorov et al. [18] attempted to determine the flow of traffic at the most hectic intersection in the Russian city of Chelyabinsk. The faster R-CNN detector was used for vehicle identification and the SORT (Simple Online and Real Time Tracker) algorithm would associate objects throughout the video. Testing revealed an error rate of 7.25% as the tracker struggles when cars overlapped while waiting at the centre of the intersection. Grents et al. [19] also used the architectural model of the faster R-CNN and SORT tracker to detect and track moving vehicles. The authors also estimated vehicles' speed to understand traffic flow using equations from Makwana and Goel [20]. However, the proposed method could only estimate speed within an error rate of 22%. Using YOLOv4, Khalaf et al. [21] achieved an impressive accuracy of 98.93% for the detection of pedestrians from the KITTI dataset

Despite all the breakthroughs concerning vehicle counting and traffic density estimation, a single setup that can compute all the key aspects of road traffic analysis is still missing. Our plan is to implement a system that is able to detect, track, count moving vehicles, estimate traffic flow, traffic density and driving speed. The proposed model should be able to obtain excellent classification accuracy while operating in real-time.

A. Object Detection Algorithms

In the realm of real-time traffic detection systems, object detection stands as a pivotal component, given its fundamental role in identifying every moving vehicle traversing the roadways. While humans effortlessly perform object detection,

machines encounter significant complexity in executing this task. This section delves into recent advancements in object detection methodologies, shedding light on notable object detectors.

1) The YOLO algorithm: At the University of Washington, Joseph Redmon and Ali Farhadi built the start of the well-known YOLO (You Only Look Once) object recognition and picture segmentation model [22]. After its initial introduction in 2015, YOLO has grown in popularity due to its fast speed and correctness [23]. The first model receives frames at a resolution of 448 × 448 pixels and applies a convolutional neural network on the whole image in one go. The network divides the input in a K × K grid, detects objects when their centres are found inside a cell and predicts the positions of bounding boxes and the likelihood of their respective classes. A threshold value is used to reject bounding boxes with low confidence score. The primary YOLO model recorded real-time processing speed of 45 frames per second and a faster version achieved a speed of 155 frames per second [22].

A year later, Redmon and Farhadi released an improved version known as YOLOv2 which implemented a technique to perform training on both object classification and identification [24]. Batch normalization was another addition to improve the precision. YOLOv2 was able to operate at 67 fps and was more robust to different sizes of input images [24]. YOLOv3 consisted of subtle upgrades which made the network layers larger and resulted into better accuracy while not impacting the speed significantly [25]. The following release, YOLOv4, brought the CSPDarknet53 as its classifier backbone along with a 10% increase in speed and launched an innovative data augmentation technique [26]. YOLO's capacity was further enhanced in 2021 with the introduction of YOLOv5 by Ultralytics, which incorporated support for panoptic segmentation and object tracking.

YOLOv8 was published by Ultralytics in 2023 [23]. This model includes a new backbone network as well as a new loss function. One of its attributes is compatibility with all the existing YOLO versions. Users may swiftly switch between and assess the performance of various versions [23]. YOLOv8 can now also perform instance segmentation and image classification in addition to object recognition. Anchor free detection is an architectural change brought into the algorithm to reduce the unnecessary large amount of predicted bounding boxes. Terminating mosaic data augmentation after a certain number of epochs is another update to the system. During testing on the COCO dataset, YOLOv8 had a 20% increase in mAP for its small version compared to YOLOv5 [27].

2) Single Shot Multibox Detector (SSD): SSD (Single Shot Multibox Detector) is a state-of-the-art object detection model. Its architecture consists of only one deep neural network. During training, SSD requires input frames and labelled boxes surrounding each object. When analyzing images, the algorithm's convolutional layers produce several default boxes at the location of each object on feature maps of different proportions. The system then compares both input's boxes and generated ones to look for matches. Those which are compatible are considered positives and the rest are considered as negatives. This technique has proven to enhance SSD accuracy for low resolution images. During detection mode, the convolutional layers generate a feature map and a 3 × 3 convolution kernel is applied on the map to predict a set of bounding boxes where objects are detected along with the likelihood of their respective classes [28].

When tested on the VOC2007 dataset, SSD is able to attain a mean average precision (mAP) of 74.3% and runs at 59 fps while using 300 × 300 pixels images. A slight increase of 2.6% in mAP was reached for 512 × 512 input frames. Nevertheless, as SSD ignores the data beyond the proposed boxes, it is commonly acknowledged that it is less reliable in recognizing smaller objects [29]. Fig. 1 shows the SSD model.

3) Mask R-CNN algorithm: Mask R-CNN is a framework introduced in 2017 by Facebook AI researchers that extended the Faster R-CNN model [30]. The latter operates in two stages. The initial phase, known as a Region Proposal Network (RPN), places bounding boxes on potential objects according to its concurrent prediction of objects limits and objectness values at each point. The following step is derived from Fast R-CNN, uses RoIPool to retrieve traits from each bounding box and classify them into their respective classes. Bounding-box regression is also done to refine localization and the size of boxes. The features identified from these two steps can be communicated between them for quicker inference. Mask R-CNN adds to the second stage by also performing a high precision segmentation of each detected object in the images. When compared to existing models, Mask R-CNN exhibits a greater average precision and does not significantly increase the overhead of faster R-CNN, but it only runs at 5fps, which makes it unsuitable for real-time applications [30].

4) EfficientDet: Tan et al. [31] noticed that system optimization has grown in significance over the last few years for the field of computer vision. They did in-depth research of neural network architectures in an effort to identify the ideal combination to build an efficient object detector. After evaluation, EfficientNet was chosen as the network backbone. Innovative features such as BiFPN (bi-directional feature pyramid network) and a new compound scaling method were introduced. BiFPN acts as the feature network and makes multiscale feature fusion simple and quick. The compound scaling solution simultaneously adjust the pixel density, depth and breadth of network for better optimization. With only 77 million parameters and 410 billion FLOPs, EfficientDet-D7 is able to obtain an average precision of 55.1% on the COCO dataset. Fig. 2 shows the architecture of EfficientDet.

B. Object Tracking Algorithms

Object tracking algorithms constitute an essential element within intelligent traffic monitoring systems. Their primary objective is to establish correspondences between identical vehicles observed across distinct frames of a recording. A proficient algorithm achieves this objective with minimal computational expenditure while ensuring a consistent and reliable tracking of a vehicle throughout its presence in the monitored scene.

1) DeepSORT: DeepSORT is an extension of the computer vision tracking model SORT (Simple Online Realtime Tracking). The SORT algorithm is a method for numerous objects tracking that emphasizes on efficient and straightforward methods to achieve real-time processing. It employs a blend of well-known methods such as the Kalman Filter and

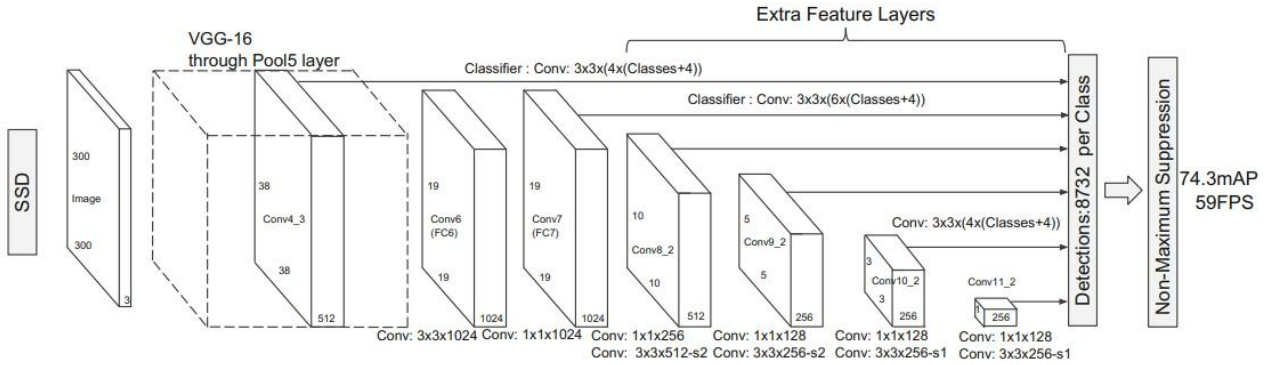

Fig. 1. SSD Model [28].

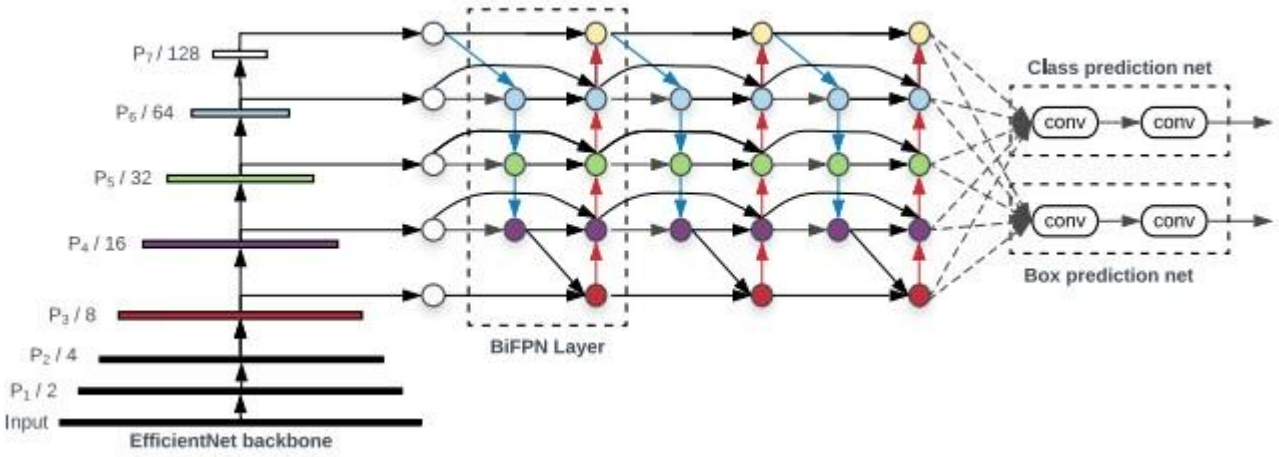

Fig. 2. EfficientDet architecture [31].

Hungarian algorithm to accomplish its goals. When an object appears or exits the frame, a distinct identity is either given to or taken from it. An identified object is labelled as untracked when its detection has an overlap smaller than the defined IOUmin (Intersection over Union) value. An IOU matrix which represents the intersection-over-union distance between each detected object and all expected bounding boxes of pre-existent entities is kept. The matrix is used by the Hungarian algorithm to associate current objects with their next position in the following frame. The Kalman Filter is used to predict future locations of every tracked target which is used for object association. Tracking is terminated if the entity is not found for a specified number of frames [32].

While using the SORT method, some objects' tracking are often lost midway through and afterwards retraced using a new identification. If counting is necessary, it could pose a significant hurdle. DeepSORT tries to include visual appearance of objects as a factor when looking for objects in the upcoming frames. A trained convolutional neural network with two convolutional layers and six residual blocks is incorporated with predicted motion information to form a better object association metric. The technique has shown to eliminate entity switches issue by around 45%. Tracking is proved to be smoother in scenarios with occlusions and unexpected motions [33].

2) ByteTrack: ByteTrack (BYTE) is a simple and robust tracker which main goal is to consider all detected bounding boxes in order to minimize tracking errors due to occluded targets, motion blur or shift in sizes. ByteTrack does not use any convolutional neural network to achieve its aim but rather uses both high and low confidence detection boxes while performing association. Boxes are categorized as low and high confidence according to a selected threshold. The Kalman filter is then applied to predict the expected path of objects in the following frame. The initial association is done with the large confidence value boxes and all the predicted tracks. At this phase, the Hungarian method is utilized to resolve the matching. During the next stage, the resulting unmatched tracks are associated with the low confidence boxes. Any unpaired path is saved so that it may be handled with the following frame. BYTE is a highly customizable model and can easily be merged with other similar tracking algorithms. It was able to obtain an accuracy of 80.3% for multi object tracking while performing at 30 fps [34].

III. Methodology

This section details the architecture and structure of the proposed system. The contents of various elements and how they interact with one another to allow the model to run successfully are listed and thoroughly explained. Before building the components that would be used to extract road traffic information from video recordings, compilation of a robust dataset is essential for training of an object detector.

A. Dataset

The dataset consists of five different classes namely buses, cars, motorbikes, trucks and vans with class ids 0 to 4, respectively. Out of 2800 frames, 22,293 cars, 4852 trucks, 3527 motorbikes, 2308 vans and 1937 buses were manually annotated to form the dataset. Data augmentation techniques such horizontal flips and 10-degree rotations have been used to take the number of frames for the training dataset to a total of 5600 frames. 280 labelled frames were set aside to be used for the validation stage. The images were captured during the day with light, medium and high traffic. Once the videos were captured, any visible faces plate numbers were blurred out as agreed with the Data Protection Office of Mauritius

B. Training of the Model

After intense research and analysis, YOLOv8m has been chosen as the detector to perform vehicle recognition. This choice was made due to the balance of speed and precision it is able to offer. The detector was trained on the dataset for 120 epochs. The process took four hours to be completed.

C. Architectural Framework and Structural Composition of the System

The architecture composes of a detection and classifier module, a tracking unit, a traffic flow computation component, a speed estimation module and a traffic density estimation unit. The detection and classifier module mainly consist of the trained YOLOv8m detector and each video frame, upon being read, is initially transmitted to this detector for processing. It firstly resizes the input image and pass it to its convolutional neural network. Positions of bounding boxes with their corresponding vehicle classes and confidence scores are then determined. Finally, a thresholding of 0.25 is applied to discard low confidence boxes. The output is then transformed into a format compatible with the ByteTrack tracking algorithm and sent to the tracking unit. A reduced ByteTrack algorithm without its association metric serves as the central component within the tracking module. Upon receipt, the detection results are processed by ByteTrack and with the use of the Kalman filter, a list of predicted tracks are created. This list will then be used together with the detection results of the upcoming image for the association of the same vehicle across the sequential video frames. Each track is assigned a tracker ID and paired with the detection exhibiting the highest intersection over union (IOU) score. In case a detection is paired with multiple tracks, only the combination with the highest IOU is considered.

These combinations are then transmitted to the other modules for traffic analysis. The traffic flow computation component is where counting of vehicles is performed. The module requires a reference line perpendicular to the driving direction with end points being pixel coordinates of the recording in order to count vehicles. The end points of the line must be placed in positions such that the visibility of moving targets is optimal while traversing the line. As a vehicle moves from one segment of the line to the other, the counter for its category is incremented. At the end of each 60 s intervals, the number vehicles counted for that period is divided by 60 to calculate traffic flow in vehicles per minute.

The speed estimation module needs two reference lines perpendicular to the driving direction to operate. The calculation of speed for individual vehicles involves determining the time taken to traverse the distance from passing the initial reference line and crossing the subsequent line. The same concept used for vehicle counting is applied to understand when a target is traversing a reference line. Distance between lines can be estimated by adding the length of individual road markings. The traffic density estimation unit makes use of a rectangular box such that two of its edges are perpendicular to the driving direction. The region of interest formed must be located where the detection of vehicle is reliable.

For each 60 s, an average count of vehicles within the specified area in each frame is calculated. This count is divided by the number of lanes and the distance between the edges perpendicular to the driving direction, and then multiplied by 10 to obtain the traffic density per lane in vehicle per 10 m. Fig. 3 shows the activities of the speed estimation module, starting by initializing the speed list to null and positioning the two reference lines needed to calculate the speed of vehicles. Through an examination of tracker IDs associated with recognized vehicles, a distinction is made between new and previously identified vehicles. Newly identified vehicles have their coordinates stored for future reference, while those previously recognized undergo a comparison between their current positions and their last known positions. This assessment aims to ascertain whether these vehicles have crossed either the initial or subsequent reference lines. When a tracker ID is observed to have traversed both lines sequentially, the average speed for that specific duration is computed and then recorded in the speed list.

Fig. 4 describes the workings of the traffic density estimation unit, beginning by defining the coordinates of the rectangular area within which the road traffic density will be estimated. Within each frame, the centroids of all identified vehicles are computed, and their presence within the designated region of interest is determined. Consequently, the traffic density for that particular frame is evaluated based on the count of vehicles within this region. Over a span of 60 s, an average traffic density per lane is calculated.

D. ByteTrack

The instance takes a list of important arguments that have huge impact on its precision and computation speed. track_thresh which is set to 0.25, defines the minimum threshold needed so that an object and a track can be considered a match. track_buffer represent the number of frames a track is kept alive without being updated. The assignment of this parameter, chosen to be 30, necessitates meticulous consideration, particularly in situations characterized by recurrent occlusions. match_thresh is the value used to know if two

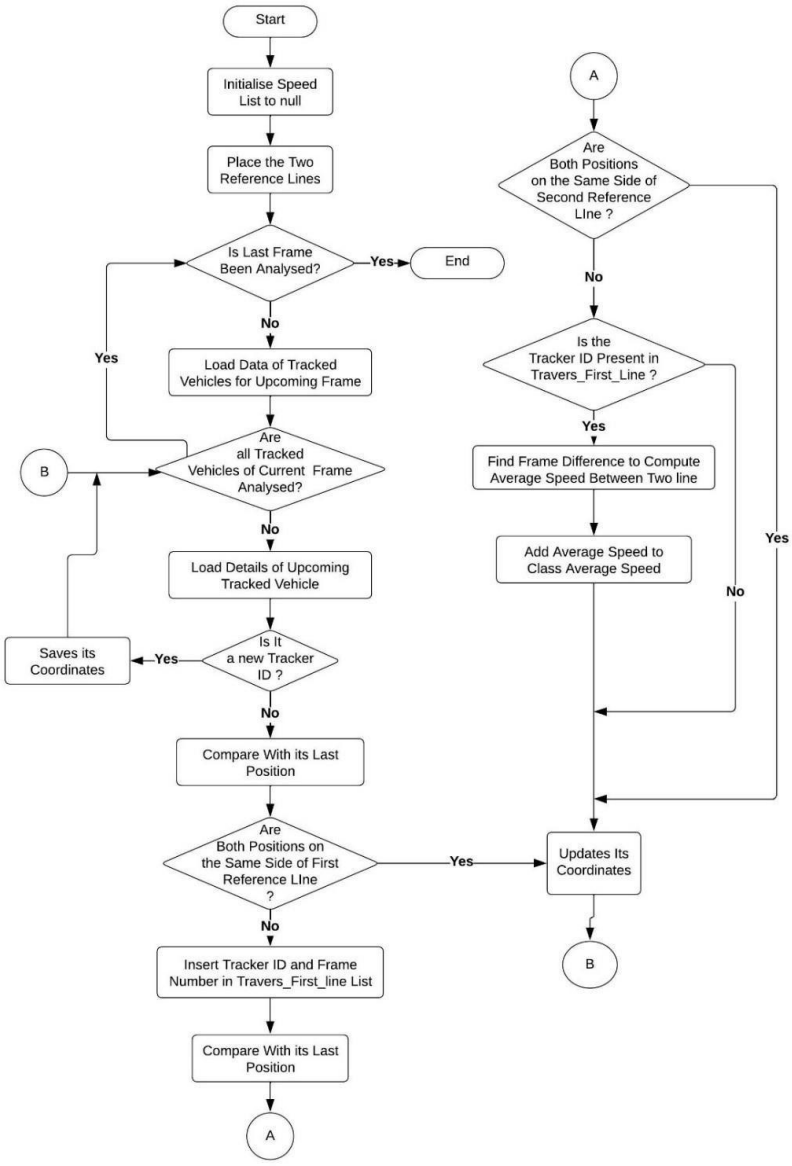

Fig. 3. Speed estimation module.

detections on a frame are the same object and it is configured to a value of 0.8. aspect_ratio_thresh define maximum aspect ratio difference two objects can have to be considered same and it is set to be 3.0. min_box_area, chosen to be 1.0, refers to the minimum area bounding boxes should have to be considered for tracking.

Each detected and tracked vehicle is defined by the co-ordinates of the four corners of its bounding box together with a tracker ID. Whenever a tracker ID is identified for the first time, the x-y coordinates of the corners are tested in a mathematical calculation to find out if they are below or above the line. The Boolean responses are stored in a dictionary. Upon coming across the tracker ID in an upcoming frame, the mathematical calculation is performed again to look for any changes. If all Boolean responses are identical, we wait until the tracker ID may be encountered again. In a situation where only two responses have changed, it would imply that only part of the vehicle has crossed the line. If all four Boolean values have changed, this indicates that the vehicle has crossed the line and is on the opposite side. Consequently, the new values are stored in the dictionary so that the vehicle is not re-identified as crossing the line whenever the tracker ID pops up again.

For each tracked bounding boxes in each frame, its centre point is found by averaging the positions of its four corners. Then, the method cv2.pointPolygonTest from OpenCV is used with the rectangular region and centre point as parameters to find if the point is inside the area. In case of a positive outcome, the vehicle represented by the bounding box is considered to be inside the rectangular box.

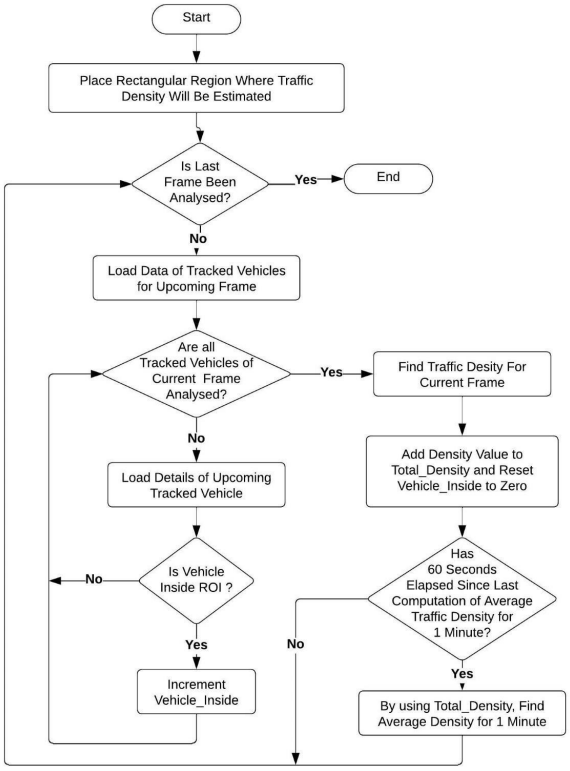

Fig. 4. Traffic density estimation unit.

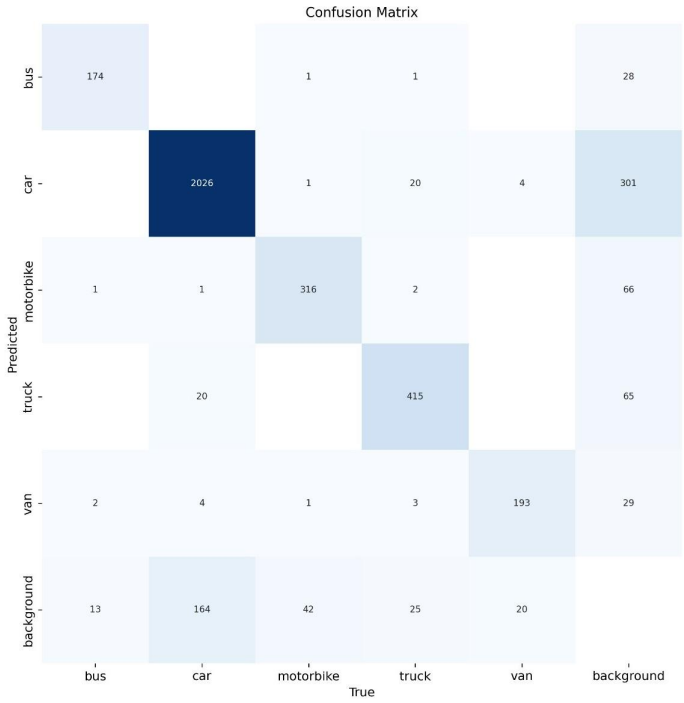

Fig. 5. Confusion matrix.

E. Validation Stage

During the dataset annotation for training purposes, 280 labelled images were set aside to be used for validation. These images were captured under identical conditions and locations as the images used for training. Fig. 5 shows the confusion matrix derived for the validation process. These matrices portray the model's capability to accurately detect and classify 90% of the vehicle instances within the frames. Notably, out of 3429 instances, 486 false positives and 264 false negatives were recorded. The model demonstrates a comparatively higher reliability in identifying buses, while being slightly less accurate for vans.

F. Testing

Test Cases used in this section include scenarios with different road traffic intensities at various locations in Mauritius. The car category includes Support Utility Vehicles (SUV) and the truck category includes lorries, and pickup trucks. The remaining categories are buses, motorbikes and vans.

G. Vehicle Counting and System Speed Comparison

The tracking and counting module have also been built on YOLOv8n and YOLOv8x so that fair accuracy and inference speed comparisons can be made among the three versions. The nano and extra-large versions have also been trained for 120 epochs on the same labelled dataset. From all the videos in test cases, a manual count of vehicles for each category has been done. Classification accuracy has been computed by dividing the count for each vehicle class by their corresponding manual count, find the average and then multiply by 100. The speed of each model has been estimated by the rate at which it can go through a video frame. The reference line for counting is also placed at an optimal position to obtain realistic feedback on correctness.

IV. Experiments, Results and Evaluation

A. Test Case 1: M1 Motorway Near Bagatelle Mall

A two minute video sequence was captured on the bi-directional M1 motorway from the bridge near Bagatelle Mall. The traffic driving to the north had a high traffic density while the traffic moving to the south was sparser. The footage was captured at around 8:30 in the morning. Tables I and II show these results

The results from both directions show that all the three YOLO versions are able to achieve excellent counting and classification accuracies. The traffic flow in both directions for the whole video and for each interval of 60s has also been determined by the system. These values are compared with the actual traffic flow as shown in Tables III and IV.

Observations from Tables III and IV suggest that all the three versions of YOLO are able to estimate traffic flow with very high accuracies. Fig. 6 shows a screenshot from the traffic video used for test case 1.

B. Test Case 2: Brabant Street at Port-Louis

A three minutes video sequence was captured on the bi-directional Brabant Street from the flyover. The road to the north consist of only one lane and had a slow moving traffic while the one to the south consist of two lanes and also had

vehicles moving slowly. The scenario is trickier compared to test case one as a bus stop is found on the road and buses tend to cause vehicle occlusions when they are stationary. This road is also frequently taken by many motorcycles. The footage was captured at around 11:30 in the morning. Tables V and VI show the results.

As test case 2 is a more challenging environment, more variations in the results are seen. YOLOv8m outperforms the

two other YOLO versions in classifying the vehicles in their respective categories. Categorization of trucks seems to be more difficult for all the three models. The results from Tables VII and VIII show that all the three versions of YOLO are able to estimate the traffic with accuracies above 80%. Table VII shows a screenshot from the traffic video used for test case 2. Fig. 7 shows the YOLOv8m output video.

Fig. 7. YOLOv8m output video.

C. Test Case 3: Motorway M1 Near Bagatelle Mall

A 4 min video sequence was captured on the bi-directional M1 motorway from the bridge near Bagatelle Mall at around 6 o'clock in the afternoon. Traffic density was very light during this time. Tables IX and X show that all three versions have performed exactly the same while achieving about 99% classification accuracy for both driving directions. The drop in illumination does not seem to have any effect on the detectors' ability to count and classify vehicles.

Tables XI and XII illustrate that all three models had the same performance for traffic flow estimation for each direction. They show that they are able to obtain traffic flow values with accuracies higher than 96%. Fig. 8 shows a screenshot from the traffic video used for test case 3.

In terms of counting accuracy, all the three YOLO versions perform close to each other with YOLOv8x having the slight edge. As predicted, counting results shows that test case 2 was the most challenging as it often had motorbikes and small

Fig. 8. YOLOv8m output video.

cars being hidden behind large buses waiting at a bus stop. This poses major difficulties for detection and tracking. As for classification accuracy, clear differences can be easily seen among the different models. YOLOv8m achieved a classification accuracy of 94.4% while the accuracy for YOLOv8x was only 88.9%. Test case 2 proved to be challenging for YOLOv8m and YOLOv8x as they misclassified or missed buses and trucks.

As for the operating speed, YOLOv8n outperforms the two others with an average fps of 18 as it is a much lighter detector with fewer parameters. YOLOv8n is more than twice faster than YOLOv8m and almost four times faster than YOLOv8x. The slight variation in speed between different test cases is due to dependency on the number of objects detected. This testing shows YOLOv8m can operate in real-time if a powerful GPU is used. All the three YOLO models are capable of evaluating traffic flow with good accuracies. YOLOv8x is slightly more suited for this task with an overall accuracy of 95.4%.

D. Traffic Density

With a known distance provided for the length of the region of interest (ROI), the system is able to determine traffic density for each lane. Values for traffic density per lane in the ROIs has been manually estimated by counting the number of vehicles present inside the selected areas, divides this figure by the length of the region and the number of lanes then multiplied by ten.

1) Test Case 4: Motorway M1 near bagatelle mall: A three minutes video was recorded on the bi-directional M1 motorway from the bridge near Bagatelle Mall at 9 o'clock in the morning. The video had about 106 vehicles moving north along with about 55 vehicles going south. Both directions consisted of three lanes. A region with a length of sixty was chosen as the length to be inspected for both directions. Tables XIII and XIV show the results.

Values obtained from test case 4 show that the system is able to estimate the traffic density with high accuracies. Fig. 9 shows the outputs from test case 4.

2) Test Case 5: Brabant street at port-louis: A three minutes video was captured on the bi-directional Brabant Street from the flyover at 11 o'clock in the morning. The road to the north consist of only one lane and while the one to the south consist of two lanes. The video had about 18 vehicles moving north along with about 31 vehicles going south. A region with a length of thirty meters was chosen as the area to be inspected for both directions. Tables XV and XVI show the results.

TABLE XIII. RESULTS OF DRIVING DIRECTION TO THE NORTH (TEST CASE 4)

Interval	Traffic Density per Lane Manually Evaluated (Vehicles/per Lane/10 m)	YOLOv8m (Vehicles/per Lane/10 m)	Accuracy (%)
0 s–60 s	1.80	1.77	98.3
60 s–120 s	1.99	1.94	97.5
120 s–180 s	2.11	2.30	91.0

TABLE XIV. RESULTS OF DRIVING DIRECTION TO THE SOUTH (TEST CASE 4)

Interval	Traffic Density Per Lane Manually Evaluated (Vehicles/per Lane/10 m)	YOLOv8m (Vehicles/per Lane/10 m)	Accuracy (%)
0 s–60 s	1.14	1.17	97.4
60 s–120 s	1.00	1.06	94.0
120 s–180 s	0.90	0.89	98.9

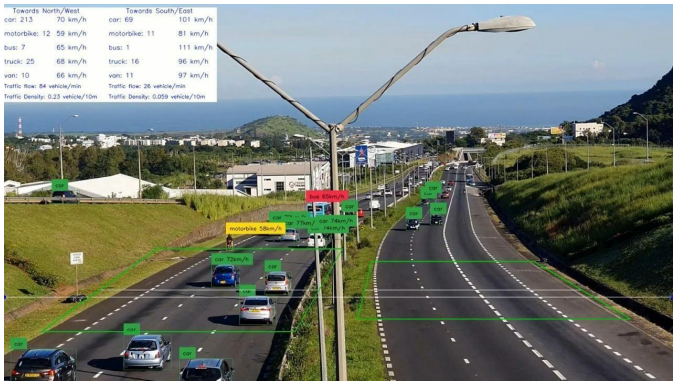

Fig. 9. Output video frame (Test Case 4).

TABLE XV. RESULTS OF DRIVING DIRECTION TO THE NORTH (TEST CASE 5)

Interval	Traffic Density per Lane Manually Evaluated (Vehicles/per Lane/10 m)	YOLOv8m (Vehicles/per Lane/10 m)	Accuracy (%)
0 s–60 s	1.86	2.00	92.5
60 s–120 s	1.61	2.02	74.5
120 s–180 s	2.46	2.55	96.3

For the north direction, during the interval 60 s–120 s, a road marking was wrongly identified as a car for a brief period of time which caused a significant decrease in the accuracy. Fig. 10 shows the outputs from test case 5.

3) Test Case 6: M1 Motorway near bagatelle mall: A three minutes recording was also captured on the bi-directional M1 motorway from the bridge near Bagatelle Mall at around 6 o'clock in the afternoon. The video had around 22 vehicles moving north along with about 30 vehicles going south. A

TABLE XVI. RESULTS OF DRIVING DIRECTION TO THE SOUTH (TEST CASE 5)

Interval	Traffic Density Per Lane Manually Evaluated (Vehicles/per Lane/10 m)	YOLOv8m (Vehicles/per Lane/10 m)	Accuracy (%)
0 s–60 s	1.22	1.26	96.7
60 s–120 s	1.20	1.24	96.7
120 s–180 s	2.71	2.71	100

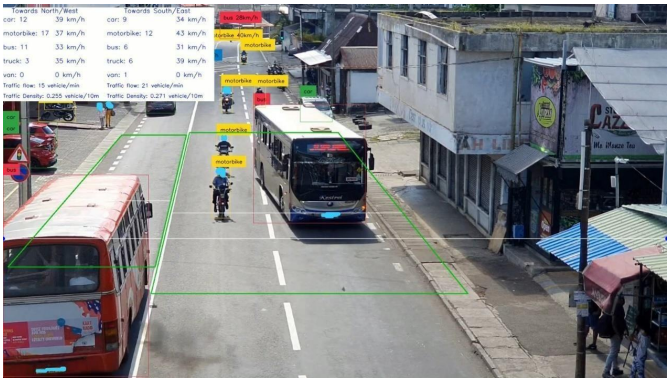

Fig. 10. Output video frame (Test Case 5).

region with a length of forty meters was chosen as the area to be inspected for both directions. There are 3 lanes in both directions. Tables XVII and XVIII show the results. Fig. 11 shows the outputs from test case 6.

TABLE XVII. RESULTS OF DRIVING DIRECTION TO THE NORTH (TEST CASE 6)

Interval	Traffic Density per Lane Manually Evaluated (Vehicle/per Lane/10 m)	YOLOv8m (Vehicle/per Lane/10 m)	Accuracy (%)
0 s–60 s	0.80	0.80	100
60 s–120 s	0.40	0.42	95.0
120 s–180 s	0.62	0.64	96.8

TABLE XVIII. RESULTS OF DRIVING DIRECTION TO THE SOUTH (TEST CASE 6)

Interval	Traffic Density Per Lane Manually Evaluated (Vehicle/per Lane/10 m)	YOLOv8m (Vehicle/per Lane/10 m)	Accuracy (%)
0 s–60 s	0.98	1.00	98.0
60 s–120 s	0.90	0.88	97.8
120 s–180 s	0.64	0.68	93.8

According to the figures obtained from the three test cases, the implementation with YOLOv8m is able to produce an overall mean accuracy of 95.3% for traffic density. An automated real-time traffic monitoring system using computer vision and deep learning offers several advantages. It provides immediate traffic data for better decision-making and congestion management. With automated vehicle counting and tracking, the system ensures higher accuracy and reduces human error. Data obtained from this system can be used by the relevant authorities for decongestion strategies. The system can also be

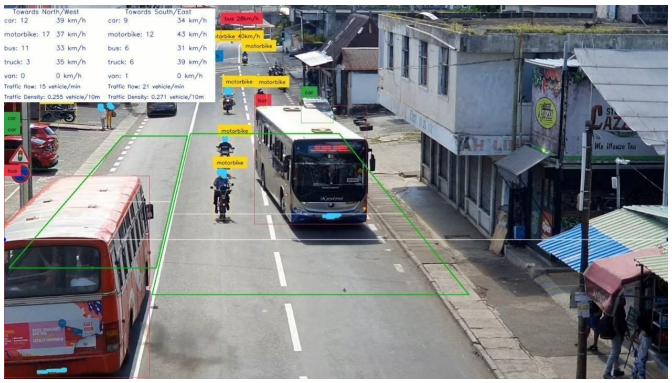

Fig. 11. Output video frame (Test Case 6).

used to enhance road safety by identifying dangerous driving patterns and enable faster emergency responses. Since less time is spent in traffic, it contributes to environmental sustainability by reducing vehicle emissions. For drivers, the system improves their overall driving experience by minimising travel time and stress.

V. CONCLUSION

The recent changes in road infrastructure to incorporate the metro pathway, combined with the constant increase in the number of vehicles in Mauritius, are causing severe traffic congestions on the country's highways and in major towns. The system designed and implemented can undoubtedly serve as the foundation for a solution to this problem. The proposed system is able to detect, track, classify and count vehicles with reasonable accuracy under different traffic conditions. Traffic flow and traffic density can also be estimated in real-time with good accuracy. The system can also estimate the speed of moving targets and give a representation of average driving speed for each category of vehicles. Once deployed, the proposed system can perform these tasks without any human intervention. It is also designed to be scalable and can be integrated with existing monitoring systems to provide detailed information about the traffic state of any roads in the Republic of Mauritius. This will enable the relevant authorities to gain a comprehensive understanding of traffic conditions on any road in Mauritius, facilitating more informed decision-making for road management and future infrastructure projects. As the system evolves, we aim to enhance its robustness by collecting and analyzing additional data from various locations and times, including night-time monitoring, to account for variations in road structures, traffic patterns, and lighting conditions. Future enhancements will focus on refining detection accuracy under challenging conditions, such as poor weather or very heavy traffic, to ensure that the system remains reliable and adaptable for the long-term needs of the transport infrastructure in Mauritius.

***Abstract*—Credit card fraud detection has emerged as a crucial area of study, especially with the rise in online transactions coupled with increased financial losses from fraudulent activities. In this regard, a refined framework for identifying credit card fraud is introduced, utilizing a stacking ensemble model along with hyperparameter optimization. This paper integrates three highly effective algorithms—XGBoost, CatBoost, and LightGBM—into a single strategy to improve predictive performance and address the issue of unbalanced datasets. To enable a more efficient search and adjustment of model parameters, Bayesian Optimization is employed for hyperparameter tuning. The proposed approach has been tested on a publicly accessible dataset. Results indicate notable enhancements over established baseline models in essential performance metrics, including ROC-AUC, precision, and recall. This method, while effective in fraud detection, holds significant promise for other fields focused on identifying rare occurrences.**

***Keywords*—Credit card fraud detection; stacking models; hyperparameter tuning; logistic regression; ensemble learning**

I. Introduction

Identifying fraudulent credit card transactions has emerged as a significant challenge for the financial sector because of the swift growth of digital transactions and online shopping. Current models find it difficult to manage the inherent imbalance in datasets for fraud detection, where fraudulent transactions are infrequent yet expensive. In this regard, every day, finance institutions need to protect billions of transactions happening online. Its fraud prevention horizon, therefore, is at an unimaginable scale. This study seeks to enhance the accuracy of credit card fraud detection by employing a stacking ensemble model along with sophisticated hyperparameter optimization methods. The investigation focuses on these key inquiries: In what ways can stacking models be refined to effectively manage imbalanced datasets? What effect does hyperparameter tuning have on the performance of fraud detection?. Indeed, all estimates point to global financial losses to fraud being in excess of billions of dollars annually, which places a high burden on businesses to create much more improved systems for fraud detection [1]. Security in financial transactions has a critical role in maintaining consumer confidence and the integrity of banking as a whole [2], [3].

The traditional methods involve Logistic Regression, Decision Trees, and Random Forest, among other traditional machine learning techniques that have so far been the bedrock of most fraud detection systems [2]. The way these models work is that they learn from historical data about the patterns which can predict if a transaction is fraudulent or real. Although they have been successful in most cases, the imbalanced nature of fraud datasets, where the ratio of positive instances corresponding to fraudulent activities is much smaller compared to the negative instances corresponding to normal activities, poses a challenge that most traditional models cannot overcome. The class imbalance problem often results in biased models towards the majority class of legitimate transactions, yielding poor detection rates associated with fraudulent activities [4].

Some techniques, therefore, such as SMOTE and undersampling, are often applied to artificially balance a dataset in order to counteract this bias. Although such methods tend to slightly improve the performance of a model, their performance is not always very satisfactory, especially when the relationship in a high-dimensional dataset is complex and non-linear. These challenges have resulted in unprecedented interest in various ensemble learning methods that can achieve better predictive performance by combining multiple classifiers. Ensemble models, more specifically the stacking model, have shown capable performance even better than those of traditional methods at times by exploiting strengths of different algorithms. The mechanism for the operation of stacking models is based on the integration of several base learners, such as Logistic Regression or XGBoost, CatBoost, and LightGBM, with a meta-learner to combine these predictions. In doing so, there can be the realization of a more flexible model that captures different patterns within the data, while improving accuracy and generalization [5], [6]. The efficiency of the stacking model in fraud detection applications follows from the fact that usually, data is high-dimensional, quite complex, with subtle fraud behavior to be captured [7].

Another very important factor for success with machine learning models is hyperparameter tuning. Hyperparameters are generally the most fundamental configurations that regulate the behavior of a machine learning model. Examples include learning rate, depth of decision trees, number of estimators, and many more. Optimizing these hyper-parameter values could highly influence both model accuracy and efficiency. Advanced hyperparameter optimization techniques, especially Bayesian Optimization, Genetic Algorithms, and grid search methods, have over the past couple of years begun to make the process easier by automating and streamlining it. These methods are able to explore the most efficient hyperparameter space with the aim of optimal performance of the model on various datasets [4], [6]. Essentially, it has been found that applying advanced hyperparameter tuning to stacking models

can yield enormous gains in fraud detection performance, typically benchmarked with the ROC AUC score, a popular metric used to measure the effectiveness of the model in distinguishing between fraudulent and legitimate transactions [7].

Fraud Detection Systems require scalability and high-volume data processing in real-time since financial systems generate millions of transactions each day. Since fraudsters continuously evolve their techniques, the machine learning models should be adaptive to keep pace with the detection of emerging trends and patterns in fraud. This means that models always need updates, retraining with new data and tuning generalization performance of the models to unseen scenarios [4]. In this paper the challenges identified are solved by a novel approach considering stacking models combined with an improved hyperparameter optimization inside of a set of base learners: Logistic Regression, XGBoost, CatBoost and LightGBM. This approach will tune the hyperparameters and overcome inherent issues associated with dataset imbalance, thus proving to be more efficient, scalable, and accurate in fraud detection systems by providing a robust solution against fraud transactions within the dynamic digital space.

The organization of the rest of the paper is as follows: Section II discusses related work, considering an in-depth analysis of fraud detection techniques' current status. Section III describes the methodology followed, describing the design of the stacking model along with its optimization process. The results obtained from the experimental evaluation are discussed in Section IV, while Section V concludes the paper and provides insights for future research prospects in this area.

II. Literature Review

A. Overview of Optimization Techniques

The area of optimization has become a stronghold for better performance in machine learning models in different application domains. This often includes tuning the model parameters or hyperparameters to maximize or minimize some objective functions, normally related to model accuracy or error. In large, there are two major levels where optimization techniques are used in machine learning: first, during model training, the adjustment of the parameters to fit the data; second, when doing hyper-parameter tuning, where non-learned parameters like learning rate, number of layers, and so on are tuned for optimal performance of the model [8], [9].

While the field has evolved from traditional approaches like Gradient Descent to other, more sophisticated metaheuristic techniques like Genetic Algorithms (GA) and Particle Swarm Optimization (PSO), developed to deal with various problems such as non-convexity, high-dimensional search space, multi-objective optimization problems [4]. They have been spectacularly improved in domains like fraud detection, healthcare, and financial forecasting, where the data is complex, noisy, and different models are called for based on fine-tuning to achieve high accuracy.

B. Hyperparameter Optimization

HPO is crucial to realize significant improvements in machine learning, which, in application domains such as fraud detection, relies on the accuracy of models. While the neural network parameters are learned during training, the Hyperparameters must be predefined and they limit the learning process, model complexity, and generalization ability [4]. Efficient hyperparameter tuning ensures that the model does not only fit well to training data but generalizes to unseen data, hence improving its overall robustness.

The early models of hyperparameter optimization include Grid Search and Random Search, which systematically search through predefined hyperparameter spaces. Grid Search tests all hyperparameter combinations exhaustively over a specified range, whereas Random Search picks random hyperparameter configurations [9]. While Grid Search ensures that the space is well-covered, this process is computationally expensive, especially for large, high-dimensional datasets, whereas Random Search often outperforms Grid Search in covering a wider area of the hyperparameter space with fewer iterations.

However, both approaches are not very efficient in the case of large hyperparameter spaces, since their convergence to the optimal configuration requires hundreds of evaluations. This consideration motivated the development of more advanced optimization strategies based on intelligent search mechanisms.

Recent development in hyperparameter optimization techniques has derived more sophisticated methods like Bayesian Optimization, Hyperband, and Evolutionary Algorithms [10]. Such methods have been adopted in various domains, including finance and healthcare, since they provide immense power for efficient model optimization in problems involving high stakes, such as fraud detection [11].

C. Overview of Machine Learning

Machine learning, or ML, has been described as one of the most revolutionary technologies in the modern era, deeply embedded in a wide variety of applications that range from segments of healthcare classification [12] and financial domains such as tax collection [13] and cybersecurity [1]. Its ability to process large datasets and find some meaning in them has turned it into an indispensable tool for troubleshooting different problems in reality. The evolution of machine learning models has equipped industries with the power to make data-driven decisions and also unlock predictions at an accuracy level previously unimaginable. ML algorithms are necessarily applied the world over to solve problems in need of precision and scalability, such as fraud detection, risk management, and modeling customer behaviors [7]. Different forms of machine learning have been created to address various kinds of issues.

D. Ensemble Learning

The technique of stacking models, particularly ensemble learning, has become increasingly popular in recent years for enhancing predictive accuracy. This method involves combining various base learners such as Decision Trees, XGBoost, and CatBoost with a meta-learner to achieve improved accuracy and generalization ability [14]. Ensemble learning outperforms different models that work on various applications ranging from fraud detection to credit scoring.

With the development of optimization techniques, computational power, and integration of ensemble learning techniques

over the past few years, the performance and efficiency of machine learning models have improved significantly. This has enabled algorithm stacking or boosting with frameworks such as XGBoost, CatBoost, and LightGBM, allowing models to capture intrinsic, nonlinear relationships within the data that were unprecedented when compared to traditional models, including logistic regression or decision trees [4], [6]. These have also proved to be particularly efficient for high-dimensional, imbalanced datasets that come up in applications related to credit-card fraud detection [5].

E. Logistic Regression

Logistic Regression is among the simplest algorithms of machine learning; it finds its applications, especially in binary classification problems [1]. It calculates the probability of a certain input to belong to one of two classes based on the logistic function. Generally speaking, LR models are linear; that is, there is a linear relationship between input variables and the log-odds of the dependent variable. Due to its simplicity, logistic regression has been widely used in many applications, including medical diagnosis, credit scoring, and fraud detection, since interpretation at low computational cost is possible [4].

However, logistic regression has one major disadvantage: it cannot model data with non-linear trends, which limits its effectiveness on more complex datasets. Hence, logistic regression is common in ensemble models, often used as a meta-learner to combine the predictions of more potent models. It plays a leading role in synthesizing outputs in stacking ensembles, where base learners like decision trees or gradient boosting models create better final predictions. This method has been especially useful in domains like fraud detection, where the relationships among features are highly complex and data are typically imbalanced [1].

F. Gradient Boosting Models

A collection of weak learners in a boosted model collaborates to form a robust predictive model. At each iteration, the model minimizes errors by adjusting for the shortcomings of earlier models. Consequently, such models excel in applications like fraud detection and similar challenges, particularly when dealing with large and imbalanced datasets. Three popular algorithms for gradient boosting are XGBoost, CatBoost, and LightGBM.

1) XGBoost: XGBoost is one of the most efficient and effective techniques that can deal with both classification and regression challenges. It is a scalable machine learning system for faster and accurate predictions [15]. As an example, some of the useful features that make XGBoost very powerful concerns with its capabilities to handle sparse data, missing values since it can handle large datasets with high efficiency, with considerable usefulness in real-world applications such as fraud detection. In XGBoost, sequential trees are created, each of which tries to correct errors of the previously misclassified one. The boosting approach lets it generate high accuracy models and makes them less prone to overfitting, especially when combined with regularizations such as L1 or L2 [4].

XGBoost has gained extraordinary popularity because it is outstandingly competitive in many machine learning competitions, and could be easily scaled to distribute systems and GPUs [15]. Because of its capability to model complicated interaction in imbalanced data, XGBoost was the widely used base learner for fraud detection systems in multilayered models. It is the ensemble technique whose regularization and parallelization features make it particularly fitted to real-life applicative scenarios involving large-scale data in circumstances where swift fraud detection is crucial [5], [14].

2) CatBoost: CatBoost: this is a relatively new-and-awesome gradient boosting algorithm, which gained popularity quite fast, since it handles categorical features better than almost any other algorithm in machine learning. In traditional models, for instance, it was common to perform basic preprocessing either by onehot encoding or label coding so that the representations were numerical values for categorical features; this kind of transformation typically increases the dimensionality of a dataset and introduces some risk related to overfitting . CatBoost handles it through native processing of categorical data that, in turn, reduces preprocessing time and enhances the model.

Probably the most characteristic feature of CatBoost is that it can handle categorical data efficiently, which by default would otherwise need to be converted to one-hot encoding in other machine learning libraries. This makes CatBoost very useful in fields like e-commerce, finance, or fraud detection, where datasets often include naturally categorical variables. Besides this, the CatBoost library uses a lot of special tricks to reduce overfitting and improve the generalization of predictive models, which is highly recommended for large-scale datasets used in the detection of rare events such as fraudulent transactions [7], [14]. Its treatment of imbalanced data further contributed to its impressive performance and hence its popularity in several industries.

3) LightGBM: Probably the most important and challenging problem in machine learning, especially in fraud detection, is that of imbalanced datasets. Usually, fraudulent transactions are a rare class, while more than 95% of transactions are usually legitimate. This leads to biased models toward the majority class. Therefore, essentially, models fail to recognize fraud, and missed fraudulent transactions are often present that result in financial losses. In order to handle it, SMOTE - Synthetic Minority Over-sampling Technique and undersampling techniques are used in order to balance the dataset [1]. Apart from SMOTE, there are scaling techniques, such as Robust Scaler, for standardizing features and reducing the perceived effect of outliers. Robust Scaler scales the features based on interquartile range, which involves less sensitivity to extreme values . This is especially useful for fraud detection datasets, since transaction amounts may have a huge span.

G. Robust Scaler and Imbalance Handling

One of the most challenging tasks for machine learning, especially in fraud detection, is dealing with imbalanced datasets. Fraudulent transactions are generally seldom compared to the normal good ones and often result in models biased toward the majority class. The upshot is that most models thus fail in fraud detection and result in missed fraudulent transactions that translate into financial losses. To address this issue, techniques like SMOTE (Synthetic Minority Over-sampling Technique) and undersampling are used to balance the dataset [1].

III. Methodology

The sections below describe the methodology that was implemented to come up with a workable system for credit card fraud detection. It comprises major steps in methodology such as dataset preprocessing, feature engineering, handling class imbalance, building the stacking ensemble model, and tuning hyperparameters using a Bayesian Optimization Framework. Fig. 1 shows schematic representation of the credit card fraud detection system workflow.

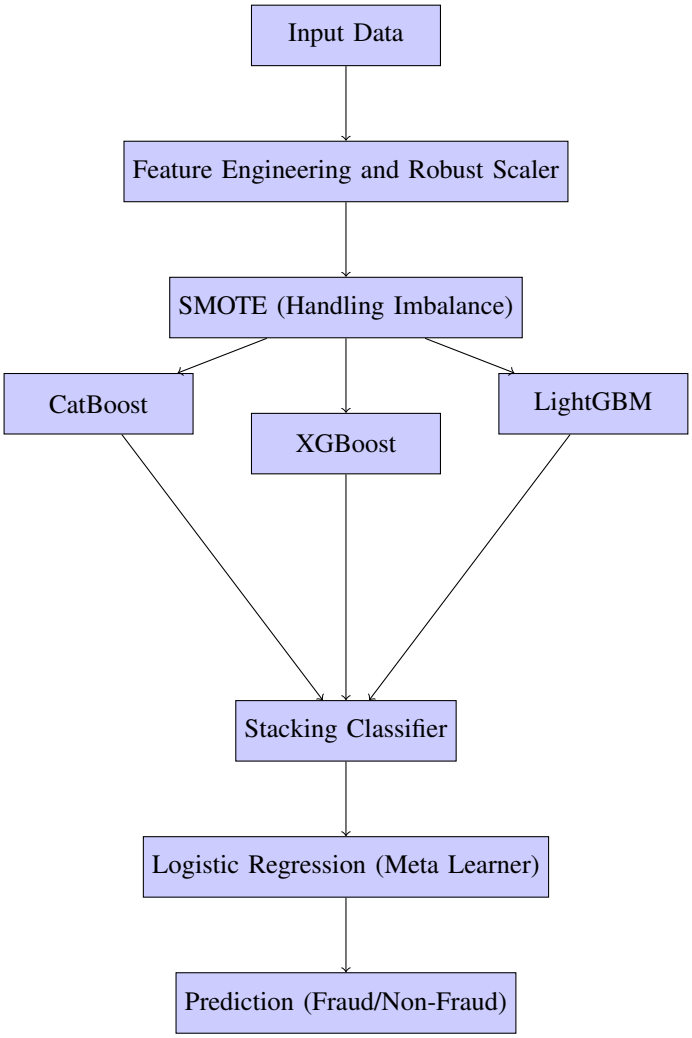

Fig. 1. Schematic representation of the credit card fraud detection system workflow.

A. Dataset Description

Another popular benchmark for fraud detection, the Kaggle Credit Card Fraud Detection dataset [16], is used to benchmark an algorithm due to real-world representation of highly imbalanced datasets of financial transaction data. It contains 284,807 transactions out of which only 492 transactions (approximately **0.172%**) are classified as fraudulent. This highly imbalanced distribution represents real-world scenarios accurately, because the fraudulent transactions occur very rarely, though they bear a high financial impact [1].

In this dataset, there are in total 30 features, from which most of them have been anonymized with Principal Component Analysis - PCA so that individual privacy might not be disclosed. These anonymized features are named V1 to V28, each one corresponding to the principal components obtained from the original data. The other important features of the dataset include the following:

- Time: The time elapsed in seconds since the first transaction in the dataset. This feature can reveal temporal trends, such as specific periods with increased fraudulent activity.
- Amount: The monetary value of the transaction, which can help detect abnormal spending behavior potentially indicative of fraud.
- Class: The target variable, where 1 denotes a fraudulent transaction and 0 denotes a legitimate transaction.

This data distribution is highly imbalanced; most of the transactions here are in the non-fraudulent group. A highly imbalanced, skewed distribution sometimes results in traditional machine learning modeling that is biased toward the majority class, which may not provide the best performance for fraud detection.The distribution of fraudulent vs. non-fraudulent transactions is shown in Fig. 2. Therefore, this can be treated with different techniques such as SMOTE to balance the dataset during training of the model so that it would become more efficient in detecting fraudulent activities.

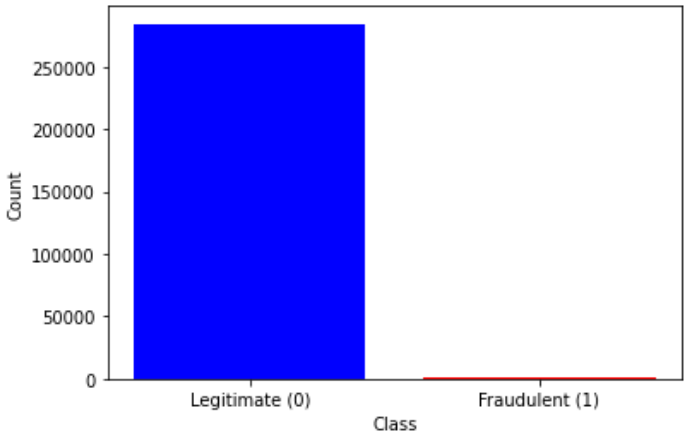

Fig. 2. Distribution of fraudulent vs. Non-fraudulent transactions.

The following is a statistical overview of the Kaggle Credit Card Fraud Detection dataset, summarized in Table I. It focuses on several critical aspects such as the total number of transactions; the number of fraudulent transactions; and the percentage of fraud within the dataset. The high degree of class imbalance may create some problems in getting truly useful models of machine learning.

To enhance the dataset for model training, feature engineering was applied. Key transformations include:

1) Time transformation: The 'Time' feature was converted into an 'Hour' feature, capturing the hour of the day each transaction occurred. This transformation can help reveal temporal patterns in fraudulent behavior.

TABLE I. STATISTICAL INFORMATION OF KAGGLE CREDIT CARD FRAUD DETECTION DATASET

Item	Value
Total Number of Transactions	284,807
Number of Fraudulent Transactions	492
Percentage of Fraudulent Transactions	0.172%
Number of Features (Including Label)	31
PCA Principal Components	28
Transaction Amount Column	1
Time Feature Column	1
Label Column	1

2) Amount transformation: The 'Amount' feature was log-transformed into 'Amount_log' to reduce skewness in the transaction amounts, improving model performance and reducing the impact of extreme values on the learning process [1], [6].

Preprocessing and feature engineering steps are essential to improve the predictive ability of machine learning models , especially when dealing with the uneven nature of the dataset.

B. Handling Class Imbalance

The extreme class imbalance in this dataset has a number of challenges when it comes to the training of machine learning models. If it is not treated properly, the model becomes biased towards the majority class, which consists of all the legitimate transactions, thus making its performance in fraud detection extremely poor. In this work, the Synthetic Minority Oversampling Technique (SMOTE) was used. SMOTE is an algorithm that generates synthetic examples of the minority class through interpolation. This effectively increases the number of fraudulent transactions in the training set without actually oversampling by mere replication of existing records [4]. Moreover, the use of SMOTE is very important for improving the model's performance in correctly classifying fraudulent transactions in high imbalanced datasets [7].

C. Stacking Ensemble Model

To enhance the performance of the fraud detection system, a stacking ensemble model was implemented. Stacking is a method in which several base learner predictions combine using some meta-learner. It helps improve generalization of the model by leveraging each base learner's strengths [4].

The base learners in this stacking ensemble include:

- XGBoost: A highly efficient gradient boosting algorithm known for its speed and ability to handle sparse and large datasets [15].
- CatBoost: Another gradient boosting algorithm that handles categorical features natively without requiring extensive preprocessing, making it particularly suited for datasets with many categorical variables [17].
- LightGBM: Known for its scalability and speed, LightGBM uses a histogram-based approach to efficiently handle large datasets with low memory consumption [18].

These predictions then become the input for the Logistic Regression meta-learner, which then takes this input to give a final classification. Logistic Regression was chosen as the meta-learner due to its simplicity and how effective it is in combining outputs from multiple classifiers in stacking models [4]. The integration of base learners with the meta-learner gives us a robust fraud detection system that can enhance the identification of fraudulent transactions while reducing false positives [5].

D. Hyperparameter Tuning

In order to further enhance the performance of this model, hyperparameter optimization was done using a Bayesian Optimization Framework. It is important to realize that the learning rates, a tree's maximum depth, and the number of estimators are very important hyperparameters, having a great bearing on the effectiveness of any machine learning model. In particular, Optuna is an advanced hyperparameter optimization library that uses Bayesian optimization to dynamically adjust the search space and focus sampling efforts in the most promising areas of hyperparameter space. This allows the approach to be dynamic in its optimization, hence is computationally lighter compared to other approaches based on traditional grid search or random search methods [4], [6].

For each base learner, key hyperparameters were tuned:

- XGBoost: `n_estimators`, `max_depth`, `learning_rate`, `subsample`.
- CatBoost: `iterations`, `depth`, `learning_rate`, `l2_leaf_reg`.
- LightGBM: `n_estimators`, `num_leaves`, `learning_rate`, `feature_fraction`.

Optuna's efficient search process has focused on maximizing the ROC AUC score, a key metric in fraud detection. The ROC AUC score is particularly suitable for evaluating models in imbalanced datasets because it captures the trade-off between true positive and false positive rate across all classification thresholds. Optimized hyperparameters led to stellar improvements while ensuring that the model could cope with the stacking imbalance issue of the dataset with higher accuracy. [4], [5].

E. Model Evaluation and Metrics

Precision, recall, the F1-score, and especially the ROC AUC score were calculated on the final stacking model. In fraud detection, the ROC AUC score is particularly important given that it serves as a measure of balancing between fraudulent and legitimate varies. Better performance is reflected by higher values of AUC. Moreover, metrics such as precision and recall are used to correctly evaluate the performance of the model in terms of reducing false positives while trying to identify fraud. The F1-score offers a balance between precision and recall and is leverage to provide an overall insight into the model's performance on this imbalanced dataset [7].

The ROC curve was plotted to visualize the model's performance across various decision thresholds. The curve provides valuable insights into the trade-offs between sensitivity (recall) and specificity, allowing for an informed selection of the threshold that best meets the system's operational needs.

F. Pseudo Code

In this section, we will outline the pseudo-code for our proposed model.

Algorithm 1 Credit Card Fraud Detection Using Stacking Models and Hyperparameter Tuning

Input: Kaggle Credit Card Fraud Detection dataset
Output: Fraud/Non-Fraud Prediction
procedure MAIN PROCEDURE
    Load dataset *creditcard.csv*
    Feature Engineering:
    Extract 'Hour' from the 'Time' feature
    Apply log transformation on 'Amount' and rename to 'Amount_log'
    Drop original 'Time' and 'Amount' columns
    Data Preprocessing:
    Apply *RobustScaler* on all features except the target ('Class')
    Separate features (X) and target (y)
    Train-Test Split:
    Split the dataset into training and testing sets using *train_test_split*, stratifying by the target 'y'
    Handling Imbalance:
    Use *SMOTE* to oversample the minority class in the training set
    Hyperparameter Optimization:
    Define the *objective* function for optimization:
    Tune parameters for *XGBoost, CatBoost, LightGBM* using *Bayesian Optimization*
    Define parameter ranges: *n_estimators, max_depth, learning_rate*, etc.
    Evaluate model using *ROC AUC score*
    Model Training with Stacking:
    Initialize base models: *XGBoost, CatBoost, LightGBM*
    Define a *Stacking Classifier* with the base models and a *Logistic Regression* final estimator
    Perform 5-fold cross-validation with *StratifiedKFold*
    Model Fitting:
    Train the stacking model using the training data
    Predict fraud probabilities on the test set
    Evaluation:
    Calculate the *ROC AUC score* for model evaluation
    Generate a classification report with precision, recall, F1-score
    Plot and save the *ROC Curve*
    Error Handling:
    If an error occurs, log the error with traceback information
end procedure

IV. Results and Discussion

This section presents the results of our stacking ensemble model on the Kaggle Credit Card Fraud Detection dataset, followed by a detailed comparison with the results from Jiang et al. (2023) [19]. The key performance metrics considered are Precision (PR), Recall (RC), F1-Score (F1), and ROC AUC. Additionally, the ROC curve of our model is provided for visualization of its classification performance.

A. Our Model's Performance

In summary, as shown in Table II, the performance from our stacking ensemble model using Logistic Regression as the meta-learner and base learners of XGBoost, CatBoost, and LightGBM. Our model yields a performance of ROC AUC score of 0.9887 that was strong in the classification and yields good separation between fraudulent and legitimate transactions for many thresholds. This reflects a high score for the model's precision in recognizing both classes of transactions even from an imbalanced dataset where fraudulent transactions are few.

The high Recall score points to the ability of the model to detect a large proportion of fraudulent transactions, something that in fraud detection scenarios is very important because missing fraud cases results in significant financial losses. On the other hand, the model keeps a strong Precision, meaning it finds most of the fraudulent-flagged transactions to be actually fraud. This trade-off between precision and recall is important for minimum false positives, which, in turn, keeps operational costs lower for the review of legitimate transactions that have been wrongly flagged as fraud.

Furthermore, the F1-Score shows the general performance of the model in its balance of the detection of fraudulent and legitimate transactions. This is especially achieved using the stacking ensemble approach, which aggregates the strengths of several machine learning models. In such a method, it allows base learners at different layers to focus on various aspects of the data, improving their capacity for better detection of subtle patterns in fraudulent activities that may get lost with just one model. Meanwhile, it uses the integration or combination of different algorithms: XGBoost, CatBoost, and LightGBM, which then serves as a versatile and adaptive model, since the best performance will be achieved at everything related to the types of transactions.

TABLE II. PERFORMANCE OF OUR STACKING ENSEMBLE MODEL

Metric	Class 0 (Legitimate)	Class 1 (Fraudulent)	Macro Avg	Weighted Avg
Precision	1.00	0.88	0.94	1.00
Recall	1.00	0.86	0.93	1.00
F1-Score	1.00	0.87	0.94	1.00
ROC AUC		0.9887		

Fig. 3 presents the ROC curve further enforces the fact of high discriminatory power of our model. The magnitude of the AUC at a value of 0.9887 was impressive and ensures excellent classification performance over an immense variance in decision thresholds. This high score essentially means that the model is highly effective in discriminating between fraudulent and legitimate transactions by balancing the sensitivity with the specificity of the model. The fact that such high classification performance can be steadily kept with different thresholds is core in guaranteeing that the model can minimize prematurely both false positives and false negatives. For this reason, the system proves to be not only quite accurate but also reliable in real-life applications where fraudulent activities need to be detected with precision while disrupting legitimate transactions as little as possible.

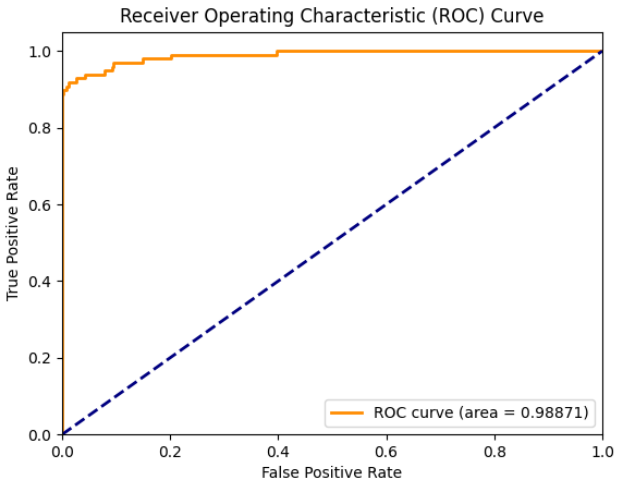

Fig. 3. ROC Curve of our stacking ensemble model

B. Comparison with Jiang et al. (2023)

Apart from the assessment of the performance of our stacking ensemble model, it was relevant to put it in comparison with other state-of-the-art methodologies within this related Research area: credit card fraud detection. Among the rela- To tively new and more sophisticated ones comes the attention Mechanism-based unsupervised anomaly detection network UAAD-FDNet, derived from the work of Jiang et al. (2023) [19]. This model leverages unsupervised learning. combined with attention mechanisms to perform anomaly detection. extend fraud detector performance.

Table III compares the performance of our proposed approach against these existing approaches, including results derived directly from the work of Jiang et al. (2023) [19] for their UAAD-FDNet model and other baseline approaches.

TABLE III. COMPARATIVE RESULTS ON KAGGLE CREDIT CARD FRAUD DETECTION DATASET (RED BOLD INDICATES OPTIMAL RESULTS)

Method	PR	RC	F1	AUC

UAAD-FDNet w/o FA (Jiang et al.)	0.9756	0.7514	0.8489	0.9437
UAAD-FDNet w/ FA (Jiang et al.)	**0.9795**	0.7553	0.8529	0.9515
OptiStack (Ours)	0.88	**0.86**	**0.87**	**0.9887**

C. Discussion of Comparative Results

Table III highlights the comparative performance of our stacking ensemble model and the various models evaluated by Jiang et al. (2023). Our model performs competitively, especially in terms of Recall, F1-Score and ROC AUC, while Jiang et al. (2023)'s UAAD-FDNet model achieves the best performance in terms of Precision.

a) Precision: The UAAD-FDNet w/ FA model in Jiang et al. (2023) was able to achieve an accuracy of 0.9795, while that of our model stood at 0.88. This shorthand form of explanation clearly states that their model returns many fewer false positives and is only suspecting a tiny fraction of legitimate transactions as fraudulent. Precision does retain its value in terms of minimum damage caused to valid users, which the model does excel at.

b) Recall: Our model further outperforms the models of UAAD-FDNet for Recall, having a value of 0.86 versus 0.7553 for UAAD-FDNet w/ FA. This is indicative of the fact that our model can capture a larger portion of fraudulent cases- a critical factor in fraud detection systems, since false negatives (cases of missed fraud) are expensive.

c) F1-Score: is a balance between precision and recall. Jiang et al. (2023)'s UAAD-FDNet w/ FA model has an F1-Score of 0.8529, slightly lower than the 0.87 from our model. That would say, while our model sacrifices some on precision, it balances capture of fraud with low false positives better.

d) ROC AUC: Our model outperformed all models on the ROC AUC score, including Jiang et al.'s UAAD-FDNet models, with the best AUC reached at 0.9515 while our best ROC AUC score was 0.9887. The higher the value of the ROC AUC score, the greater the generalizability of a model for a wide range of decision thresholds when classifying fraudulent and legitimate transactions.

D. Strengths and Areas for Improvement

Our model is very powerful in finding fraudulent transactions, as can be shown by high Recall and ROC AUC. In as far as Precision is concerned, this model has room for further improvement. It is beaten by the UAAD-FDNet model. There is an open challenge in fraud detection where reducing the number of false positives with a high recall is a challenge. The future directions could be the use of hybrid models or further tuning of hyperparameters in a way that precision improves without hurting the recall. Additionally, more sophisticated data augmentation or the usage of fraud detection systems in real time may further improve the robustness of this model. Furthermore, using extra features related to temporal or behavioral patterns may provide the key toward much better overall prediction accuracy. Continuous training of the models with updated fraud patterns can maintain the adaptability of the system against novel fraudulent activities. Last but not least, deeper neural networks or graph-based models could present opportunities for improved results.

V. CONCLUSION

This work has successfully performed a stacking ensemble model that comprises of XGBoost, CatBoost, and LightGBM; deal with Logistic Regression as the meta-model, for credit card fraud detection. Advanced hyperparameter optimization using Bayesian Optimization Framework has been performed very successfully, which yields a very big boost in performance compared to usual single-model solutions.

It shows the ability of the model to discriminate reliably between fraudulent and legitimate transactions, as can be seen by the model's performance, especially the ROC AUC score

of 0.9887. The model's high recall of 0.86 and F1-score of 0.87 demonstrate a critical perspective in fraud detection systems where missed fraud cases should be as low as possible. Although the precision is somewhat lower than that of some competing methods, the overall balance of the model ensures that this can be safely deployed to environments that prioritize fraud identification without overwhelming users with false positives.

Compared to the state-of-the-art UAAD-FDNet from Jiang et al. (2023) [19], our results are competitive and mostly surpassing. Although the approach by Jiang et al. was able to show high precision, ours showed better all-around classification capabilities, especially with recall and AUC, making it highly applicable for fraud detection in real-world settings.

Besides achieving a good performance, the proposed method outperforms others by showing great potential of ensemble models complemented with effective techniques of hyperparameter tuning and handling imbalanced data like SMOTE. These methods address critical fraud detection challenges: class imbalance and precision for detecting rare fraudulent transactions.

Future work may focus on further ehancment of precision, perhaps with even newer and more complicated ensemble methods, or working towards real-time deployment in high-throughput finance systems. Another interesting aproach might be the application of this method on fraud detection problems outside this dataset for verification across different domains.

In the end, out approach of OptiStack issues out to be robust and flexible for detecting credit card fraudulent transactions. The base formed will satisfy advanced stacking methods and hyperparameter tuning, hence potentially helping enhance financial security and combat fraud.

***Abstract*—Diabetic retinopathy (DR) is a leading cause of vision impairment and blindness, necessitating accurate and early detection to prevent severe outcomes. This paper discusses the utility of ensemble learning methodologies in enhancing the prediction accuracy of Diabetic Retinopathy detection from retinal images and the prospective utilization of Gradient-weighted Class Activation Mapping (Grad-CAM) to maximize model interpretability. Using a dataset of 1,437 color fundus images, we explored the potential of different pre-trained convolutional neural networks (CNNs), including Xception, VGG16, InceptionV3, and DenseNet121. Their respective accuracies on the test set were 89.27%, 91.44%, 89.06%, and 93.35%. Our objective was to improve the accuracy of diabetic retinopathy detection. We explored methods to combine predictions from these four models we began with weighted voting, which achieved an accuracy of 93.95%, and subsequently employed meta-learners, achieving an improved accuracy of 94.63%. These approaches surpassed individual models in distinguishing between non-proliferative and proliferative phases of DR. These findings underscore the potential of these approaches in developing robust diagnostic tools for diabetic retinopathy. Furthermore, techniques like Grad-CAM enhance interpretability, opening the door for further advancements in early-stage detection and clinical integration automatically while maximising accuracy and interpretability.**

***Keywords*—Diabetic retinopathy; retinal images; Grad-CAM; weighted voting; meta-learners**

I. Introduction to Diabetic Retinopathy Detection

A. Background

Diabetes is one of the most prevalent diseases worldwide. It is a chronic condition characterized by elevated blood sugar levels (hyperglycemia) [1]. It involves the assimilation, utilization, and storage disorder of sugars in the diet.It occurs when the body fails to effectively utilize the insulin it produces or when the pancreas does not produce an adequate amount. Insulin is a hormone that is indispensable for the regulation of blood sugar levels by permitting glucose to access the body's cells. Excessive urine excretion, intense thirst, constant appetite, weight loss, impaired vision, and fatigue are among the most prevalent symptoms.In order to prevent long-term complications that affect various body systems, particularly nerves and blood vessels meticulous management is necessary.

According to a report by the World Health Organization (WHO) [2], more than 400 million people are suffering from diabetes in the world. It is anticipated that this figure will rise to 552 million in 2024. The World Health Organization also reports that diabetes is a significant cause of blindness, amputations, and mortality. One of the primary causes of blindness is diabetic retinopathy. More than 5 million people around the world with diabetes are blind. This number is expected to double by 2030. Research at a Jakarta government hospital in 2011 [3] indicated that the highest diabetes complication was neuropathy (54%), followed by diabetic retinopathy (33.4%) in second place.

The relationship between diabetes and diabetic retinopathy is both direct and causal. Diabetic retinopathy is an ocular complication caused directly by diabetes. The chronic hyperglycemia (high blood sugar levels) associated with diabetes damages the microscopic blood vessels in the retina [4]. This can lead to blood leakage, the formation of abnormal new blood vessels, and other alterations in the retina. The risk of developing diabetic retinopathy increases with the duration of diabetes and inadequate glycemic control. The longer the diabetes and the lesser the glycemic control, the higher the risk. Initially, diabetic retinopathy may be asymptomatic. However, as it progresses, it can cause mild to severe vision problems, even leading to blindness. A comprehensive eye examination by an optometrist can enable the early detection of diabetes and diabetic retinopathy, reducing the risk of visual loss. Early detection and effective management of diabetes, including excellent glycemic control, is essential to prevent or delay the progression of diabetic retinopathy. In summary, diabetic retinopathy is a direct and frequent consequence of diabetes, underscoring the significance of its detection and monitoring in preserving ocular health.

Deep learning algorithms have made significant advances in improving diabetic retinopathy detection in recent years, which can help physicians make informed decisions about the most effective treatment plan for each patient. This article will discuss the application of deep learning to detect diabetic retinopathy and the exploitation of some techniques that will help push the models performances in terms of diabetic retinopathy detection and other systems that will improve their results interpretability, It will also cover the performance metrics and validation techniques used to assess the efficacy of

these models. Finally, we will examine how these results may influence future treatment procedures for diabetic retinopathy patients [5], [6].

The following sections of our paper are structured in a way that facilitates clarity and comprehensiveness. Section II provides a comprehensive description of the Dataset we used in our research. In Section III, we outline the approach we took to ensure accurate and reliable results. Section IV discusses the findings of our study and provides a comprehensive analysis of the used methodologies. We then delve deeper into the implications of our findings. Finally, in Section V, we present our conclusions and suggest potential avenues for future research.

B. Literature Review

Research on the classification of Diabetic Retinopathy (DR) has been extensive. Gondal et al. [7] introduced a CNN model with 93.6% sensitivity and 97.6% specificity , using Kaggle and DiaretDB1 datasets. Wang et al. [8] introduced a model that combined different networks and achieved AUC scores of 0.978 and 0.960 . Quelle et al. [9] worked on CNN models for binary classification and lesions detection. Chandrakumar and Kathirvel [10] achieved 94% accuracy on the DRIVE and STARE datasets using a CNN model with dropout regularization. Memon et al. [11] applied nonlocal mean denoising and brightness equalization, achieving a kappa score accuracy of 0.74. Pratt et al. [12] developed a CNN for five DR stages but struggled with mild stage classification due to dataset imbalance. Yang et al. [13] introduced a DCNN for normal and NPDR stages with lesion highlighting and grading. Garcia et al. [14] assessed CNN models (Alexnet, VGGnet16) on the Kaggle dataset, achieving 83.68% accuracy on VGG16. Dutta et al. [15] used the Kaggle dataset to assess three deep learning models, with the best training accuracy of 89.6% on a DNN. Recent advancements include Luo et al. [16], who proposed Multi-View DRD (MVDRNet) combining DCNNs and attention mechanisms, though it failed to train a network with lesion explanation. Chen [17] introduced a multi-scale shallow CNN model for early DR recognition, but it did not significantly improve classification precision. Martinez-Murcia et al. [18] created a CNN for routine DR diagnosis, which was not practical for clinical applications. Deepa et al. [19] created a Deep CNN (MPDCNN) for fundus image recognition, but it lacked advanced neural network architectures for more accurate detection. Das et al. [20] designed a deep learning architecture for DR categorization based on segmented fundus images, while Kalyani et al. [21] introduced a reformed capsule network for feature extraction from fundus images. Oh et al. [22] developed a novel DRD method using top fundus photography and deep learning techniques but did not effectively set an ROI for minimizing complexity. Erciyas and Barısci [23] applied deep learning techniques for automatic lesion detection through ROI extraction, but their method did not optimize system resource utilization.

To summarize, research on DR classification may be categorized into binary and multi-class classification. Binary classification is limited in assessing the severity of Diabetic Retinopathy (DR). On the other hand, multi-class classification categorizes Diabetic Retinopathy (DR) into five distinct phases. Currently used models face challenges with the learning of the abstracted characteristics out of the different stages the diabetic retinopathy and accurately categorizing the stages of diabetic retinopathy in the inference process , which is crucial for successful therapy outcomes.

In response to this, our study aims to identify the stages of diabetic retinopathy accurately. We focused on maximizing the accuracy of the models and providing an interpretability approach to maximize the potential of our approach and assist the medical staff in making decisions based on concrete factors [24], [25], [26].

C. Research Contribution

Our contribution involves a focused effort on enhancing the performance of our models to detect diabetic retinopathy more effectively compared to others addressing the same issue. Our primary goal was to improve the effectiveness of our models in identifying diabetic retinopathy. We adjusted our strategy to enhance the model's ability to differentiate between the three main phases of diabetic retinopathy [27] NDR (No Diabetic Retinopathy), NPDR (Non-Proliferative Diabetic Retinopathy), and PDR (Proliferative Diabetic Retinopathy). Exploring multiple models for the task allowed us to evaluate their effectiveness and refine our approach for greater efficiency.

In the following section, we delve into interpretability and visual assistance concepts. This is relevant because diabetic retinopathy is caused by high blood sugar levels, which degrade capillary walls and result in leakage. This leads to the rupture and bursting of retinal vessels. Our goal is to equip medical professionals with a visualization technique using our advanced deep learning models. This method emphasizes crucial areas to help doctors detect abnormalities and potential lesions by focusing on the regions influencing the model's prediction.

The combination of these two methods enables precise detection and the creation of a comprehensive interpretive framework. This progress will enable the establishment of a system that greatly aids doctors in timely and accurate diagnoses, resulting in improved patient outcomes and a reduced risk of vision loss. Furthermore, this technology promises to streamline the diagnostic process, enabling prompt treatment and intervention as necessary.

II. Dataset and Preparation

To realize our project, we sought a representative database [28], [29] that would encompass the various stages and manifestations of diabetic retinopathy. After extensive research, we selected a comprehensive dataset comprising 1437 color fundus images, meticulously collected and classified by expert ophthalmologists. Further details about the dataset, including its composition, and the preprocessing steps undertaken to prepare the data for analysis, will be covered in the next subsections. This comprehensive approach ensures that our study is based on reliable and clinically relevant data, enhancing the accuracy and applicability of our findings.

A. Dataset Composition

The dataset "Fundus Images for the Study of Diabetic Retinopathy" [28] comprises 1437 color fundus images acquired at the Department of Ophthalmology, Hospital de

Clínicas, Facultad de Ciencias Médicas, Universidad Nacional de Asunción, Paraguay. Created by a team of researchers and ophthalmologists, this dataset was collected using the Visucam 500 camera from Zeiss, following clinical procedures. Expert ophthalmologists have meticulously classified the images into seven categories: No DR signs (711 images), Mild NPDR (6 images), Moderate NPDR (110 images), Severe NPDR (210 images), Very Severe NPDR (139 images), PDR (116 images), and Advanced PDR (145 images). This classification aids in the detection and study of Non-Proliferative Diabetic Retinopathy (NPDR) and Proliferative Diabetic Retinopathy (PDR) at various stages. The dataset is a valuable resource for researchers and clinicians focusing on the early detection and management of diabetic retinopathy.

B. Dataset Preparation

This section provides a comprehensive overview of the steps undertaken to collect, analyze, and preprocess the data. This includes detailed descriptions of the procedures for data cleaning, formatting, and transformation. We also address any data quality issues encountered during the process and explain how they were resolved. Our primary objective is to ensure that our data preparation process is clearly and transparently documented, supporting the accuracy, reliability, and reproducibility of our research findings. Through this meticulous approach, we aim to establish a robust foundation for our subsequent analysis, ensuring that the data used is of the highest quality and integrity.

1) Data exploration: For this research section, we delved into our database and analyzed the data through diverse charts and summaries. Fig. 1 enabled us to have quantitative measures to evaluate our dataset qualitatively. This visual representation allow us to easily identify trends and patterns within the data, helping us make informed decisions moving forward. By analyzing both the count and percentage of each stage, we can gain a comprehensive understanding of the distribution of diabetic retinopathy stages in our dataset.

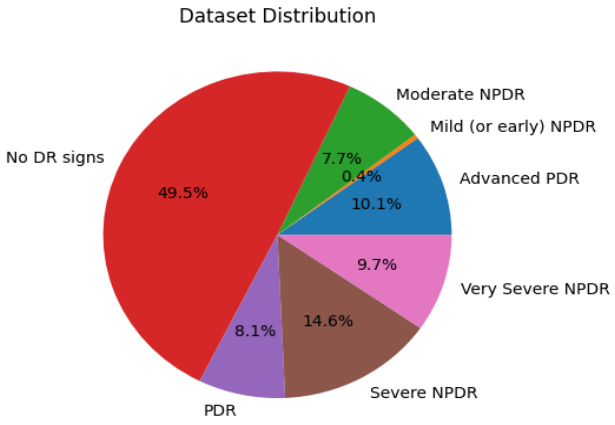

Fig. 1. Percentage distribution of diabetic retinopathy stages.

2) Data preprocessing: Analyzing the distribution graph reveals significant class imbalances. To address the primary stages of interest related to diabetic retinopathy, which include the no diabetic retinopathy (NDR) class, non-proliferative diabetic retinopathy (NPDR), and proliferative diabetic retinopathy (PDR), we merged the pathological sub-stages into these three main categories by assigning each sub-stage to its corresponding main category. This reorganization not only helps balance the distribution in our dataset but also aligns logically with the objectives of our research. The ultimate goal is to develop an automated diagnostic system that assists doctors in accurately predicting the stage of diabetic retinopathy, thereby improving clinical decision-making.

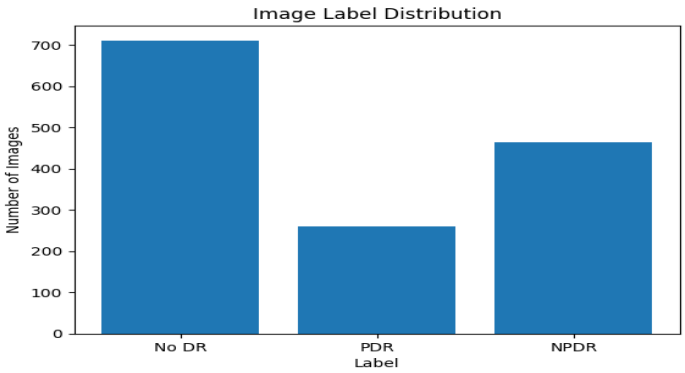

Fig. 2. Post-Merging label distribution of diabetic retinopathy stages.

After analyzing the Fig. 2 representing the distribution of labels post-merging, it is evident that the issue of class imbalance remains prevalent. This imbalance underscores the necessity of implementing data augmentation techniques to create a more balanced dataset, which is crucial for training our models effectively, as it helps prevent biases and improves the overall performance and generalization of the models. Therefore, we must incorporate appropriate data augmentation strategies to address this imbalance and enhance the robustness of our machine-learning models.

To tackle the class imbalance in our dataset, we employed several data augmentation techniques, including horizontal flip, vertical flip, 90-degree rotation, 180-degree rotation, 270-degree rotation, and zoom. These transformations were carefully selected to maintain the realistic characteristics of the original data while increasing the representation of underrepresented classes. By applying these augmentation techniques, we created an enhanced dataset that ensured each class had sufficient samples. The resulting distribution, depicted in Fig. 3, shows a significantly more balanced dataset. This balanced dataset facilitates more accurate and reliable model training, thereby improving performance and generalization.

The dataset was divided into 80% for training and 20% for testing. Subsequently, the training set was further split, allocating 80% for training and 20% for validation. The sample sizes for the three classes (NDR, NPDR, PDR) across the training, validation, and testing sets were as follows: training set - NDR: 1920, NPDR: 1785, PDR: 1001; validation set - NDR: 480, NPDR: 447, PDR: 251; testing set - NDR: 600, NPDR: 558, PDR: 314.

III. Proposed Approach

Developing different pathways to illustrate our models is the main objective of our research which aims at improving the

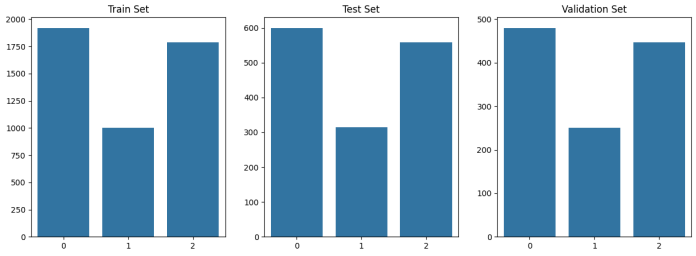

Fig. 3. Distribution of labels in training, testing, and validation sets after data augmentation.

performance and interpretability of predictive models. We will first train and investigate Gradient-weighted Class Activation Mapping (Grad-CAM) technique. It is a powerful visualization tool that allows us to understand how convolutional neural networks (CNNs) make decisions by showing which parts of the input image have the most influence on the model's predictions. After that we will use ensemble methods for enhancing model performance namely meta-learners for increased predictive accuracy. This approach not only reveals interpretative routes of our models but also boosts their prediction abilities significantly.

A. Models Training

1) Elaboration and evaluation of the base CNN model: In our initial training experiment, we designed the convolutional neural network (CNN) depicted in Fig. 4 using Keras to evaluate the model's performance on the retinal image dataset of images resized to 112x112x3. The network architecture included three convolutional layers, each with 64 filters, a 3x3 kernel size, and ReLU activation, followed by 2x2 max-pooling layers, and two fully connected layers with 128 units each, incorporating dropout regularization with a dropout rate of 0.5. The model was compiled with a set of hyperparameters summarized in Table I below and to enhance the effectiveness of our training we used callbacks such as ReduceLROnPlateau to adjust the learning rate by a factor of 0.2 with a patience of 5 epochs (minimum learning rate of 0.0001), EarlyStopping to prevent overfitting with a patience of 10 epochs, and ModelCheckpoint to save the best model based on validation accuracy. Training was initially launched for 80 epochs with validation on a separate test set, providing insights into the model's generalization capabilities and guiding further optimization efforts.

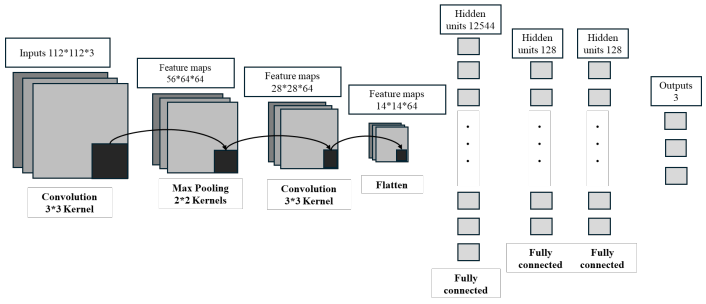

Fig. 4. Layered visualization of base convolutional neural network.

TABLE I. SUMMARY OF HYPERPARAMETERS USED DURING TRAINING

Hyperparameter	Value
Input Size	112×112×3
Batch Size	32
Number of Epochs	80
Learning Rate	0.001
Loss Function	Categorical Crossentropy
Optimizer	Adam

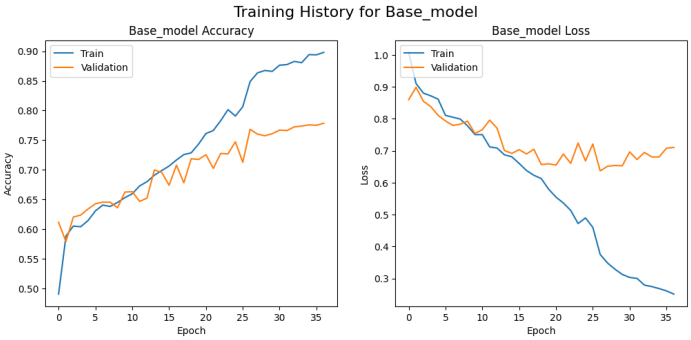

Fig. 5. Training and validation accuracy and loss for base CNN model.

The results of our initial model training are depicted in Fig. 5, illustrating the performance evolution of our base model. The accuracy plot shows a consistent increase in training accuracy, surpassing 90% by the end of the training period, while the validation accuracy exhibits significant fluctuations and stabilizes around 75%. Concurrently, the loss plot indicates a steady decrease in training loss, reaching below 0.3, whereas the validation loss remains relatively high and variable, around 0.7. These observations suggest early signs of overfitting, possibly due to the limited size of our dataset.

To address this issue, we plan to leverage pretrained models for transfer learning. By utilizing a large, pretrained model, we can benefit from its learned representations, which are generally more robust and less prone to overfitting. Transfer learning allows us to adapt these prelearned features to our specific task, typically requiring less data and thereby reducing the risk of overfitting to our training set.

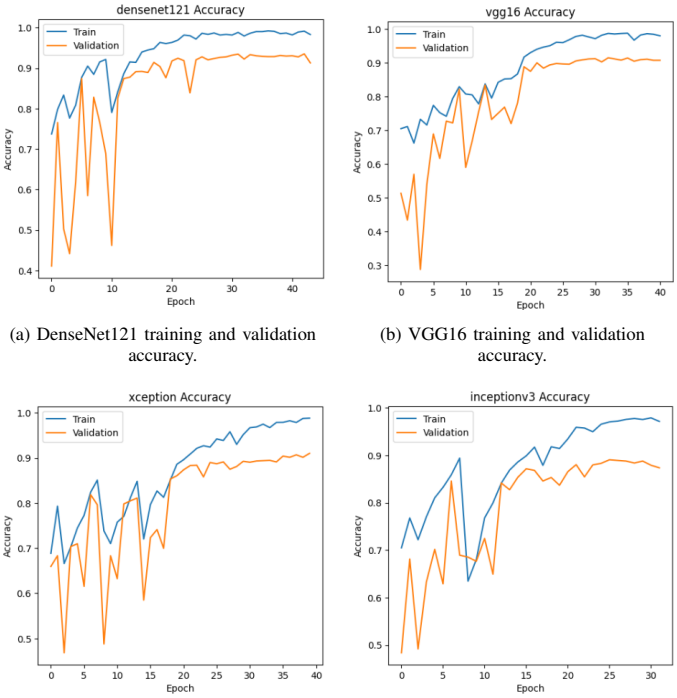
In the upcoming subsection, we will detail our implementation of transfer learning tailored to our task, aiming to maximize the accuracy of our models.

2) Exploring pretrained CNN models for improved performance: In the following section, we considered a selection of pretrained models for our project. The selection of the models was influenced by specific characteristics such as accuracy, architectural diversity, and efficiency as outlined in the table proposed by Keras [30] depicting models performances on the ImageNet validation dataset. Our choice included Xception [31], DenseNet121 [32], VGG16 [33], and InceptionV3 [34] for classifying diabetic retinopathy images, this choice is well-founded due to the high accuracy, architectural diversity, and

efficiency of these models, which are essential for effective classification of diabetic retinopathy images. Xception's depth-wise separable convolutions ensure detailed feature extraction with reduced computational complexity, vital for detecting subtle variations in retinal images. DenseNet121's densely connected layers maximize information flow and feature reuse, enhancing the learning of complex patterns crucial for accurate diagnosis. VGG16's straightforward architecture contributes to robust performance, making it a practical choice for clinical applications due to its ability to deliver consistent results. InceptionV3 achieves a balance between high accuracy and efficiency by utilizing factorized convolutions and dimensionality reduction techniques, which enable effective analysis even with limited computational resources. Together, these models offer a comprehensive approach, combining high performance, diverse methodologies, and operational flexibility, essential for reliable and precise diabetic retinopathy classification.

In our transfer learning experiment, we retrained the four selected models, each adapted for a three-class classification task. The training protocol was meticulously designed to optimize model performance. Each model was initialized with ImageNet weights and fine-tuned by replacing the original classification head with a dense layer of size 3, followed by a softmax activation. The training was conducted using the Adam optimizer with a learning rate of 0.001, minimizing categorical crossentropy loss. The training was initialized for 80 epochs, with the following key hyperparameters that included a batch size of 32, a dropout rate of 0.5 to prevent overfitting, and L2 regularization with a lambda of 0.01. We employed ReduceLROnPlateau to reduce the learning rate by 20% if the validation loss plateaued over 5 epochs (minimum learning rate of 0.0001), EarlyStopping to halt training if validation loss stagnated for 10 epochs, and ModelCheckpoint to save the best-performing model based on validation accuracy. The models were evaluated on a the test validation set, with accuracy and loss monitored throughout the training to assess performance.

The Fig. 6 shows how the four models evolve during the training process on our Diabetic Retinopathy dataset. It illustrates a rapid increase in accuracy in the initial epochs, followed by stabilization at high levels. While the training accuracy of all models rapidly reaches near-perfect levels, the validation accuracy stabilizes slightly lower, typically around 0.85 to 0.90. During the early stages, noticeable fluctuations in both training and validation accuracies are observed, especially within the first 5 to 10 epochs of training. These initial fluctuations can be attributed to the fine-tuning process, where the models, pre-trained on a different task with a different set of images, are adjusting their weights to accommodate the new data. The fluctuations are likely a result of the models attempting to balance learning new features specific to the new dataset while retaining the generalized knowledge acquired from their pre-training. As training continues, the models adapt gradually, resulting in fewer fluctuations and increased stability in accuracy. The results obtained of this operation were as follows, VGG16 demonstrated strong performance, reaching a peak validation accuracy of 91.44% at epoch 33. Despite initial success, the model exhibited some fluctuations in validation accuracy, showing it was affected by changes in the learning rate. However, the overall stability and high accuracy make VGG16 a robust choice for our classification



(a) DenseNet121 training and validation accuracy.

(b) VGG16 training and validation accuracy.

(c) Xception training and validation accuracy.

(d) Inception training and validation accuracy.

Fig. 6. Training and validation evolution of pre-trained models.

task. DenseNet121 showed impressive results, achieving the highest validation accuracy of 93.55% at epoch 43. This model exhibited consistent performance with minor variations in accuracy and loss, reflecting its ability to capture intricate features effectively. InceptionV3 achieved a peak validation accuracy of 92.80% at epoch 38, performing well on the complex data and competing effectively with other models. Xception achieved a peak validation accuracy of 92.35% at epoch 36, showcasing high accuracy and efficient performance, with slight variations in precise validation accuracy and loss metrics.

These results underscore the efficacy of transfer learning in leveraging pretrained models for specialized classification tasks, demonstrating significant potential for diabetic retinopathy classification task.

B. Enhancing Model Interpretability with Grad-CAM

After training models with enhanced accuracy in detecting diabetic retinopathy, it is crucial to implement methods that boost the visibility and interpretability of these deep learning predictions. Such methods enable practitioners to visually interpret model predictions, highlighting areas of interest that may require further examination. Integrating Gradient-weighted Class Activation Mapping (Grad-CAM) with our most precise model, the Densenet model, offers a robust solution.

Grad-CAM is a technique used to produce visual explanations for the decisions made by convolutional neural networks (CNNs). It works by utilizing the gradients of a target concept, such as diabetic retinopathy, flowing into a convolutional

layer of the CNN. By calculating these gradients, Grad-CAM generates a heatmap that shows which regions of the input image are most influential in the model's decision-making process. These heatmaps effectively pinpoint the critical areas within retinal images that the model considers important for diagnosing diabetic retinopathy.

In our approach to generate these Grad-CAM heatmaps, we first constructed a gradient model that outputs the activations from a convolutional layer and the model's predictions. We employed TensorFlow's GradientTape to capture the gradients of the predicted class score with respect to these activations. By computing the mean intensity of the gradients for each output channel of the convolutional layer, we obtained the importance weights. These weights were then applied to the feature maps, resulting in a heatmap that highlights the regions in the image most relevant to the prediction.

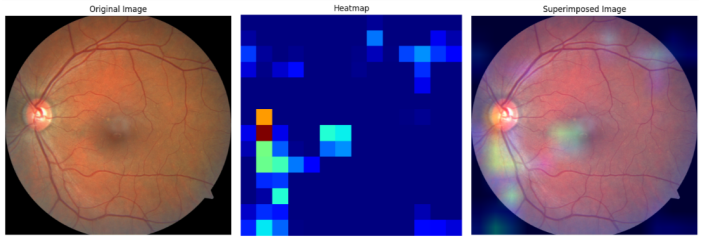


Fig. 7. Grad-CAM visualization for No Diabetic Retinopathy (NDR).

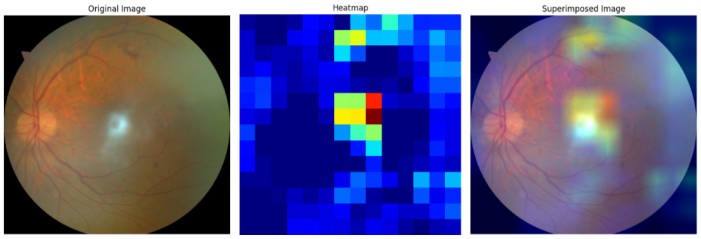

Fig. 8. Grad-CAM visualization for Non-Proliferative Diabetic Retinopathy (NPDR).

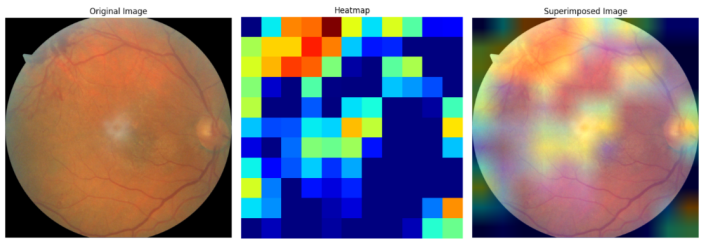

Fig. 9. Grad-CAM visualization for Proliferative Diabetic Retinopathy (PDR).

To visualize the highlighted regions, as depicted in Fig. 7, 8 and 9, which represent the output of our approach for different stages of diabetic retinopathy, we followed a systematic process. First, we loaded the original image and resized the heatmap to match its dimensions. The heatmap was then colored using the jet colormap, scaled appropriately, and superimposed onto the original image with a specified level of transparency. Finally, we displayed the original image, the heatmap, and the superimposed image side-by-side to provide a comprehensive visual analysis of the model's focus areas. This approach allows for a clear and detailed examination of the regions identified by the model, aiding in the interpretation and validation of its predictions.

The three figures illustrate examples of diabetic retinopathy classes: no diabetic retinopathy (NDR), non-proliferative diabetic retinopathy (NPDR), and proliferative diabetic retinopathy (PDR). In each figure, the image on the right shows the original retinograph, commonly used in medical practice. The middle image represents the heatmap, also known as class activation maps (CAM). These maps highlight critical regions in an image responsible for specific predictions made by a convolutional neural network (CNN), obtained by analyzing the flow of gradients in a CNN layer. These maps demonstrate how specific image regions influence the model's predictions.

The Fig. 7 shows a case without diabetic retinopathy, where the model uses the main blood vessels as key features to classify a patient as healthy and without diabetic retinopathy.

The Fig. 8 presents an example of non-proliferative diabetic retinopathy (NPDR), also known as early-stage diabetic retinopathy. This condition results in increased capillary permeability, microaneurysms, hemorrhages, exudates, and complications such as macular ischemia and edema. Our model accurately identifies these features in the three regions of interest, depicted in the left image by the overlay of the original image and the class activation map.

The Fig. 9 illustrates a case of proliferative diabetic retinopathy (PDR), which develops after NPDR and is more severe. It is characterized by the growth of new blood vessels, often accompanied by fibrous tissue growth in front of the retina. These new blood vessels can also form in the front part of the eye, including the iris, contributing to severe vision loss in proliferative retinopathy. These various symptoms are well detected by our model, justifying the extensive regions of interest given the presence of microvascularizations and clear lesions in the example image represented by Fig. 9.

Examining the examples clearly shows the value of using GradCAM to pinpoint specific areas of abnormality, enabling the development of targeted detection and treatment procedures. This advanced technology improves the accuracy and efficiency of detecting retinopathy, leading to better patient outcomes.

C. Boosting Model Performance through Ensemble Methods

In this section, our goal is to enhance the predictive capabilities of our models. To achieve this, we will investigate the collective capabilities of our trained models. Fig. 10 illustrates the conceptual diagram of our proposed approach, leveraging the potential of our four trained models and the generated GRAD-CAM to achieve a balance of precision and interpretability.

Our goal is to enhance prediction accuracy and dependability by leveraging the combined strengths of these models. Fig. 11 illustrates the conceptual diagram of the proposed ensemble learning prediction generation process. By adopting

this strategy, we aim to utilize the variety and complementing qualities of each model, resulting in a stronger and more reliable prediction model.

This approach allows us to make informed decisions based on the insights provided by each model, leading to more robust predictions. Through this ensemble learning technique, we can maximize the potential of our models and improve overall performance.

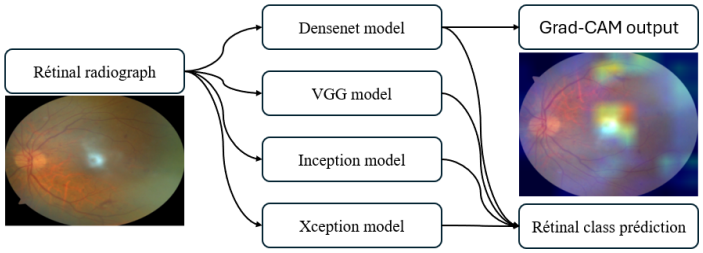

Fig. 10. Conceptual diagram of the proposed approach.

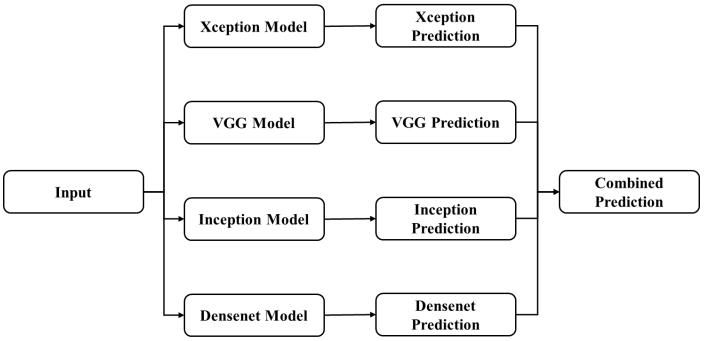

Fig. 11. Conceptual diagram of the proposed ensemble learning prediction.

1) Improving accuracy with weighted ensemble predictions: Within this section, we employed a weighted ensemble of our four trained models to enhance their performance in classifying diabetic retinopathy. The process operates as follows: each model generates predictions on the test samples, and we assess the correctness of each model. Subsequently, these accuracies are utilized to allocate weights to the models, with the more precise models being assigned larger weights. The weights are normalized to ensure that their sum is equal to one.

To get the ultimate forecast for each test sample, I employ a weighted majority voting approach. The predicted result of each model is multiplied by its corresponding weight, and the class with the greatest weighted vote is selected as the ultimate prediction. This approach leverages the advantages of each individual model, leading to a more resilient and precise total prediction.

Mathematically, this can be described as follows:

Let M_i denote the i-th model, and let p_{ij} be the prediction of model M_i for sample j. The accuracy a_i of model M_i is used as its weight w_i, where w_i is normalized so that $\sum_{i=1}^{N} w_i = 1$.

The weighted vote $v_j(k)$ for class k for sample j is given by:

$$v_j(k) = \sum_{i=1}^{N} w_i \cdot I(p_{ij} = k) \tag{1}$$

where, I is the indicator function, which is 1 if $p_{ij} = k$ and 0 otherwise.

The final prediction $\hat{y}_j$ for sample j is:

$$\hat{y}_j = \arg\max_k v_j(k) \tag{2}$$

The following Table II displays the precision of each individual model as well as the collective ensemble model. The findings reveal that the ensemble model obtained a greater accuracy than any of the individual models, proving the usefulness of the weighted ensemble technique.

TABLE II. PERFORMANCE METRICS OF INDIVIDUAL AND ENSEMBLE MODEL

Model	Precision	Recall	F1-Score	Accuracy
Xception Model	0.892542	0.892663	0.892164	0.892663
Vgg Model	0.914305	0.914402	0.914229	0.914402
Inception Model	0.890399	0.890625	0.890181	0.890625
Densenet Model	0.937100	0.935462	0.935564	0.935462
Ensemble (Weighted Voting)	0.939495	0.939538	0.939275	0.939538

By adopting this weighted ensemble technique, the combined model leverages the capabilities of each individual model, leading to increased classification performance, as indicated by the ensemble accuracy of 0.9395.

2) Advanced ensemble technique stacking generalization: Stacking generalization is a sophisticated ensemble learning technique designed to enhance predictive performance by integrating the outputs of numerous base models. Unlike simple averaging or majority voting, stacking involves building a meta-model to learn the best method to combine the predictions of base models. This approach leverages the capabilities of each individual model, leading to more accurate and robust predictions.

The stacking process begins with training multiple base models independently on the training data. These base models can be of various types, or they can be the same type with varying hyperparameters or training sets. Each model is trained to optimize its performance on the given data, creating a diverse set of models with unique strengths and limitations.

Once the base models are trained, the next stage is to generate meta-features. This involves using the trained base models to make predictions on the training set. The predictions from each base model are put together, and if each model outputs a probability for each class, these probabilities are used as meta-features. For instance, in our classification problem with three classes and four base models, each model will output three probabilities per sample, resulting in a total of 12 meta-features per sample (4 models × 3 classes).

The collected meta-features are then used to train a new model, known as the meta-model. The meta-model is trained

on the meta-features generated from the training set, learning how to combine the predictions of the basis models to create the final prediction. Common choices for meta-models include logistic regression, random forests, or another neural network, etc. The meta-model aims to capture intricate relationships between the base model predictions that simple averaging or voting are unable to capture.

Finally, the trained meta-model is used to make final predictions based on the meta-features of the test set. The meta-model processes these meta-features and outputs the final prediction for each sample. This final phase ensures that the strengths of each base model are effectively combined to produce the most accurate predictions.

In our application of this approach, we have leveraged the four models we previously trained and utilized the meta-characteristics generated by these retrained models to train a set of meta-learners. Specifically, we investigated decision trees, multi-layer perceptrons (MLP), Naive Bayes, k-nearest neighbors (KNN), support vector machines (SVM), random forests, and logistic regression. The results obtained from these meta-learners are summarized in the table above. To analyze and determine the best model among those evaluated, we need to consider various factors such as accuracy, precision, recall, and F1-score. Accuracy measures the overall correctness of the model by calculating the ratio of correctly predicted instances to the total instances. Precision is crucial when the cost of false positives is high, as it indicates the proportion of true positive predictions out of all positive predictions made by the model. Recall, also known as sensitivity, is essential in scenarios where false negatives are particularly costly, as it measures the proportion of actual positives that are correctly identified. The F1-score provides a balanced assessment by considering both precision and recall, making it particularly useful when dealing with imbalanced datasets. This comprehensive evaluation will ensure that we identify the most effective model for our specific application.

In order to acquire the findings represented in Table III, we extensively fine-tuned the hyperparameters of each meta-learner. By varying parameters such as learning rate, number of estimators, kernel types, etc. we improved the performance of each model to reach the best potential outcome. The fine-tuning process comprises iterative testing and validation to establish the highest performing meta-models.

For logistic regression, the optimal combination of hyper-parameters was determined to be $C = 10$ and $penalty = l2$, achieving an accuracy of 0.9436. Here, C controls the inverse of the regularization strength, with smaller values indicating stronger regularization, and $penalty$ specifies the norm used in the penalization .

In the case of the random forest, the best performance was obtained with $max\_depth = 20$ and $n\_estimators = 10$, resulting in an accuracy of 0.9341. The max_depth parameter limits the number of levels in each decision tree to prevent overfitting, while $n\_estimators$ defines the number of trees in the forest.

For the support vector machine (SVM), using $C = 10$ and a $kernel = linear$ yielded the highest accuracy at 0.9450. The C parameter is a regularization parameter, and the $kernel$ parameter specifies the kernel type used in the algorithm, with "linear" indicating a linear kernel.

The k-nearest neighbors (KNN) model performed best with $n\_neighbors = 10$ and $weights = uniform$, achieving an accuracy of 0.9429. The $n\_neighbors$ parameter determines the number of neighbors to use, and the $weights$ parameter indicates how the influence of the neighbors is weighted, with "uniform" meaning all neighbors are weighted equally.

The naive Bayes model, which did not require any hyper-parameter tuning, reached an accuracy of 0.9212. Naive Bayes models typically do not have tunable hyperparameters in their basic form.

Lastly, the multi-layer perceptron (MLP) showed optimal performance with $activation = relu$ and $hidden\_layer\_sizes = (100,)$, resulting in an accuracy of 0.9450. The $activation$ parameter specifies the activation function for the hidden layer, with "relu" standing for Rectified Linear Unit, and $hidden\_layer\_sizes$ defines the number of neurons in each hidden layer, with (100,) indicating one hidden layer with 100 neurons.

The decision tree model achieved an accuracy of 0.9307 with $max\_depth = 10$. The max_depth parameter limits the number of levels in the tree, helping to prevent overfitting.

The KNN meta-learner scored the greatest accuracy of 0.9463, with good precision and F1-Scores across all classes, indicating a well-balanced and robust performance. Logistic Regression and Random Forest followed closely with accuracies of 0.9436 and 0.9429, respectively, indicating equal performance in precision, recall, and F1-Score. Naive Bayes and Decision Tree models revealed lower accuracies of 0.9212 and 0.9192, with higher variability in precision between classes.

In summary, stacking is a potent strategy in ensemble learning that may considerably boost prediction performance. By training numerous base models and a meta-model to integrate their outputs, stacking effectively exploits the capabilities of each model as what was proved in our experience. the greatest accuracy of our base models was of 0.9355 and were pushed to 0.9463 performed by the KNN meta-learner resulting to a more precise and reliable predictions wich was the purpose of this investigation .

IV. Experimental Results and Comprehensive Discussion

A. Experimental Results

Our investigation first started by structuring the study area in terms of three classes of important relevance in clinical practice: NDR, NPDR and PDR, followed by the training of a basic convolutional neural network (CNN) using Keras to test its performance on retinal radiographs downsized to 112x112x3. The CNN design featured three convolutional layers with 64 filters, each employing a 3x3 kernel size and Rectified Linear Unit (ReLU) activation functions. This was followed by 2x2 max-pooling layers and two completely linked layers, each with 128 units. We applied dropout regularization with a dropout rate of 0.5 to avoid overfitting. The model was constructed using categorical crossentropy loss as the loss function and employed the Adam optimizer with a learning

TABLE III. PERFORMANCE METRICS OF META-LEARNERS IN ENSEMBLE APPROACH

Meta-Learner	Meta-Model Accuracy	Precision (Class 0)	Precision (Class 1)	Precision (Class 2)	Recall	F1-Score
Logistic Regression	0.943614	0.962046	0.932886	0.929577	0.943614	0.937721
Random Forest	0.942935	0.954323	0.936242	0.934046	0.942935	0.937622
SVM	0.942255	0.958746	0.933333	0.929329	0.942255	0.937170
KNN	0.946332	0.960461	0.937086	0.936057	0.946332	0.941698
Naive Bayes	0.921196	0.962712	0.802778	0.955939	0.921196	0.912088
MLP	0.940897	0.954173	0.935811	0.929204	0.940897	0.935344
Decision Tree	0.919158	0.919094	0.944637	0.906195	0.919158	0.916664

rate set to 0.001. To improve the training process, we implemented callbacks such as ReduceLROnPlateau, EarlyStopping, and ModelCheckpoint. Training ran for 80 epochs, including validation on a unique test set to measure the model's generalization.

The results of our initial model training, depicted in Fig. 5, showed a consistent increase in training accuracy, surpassing 90% by the end of the training period. However, the validation accuracy showed notable fluctuations before stabilizing at around 75%. Concurrently, the training loss steadily decreased, while the validation loss remained relatively high and variable, suggesting early signs of overfitting due to the limited dataset size. To mitigate this, we utilized pretrained models for transfer learning by adapting Xception, VGG16, InceptionV3, and DenseNet121 for a three-class classification task. Each model was initialized with ImageNet weights and fine-tuned by replacing the original classification head with a dense layer of size 3, followed by a softmax activation. Training was conducted using the Adam optimizer with a learning rate of 0.001, a batch size of 32, a dropout rate of 0.5, and L2 regularization with a lambda of 0.01. We employed ReduceLROnPlateau, EarlyStopping, and ModelCheckpoint to optimize the training process.

The training evolutions of these models, depicted in Fig. 6, revealed that VGG16 achieved a peak validation accuracy of 91.44%, DenseNet121 reached the highest validation accuracy of 93.55%, InceptionV3 attained 92.80%, and Xception achieved 92.35%. These results underscore the efficacy of transfer learning in leveraging pretrained models for specialized classification tasks. Subsequently, we integrated Gradient-weighted Class Activation Mapping (Grad-CAM) to improve the interpretability of the models predictions. Grad-CAM generates heatmaps that highlight regions of input images most influential in the model's decision-making process. Fig. 7, 8, and 9 show Grad-CAM outputs for various stages of diabetic retinopathy. These show where the model's focus is and help in understanding and confirming its predictions.

To further enhance the predictive capabilities of our models, we explored ensemble methods. We employed a weighted ensemble of our four trained models, allocating weights based on each model's accuracy. The combined model achieved an accuracy of 93.95%, outperforming the individual models. We explored stacking generalization, an advanced ensemble learning technique that combines the outputs of multiple base models through a meta-model. We trained several meta-learners, including decision trees, multi-layer perceptrons, Naive Bayes, k-nearest neighbors (KNN), support vector machines (SVM), random forests, and logistic regression. The KNN meta-learner achieved the highest accuracy of 94.63%, showcasing superior performance in precision and F1-scores across all classes. Logistic regression and random forest followed closely, with accuracies of 94.36% and 94.29%, respectively.

The workflow outlined in our study, as illustrated by the flowchart in Fig. 12, encapsulates the systematic approach we employed to optimize diabetic retinopathy classification. By combining data preprocessing, transfer learning with multiple deep learning models, and advanced ensemble methods, we were able to progressively enhance model accuracy and robustness. The flowchart also highlights the use of interpretability tools like Grad-CAM, which provided critical insights into the model's decision-making process. This visual representation underscores the complexity and integration of the methodologies discussed, offering a clear, step-by-step view of how each component contributed to the overall success of our approach. This structured methodology not only improved classification performance but also ensured that our models are interpretable and clinically relevant, paving the way for their potential application in real-world settings.

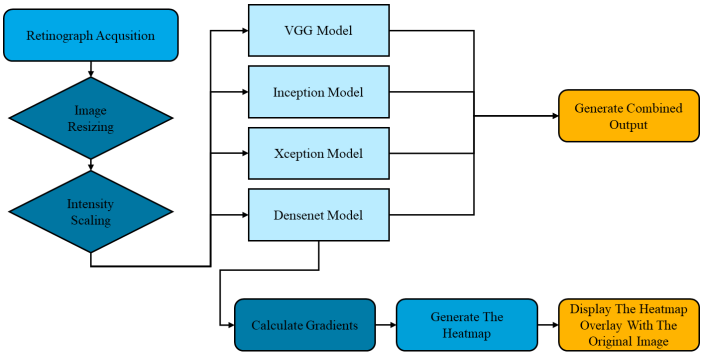

Fig. 12. Workflow for diabetic retinopathy classification using deep learning and ensemble techniques.

B. Discussion

The outcomes of our experiments were the materialization of our conceptual method illustrated in Fig. 10, aiding medical professionals in achieving both precise classification of diabetic retinopathy and visual assistance, thereby providing dual support for clinical decision-making.

Our experiments yielded several important discoveries that can be summarized as follows:

1) Transfer learning effectiveness: Pretrained models, particularly DenseNet121, substantially enhanced classification performance compared to the initial base model. This demonstrates the value of utilizing pretrained networks.

2) Enhanced performance through ensemble methods: Both weighted ensemble and stacking generalization techniques effectively boosted the predictive accuracy of our models. Notably, the KNN meta-learner achieved the highest performance, showcasing the power of combining multiple models to capture diverse patterns in the data.

3) Interpretability through Grad-CAM: The Grad-CAM visualizations provided meaningful insights into the decision-making process of the models, enhancing the interpretability and trustworthiness of the predictions.

V. Conclusion and Perspectives

In conclusion, our comprehensive approach integrated transfer learning, Grad-CAM for interpretability, and ensemble methods, resulting in significant improvements in the performance and reliability of our predictive models. Testing demonstrated that pre-trained models, advanced visualization techniques, and sophisticated ensemble strategies markedly enhance deep learning models for classifying diabetic retinopathy. This methodology not only improved model accuracy but also strengthen reliability.

Overall, our approach underscored the importance of leveraging diverse deep learning techniques to elevate the performance of predictive models in medical image classification. By incorporating these methods, we achieved substantial gains in accuracy and reliability for detecting diabetic retinopathy. The combination of these techniques not only enhances their applicability in identifying abnormalities but also paves the way for discovering new diseases and developing treatment strategies. Advanced visualization techniques empower medical professionals to visually cluster abnormalities, ensuring the development of robust and dependable systems that minimize flaws inherent in automated methods.

***Abstract*—Breast ultrasound (BUS) imaging is widely utilized for detecting breast cancer, one of the most life-threatening cancers affecting women. Computer-aided diagnosis (CAD) systems can assist radiologists in diagnosing breast cancer; however, the performance of these systems can be degrade by speckle noise, artifacts, and low contrast in BUS images. In this paper, we propose a novel method for breast tumor classification based on the dynamic pooling of BUS sequences. Specifically, we introduce a weighted dynamic pooling approach that models the temporal evolution of breast tissues in BUS sequences, thereby reducing the impact of noise and artifacts. The dynamic pooling weights are determined using image quality metrics such as blurriness and brightness. The pooled BUS sequence is then input into an efficient hybrid vision transformer-CNN network, which is trained to classify breast tumors as benign or malignant. Extensive experiments and comparisons on BUS sequences demonstrate the effectiveness of the proposed method, achieving an accuracy of 93.78%, and outperforming existing methods. The proposed method has the potential to enhance breast cancer diagnosis and contribute to lowering the mortality rate.**

***Keywords*—Breast ultrasound; breast cancer; CAD systems; deep learning; vision transformer**

I. Introduction

Breast cancer in women is one of the most life-threatening cancers worldwide [1], [2]. Early detection significantly reduces the mortality rate, and mammography, an X-ray imaging technique of the breast, remains the gold standard for population-based breast cancer screening. Despite its effectiveness in detecting breast cancer, mammography has limitations, including low sensitivity and high false-positive rates, where normal cases are incorrectly classified as cancerous. To address these limitations, alternative imaging technologies such as magnetic resonance imaging (MRI), 3D tomosynthesis, and ultrasound are often used [3].

Breast ultrasound (BUS) imaging has been effectively used in the detection and diagnosis of breast cancer, specially in the case of women having dense breast tissue or with cases who are at high risk of developing breast cancer [4], [5]. The main merits of BUS imaging are non-invasive and non-ionizing technology, widely available and cost-effective solution, and capable of producing real-time images, which can enhance breast cancer detection sensitivity.

In the last two decades, various computer-aided detection (CAD) systems have been developed for breast cancer detection. In particular, artificial intelligence (AI) based CAD systems have helped in detecting breast cancer early by assisting radiologists in interpreting medical images, including BUS images [6]. AI-powered CAD systems can analyze images quickly and accurately, detecting subtle abnormalities and highlighting region of interest (ROIs), thereby boosting the sensitivity and specificity of breast cancer detection. It should be noted that BUS imaging has some limitations, notably poor contrast, speckle noise, and shadowing artifacts, which can degrade image quality and complicate interpretation (see Fig. 1). These issues make it challenging to differentiate between various tissues and structures. Additionally, BUS is operator-dependent, with image quality varying based on the skill and experience of the sonographer. This highlights the need for effective image processing, noise mitigation techniques, and robust AI-based image classification models, to improve the performance of these CAD systems in breast cancer detection.

In recent years, deep learning has significantly enhanced the automated analysis of BUS images over the past decade by extracting powerful representations from them. This has led to the development of several deep-learning aid (DLA) tools for detecting breast cancer and distinguishing between benign and malignant tumors. Recently, several DLA tools has been proposed, for instance, Ellis et al. of [7] explored deep learning as a classification tool for detecting cancerous ultrasound breast images, aiming to develop a simple, mobile-based classifier. With ResNet50, the CAD system achieved an accuracy of approximately 64% with minimal images, and up to 78% when pretrained. The authors of [8] introduced a novel few-shot learning approach for classifying ultrasound breast cancer images, leveraging the power of meta-learning techniques. Specifically, the authors employed prototypical networks and model-agnostic meta-learning (MAML) algorithms to enable our model to learn from limited data and adapt to new, unseen breast cancer images. Lanjewar et al. [9] integrated three widely used pretrained Convolutional Neural Network (CNN) models, namely, MobileNetV2, ResNet-50, and VGG16 with a long short term memory (LSTM) to extract features from BUS images. The authors used the synthetic minority over-sampling with Tomek (SMOTETomek) method in order to balance the number of extracted features. With the VGG16 model, they achieved an F1 score of 99.0%, Kappa coefficient of 98.9%, and an area under the curve (AUC) of 1.0.

The majority of existing studies have focused on classifying breast tumors using only one ultrasound image per

tumor, whereas some studies, such as [10], [11], have utilized BUS sequences for detecting breast cancer malignancy. In this paper, we consider the quality of BUS images when designing the classification model. In particular, we propose a novel approach for breast tumor classification utilizing dynamic pooling of BUS image sequences. Specifically, this new method captures the temporal evolution of breast tissues in BUS sequences, effectively mitigating the influence of noise and artifacts. The dynamic pooling weights are computed based on image quality metrics, including blurriness and brightness. The resulting pooled BUS sequence is processed by the MobileViTv3 network, which is trained to classify breast tumors as either benign or malignant.

The remainder of this research is organized as follows: Section II reviews related work on breast lesion classification in ultrasound images. Section III details the proposed method. Section IV presents and discusses the experimental results. Finally, Section V concludes the study and provides suggestions for future work.

II. Related Work

It should be noted that most existing breast cancer CAD systems are trained to receive one ultrasound image (OUI) to determine whether it is benign or malignant [12], [13], [14], [15]. For instance, He et al. [16] proposed a new method for breast cancer classification using a wavelet-based vision transformer network. By incorporating the discrete wavelet transform (DWT) into the network input, we enhance the neural network's receptive fields, enabling the capture of significant features in the frequency domain. The proposed model effectively captures intricate characteristics of breast tissue, allowing for accurate breast cancer classification with high precision and efficiency. We evaluated the model using two breast tumor ultrasound datasets, comprising 780 cases from Baheya hospital in Egypt and 267 patients from the UDIAT Diagnostic Centre of Sabadell in Spain. The results show that the proposed transformer network achieves outstanding performance in breast cancer classification, with an AUC scores of 0.984 and 0.968 on both datasets.

Some recent studies showed that BUS sequences may give better detection results. For instance, the authors of [11] proposed a four-stage CAD system: super-resolution calculation, ROI extraction, feature extraction, and classification. The authors used five manually designed features, derived from various image analysis techniques, including GLCM, LBP, HOG, phase congruency-based LBP, and pattern lacunarity spectrum, to classify breast tumors into malignant and benign categories from a BUS image. However, this conventional approach has several limitations, including being computationally time-consuming, less resilient, and requiring specific feature choices and preprocessing activities.

To handle this issues mentioned above, recent studies employed deep learning networks for feature extraction. For instance, Yang et al. [17] presented a temporal sequence dual-branch network (TSDBN) breast cancer classification based on BUS and contrast-enhanced ultrasound (CEUS) sequences. It has two branches: one for BUS sequences and the other for CEUS sequences. In the branch of the BUS sequences, the ResNeXt-18 is employed. In the other branch, temporal sequence regression and a shuffle temporal sequence mechanisms are employed to enhance the temporal features of CEUS sequnces. They used a private dataset to evaluate their method. The dataset has 268 samples: 146 malignant and 122 benign. For each case, the BUS and CEUS sequences were recorded. TSDBN achieved an accuracy of 92.2%. One of the main limitation of this method is that it requires US and CEUS sequences for the same cases, which may not be available. Also, it does not consider the effect of noise and artifacts in US and CEUS sequences in the classification results. The study of [18] used 3D ResNet-50 to classify breast lesions in BUS sequences and 2D ResNet-50 to classify the same lesions in static images, finding that the BUS sequences lead to a higher AUC value of 0.969.

Han et al. [19] presented a ResViT model that combines residual neural networks with vision transformer to extract features from CEUS sequences, and employed a temporal segment network (TSN) to aggregate the spatio-temporal features of all frames in the input sequences. They achieved an accuracy of 78.79% with a private CEUS sequence dataset. Zhang et al. [20] proposed a segment-attention generator (SAG) module that can help deep learning classification models to focus on BUS sequence segments that have clear appearances for classifying breast lesions. The study of [10] introduced a deep-learning-based radiomics approach utilizing BUS sequences, comprising three key components. The ConvNeXt network, a deep CNN trained in the vision transformer style, is employed for radiomic feature extraction. An efficient pooling mechanism is also proposed to combine the malignancy scores of each breast US sequence frame, based on image-quality statistics. Finally, visual interpretations are provided to facilitate understanding. However, this methods achieved acceptable results, there is a big room for further enhancing the classification accuracy.

As mentioned earlier, a common limitation of existing studies is that they neglect the temporal information and image quality of BUS videos when developing classification models. Moreover, they rely on a single BUS image to develop their methods. However, the noisy nature of BUS images, the similarity between normal and abnormal tissues, and the degradation of image quality due to dense breast fat and glandular tissue, which attenuate ultrasonic waves, make accurate diagnosis challenging. These issues pose a significant challenge to building a robust BUS image classification model. The proposed method consider that the temporal information embedded in the BUS sequences and mitigate the effect of the noise utilizing the the weighted dynamic pooling technique.

III. Material and Method

A. Dataset

The proposed CAD system was developed and evaluated using a database consisting of 31 malignant and 28 benign BUS sequences, with each sequence corresponding to a single patient. The BUS sequences created by the Engineering Department of Cambridge University[1]. This dataset is a subset of a larger clinical database of ultrasonic radiofrequency strain imaging data, which was created by the Engineering Department at Cambridge University. The dataset includes 3911

[1] http://mi.eng.cam.ac.uk/research/projects/elasprj/

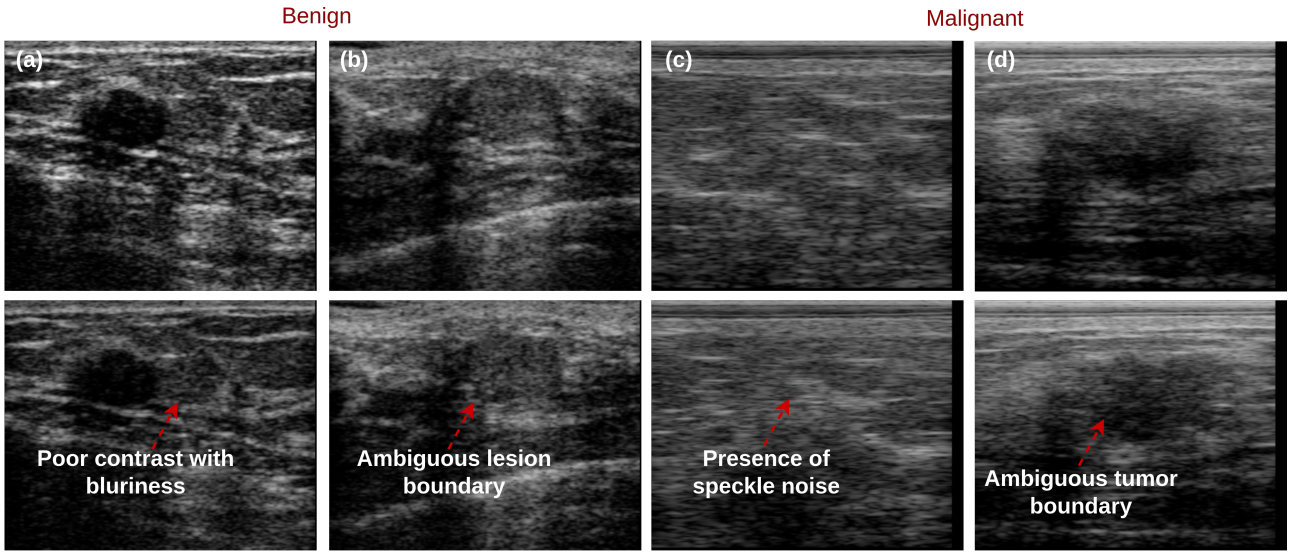

Fig. 1. Examples of BUS images having malignant tumors and benign lesions with various artifacts and challenges like poor contrast, ambiguous lesion or tumor boundaries, and speckle noise.

images containing benign tumors and 5245 images having malignant tumors.

B. Proposed Method

Fig. 2 presents the key components of the proposed method: 1) generating dynamic BUS image from the input BUS sequence, 2) applying transfer learning on MobileViTv3 [21] to extract local and global features from BUS images to differentiate between benign and malignant tumors, and 3) employing different visual interpretation methods to explain the decisions of the classification model.

1) Dynamic BUS sequence pooling: Let $S = [s_1, s_2, \ldots, s_M]$ is an input BUS sequence, where s_i

$$q_t = \frac{1}{W}\sum_{i=t}^{t+W} s_i. \tag{1}$$

where W is a time window.

TVA can be expressed as follows:

$$q_t = \frac{\frac{1}{t}\sum_{i=1}^{t} s_i}{\|\frac{1}{t}\sum_{i=1}^{t} s_i\|}. \tag{2}$$

After obtaining the smoothed version of BUS images, a rank-pooling method can be employed to learn the relative ranks of the BUS images in the input sequence, for instance q_n comes after q_{n-1}, q_{n-1} comes after q_{n-2}, and so on. This relative ranks can expressed as follows:

$$q_n \succ q_{n-1} \succ q_{n-2} \ldots q_1 \tag{3}$$

The rank-pooling technique is used to learn pairwise linear functions $\rho(q_t;\alpha)$, where $\alpha \in R^D$. The ranking score of q_t is computed as $\rho(q_t;\alpha) = \alpha^T.q_t$.

The parameters α of $\rho(q_t;\alpha)$ are optimized using the following objective function [22]:

$$\arg\min_{\alpha} \quad \frac{1}{2}\|\alpha\|^2 + \delta \sum_{\forall i,j,q_i \succ q_j} \theta_{ij}, \quad s.t. \quad \alpha^T(q_{t_i} - q_{t_j}) \geq 1 - \theta_{ij}, \quad \theta_{ij} \geq 0, \tag{4}$$

In this expression, δ stands for the regularization parameter and θ stands for the tolerance margin. The term $\{\alpha^T(q_{t_i} - q_{t_j}) \geq 1 - \theta_{ij}\}$ represents the the constraint of the objective function $\forall t_i, t_j \quad q_{t_i} \succ q_{t_j} \iff \alpha^T.q_{t_i} \succ \alpha^T.q_{t_j}$.

2) Image quality-aware dynamic BUS image generation: The quality of the BUS images can considered when generating the dynamic BUS image from the input BUS sequence by modifying Eq. 1 and Eq. 2 as follows:

$$q_t = \frac{1}{W}\sum_{i=t}^{t+W} \omega_i.s_i. \tag{5}$$

$$q_t = \frac{\frac{1}{t}\sum_{i=1}^{t} \omega_i.s_i}{\|\frac{1}{t}\sum_{i=1}^{t} \omega_i.s_i\|}. \tag{6}$$

where ω_i represents the quality of the th BUS image in the input sequence. The value of w_i may be 0 or 1, where a value of 1 denotes that the BUS image quality exceeds the thresholds of the BUS image quality metrics.

In this study, two efficient general-purpose image quality assessment metrics are used to estimate the quality of BUS images, namely the brightness and blurriness [23], [24], [25].

BUS image blurriness metric: Here, we employ the image blurriness measure presented in [24], where a Gaussian filter

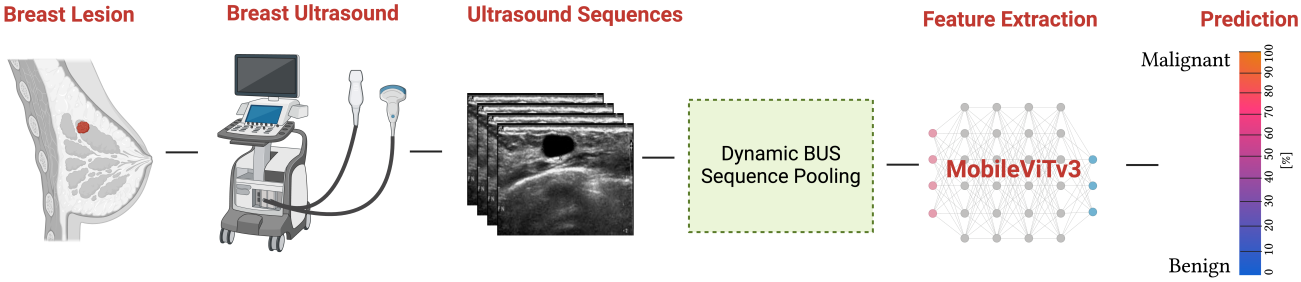

Fig. 2. Overview of the proposed method which consists of three consecutive steps: dynamic BUS sequence pooling, feature extracting using MobileViTv3 and malignancy classification.

is used to suppress the noise from the input image. Let I is a BUS image, the Gaussian filter can be written as:

$$f(a,b) = \frac{1}{(2\pi\sigma^2)} e^{-\frac{\left(a^2+b^2\right)}{2\sigma^2}}, \tag{7}$$

Here, σ is the standard deviation of the Gaussian distribution, and a and b are the coordinates of I.

After suppressing the noise, the variance of Laplacian operator is computed and used as a blurriness score. The 2D Laplacian operator can be expressed as follows:

$$\nabla^2 I(a,b) = \frac{\partial^2 I}{\partial a^2} + \frac{\partial^2 I}{\partial b^2}, \tag{8}$$

BUS images with a blurriness score lower than a threshold are considered as blurry images. Following [24], the blurriness threshold is set to the average blurriness value of benign and malignant BUS images from the training dataset.

BUS image brightness/darkness metric: In this study, we employ the brightness estimation algorithm proposed by Bezryadin et al. [25] as a BUS image quality metric. Following the study of [10], we selected the range from 10 to 30 for the brightness score.

3) Feature extraction: The main powerful approaches to extract features from images are CNNs and ViTs. In the context of breast tumors in ultrasound images, previous studies such as [9], [7] focused in the use of CNN models, [26], [27] used vision transformers, while [28] combined the decisions of different CNN and vision transformers. ViTs produce features representing global information in the images, due to their self-attention mechanism. CNNs extract local features in the images. Several hybrid models have emerged, integrating the strengths of both CNNs and ViTs into a single architecture. By combining the self-attention mechanism of ViTs, which excels at capturing long-range dependencies, with the local kernels of CNNs, which are adept at extracting local information, these models aim to achieve superior performance on various vision tasks. In order to extract robust descriptors from BUS images, in this paper we employ one of the most effective deep learning model that combines CNNs and ViTs, namely, MobileViTv3 [21].

Fig. 3 shows the block diagram of the MobileViTv3 that contains three blocks: local representation (LR) block, global representation (GR) block, and fusion block. The LR block (CNN components) consists of two layers: a 3×3 depthwise convolution layer and a 1×1 convolution layer. The GR block (ViT components) includes N linear transformations (self-attention). The fusion block uses 1×1 convolution layer to fuse the local and global features.

This study involves adapting and training various self-attention based deep vision transformer architectures to extract robust features, which can classify breast cancers as benign or malignant and predict the malignancy score of each input ultrasound image. By leveraging the transfer learning theory, the pre-trained vision transformer network and its parameters can be fine-tuned and applied to the target breast ultrasound dataset, enabling effective knowledge transfer. A support vector machine (SVM) classifier with a radial basis function (RBF) is used for classification.

4) Visual interpretation: To produce visual interpretations (explanations) for the proposed breast tumor classification model, this study employs the Grad-CAM (Gradient-weighted Class Activation Mapping) [29] and Local Interpretable Model-agnostic Explanations (LIME) techniques [30]. Let's denote the input image as I, the class of interest (benign or malignant) as c, and the output probability of the class as $P(c|I)$. The goal of Grad-CAM is to generate a heatmap $L^c_{Grad-CAM}$ that highlights the important regions of each BUS image that contribute to the prediction of the proposed model.

LIME is a model-agnostic method, which works by generating a dataset of similar instances around a specific instance for which we want to understand the model's prediction. Let's denote the original machine learning model as f, and the instance for which we want to explain the prediction as $\mathbf{x}$. LIME generates a dataset of m perturbed instances around $\mathbf{x}$, denoted as $\mathbf{x}'$, by randomly sampling from a distribution $\pi(\mathbf{x}'|\mathbf{x})$. The perturbed instances $\mathbf{x}'$ are then used to generate a new dataset $\mathcal{D} = (\mathbf{x}'_1, f(\mathbf{x}'_1)), \ldots, (\mathbf{x}'_m, f(\mathbf{x}'_m))$. Next, LIME trains an interpretable model g (e.g. a linear model) on the dataset $\mathcal{D}$ to approximate the behavior of the original model f locally around $\mathbf{x}$.

C. Evaluation metrics

To assess the performance of the proposed method for breast tumor classification in BUS sequences, we employ four well-known evaluation metrics, namely, the accuracy, precision, recall, and F1-score. The mathematical expression

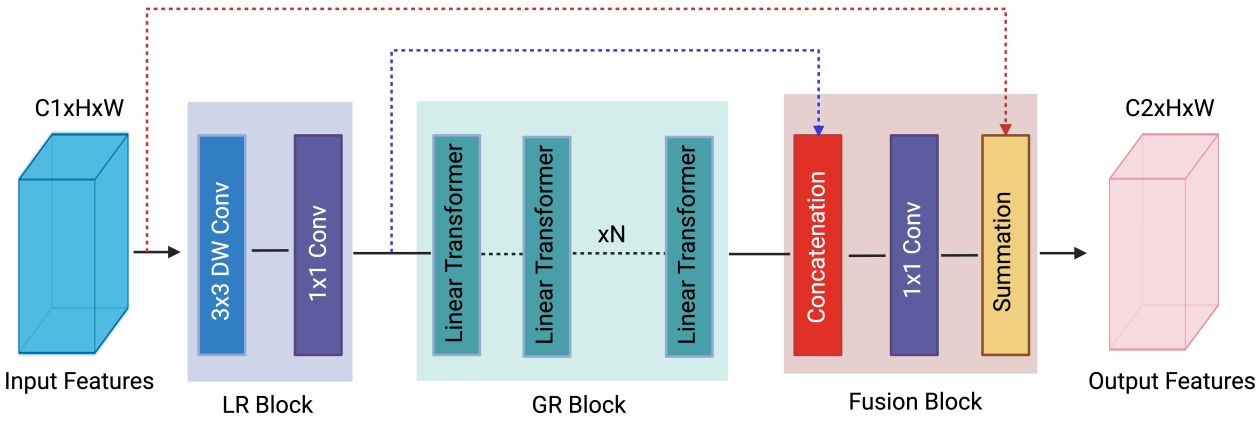

Fig. 3. Overview of the block diagram of the MobileViTv3 that consists of three interconnected blocks: LR, GR, and fusion.

of each evaluation metric is given below:

$$\text{Accuracy} = \frac{TP + TN}{P + N} \tag{9}$$

$$\text{Precision} = \frac{TP}{TP + FP} \tag{10}$$

$$\text{Recall} = \frac{TP}{TP + FN} \tag{11}$$

$$\text{F1-score} = \frac{TP}{TP + 0.5(FP + FN)} \tag{12}$$

In these expressions, TP and TN denote the number of BUS sequences having malignant and benign tumors that have been successfully detected by the proposed method, respectively. Conversely, FN stands for the number of malignant tumors wrongly identified by the proposed method as benign tumors. FP stands for the number of benign tumors wrongly identified by the proposed method as malignant tumors.

IV. Experimental Results

A. Training Details

As the BUS images varied in size, all were resized to 224×224 pixels. The AdamW optimizer was employed with an initial learning rate of 0.001, a weight decay of 0.01, and a cosine learning rate scheduler, using binary cross-entropy loss to optimize the model. The training process was conducted with a batch size of two images over 50 epochs. To augment the training data, the input BUS sequences were split into overlapping sub-sequences with a window size of 20, generating multiple dynamic BUS images from each sub-sequence. Additional data augmentation techniques were applied, including 90-degree image rotation, 0.2 image scaling, horizontal flipping (with a probability of 0.5), median filter blurring, and contrast-limited adaptive histogram equalization. All models were developed in Python using the PyTorch framework and trained on an NVIDIA GeForce GTX 1070Ti GPU with 8 GB of RAM.

B. Results

Table I compares various backbone feature extractors, including CNNs, vision transformers, and hybrid models. MobileViTv3-S emerges as the top-performing model, significantly outperforming others with an accuracy of 89.33%, which is more than 1.2% higher than the second-best model, ConvNeXt V2. This demonstrates the strength of hybrid architectures like MobileViT, which combine the local feature-capturing ability of CNNs with the global context awareness of transformers. Despite its depth, ResNet-150 performs good but does not achieved similar results as MobileViTv3-S, recommending that deeper CNNs do not necessarily yield better performance in this task.

The transformer-based models, DEiT and BEiT v2, show satisfactory performance, indicating that transformers may require more fine-tuning for optimal results. XCiT performs the weakest, further highlighting the limitations of transformers without additional optimization. In contrast, the MobileViTv3 family, particularly MobileViTv3-S, shows the advantage of hybrid architectures, offering the best balance between efficiency and accuracy. Even the smaller versions, MobileViTv3-XS and XXS, perform well, making them suitable for resource-constrained situation while still providing competitive performance.

Table II presents the affect of various smoothing techniques on the performance of the proposed method for classifying breast ultrasound images into benign and malignant. Firstly, without applying any smoothing, the model achieved satisfactory results in classifying between the two types of lesions. When the MA smoothing technique was applied, there was a slight improvement in the model's ability to accurately classify the ultrasound images.

However, the most important advancement was observed when the TVA smoothing technique employed. TVA leads to a significant improvement in the classification performance, enhancing the accuracy, precision, recall, and F1-score by approximately 2%. This suggests that TVA allows the model to more effectively capture and utilize the subtle variations in ultrasound imaging data, which is critical for differentiating between benign and malignant lesions. TVA's ability to smooth

TABLE I. RESULTS OF THE PROPOSED METHOD WITH VARIOUS BACKBONE FEATURE EXTRACTORS WITHOUT SMOOTHING

Method	Accuracy	Precision	Recall	F1-score
ResNet-152 [31]	85.91	85.18	84.66	84.91
MobileViTv3-S [21]	89.33	88.90	88.79	88.84
MobileViTv3-XS [21]	86.55	84.61	84.02	84.31
MobileViTv3-XXS [21]	83.76	81.97	80.35	81.15
ConvNeXt V2 [32]	88.10	88.22	86.05	87.12
DEiT [33]	86.75	85.82	84.95	85.38
BEiT v2 [34]	85.46	84.24	83.74	83.98
XCiT [35]	83.67	82.54	81.78	82.15

the data while preserving key features seems to help the model focus on more relevant regions, thus improving overall diagnostic accuracy and reducing the risk of misclassification, which is crucial in breast cancer detection.

TABLE II. RESULTS OF THE PROPOSED METHOD WITH DIFFERENT SMOOTHING METHODS

Method	Accuracy	Precision	Recall	F1-score
W/o smoothing	89.33	88.90	88.79	88.84
MA	89.56	88.94	88.86	88.89
TVA	**91.58**	**90.76**	**90.11**	**90.43**

Table III compares the performance of the proposed method with and without the use of quality weights, evaluating key metrics. The inclusion of quality weights clearly improves performance across all metrics. When quality weights are not applied, the method achieves an accuracy of 91.58%, with a precision of 90.76%, recall of 90.11%, and F1-score of 90.43%. These are strong results, indicating that the model can effectively make predictions, but there is room for improvement in its ability to generalize and balance precision and recall.

TABLE III. RESULTS OF THE PROPOSED METHOD WITH AND WITHOUT QUALITY WEIGHTS

Method	Accuracy	Precision	Recall	F1-score
w/o quality weights	91.58	90.76	90.11	90.43
with quality weights	**93.78**	**93.65**	**92.94**	**93.29**

When quality weights are introduced, the performance improves substantially, with accuracy increasing to 93.78%, a significant boost over the baseline. Similarly, precision rises to 93.65%, recall to 92.94%, and the F1-score to 93.29%. This improvement can be attributed to the model's ability to assign higher importance to more informative lesion or tumor related features during training, resulting in more refined feature extraction and better classification outcomes. The use of quality weights enhances the model's ability to focus on higher-quality data, leading to better overall predictions and higher consistency in its results. Fig. 4 shows the area under the receiver operating characteristic (AUROC) scores of 0.94 and 0.97 for the model without and with quality weights, respectively.

Fig. 5 shows the explainability of the proposed model using GradCam and LIME. The red refers to a higher probability of the presence of lesion or tumor, while the blue represents a lower probability of the existence of background region. Based on visual inspection, the model correctly identified both benign lesions [Fig. 5(a), (b)] by focusing on hypoechoic regions.

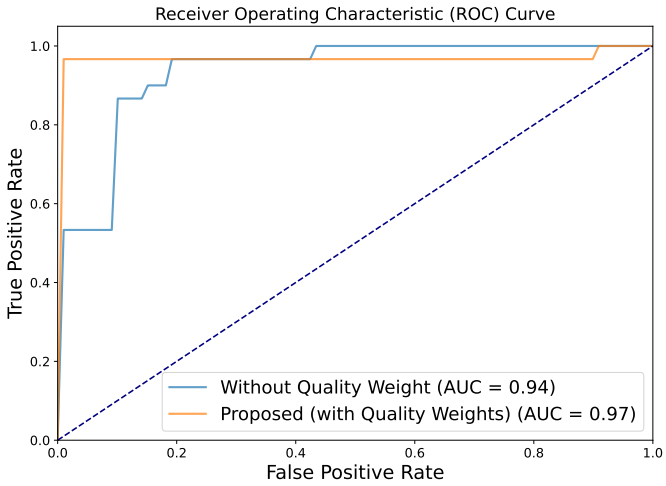

Fig. 4. The AUROC curves of the proposed method with and without quality weights.

Additionally, small tumors [Fig. 5(c), (d)] with ambiguous boundaries were accurately classified as malignant, with the model highlighting critical regions while ignoring background pixels.

C. Comparisons with Related Methods and Discussion

Table IV compares the performance of the proposed method with an existing method from the literature, specifically the method from [10]. The proposed method achieves the highest performance across all metrics, with an accuracy of 93.78%, precision of 93.65%, recall of 92.94%, and F1-score of 93.29%. These results demonstrate a clear improvement over the existing method, which, while still effective, yields slightly lower accuracy (91.66%) and F1-score (92.33%).

The improved performance of the proposed method can be attributed to its ability to better capture important features and balance precision and recall. The higher F1-score indicates that the proposed method handles the trade-off between precision and recall more effectively, resulting in more accurate and reliable predictions. In comparison, while [10] method performs well, it falls short in terms of overall accuracy and F1-score, suggesting that the proposed method offers a more refined approach to the problem.

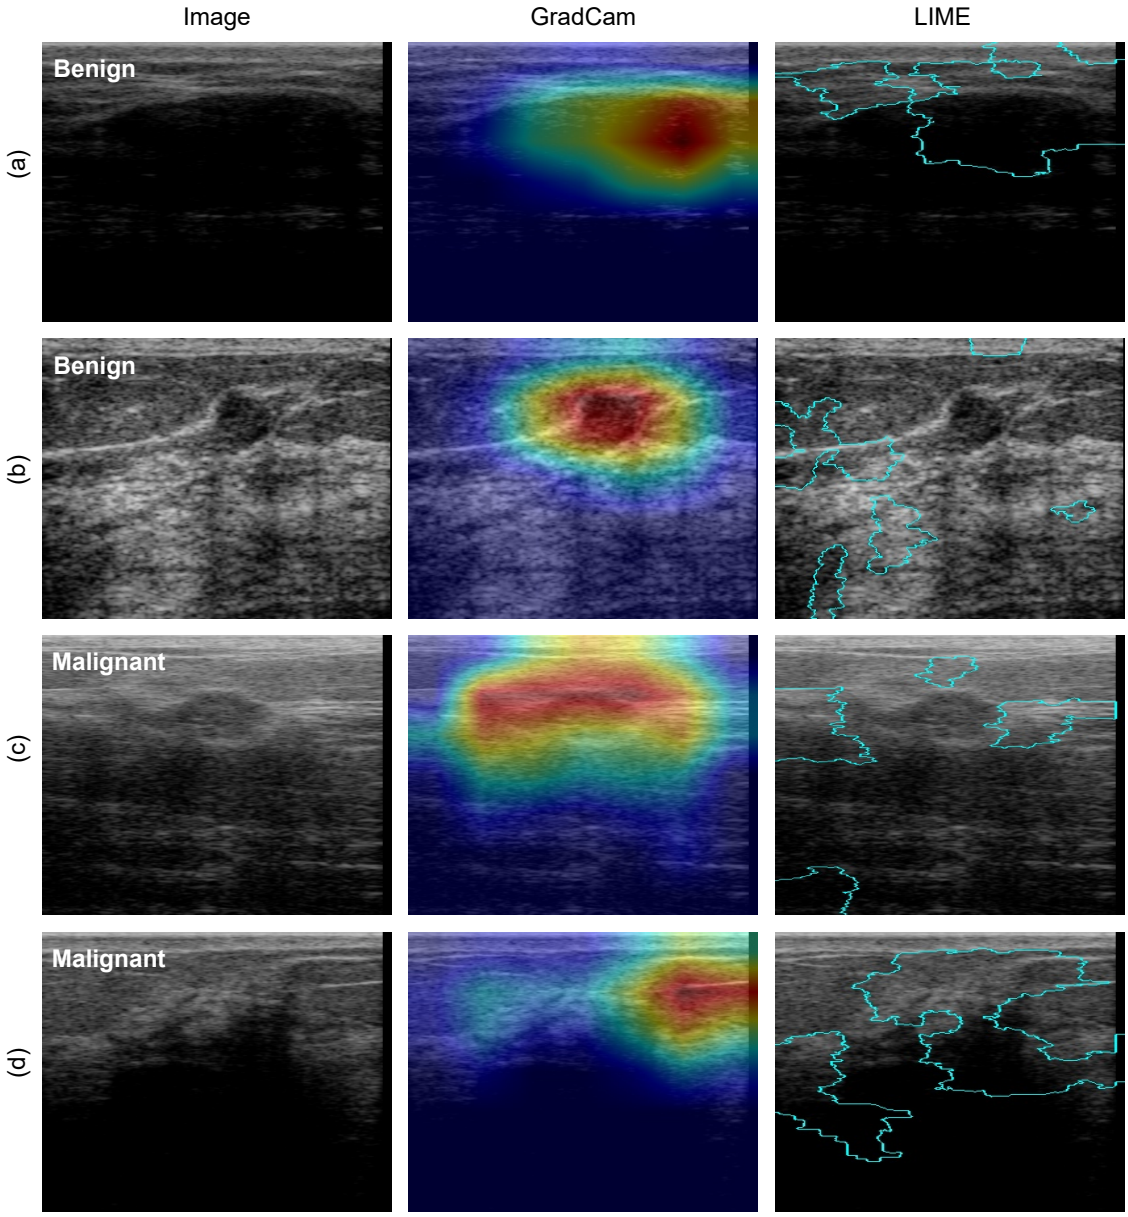

Fig. 5. Explanation of the proposed model using Grad-CAM [29] and LIME [30] methods. (a,b) benign cases, and (c,d) malignant cases.

TABLE IV. STATE-OF-THE-ART RESULTS COMPARISON

Method	Accuracy	Precision	Recall	F1-score
Proposed	**93.78**	**93.65**	**92.94**	**93.29**
[10]	91.66	93.05	92.69	92.33

V. Conclusion and Future Work

This paper presents a novel approach to breast tumor classification using dynamic pooling of BUS sequences, combining the strengths of both CNN and transformer architectures. By incorporating weighted dynamic pooling based on image quality metrics, such as blurriness and brightness, our method effectively mitigates the impact of noise and artifacts commonly found in BUS images. Comprehensive experiments demonstrate that our approach, particularly when using MobileViTv3-S, significantly outperforms existing methods, achieving an accuracy of 93.78%. The inclusion of quality weights further enhances classification performance, highlighting the importance of prioritizing high-quality image frames. Not only does our model achieve higher accuracy, but it also provides better interpretability through Grad-CAM visualizations, facilitating the understanding of tumor characteristics. The results suggest that our approach can offer a robust, reliable, and interpretable solution for breast cancer detection in clinical settings.

One limitation of this study is the reliance on a single BUS video sequence dataset to evaluate the efficacy of the proposed method. Additionally, the small sample size of the dataset presents another limitation.

Future work will focus on integrating additional ultrasound modalities (e.g. BUS and CEUS) with the proposed method to further enhance classification accuracy. Additionally, larger and more diverse datasets will be collected to improve the robustness and performance of the developed classification models.

***Abstract*—Artificial intelligence tools have revolutionized many fields, bringing significant progress in automating tasks and solving complex problems. In this article, we focus on the legal domain, where the data to be processed are specific and in large quantities. Our study consists in carrying out an automatic classification of Moroccan legal and legislative texts in Arabic. In addition, we will conduct a series of experiments to evaluate the impact of stemming, class imbalance and the impact of data quantity on the performance of the models used. Given the specificity of the Arabic language, we used Natural Language Processing (NLP) tools adapted to this language. For classification, we worked with the following models: Support Vector Machine (SVM), Random Forests (RF), K Nearest Neighbors (KNN) and Naive Bayes (NB). The results obtained are very impressive, and the comparison of model outputs enriches the debate on specificities of each model.**

***Keywords*—Classification Arabic text; natural language processing; legal data; machine learning**

I. Introduction

Approaching textual data in the Arabic legal field presents dual challenges due to linguistic and legal complexities. The Arabic language is an extremely rich Semitic language both linguistically and culturally. It is the official language in over 20 countries and serves as one of the six official languages of the United Nations (UN). Textual data in the Arabic language presents a challenge due to the language's specificity and complexities. These complexities are evident in the distinction between Literary Arabic comprising Classical Arabic and Modern Standard Arabic (MSA), and Dialectal Arabic, which is highly diverse due to regional and national variations. Furthermore, the linguistic richness of the Arabic language imparts complexity at the syntactic, morphological, semantic, and orthographic levels [1]. Regarding the legal domain, which is a highly interesting field and happens to be the focus of our study, it has been approached using machine and deep learning techniques in diverse languages to explore prediction of judicial decisions [2], synthesis [3], and translation of legal texts [4]. However, not as much research has been done on the subject of Arabic. NLP tools, machine learning, and deep learning models are applied to legal texts to automate certain tedious tasks and enable professionals to focus on high-value-added tasks. In this paper, we have focused on applying these techniques to classify legal texts related to Moroccan regulations and legislation. Several models have been trained, including SVM, RF, KNN and NB classifiers. The aim of our study is to work with a wide range of data and to evaluate the behavior of the models in relation to different situations. We have chosen Moroccan legal and legislative texts covering different fields. These texts include the Civil Status Law, the Organic Finance Law, the Judicial Organization Law, the Traffic Code, the Family Code, the Criminal Procedure Law and the Commercial Code. Each text deals with distinct subjects and uses terms specific to those subjects. To our knowledge, this corpus has not been approached before.

The approach adopted in this work concerns the evaluation of the impact of stemming and data quantities on model performance. According to our information, previous work has not dealt with these aspects when approaching legal data in Arabic. By comparing the performance of models trained on stemmed and non-stemmed data, we can evaluate the behavior of each model in relation to the application or non-application of the stemming approach. In this study, we also analyzed the impact of class imbalance on model performance. Thus, we first evaluated the results obtained when training the models on a dataset containing minority classes, then we trained the models on a dataset where the classes are more balanced. Furthermore, we examined the effect of varying data quantity on the performance of these classifiers. By systematically varying the size of our dataset, we were able to observe how each model responded to different volumes of training data. This analysis provides valuable information on the scalability and robustness of each classifier.

To carry out this study, we have structured our article as follows: The characteristics and specifications of the Arabic language are discussed in Section II. Section III is devoted to the state of related research, while the Section IV outlines the methodology followed and details the experiments conducted in this study. The results obtained are presented and discussed in the Section V. In the conclusion we summarized the results obtained and proposed new perspectives for future work to tackle new legal tasks and enrich the current state of the art.

II. Arabic Language: Characteristics and Specificities

The Arabic language incorporates several particularities that differentiate it from Western languages. In addition to linguistic complexities, Arabic is distinguished by its writing direction, from right to left, and the use of diacritical marks that determine the phonological meaning of a word [5]. The language also includes additional characters, such as "إ، آ، أ، ء، ئ، ؤ، ى" and "ة", whose basic form are the Arabic letters "ا" and "ه" respectively. Furthermore, the syntax of the Arabic language differs from that of Western languages, especially concerning word order. For example, in the sentence "أصدرت المحكمة الحكم" where the direct translation is "issued

the court the judgment", the order of the subject and the verb is reversed compared to their order in the English language, where it is "the court issued the judgment". A deep understanding of grammatical and syntactical structures is essential for an enhanced mastery of the language and to ensure a smooth translation between multiple languages.

Morphologically, a trilateral root has the ability to generate multiple derivatives by adding prefixes, suffixes, or modifying vowels. For instance, the trilateral root "حكم" meaning "to judge" can give rise to various words related to the field of judgment and law. These include "حُكْم" (hukm) meaning "judgment", "حكمة" (hik-ma) meaning "wisdom" and "محكمة" (mah-ka-ma) meaning "court". Derivatives also provide the opportunity to express various nuances, such as gender, with "حاكم" (ha-kim) meaning male judge and "حاكمة" (ha-ki-ma) meaning female judge, as well as the dual form with "حاكمان" (ha-ki-ma-an) or plurals "حكام" (hu-kka-m), and so forth.

Regarding the semantic aspect, there are words that are written in the same way but differ in terms of meaning and pronunciation. Understanding the correct sense and determining the correct pronunciation are made possible by the context of use. The term "شهادة" for example, can have various meanings such as "testimony" or "certificate," and only the context of the sentence or surrounding discourse allows for determining the specific meaning.

The spelling of Arabic letters is also very specific. The shape of the letters changes according to their position in the word. The letter "ع" for example, has four forms: one form at the beginning of the word as in "عقد", a middle form as in the word "تعلم", and two forms at the end of the word as in the words "استماع" and "بيع."

III. Related Works

The use of machine learning tools has gained momentum in the approach to judicial data. Aleteras et al [2] conducted the first study to combine machine learning and NLP tools to predict judicial decisions regarding the violation of human rights convention articles. This study used the Support Vector Machine (SVM) classifier and served as a reference for several subsequent works, particularly those conducted by Sulea et al. [6] and Liu and Chen [7]. In 2017, Katz et al. [8] presented a study in a generalized, consistent, and out-of-sample framework using the Random Forest classifier to predict US Supreme Court behavior. The promising outcomes in predicting judicial case have piqued the interest of researchers worldwide. For instance, Walt et al. [9] applied the Naive Bayes classifier to German jurisdiction, particularly German tax law cases. Likewise, Virtucio et al. [10] utilized Aletras's method to predict decisions of the Philippine Supreme Court. On the other hand, deep learning models were initially experimented by the Chinese for predicting legal judgments as a multitask problem. Luo et al.'s study [11] focused on simultaneously modeling relevant law extraction and charge prediction. Zhong et al. [12] opted for topological learning for predicting three dependent subtasks: applicable law articles, charges, and penalties. On the other hand, Long et al. [13] developed a model based on legal reading comprehension to express complex semantic interactions between factual descriptions, pleadings, and law articles. Ye et al.'s [14] work revolves around a Seq2Seq model to combine charge prediction and court opinion generation. Meanwhile, Hu et al [15] designed a model focused on predicting infrequent charges.

The deep learning models have attracted the attention of other researchers who have worked on datasets from different courts and jurisdictions. Kowsrihawat et al.[16] utilized the BI-GRU model with an attention mechanism to analyze a corpus of criminal cases from the Thai Supreme Court and predict the guilt or innocence of an accused. Chalkidis et al. [17] also worked on data from the European Court of Human Rights (ECHR) for prediction purposes. They tested several models, including SVM BOW, BIGRU-Attention, Hierarchical Attention Network, Label-Wise Attention Network, and HIERARCHICAL-BERT. Their analysis showed that deep learning models perform better. For their part, Malik et al. [18] designed a prediction system for Indian Supreme Court cases, with the capability of explaining the obtained predictions. For prediction, the authors explored classical, sequential, and hierarchical models as well as transformer-based models.

The application of machine learning methods to judicial data in various languages has led to great interest in the exploration of Arabic court data. Study [19] focused on predicting Arabic judgments from the Errachidia court in Morocco, specifically targeting accident cases. Deployed machine learning models included Linear Regression, Random Forest, and Decision Trees, achieving encouraging results with 91% accuracy for Random Forest. Shamma et al. [20] addressed information extraction from Arabic legal documents, applying Arabic-specific natural language processing techniques and machine learning models like SVM, Decision Trees, and KNN. In study [21], researchers examined the prediction of verdicts, legal articles, and probabilities of judgment, focusing on child custody and marriage annulment cases in the Arabic language. They experimented with TF-IDF and word2vec representation techniques and used various machine and deep learning models including SVM, Logistic Regression (LR), LSTM, and BiLSTM. Article [22] introduces TaSbeeb, an innovative decision support tool for the Saudi judicial system. Designed for Arabic language, it retrieves judicial reasoning and performs multiclass classification of legal cases. The study proposes deep models Att-GRU, BiLSTM, and BiGRU with stacking approach, both homogeneous and heterogeneous, along with an Arabic judicial language model called Jud_RoBERTa.

In general, the research works that have approached the legal field in Arabic remain limited. Table I below presents some of these works. Most of them focus on judgments or judicial decisions in narrow fields. In addition, this type of data can sometimes lack precision, which can have an impact on the final decision given by the models. Another limitation encountered by the authors lies in the quantities of data available, whereas the models require adequate and representative quantities of data for better training. In our study we worked with legal and legislative data covering seven different domains. In addition, we focused on the impact of data on model performance by changing the amounts of data used and evaluating the impact of class imbalance and

stemming on model performance.

TABLE I. STUDIES ON THE APPLICATION OF ARTIFICIAL INTELLIGENCE APPROACHES TO ARABIC LEGAL DATA

Articles	Experiment	Data
[19]	Predicting the outcome of accident cases	Accident cases issued by the Errachidia court in Morocco
[20]	Information extraction from Arabic legal documents	Appeal cases for leased premises lawsuits
[21]	Predicting judgments and legal articles or proof as well as probabilities of expected results	Marriage annulment and child custody cases
[22]	Development of a decision support system for the Saudi judicial court	Family and personal status cases
[25]	Classification of Arabic legal documents	Judgments relating to real estate and road traffic issued by the Moroccan Supreme Court

IV. METHODOLOGY

The categorization of textual data is one of the fundamental pillars of much research that has explored the contributions of artificial intelligence tools to the legal field. This importance stems from the need to optimize time and resources, particularly in view of the large quantities of data to be processed, including judgments, legal texts and investigation reports. The classification of this type of data provides invaluable assistance to legal professionals, facilitating access to relevant information, comparative analysis between different laws or regulations, and research into previous similar cases.

In this study, we focused on Arabic-language legal data relating to Moroccan regulations. To classify this text data, it is important to follow a clearly defined process, including data collection and pre-processing, vector representation of the texts, model application and performance evaluation (Fig. 1).

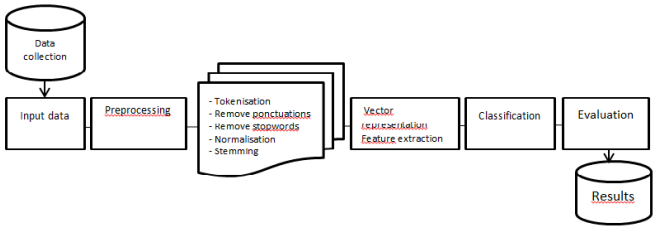

Fig. 1. Classification process for legal and legislative texts.

A. Data Collection

The dataset represents the input for algorithms and the foundation of learning. The models' performance depends entirely on the quality and quantity of the chosen corpus.

In this study, we have gathered seven Moroccan legislative and legal texts, detailed in (Table II). These texts include articles related to the Civil Status Law, the Organic Finance Law, the Judicial Organization Law, the Traffic Code, the Family Code, the Criminal Procedure Law and the Commercial Code. The number of articles varies from one legal text to another, and similarly, the number of words in these articles varies from one article to another. The total number of articles is 2510. The Commercial Code and the Criminal Procedure Law are the most extensive, with 798 and 757 articles, respectively. Since the assignment of articles to a class is determined by the designation of the appropriate legal text, the distribution of classes in our dataset is not balanced.

TABLE II. OVERVIEW OF STUDIED DATA

Legal text	Number of articles
"القانون رقم " 36.21 "المتعلق بالحالة المدنية"	59
"القانون التنظيمي رقم " 130-13 "قانون المالية"	70
" القانون رقم " 38.15 "المتعلق بالتنظيم القضائي"	111
"مدونة السير على الطرق"	318
"مدونة الأسرة"	400
"القانون رقم " 22.01 "المتعلق بالمسطرة الجنائية"	757
"مدونة التجارة"	798

B. Preprocessing

Given our interest in the Arabic legal domain, we have examined NLP tools applied to Arabic-language data. Below, we present the main pre-processing steps required to prepare textual data and make it easy and suitable to handle.

1) Tokenization: Segmentation of text into meaningful linguistic entities.

2) Removing stop words: Elimination of words that don't provide significant information, using the Arabic stop words list.

3) Normalization: Normalization involves writing words in a specific form, bringing letters back to their base form. For example, converting "hamza" in all its forms "إ، آ، أ، ء، ئ، ؤ، ى" to "alef" "ا".

4) Stemming: The process of reducing words to their base form. Among the most frequently employed stemmers for the Arabic language, there are Khoja stemmer and ISRI Stemmer [23]. In this study, we used ISRI Stemmer.

	Sentence1	Sentence 2
Input text	يأمر قاضي التحقيق بتبليغ الشكاية إلى وكيل الملك أو الوكيل العام للملك لتقديم ملتمساته.	تشتمل النفقات المتعلقة بالدين العمومي على النفقات من فوائد وعمولات والنفقات المتعلقة باستهلاكات الدين المتوسط والطويل الأجل
Pre-processed text without stemming step	يامر قاضي التحقيق بتبليغ الشكايه وكيل الملك الوكيل العام للملك لتقديم ملتمساته	تشتمل النفقات المتعلقه بالدين العمومي النفقات فوائد وعمولات والنفقات المتعلقه باستهلاكات الدين المتوسط والطويل الاجل
Pre-processed text with stemming step	امر قضي حقق بلغ شكي وكل ملك وكل عام ملك قدم ملتمساته	شمل نفق تعلق دين عمم نفق فئد عمل نفق تعلق باستهلاك دين توسط طول اجل

Fig. 2. Examples of sentences illustrating the pre-processing of legal and legislative texts.

Fig. 2 illustrates the pre-processing of two sentences, the first extracted from the Criminal Procedure Law and the second from the Organic Finance Law. The results of the pre-processing show that the tools applied have succeeded to a

certain extent in approximating the Arabic text. However, the difficulties encountered include the case of attached words, where it is difficult to identify stop words. We take as an example the word "باستهلاك" composed of two elements "ب" which is a preposition and the word "استهلاك" meaning "consumption". In principle the stop word should be removed. And the term "استهلاك" should undergo stemming. By analyzing the output of the preprocessing with stemming and without stemming step, we noticed that the tool used has succeeded in reducing words to their roots, such as transforming "التحقيق" into "حقق" and "الوكيل" into "وكل" . However the stemming of some words failed. For example the word "فوائد" was rendered to a non-existent word in the Arabic language "فئد" and the words "ملتمساته" and "استهلاك" were not stemmed.

C. Vector Representation Methods

To ensure that textual data is readable and interpretable by algorithms, it must be converted into vector representations. The methods commonly used for this conversion are as follows:

1) BOW: Vector representation of the document that associates each word with its frequency of occurrence.

2) TFIDF: A representation that emphasizes the importance of a word in a document relative to its occurrence in the entire corpus.

$$TF - IDF(term) = TF(term) \times log(\frac{N}{DF(term)}) \quad (1)$$

TF: the number of times the term occurs in a document

DF: the number of documents in which the term is present

N : total number of documents

3) Word embedding: Representations that capture semantic relationships between words. These representations are generated by widely used models such as Word2Vec, GloVe and FastText [24], initially designed for Western languages and applied to the Arabic language.

D. Model Application

Machine learning models are selected according to the nature of the data and the specific objectives of the task. In this study, we chose to use four of the best-known classical classification models: SVM, KNN, Random Forest and Naive Bayes, based on the scikit-learn implementation.

1) Support Vector Machine (SVM): A supervised learning method employed for classification tasks. SVM focuses on choosing the optimal hyperplane to maximize margin separation and incorporates the Kernel function. This function facilitates the projection of data into a higher-dimensional space to handle non-linear classification challenges. The SVM classifier has proven to be very interesting for text classification [25]. Its application to Arabic legal data has been conducted for several tasks, including classification [21] and information retrieval [20].

2) K Nearest Neighbors (KNN): A straightforward and non-parametric classification model based on neighborhood principle. It depends on selecting a distance metric to calculate the distance between instances. The classification of a new instance is decided by the majority class of the k nearest data points in the training set. Although this technique is widely used in text classification, its application to Arabic legal data remains limited, among the few works that have used it, we can cite the study by Ikram and Chakir [25] to classify Moroccan court rulings.

3) Naive bayes: A probabilistic model grounded in Bayes' theorem with conditional independence assumption. This means that the values of predictors of a given class are conditionally independent of each other.

$$P(c_k \mid x_i) = \frac{P(c_k) \times \prod_{j=1}^{n} P(x_{ij} \mid c_k)}{\sum_{s=1}^{K} P(c_s) \prod_{j=1}^{n} P(x_{ij} \mid c_s)} \quad (2)$$

K: number of class modalities
$C = (c_1, c_2, ...c_k, ..., c_K)$: the class variable
n: the number of features or explanatory variables

$x_i = (x_{i1}, ...x_{ik}...x_{in})$: vector of explanatory variables

$P(c_k \mid x_i)$: the probability that the document represented by x_i, belongs to the class c_k.

$P(x_{ij} \mid c_k)$: The likelihood of the feature x_{ij} conditioned on the class c_k

P(c_k): represents the prior probability associated with the class c_k

The target class is the class for which the probability P($c_k \mid x_i$) is maximum:

$$c_k = ArgMax(P(c_k) \prod_{j=1}^{n} P(x_{ij} \mid c_k) \quad (3)$$

The Naive Bayes classifier has been widely used in various research exploring the legal domain across multiple languages and it is also employed in the classification of legal texts in Arabic [25][26].

4) Random forest: An ensemble machine learning model that combines decision trees of CART-type through aggregation. Each tree is built from a bootstrap sample of the training set, using a random subset of features. The model's prediction is established through a majority vote from all the trees. Random Forest is a widely used model for text data analysis. It has been employed by researchers such as Katz [8], Liu and Chen [7] and others to approach judicial data. Concerning the Arabic language, this model has been applied to tasks such as isolated Arabic character recognition [27] and legal document classification [25].

E. Evaluation

The performance of classification and prediction models is evaluated through various metrics. This approach aims to analyze the quality of results, the overall efficiency of models, and to understand their behavior in a variety of situations. The most commonly used measurements in this context include:

Accuracy: Proportion of correctly classified cases to the total number of cases.

$$Accuracy = \frac{TP + TN}{Total} \tag{4}$$

Recall: Proportion of cases correctly assigned to a class i to all cases in that class.

$$Rappel = \frac{TP}{TP + FN} \tag{5}$$

Precision: Proportion of cases correctly assigned to class i compared to all cases predicted to be assigned to class i.

$$Precision = \frac{TP}{TP + FP} \tag{6}$$

F1 score: Harmonic mean of precision and recall.

TP: True positive

TN: True negative

FP: False positive

FN: False negative

These performance measures are typically used for binary classification, however, there are methods to generalize them to include multiple classification:

1) Micro approach: The global metrics are calculated from the set contributions of all classes. The TP, TN, FP and FN of all classes are combined to calculate a single accuracy, precision, recall and F1-score.

2) Macro approach: consists of calculating the metrics for each class individually and then calculating an average of all the classes for each measure. These averages can be arithmetic when the classes are balanced and weighted averages when the classes are unbalanced.

F. Experimentation

Due to our interest in applying machine learning tools in the legal field, we conducted a series of experiments to evaluate the impact of stemming, class imbalance and data quantity on model performance.

Our data corpus consists of articles from seven legal and legislative texts (Table II). The designation of the appropriate text constitutes the class assignment for the articles, resulting in a total of seven classes. To ensure the quality of our analysis, we first prepared our data using preprocessing techniques mentioned above. We then applied our models and evaluate the performance obtained. We conducted five distinct experiments to assess the performance of our models in different scenarios. First, we trained classification models on the entire corpus and evaluated performance (Table III). This first experiment served as a basis of comparison for some of the subsequent experiments. In the second experiment, we drew inspiration from the study by Taghva et al. [23]to evaluate the effectiveness of stemming on the performance of our models. In this experiment, we eliminated the stemming step and compared the results (Table IV) with those of the first experiment. Inspired by Sulea et al's study [6] of French-language court decisions, we came up with the idea of assessing the impact of class imbalance and the presence of minority classes when exploring Arabic-language legal documents. Thus, in a third experiment, we assessed the impact of minority classes on model performance by eliminating classes with fewer than 200 articles and retraining our models (Table V). This reduced the corpus to four classes, and the results were compared with those from the first experiment. In the fourth experiment, we evaluated the impact of class imbalance on model performance (Table VI). To do this, we worked with the four classes from the previous experiment and retained 300 articles per class. Finally, to assess the impact of data quantity, we conducted a fifth experiment where we reduced the number of articles to 50 per class(Table VII).

V. Discussion

Our study focuses on the analysis of Moroccan legislative and legal texts using natural language processing tools specifically designed for the Arabic language. We conducted classification experiments on this corpus of data using four classifiers: SVM, KNN, Random Forest and Naive Bayes.

TABLE III. Model Performance with Stemming Step

Classifier	Accuracy	Precision	Recall	F1 score
SVM	94.58	94.9	94.58	94.45
KNN	92.17	92.56	92.17	92.26
Random Forest	91.16	91.91	91.16	90.75
Naive Bayes	92.17	92.72	92.17	91.82

TABLE IV. Model Performance without Stemming Step

Classifier	Accuracy	Precision	Recall	F1 score
SVM	92.57	93.16	92.57	91.86
KNN	92.57	93.16	92.57	92.77
Random Forest	91.97	92.4	91.97	91.75
Naive Bayes	95.38	95.6	95.38	95.19

TABLE V. Model Performance Without Minority Classes

Classifier	Accuracy	Precision	Recall	F1 score
SVM	95.82	95.89	95.82	95.83
KNN	96.26	96.28	96.26	96.26
Random Forest	94.95	94.98	94.95	94.95
Naive Bayes	93.41	93.48	93.41	93.41

TABLE VI. Model Performance on Balanced Classes (300 Articles Per Class)

Classifier	Accuracy	Precision	Recall	F1 score
SVM	96.25	96.38	96.25	96.25
KNN	95.42	95.51	95.42	95.42
Random Forest	93.33	93.54	93.33	93.34
Naive Bayes	95.83	96.04	95.83	95.88

TABLE VII. MODEL PERFORMANCE ON SMALL BALANCED DATA (50 ARTICLES PER CLASS)

Classifier	Accuracy	Precision	Recall	F1 score
SVM	92.5	95.00	92.5	93.01
KNN	95	95.23	95	95.02
Random Forest	92.5	93.75	92.5	92.72
Naive Bayes	97.50	97.86	97.50	97.55

The graph in Fig. 3 summarizes the accuracy of all the models across the five experiments detailed above.

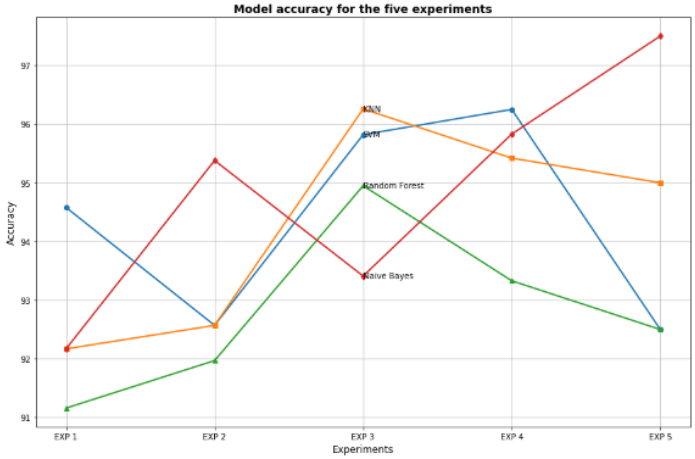

Fig. 3. Model accuracy for the five experiments.

The results of the first experiment (Table III), carried out on the whole corpus, are very promising, exceeding 90% for all models. The SVM classifier achieved the best performance across all metrics, with an accuracy of 94.58% and an F1 score of 94.45%. This finding is consistent with that of Liu and Chen [7], who worked on English-language data from the European Court of Human Rights and confirmed that SVM was the most efficient classifier.

In the second experiment, where we omitted the stemming step (Table IV), we observed that the classifiers behaved differently. The performance of the SVM model decreased, achieving 92.57% accuracy, while the performance of KNN, Random Forest and Naive Bayes has improved, achieving 92.57%, 91.97% and 95.38% accuracy respectively. This difference in behavior is explained by the fact that each classification algorithm has its own characteristics and assumptions. This experiment showed that the KNN, Random Forest and Naive Bayes algorithms are sensitive to the changes introduced by stemming, and are less tolerant of the loss of information it generates. These models are better suited to exploiting the lexical diversity of non-stemmed data, giving them a better understanding of nuances and relationships between words. On the other hand, the SVM classifier, whose performance decreased when trained on non-stemmed words, has been shown to be sensitive to the noise introduced by morphological variations. In addition, the use of stemmed words, allowed the SVM to benefit from the dimensionality reduction introduced by stemming.

The third experiment, in which the minority classes were removed (Table V), revealed an improvement in the performance of all models, with an accuracy of 95,82% for SVM, 96,26% for KNN, 94,95% for Random Forest and 93,41% for Naive Bayes. This suggests that the presence of minority classes was limiting the models' ability to train effectively and identify underlying patterns in the data. By eliminating these minority classes, the models were able to focus on more representative classes, reducing noise and imbalances in the training data. This simplification of the dataset enabled the algorithms to generalize better and produce more accurate and consistent results.

The fourth experiment assessed the impact of class balance, retaining 300 articles per class for the four classes selected in the previous experiment. This approach ensured a fair distribution of data between classes, reducing the bias introduced by class imbalances. By balancing the number of articles per class, the models were able to train on representative datasets, achieving interesting levels of accuracy: 96.25% for SVM, 95.42% for KNN, 93.33% for Random Forest and 95.83% for Naive Bayes (Table VI).
These last two experiments demonstrate the importance of class balance in the machine learning model training process, contributing to more robust performance.

By reducing the amount of data in the fifth experiment (Table VII), we observed a decrease in the performance of the SVM, KNN and Random Forest classifiers compared with the fourth experiment. The accuracy of these classifiers is reduced to 92.5%, 95% and 92.5% respectively. This decrease can be attributed to various factors inherent to these algorithms, mainly the careful tuning of hyperparameters. This tuning process is often made more difficult when the available data is limited. In addition, the Random Forest model, for example, requires a sufficient amount of data for each tree to learn meaningful and diverse patterns. By contrast, the Naive Bayes classifier performed better with small amounts of data. This performance is attributed to the simplicity of the model and its conditional independence assumption, which assumes that each feature contributes independently to the probability of each class.

VI. CONCLUSION

In this study, we were interested in the application of natural language processing and machine learning tools to classify Moroccan legal and legislative data. Given that our datasets are in Arabic, this adds a second level of complexity to our study. The texts under study include the Law on Civil Status, the Organic Law on Finance, the Law on Judicial Organization, the Traffic Code, the Family Code, the Law on Criminal Procedure and the Commercial Code. To the best of our knowledge, this data has not been covered before. Our task was to train the SVM, KNN, Random Forest and Naive Bayes models to assign each article to the appropriate class. In addition to this classification task, we evaluated the impact of stemming, class imbalance and data quantity on the behavior of the models used. In general, our experiments have shown that models perform better with balanced classes, but react differently to stemming and data quantity. Although these classical models generally perform well, it's important to note that they remain sensitive to word variations and the size of the training datasets. In future work, we will explore new perspectives by investigating other models, including deep

learning and language models, in order to tackle new legal tasks.

***Abstract*—Image dehazing is a crucial preprocessing step in computer vision for enhancing image quality and enabling many downstream applications. However, existing methods often do not accurately restore hazy images while maintaining computational efficiency. To overcome this challenge, we propose ERCO-Net a new fusion framework that combines edge restriction and contextual optimization methods. By using boundary constraints, ERCO-Net extend the boundaries that help in protecting the edges and structures of an image. Contextual optimization impacts the final quality of the dehazed image by enhancing smoothness and coherence. We compare ERCO-Net with conventional approaches such as dark channel prior (DCP), All-in-one dehazing network (AoD), and Feature fusion attention network (FFA-Net). The comparative evaluation highlights the effectiveness of the proposed fusion method, providing significant improvement in image clarity, contrast, and colors. The combination of edge restriction and contextual optimization not only enhances the quality of dehazing but also decreases computational complexity, presenting a promising avenue for advancing image restoration techniques. The source code is available at https://github.com/FatimaAyub12/Image-Dehazing-.**

***Keywords*—Image dehazing; edge restriction; contextual optimization; transmission map estimation; haze removal**

I. Introduction

Enhancing visibility in foggy or hazy conditions is a crucial objective in image processing, with picture dehazing playing a key role in achieving this improvement [1], [2]. Dehazing techniques improve image clarity and expose latent details by lowering the effect of ambient scattering. These methods quantify and eliminate haze-generated degradation using mathematical models while analysing pixel intensities and colours [3]. Popular techniques for enhancing image contrast and visibility include the dark channel prior [4] and atmospheric light estimation [5]. Where effective analysis and decision-making depend on clear, detailed images, dehazing finds uses in many disciplines including computer vision, surveillance and remote sensing. [6]. An illustration of a hazy image and its corresponding dehazed version is presented in the Fig. 1.

Early methods for haze reduction mostly depended on either several views of the same image or extra depth information. Notable contributions in this field are shown by several papers, including [2], [1], [3], [4]. Particles in the atmosphere partially polarise light as Schechner et al. [7] noted. The researchers used this finding to propose a method for quickly reducing haze using polarisation to take two pictures from different angles.

Fig. 1. Example of the image with haze (left) and dehazed image (right).

However, despite the advancements in this field, existing dehazing methods often struggle with maintaining a balance between image restoration quality and computational efficiency. Many of these techniques tend to either oversimplify the haze model or fail to preserve critical image details, such as edges and textures, resulting in suboptimal dehazed images with artifacts and color distortions. Furthermore, the increasing complexity of deep learning-based approaches introduces significant computational overhead, making real-time dehazing a challenging task Single image dehazing poses a challenge due to its inherent lack of complete information, making it an under-constrained problem. To address this, the conventional approach involves integrating additional priors or constraints. This paper delves into this notion by establishing an inherent boundary constraint concerning scene transmission. For the purpose of obtaining the illusive transmission parameters, an optimisation framework is constructed using this restriction alongside with a weighted L_1 norm-based contextual optimisation among neighbouring pixels. ERCO-Net operates on a set of fundamental assumptions and demonstrates the capability to produce high-quality, haze-free images with accurate color representation and intricate edge details. Summarizing, the main contributions of this paper are:

*Corresponding authors.

- Firstly, we introduce a novel constraint concerning scene transmission. This straightforward constraint, with its clear geometric interpretation, proves remarkably effective in image dehazing.
- Secondly, we propose a contextual optimization method that allows us to integrate a filter bank into the image dehazing process. These filters play a crucial role in reducing image noise and enhancing significant image features, such as abrupt edges and corners.
- Finally, we present an efficient optimization scheme, enabling rapid dehazing of large-sized images.

The remainder of this paper is organized as: Section II presents a detailed literature review, highlighting existing approaches to image dehazing. Section III introduces the proposed ERCO-Net framework, including edge restriction and contextual optimization techniques. Section IV discusses the methodology behind the edge restriction from the radiance cube and contextual regularization. Section V provides a comprehensive analysis of experimental results and a comparison with other state-of-the-art methods. Finally, Section VI concludes the paper with a summary of findings and future research directions.

II. Literature Review

The related work critically examines seminal works in image processing, atmospheric scattering models, and computational photography. It highlights the strengths and limitations of existing algorithms, emphasizing the need for novel approaches to address challenges in dehazing, such as preserving image details, handling varying haze densities, and improving computational efficiency. By synthesizing insights from diverse scholarly contributions, this review sets the foundation for proposing innovative solutions to enhance visual clarity and fidelity in hazy environments.

A. Network-Based Approaches for Image Dehazing

Convolutional Neural Networks (CNNs) play a pivotal role in modern deep learning-driven dehazing networks. These networks utilize different modules including standard convolution, dilated convolution, multi-scale fusion, feature pyramid, cross-layer connections, and attention mechanisms. Typically, these modules are combined into multiple basic blocks within a dehazing network architecture. This approach aids in comprehending the underlying principles of different dehazing algorithms. To facilitate understanding, the commonly used basic blocks in network architectures are summarized as follows.

1) Standard convolution neural network: Research has demonstrated the effectiveness of employing standard convolution in a sequential manner for constructing neural networks. Hence, it is a common practice to integrate standard convolution into dehazing models alongside other blocks [8], [9], [10], [11].

2) Dilated convolution: In Dilated Fusion, a method is used that enlarges the receptive field without changing the dimensions of the convolution kernel. Various studies [12], [13], [14], [15], [16] have shown its effectiveness in improving global feature extraction. Additionally, integrating convolution layers with varying dilation rates allows for the extraction of features from different receptive fields.

3) Multi-scale fusion: Research has shown that employing Convolutional Neural Networks (CNNs) with multi-scale convolution kernels can effectively extract features across various visual tasks. This approach utilizes convolution kernels of different scales and combines the extracted features, proving beneficial in tasks such as dehazing [17], [18], [19], [20]. Through fusion strategies, these methods achieve multi-scale details essential for image restoration. Typically, during feature fusion, output features obtained from convolution kernels of varying sizes are spatially concatenated or added together.

4) Feature pyramid: In the domain of digital image processing research, the concept of a feature pyramid emerges as a powerful tool. This pyramid allows for the extraction of information at various resolutions from an image. Within the domain of deep learning-based dehazing networks, researchers [21], [22], [23], [24], [25], [11], [26] have employed this strategy within the intermediate of the network layers. Here, the aim is to capture diverse scales of spatial and channel information, enhancing the ability of network to effectively dehaze images. The author in [27] introduces a novel transformer-based architecture for image dehazing that embeds transmission-aware information into the position encoder, addressing the challenge of varying haze densities across different spatial regions. It offers a new method of global and local feature integration for enhanced image clarity.

5) Cross-layer interconnection: To improve information exchange across different layers and strengthen the network's ability to extract features, CNNs frequently use cross-layer connections. In the domain of dehazing networks, three primary types of cross-layer connections emerge: The authors initially proposed ResNet, this approach is widely utilized in [28], [29], [30], [31], [32]. The second type, Dense Connection is applied in the works of [33], [34], [35]. While the third, Skip Connection have been integrated into various architectures [26], [36], [17], [13].

6) Attention dehazing: The attention mechanism has proven to be highly effective in natural language processing research. In the realm of computer vision, two commonly used attention mechanisms are channel attention and spatial attention. Channel attention plays a crucial role in the feature extraction and reconstruction of 2D images. It emphasizes the significant channels in a feature map, allowing the model to concentrate on essential feature details. This targeted approach boosts the efficiency of feature extraction. Meanwhile, spatial attention centers on the variations in feature positions within the map. For example, it can identify and prioritize regions with distinct characteristics, such as areas heavily affected by haze across the entire map. Integrating these attention mechanisms into neural networks has led to significant advancements in various tasks, including image dehazing. Several state-of-the-art dehazing methods [28], [37], [13], [30], [38], [39], [40], [41], [14], [23], [42], [11] have been applied by a number of advanced dehazing methods, which has greatly led to their commendable performance gains. As shown in [43], adversarial auto-augmentation techniques can improve the generalization of dehazing networks. This method adjusts haze density and distribution, allowing the network to generalize better across synthetic and real-world datasets.

The use of deep networks for image dehazing faced some challenges that include increased computational complexity

TABLE I. COMPARATIVE ANALYSIS OF IMAGE DEHAZING TECHNIQUES

Method	Key Features/Approach	Advantages	Limitations	Performance (PSNR / SSIM)
Dark Channel Prior (DCP) [44]	Atmospheric scattering model, dark channel prior used to estimate transmission map	Simple and effective for natural outdoor scenes	Fails with bright sky regions, introduces halo artifacts	16.62 / 0.817 (NHHaze)
All-in-One Dehazing Network (AoD) [8]	CNN-based approach with end-to-end learning	High computational efficiency, suitable for real-time applications	May oversimplify dehazing, causing loss of details	19.06 / 0.85 (NHHaze)
Feature Fusion Attention Network (FFA-Net) [40]	Multi-scale CNN with attention mechanisms for feature fusion	Preserves fine details, improves image contrast	High computational cost, may overfit on synthetic datasets	34.59 / 0.975 (NHHaze)
ERCO-Net (Proposed)	Edge restriction and contextual optimization, boundary constraints on transmission map	Maintains edge details, smooths transitions, reduces computational complexity	Slightly more complex than basic CNN methods	37.61 / 0.991 (NHHaze)

and possible overfitting due to high parameters' count. Moreover, sometimes deep networks do not work well enough for capturing complex atmospheric scattering effects appropriately in order to gain unsatisfactory quality in dehazed images. In contrast, employing edge restrictions and contextual optimization offers distinct advantages. These methods provide explicit guidance on preserving important image features and structural details during dehazing, ensuring more accurate and visually pleasing results. Moreover, they facilitate better incorporation of prior knowledge about haze distribution and scene characteristics, leading to improved generalization and robustness in various environmental conditions. Table I provides a comparative analysis of the key methods discussed in the literature, highlighting their features, advantages, limitations, and performance. This analysis demonstrates the efficiency of the proposed ERCO-Net method compared to existing approaches

III. EDGE RESTRICTION AND CONTEXTUAL OPTIMIZATION

Edge restriction in image processing is closely related to using spatial information, where certain attention is paid to edges and contours of images as needed [45], [46]. It also emphasizes the importance of providing margins and other small details in various image enhancements. More specifically, in the dehazing model, the boundary constraints must be applied to enhance the accuracy of estimates of the transmission map. This map is particularly useful when wanting to determine the extent of the haze that may be obscuring parts of the image [47], [48].

The core concept of the method entails controlling the dehazing operation based on understanding the type of change between objects or parts in the scene. It is mostly represented in equation form as a regularizer added to the energy function within the dehazing algorithm. Due to the priority given to edges and boundaries, the given algorithm risks receiving an infested image that lacks most of its necessary details while at the same time maintaining the clean image as natural as possible.

A. Working of Edge Restriction

The downsizing of the edges in the ERCO-Net is a significant component of the enhanced procedure. Because the transmission map would be required to estimate the edges of the objects, enhance edge preservation by the dehazing algorithm would be necessary [1]. Through the assignment of boundary constraints, the algorithm takes advantage of spatial information to improve the accuracy of the regression equations for the estimation of transmission map. Mathematically, this can be expressed in the following equation:

$$E_{\text{boundary}} = \lambda_b \int \|\nabla I - \nabla J\|^2 \, dx \tag{1}$$

In this context, E_{boundary} denotes the energy associated with boundary constraints. The variable I represents the hazy input image, J stands for the resulting dehazed image, and λ_b is a parameter that weights the boundary constraints appropriately.

B. Contextual Optimization in Dehazing

Contextual Optimization is the another prominent feature of the given approach which is crucial to be considered. It should resolve the issue of enhancing the dehazing process using contextual data at similar effectiveness. Contextual Optimization tends to enhance the neighboring pixels' coherency in an image thus enhancing the quality of the dehazed image [4]. Mathematically, it can be formulated as:

$$E_{\text{context}} = \lambda_c \int \|\nabla^2 J\|^2 \, dx \tag{2}$$

In this context, E_{context} denotes the energy associated with contextual optimization. The variable J represents the dehazed image, and λ_c is a parameter that optimizes this process.

By integrating edge restriction and contextual optimization, ERCO-Net aims to advance single-image dehazing techniques, providing a more robust solution to the challenges posed by atmospheric haze.

The flow of ERCO-Net is illustrated in Fig. 2.

ERCO-Net brings three key improvements. Firstly, introduce a new rule for how light travels through a scene. This rule is straightforward and easy to understand, and it turns out to be remarkably effective in clearing up hazy images. Secondly, introduce a new way to smooth out images by using a set of filters. These filters not only reduce unwanted noise in the images but also make certain features, like sudden changes and corners, stand out more. Lastly, a faster method has been developed to clean up large images, allowing for

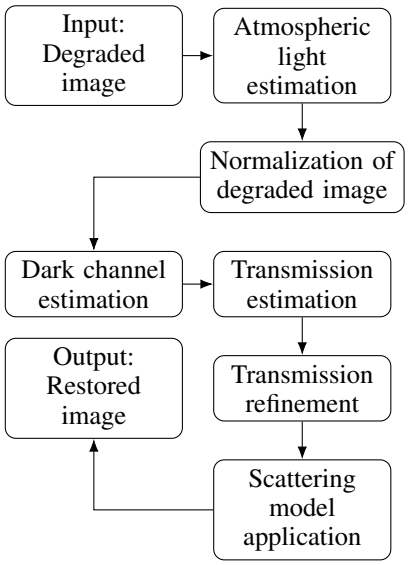

Fig. 2. Flowchart of the ERCO-Net dehazing process.

quick improvements in image clarity without taking much time.

The haze in the image is represented formally in a number of noteworthy work reported in [44], [49], [50], [51], depicted as follows:

$$Img(x) = st(x)R(x) + (1 - st(x))At \tag{3}$$

where, $Img(x)$ is the observed image, $R(x)$ is the scene radiance, At is the global atmospheric light, and $st(x)$ is the scene transmission. It is worthy to mention that the transmission function $st(x) : (0 \leq st(x) \leq 1)$ is related to the image depth.

The key objective of the image dehazing is to recover the image radiance $R(x)$ from $Img(x)$ based on Eq. 3. This requires us to estimate the transmission function $st(x)$ and the global atmospheric light At. Once $st(x)$ and At are estimated, the scene radiance can be recovered by:

$$R(x) = \frac{Img(x) - At}{[\max(st(x), \epsilon)]^{\lambda}} + At \tag{4}$$

IV. Edge Restriction from Radiance Cube

The concept of Boundary Constraint from Radiance Cube is a critical aspect in the context of image dehazing. The Radiance Cube represents the radiance values at different combinations of scene radiance and atmospheric light. The Boundary Constraint is employed to ensure that the estimated radiance values are constrained within physically meaningful bounds. In the context of image dehazing, this helps in preventing unrealistic or exaggerated scene radiance estimations.

- Atmospheric Light Constraint: The atmospheric light (A_t) is constrained to be within the range of 0 to 1. $0 \leq A_t \leq 1$
- Scene Radiance Constraint:
  The estimated scene radiance ($R(x)$) should be non-negative. $R(x) \geq 0$
- Transmission Constraint:
  The transmission ($st(x)$) lies between 0 and 1. $0 \leq st(x) \leq 1$
  4. Radiance Cube Constraint:
  The radiance cube values should be within a valid radiometric range.
  $L_{\text{min}} \leq L(x, \lambda) \leq L_{\text{max}}$
  Here, L_{min} and L_{max} represent the minimum and maximum radiance values, respectively.
- Boundary Constraint Equation:
  Combining the above constraints into a comprehensive boundary constraint equation:

$$R(x) = \frac{Img(x) - A_t}{[\max(st(x), \epsilon)]^{\lambda} + A_t} \tag{5}$$

This equation ensures that the estimated scene radiance ($R(x)$) is computed within the physically plausible boundaries while considering atmospheric light, transmission, and the Radiance Cube constraints.

These equations collectively enforce the Boundary Constraint, contributing to more realistic and physically meaningful results in the context of image dehazing. Adjustments to the parameters (ϵ and λ) may be made based on specific dehazing algorithms and requirements.

The above calculations can be depicted in Fig. 3.

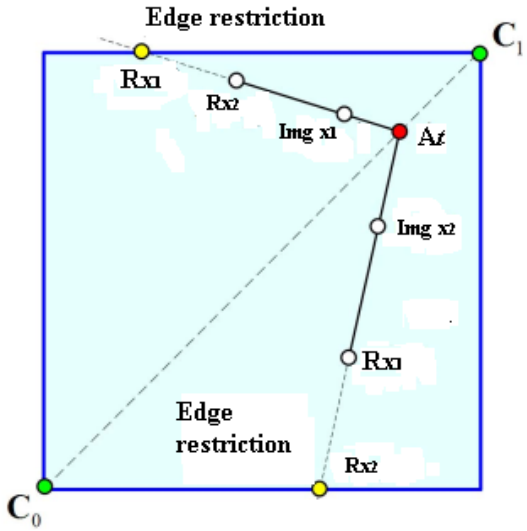

Fig. 3. A cube with boundary limitations that emits light. For every value of x, it is essential that the estimation of $J(x)$ does not surpass the limits of the radiance cube. $J_b(x_1)$ and $J_b(x_2)$ denote the precise positions that define the boundary constraints.

In geometric terms, as described by Eq. 3, when fog affects a pixel $Img(x)$, it tends to shift closer to the overall atmospheric light A_t, as illustrated in Fig. 3. Consequently, this effect can be counteracted by reversing the process and restoring the original clarity of the pixel, denoted as $R(x)$, through a linear extrapolation from A_t to Img_x. The extent of this extrapolation is determined as follows:

$$\frac{1}{st(x)} = \frac{|R(x) - A_t|}{|Img(x) - A_t|} \tag{6}$$

Let us contemplate the notion that the radiance of the scene within a particular image remains constrained; that is to say

$$C_0 \leq R(x) \leq C_1, \quad \forall x \in \Omega \tag{7}$$

In the context of the provided image, two constant vectors, C_0 and C_1, hold significance. Thus, it is imperative that for any given value of *x*, the extrapolation of $Rx)$ should fall within the radiance cube delineated by C_0 and C_1, as depicted in Fig. 3.

The requirement stated above for $R(x)$ leads to an edge restriction on $st(x)$. Assuming the global atmospheric light A_t is provided, the respective boundary constraint point $R(x_1)$ can be calculated for each *x* (see Fig. 3). Consequently, utilizing Eq. 6 and Eq. 7, a minimum value for $st(x)$ can be established, thereby setting the boundary constraint on $st(x)$ as follows:

$$0 \leq st_b(x) \leq st(x) \leq 1 \tag{8}$$

where $st_b(x)$ is the lower bound of $st(x)$, given by

$$st_b(x) = \min \left\{ \max_{c \in \{r,g,b\}} \left(\frac{A_t^c - \text{Img}(x)^c}{A_t^c - C_0^c}, \frac{A_t^c - \text{Img}(x)^c}{A_t^c - C_1^c} \right), 1 \right\} \tag{9}$$

here $Img(x)^c$, ${A_t}^c$, C_0^c and C_1^c are the color channels of $Img(x)$, A_t, C_0 and C_1, respectively

The edge constraint imposed by $st(x)$ provides a novel geometric viewpoint on the well-known dark channel prior [44]. Let's assign $C_0 = 0$ and suppose that the total atmospheric light A_t is brighter than any pixel in the foggy image. This enables us to compute $st_b(x)$ directly using Eq. 3, under the assumption that the dark channel of $R(x)$ at each pixel is zero. In addition, by assuming that the transmission remains constant inside a local image patch, the transmission for each patch $t\ddot{E}IJ(x)$ can be easily calculated using the method described in [44]. This is achieved by applying maximum filtering on $st_b(x)$ using Eq. 10.

$$\tilde{st}(x) = \max_{y \in \omega_x} st_b(y) \tag{10}$$

here ω_x is a local value being originated at *x*.

It is noteworthy that the edge restriction holds greater significance. In general, the ideal global atmospheric light is usually less bright than the brightest pixels in an image. These pixels often come from prominent light sources in the environment, like a brilliant sky or automobile headlights. While the dark channel prior may not effectively capture these bright pixels, the proposed edge restriction remains relevant.

Furthermore, it is of key importance that the commonly utilized constant assumption regarding transmission within a local image patch can be quite stringent. Consequently, the patch-wise transmission, as proposed in [44], [52] based on this assumption, is frequently undervalued. In this context, a more precise patch-wise transmission method is introduced that loosens the aforementioned assumption, thereby permitting slight variations in transmissions within a local patch. Eq. 11 depicts the formation of new patch-wise transformation:

$$\tilde{st}(x) = \min_{y \in \omega_x} \max_{z \in \omega_y} st_b(z) \tag{11}$$

The patch-wise transmission $\tilde{st}(x)$ can be efficiently calculated by simply applying a morphological closing operation on $st_b(x)$. Fig. 4 shows a comparison of the dehazing results achieved by using patch-wise transmissions derived from both the dark channel prior and the boundary constraint map. It is clear that the transmission derived from the dark channel prior is less effective in areas with bright sky. Furthermore, the dehazing results display noticeable halo artifacts.

Fig. 4. Results of image dehazing by applying patch-wise transmission from dark-channel and ERCO-Net (edge restriction). (a) The foggy image, (b) output dehazed image by dark-channel, (c) dehazing result be edge restriction.

A. Contextual Regularization based on L1-norm

Typically, pixels within a localized section of an image exhibit comparable depth values. Leveraging this presumption, a transmission method based on patch-wise constraints has been formulated. Nevertheless, this contextual inference frequently proves inadequate for image sections characterized by sudden depth changes, resulting in pronounced halo artifacts in the dehazing outcomes. This issue can be resolved by computing a weighting function wt on the edge restrictions, given below in Eq. 12.

$$wt(x, y)(st(y) - st(x)) \approx 0 \tag{12}$$

In the context of image processing, the relationship between adjacent pixels, denoted as *x* and *y*, is influenced by a weighting function. This function acts as a sort of "switch" determining the constraint between these pixels. Specifically, when the weighting function, $wt(x, y)$, equals zero, it effectively nullifies the contextual constraint of $st(x)$ between *x* and *y*. The suitable value of $wt(x, y)$ was determined to be inversely proportional to the difference between the values of *x* and *y*; i.e. the larger the distance between *x* and *y*, the lower the weight value. Additionally, it was determined that depth jumps primarily occur at the boundaries of images and within localized areas (or patches), where pixels of similar colors are likely to possess comparable depth values. This suggests that color variation among neighboring pixels can be calculated to create a weighting function. Two instances are provided to

demonstrate the formulation of such weighting functions. One approach entails computing the squared discrepancy between the color vectors of adjacent pixels, as seen in Eq. 13.

$$wt(x,y) = \frac{e^{-|Img(x)-Img(y)|^2}}{2\sigma^2} \tag{13}$$

Here σ acts as tune-able parameter. Same calculation is computed by considering (in Eq. 14) the difference in luminance of the neighboring pixels.

$$wt(x,y) = ((|lum(x) - lum(y)|)^{\alpha} + \epsilon)^{-1} \tag{14}$$

In this context, lum(x) refers to the logarithmic luminance channel of the image Img(x). The exponent $\alpha \geq 0$ determines the level of sensitivity to differences in luminance between two pixels, while ϵ is a small constant (typically 0.0001) used to prevent division by zero. The integration of the weighted contexts throughout the entire image leads to the subsequent contextual optimisation for $st(x)$:

$$\sum_{i \in I} \sum_{j \in \omega_i} wt_{ij} |st_i - st_j| \tag{15}$$

Here *I* is the index set of image pixels, wt_{ij} is the discrete versions of $wt(x,y)$.

B. Estimation of Scene Transmission

In image dehazing, estimating the scene transmission is a crucial step to recover the haze-free image from a hazy input. The scene transmission, denoted by $st(x)$, represents the proportion of light that is transmitted through the atmospheric medium at each pixel x in the image. A common model used for estimating scene transmission is the dark channel prior (DCP) proposed by [44].

The dark channel prior exploits the statistical property that in most outdoor natural images, there exist some pixels with very low intensity values in at least one color channel. This property holds true even in hazy images.

The dark channel $J^{dark}(x)$ of an image J is defined as:

$$J^{dark}(x) = \min_{y \in \Omega(x)} (\min_{c \in \{r,g,b\}} (J^c(y))) \tag{16}$$

where $J^c(y)$ represents the intensity of channel c at pixel y, and $\Omega(x)$ is a local patch centered at pixel x.

The scene transmission $t(x)$ can then be estimated using the dark channel prior as:

$$t(x) = 1 - \omega \cdot \min_{y \in \Omega(x)} (J^{dark}(y)) \tag{17}$$

where ω is a small positive constant used to control the amount of haze removal.

By utilizing the dark channel prior to estimate the scene transmission, the areas of the image impacted by haze can be accurately detected and their intensity appropriately reduced throughout the dehazing procedure.

V. Results with Discussion

Fig. 5 depicts the process of scene transformation estimation of the image performed in different iterations, by applying Eq. 16 and Eq.17.

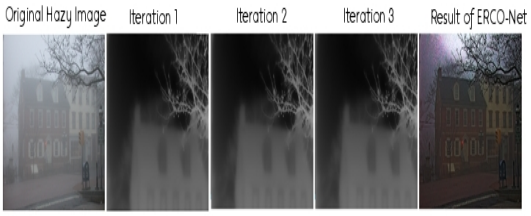

Fig. 5. Results of applying scene transmission estimation on hazy image. The results are shown in iteration followed by the final output.

The results are generated by adjusting the value of *w* to 0.5 in Eq. 17. The edge restriction is set to the C_0 to $(20, 10, 20)^T$ and C_1 to $(150, 150, 300)^T$ in Eq. 9. These adjustments assist in adjusting the haze map with in the view-able window.

The results demonstrate ERCO-Net ability to effectively restore intricate details and vibrant color information within hazy regions of images. It's important to emphasize that the estimated transmissions displayed in the three images on the right side of the figure are not merely scaled versions of depth maps. This is due to the non-uniform distribution of haze across these images, particularly evident in image featuring expansive clear sky areas. Essentially, the transmission function serves as a reflection of the haze density present within the captured image, rather than simply representing depth.

A. Comparison with Other Approaches

For evaluation purposes, the ERCO-Net results were also compared with some state-of-the-art models. These models include dark channel prior (DCP) [44], Atmospheric Light Estimation (ALT) [53], Image Fusion [54], and multiscale retinex [55].

Fig. 6 depicts the comparison of our approach with the algorithms aforementioned.

Fig. 6. Comparison with DCP, ALT, Image Fusion, and MSR approaches using ERCO-Net on the NH-Haze2 dataset [56].

Similarly, Fig. 7 shows the output of our algorithm in comparison with other models.

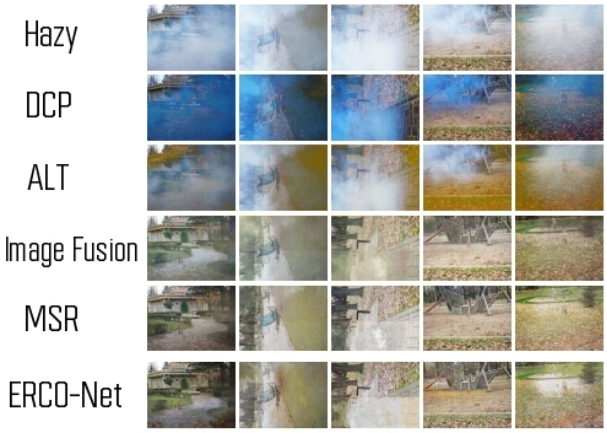

Fig. 7. Comparison with DCP, ALT, Image Fusion, and MSR approaches using ERCO-Net on the NH-Haze2 dataset [57].

For evaluation purposes, two metrics are employed: the Structural Similarity Index (SSIM) and the Peak Signal-to-Noise Ratio (PSNR). These metrics are frequently utilized in image processing to evaluate the quality of images.

Table II presents the comparison of our approach with other algorithms over NHHaze and NHHaze-2 datasets.

TABLE II. QUANTITATIVE COMPARISONS OVER NHHAZE AND NHHAZE-2 DATASETS FOR DIFFERENT METHODS AND ERCO-NET APPROACH

Methods	NHHaze		NHHaze2	
	PSNR	SSIM	PSNR	SSIM
DCP	16.62	0.817	12.92	0.505
ALT	19.06	0.85	17.69	0.616
Image fusion	30.23	0.975	19.5	0.66
MSR	34.59	0.975	23.53	0.754
ERCO-Net	**37.61**	**0.991**	**25.54**	**0.783**

VI. CONCLUSION

In the field of single image dehazing, a significant challenge arises from the inherent ambiguity between image color and depth. This ambiguity often leads to difficulty in distinguishing between haze-affected and unaffected pixels, particularly when their coloration is similar. ERCO-Net addresses this challenge by combining edge restriction and contextual optimization, which improves image clarity and preserves critical details. The method demonstrated reliable dehazing performance with reduced computational complexity, highlighting its potential for practical applications. Future work will focus on further optimizing ERCO-Net for large-scale datasets and addressing limitations in extreme haze conditions. Additionally, improvements in edge detail retention and the exploration of its applicability to other image restoration tasks will be key areas of investigation.

ACKNOWLEDGMENT

We would like to express sincere gratitude to AlMaarefa University, Riyadh, Saudi Arabia, for supporting this research.

Optimizing Text Summarization with Sentence Clustering and Natural Language Processing

Zahir Edress*, Yasin Ortakci
Department of Computer Engineering, Karabuk University, Karabuk, Turkey

***Abstract*—Text summarization is an important task in natural language processing (NLP), with significant implications for information retrieval and content management. Traditional summarization methods often struggle with issues like redundancy, loss of key information, and inability to capture the underlying semantic structure of the text. This paper addresses these challenges by presenting an advanced approach to extractive summarization, which integrates clustering-based sentence selection with the BART model.The proposed method tackles the problem of redundancy by using Term Frequency-Inverse Document Frequency (TF-IDF) for feature extraction, followed by K-means clustering to group similar sentences. This clustering step is designed to reduce redundancy by ensuring that each cluster represents a distinct theme or topic. Representative sentences are then selected from these clusters based on their cosine similarity to a user query, which helps in retaining the most relevant information. These selected sentences are then fed into the BART model to generate the final abstractive summary. This combination of extractive and abstractive techniques addresses the common problem of information loss, ensuring that the summary is both comprehensive and coherent. The approach is evaluated using the CNN/DailyMail and XSum datasets, which are widely recognized benchmarks in the summarization domain. Results assessed through ROUGE metrics demonstrate that the proposed model substantially improves summarization quality compared to existing benchmarks.**

Keywords*—Abstractive summarization; extractive summarization; sentence clustering; language understanding; information retrieval

I. Introduction

Text summarization task aims to generate a concise and coherent summary from a given text while preserving its key information and meaning[1]. The challenge lies in effectively capturing the essence of the original content, which can vary widely in length, complexity, and structure. In the realm of text summarization, there are two primary approaches [2]: extractive and abstractive summarization, extractive summarization involves selecting and compiling sentences or phrases directly from the source text to form a summary. This approach relies on identifying the most important segments of the text, but may lack coherence and fluidity in the final output. On the other hand, abstractive summarization involves generating new sentences that convey the core ideas of the text [3], often resulting in more human-like and fluent summaries. However, this approach requires advanced techniques to ensure that the generated summary is both accurate and contextually relevant [4].

Extractive summarization is the most widely utilized and rapidly developed approach [5]. Despite its advancements, extractive summarization faces challenges, particularly in initial center selection and redundancy issues. In articles with complex sentence structures, the summarized sentences often exhibit high redundancy. This occurs because the extracted sentences may share significant semantic similarity, leading to repetitive content in the summary. Consequently, even if the summary includes relevant concepts, it may contain redundant information due to the repetition of similar concepts. This redundancy can make the summary unnecessarily lengthy and less concise. To solve the above problems this paper explores an enhanced summarization approach that combines clustering-based extractive methods with the BART model. the methodology starts by employing TF-IDF to evaluate the significance of each sentence within the original text and subsequently apply K-means clustering to group similar sentences into clusters. This process helps in identifying thematic groups within the text, which reduces redundancy and ensures a more diverse representation of content. For each cluster, representative sentences are selected based on cosine similarity to a query sentence. By selecting sentences that closely match this query, key information from each cluster is accurately captured, the selected sentences are then used to form a context for the BART model, which generates the final summary.

The proposed approach is evaluated using several well-established benchmark datasets, including CNN/DailyMail and XSum. Performance is assessed using ROUGE metrics, and the experimental results indicate that the model achieves superior ROUGE scores compared to other benchmark summarization methods. Specifically, the approach demonstrates significant improvements in terms of informativeness and coherence, reflecting a more accurate and fluid representation of the original text.

The main contributions of this work are summarized as follows:

- A novel framework for text summarization is proposed that enhances the coherence and human-likeness of the generated summaries.
- An effective sentence sampling strategy is introduced within the rewrite model, which significantly improves the quality and relevance of the summaries.
- The extensive experiments demonstrate that the proposed model consistently outperforms existing state-of-the-art baselines in text summarization.

The rest of the paper is organized as follows. Section II reviews related work of this paper. Section III gives a detailed explanation of the methodology. Section IV describes the experimental setups, which is followed by the experimental results in Section V. The paper is concluded in Section VI.

II. Related Work

Automatic Text summarization (ATS) has been extensively researched, with various methods proposed to address its challenges [6]. Early work in extractive summarization focused on approaches such as frequency-based methods, graph-based algorithms like Text Rank, and machine learning techniques [7]. These methods generally perform well in selecting salient sentences but often struggle with generating coherent summaries. Recent advancements in abstractive summarization have been driven by transformer-based models. Models like BERT (Bidirectional Encoder Representations from Transformers) and its variants have achieved state-of-the-art performance on summarization tasks by capturing deep contextual information [8]. BART a more recent model, combines the strengths of both bidirectional and autoregressive transformers, making it particularly effective for text generation tasks [1]. This section provides a summary of relevant research that informs the hybrid summarization approach, which combines extractive and abstractive techniques.

A. Extractive Text Summarization

The extractive summarization method involves selecting key sentences and keywords directly from the original text [9], It works by scoring sentences based on their importance, with higher scores indicating more significant sentences [10]. The summary is created by sequentially choosing the highest-scoring sentences from the text [11]. Liu et al. [7] enhanced extractive summarization by combining the improved TextRank algorithm with K-means clustering, This approach utilizes the BM25 model to compute sentence similarity and derive TR scores which are used to select initial cluster centers and reduce redundancy. Mohsen et al. [12] developed a hierarchical self-attentive neural network model that integrates reinforcement and supervised learning to rank sentences by directly optimizing the ROUGE metric. The model leverages hierarchical self-attention to create document and sentence embeddings that capture the document's structure, enhancing feature representation and summarization quality.

B. Abstractive Text Summarization

The abstractive summarization method creates summaries by generating new words and phrases, rather than directly extracting from the original text [13]. It uses natural language understanding to analyze the grammar and semantics of the document [14], allowing it to convey the main ideas in a newly formulated text [15]. Jain et al. [16] developed a specialized dataset for abstractive summarization to increase the number of training samples while maintaining manageable lengths for each sample. Bahrainian et al. [17] developed CATS an advanced abstractive neural summarization model that enhances the traditional sequence-to-sequence approach by introducing a mechanism for controlling the latent topic distribution of the generated summaries Su et al. [18] proposed a two-stage method for variable-length abstractive summarization using a text segmentation module and a Transformer-based summarization model. It first segments the text using BERT and BiLSTM, then applies a two-stage training approach with BERTSUM for document and segment summarization.

C. Hybrid Text Summarization

The hybrid summarization method combines both extractive and abstractive techniques to leverage the strengths of each approach. Initially, an extractive summary is generated using extraction models or trainers [8]. This summary is then refined through semantic analysis and rephrasing to produce an abstractive summary [19]. This dual approach aims to create a more comprehensive summary by integrating the benefits of both methods [20]. Recent studies have increasingly focused on combining extractive and abstractive methods [21]. For instance, using extractive summaries as inputs for abstractive models has demonstrated improved performance [22], highlighting the efficacy of this integrated approach in enhancing summary quality. Zhang et al. [1] proposed framework as Extract-then-Abstract approach, an initial extractive summarization model is used to identify and select relevant sentences from the text. This extractive summary is then refined using an abstractive model to generate summary. Morozovskii and Ramanna [23] proposed supervised learning model employs a hybrid approach that integrates both extractive and abstractive elements to enhance the inclusion of crucial information in news summaries. Wang et al. [13] introduced the Topic-Injected Bidirectional Encoder Representations from Transformers (TP-BERT) by incorporates contrastive learning during training.

The previous studies highlights various methodologies and advancements in text summarization. Table I summarizes different studies, detailing the year of the study, the methods employed, key contributions, and the limitations encountered. the proposed approach introduces a novel enhancement by integrating clustering-based sentence selection with the BART model. Unlike traditional extractive methods that select sentences based on frequency or similarity alone, the method utilizes TF-IDF for feature extraction and K-means clustering to group similar sentences. This clustering process identifies thematic groups within the text, reducing redundancy and ensuring a more diverse representation of content. By selecting representative sentences from each cluster based on cosine similarity to a query sentence, the approach effectively captures essential information while minimizing redundancy. This method addresses the limitations of improved TextRank, which may not fully achieve thematic coherence. Moreover, the integration with BART enhances the fluency and coherence of the final summary, leading to more contextually accurate and readable outputs.

III. Methodology

Our proposed summarization approach integrates extractive and abstractive techniques to enhance the relevance and coherence of generated summaries. The methodology is designed to capture key information from the source text while producing fluent and contextually accurate summaries. The process involves data preprocessing, vectorization, clustering-based sentence selection, representative sentence extraction, and abstractive summarization using BART as shown in Fig. 1.

A. Data Preprocessing

The preprocessing steps included Articles were retrieved from the dataset based on user-defined keywords using a

TABLE I. SUMMARY OF RELATED WORK IN TEXT SUMMARIZATION

Study	Year	Method	Key Contributions	Limitations
Wang et al [13]	2024	Integrates topic words into sentences and uses contrastive learning during training	Improving semantic consistency and summarization quality	Incorporating topic words and contrastive learning may add complexity to the model, potentially increasing computational requirements.
Jain et al [24]	2024	Generating additional training samples by creating multiple extractive summaries	Handling long documents	Potential information loss from segmenting documents into 512-token
Liu et al [7]	2024	Employs an improved BM25 model to compute BM25 similarity between sentences.	Reduce sentence redundancy	The method does not account for the position of sentences in the final summary, which might affect the coherence and readability of the summary
Morozovskii and Ramanna [23]	2023	Proposes an enhancement to the transformer model's attention mechanism by integrating frequency information for each word to better handle rare words.	Enhanced Attention Mechanism	The model may include less relevant information due to its distribution of attention across words
Zhang et al [1]	2023	Implements sentence sampling strategy to create parallel data for the rewrite model without manual annotation	Develops a pipeline using topic modeling to select the most relevant sentences	The extractive stage might still result in summaries that lack smooth transitions between sentences
Bahrainian et al[17]	2022	Neural sequence-to-sequence model with encoder-decoder and topical attention	Introduces customizable abstractive summarization using topic modeling.	Need for comparison with transformer-based models.
Su et al [18]	2020	Two-stage Transformer-based summarization model with text segmentation	Employs BERT and LSTM for segmentation and uses collaborative training.	The integrating of multiple models and collaborative training might imply potential challenges in practical implementation.
Mohsen et al [12]	2020	Hierarchical self-attentive reinforced neural network-based summarization model	Combines reinforcement and supervised learning to optimize the ROUGE evaluation metric directly.	The complexity of the model may lead to increased computational requirements.

search function that scans through the dataset and returns the top results. This search is limited to a maximum of five articles to maintain manageability. Each article was segmented into sentences using NLTK's "sent tokenize" function to facilitate clustering and similarity computations [25]. Sentence segmentation enables us to process and analyze each sentence independently [26]. Further preprocessing included stop words removal, which involved eliminating common but less informative words (e.g. "the", "and") to focus on more meaningful terms [27]. Also, word alignment process is to remove punctuation and numbers from each sentence. Finally, Lemmatization was applied to reduce words to their base or root forms (e.g. transforming "running" to "run") [28], Fig. 2 summarizes these steps.

B. Vectorization

In this step, the Term Frequency-Inverse Document Frequency (TF-IDF) vectorizer is employed to convert sentences into numerical feature vectors, this process begins with applying the vectorizer to the preprocessed sentences, transforming them into a high-dimensional space where each dimension corresponds to a term in the vocabulary. The (TF-IDF) model assigns weights to terms based on their importance within each sentence relative to the entire corpus. By capturing both the frequency of terms within individual sentences (Term Frequency) and their significance across the corpus, the TF-IDF vectorizer produces feature vectors that effectively represent the content and context of each sentence.

C. Clustering Process

A clustering-based approach was employed to identify representative sentences [7]. Specifically, the K-means algorithm was used to cluster sentences into a predefined number of clusters. K-means partitions sentences based on their vector representations [1], grouping similar sentences together [29]. the elbow method was utilized to determine the optimal number of clusters as illustrated in Fig. 3. This method involves plotting the within-cluster sum of squares (inertia) against the number of clusters [30]. Inertia measures the sum of squared distances between each point and its assigned cluster center, reflecting the compactness of the clusters [31]. the K-means algorithm was executed across a range of cluster counts (from 1 to 10) and computed the inertia for each count.The resulting plot displays the number of clusters on the x-axis and the corresponding inertia on the y-axis. The "elbow" of the plot, where the rate of decrease in inertia slows down, indicates the optimal number of clusters. This point represents a balance between minimizing inertia and avoiding overfitting by selecting too many clusters [32]. choosing the optimal number of clusters affects the thematic diversity and coherence of the summary. Fewer clusters may lead to excessive redundancy, while more clusters can cause over-segmentation and loss of crucial information. The elbow method helps in finding a balance that improves summary quality by ensuring each

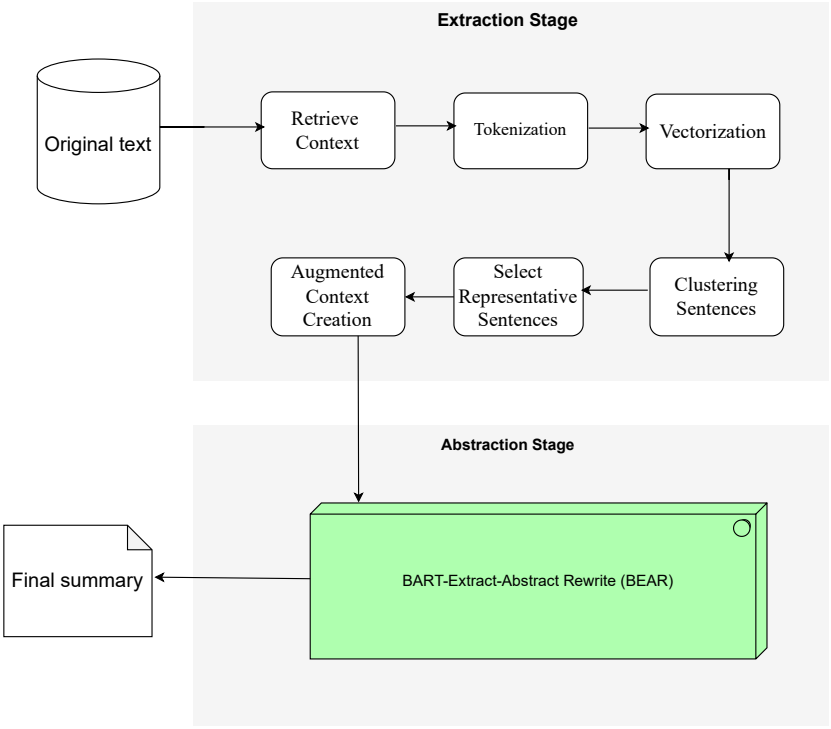

Fig. 1. The general structure of the proposed model.

cluster represents a distinct theme or topic, which enhances the effectiveness and the summarization results [33].

D. Selecting Representative Sentences

To refine the selection of representative sentences from each cluster, cosine similarity was calculated between a query sentence and each sentence within a cluster. The query was constructed from the first few sentences of the article to effectively represent the main context. For each cluster, the sentence with the highest cosine similarity to the query was selected as outlined in the Algorithm 1. cosine similarity was chosen because it effectively quantifies the similarity between sentences based on their term frequency representation [34], this metric is particularly useful for identifying sentences that closely match the thematic context of the query sentence [35], ensuring that the representative sentences are contextually relevant.

E. Summarization with BART

The BART (Bidirectional and Auto-Regressive Transformers) model, specifically the pre-trained facebook/bart-large-cnn version was used for generating summaries due to its strong performance on summarization tasks [1]. The model was configured to produce summaries with a maximum length of 150 tokens and a minimum of 40 tokens. It was fed with an augmented context, which was created by concatenating representative sentences selected through a clustering process. This augmented context helped the model generate a more coherent and comprehensive final summary.

Algorithm 1: Clustering-Based Extractive-Then-Abstractive Summarization

Input Text document D, User query Q
Output Final summary S
Feature Extraction: Calculate the Term Frequency-Inverse Document Frequency (TF-IDF) for each sentence in document D Represent each sentence as a TF-IDF vector
Sentence Clustering: Apply K-means clustering to group the sentences into K clusters based on their TF-IDF vectors
Representative Sentence Selection: for *each cluster* **do**
Calculate the cosine similarity between each sentence and the user query Q Select the sentence with the highest cosine similarity within each cluster as the representative sentence
Input to BART Model: Combine the selected representative sentences into a coherent sequence Feed the sequence of selected sentences into the pre-trained BART model
Generate Final Summary: The BART model generates an abstractive summary S from the input sequence of representative sentences
return Final summary S

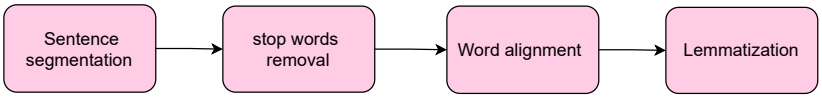

Fig. 2. Data preprocessing steps.

IV. Experiments

In this section, The experiments conducted to evaluate the effectiveness of the proposed summarization model are presented. These experiments are designed to assess the performance of various summarization methods across different datasets, with a focus on comparing baseline methods and the proposed approach.

A. Datasets

To evaluate the performance of the framework, it is assessed using two benchmark summarization datasets: CNN/DailyMail [36] and XSum [37], detailed statistical information for these datasets is provided in Table II.

1) The CNN/DailyMail: dataset is widely used for evaluating text summarization models. It consists of approximately 93,000 articles from CNN and 220,000 articles from the Daily Mail newspapers, totaling around 313,000 news articles [6]. Each article in the dataset is paired with multiple reference summaries, which are generally several sentences long, and are written by humans. The summaries are derived from the article highlights, typically found as bullet points making this dataset suitable for both extractive and abstractive summarization tasks.

2) The XSum: (Extreme Summarization) dataset is a benchmark dataset specifically designed for single-document abstractive summarization tasks. It consists of approximately 227,000 online articles from the BBC, covering a wide range of topics, including news, sports, and lifestyle. Each article is paired with a corresponding one-sentence summary, known as the "extreme summary", which captures the key point of the article. The one-sentence summaries are often highly abstractive, meaning they are not simply extracted sentences from the original text but are instead newly generated sentences that convey the main idea [7].

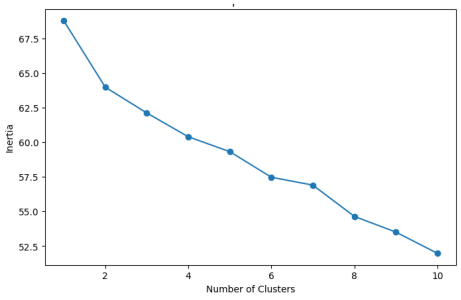

Fig. 3. Elbow method for determining the optimal number of clusters.

B. Baseline Methods

A range of high-performing models is selected for evaluation, relevant models from recent years as the baseline.

TABLE II. Statistics of the CNN/DailyMail and XSum Datasets

Dataset	#Docs	#Avg. sent.	#Avg. words	Domain
CNN/DailyMail	287,113	45.7	781	News
XSum	204,045	19.77	431	News

1) Lead-3: method simply selects the first three sentences from the document as the summary. It exploits the tendency of news articles to place the most important information at the beginning [38].

2) PacSum: (Parameterized Summarization) uses a heuristic-based approach to select sentences based on their importance, as determined by a parameterized model. It is known for its effectiveness in extracting informative sentences that contribute to high-quality summaries [39].
FAR (Focus-Aware Ranking) incorporates focus-aware ranking strategies to select the most relevant sentences. It improves upon simple extraction methods by considering the relevance and focus of the content [40].

3) SUMO: (Summarization with Meaningful Overlaps) focuses on identifying and using significant overlaps in sentence content to improve summary quality. It aims to balance informativeness and redundancy in the selected sentences [41].

4) PGNet: (Position-Aware Graph Network) incorporates position information and graph-based methods to rank sentences based on their importance in a given document. It improves upon traditional methods by leveraging positional information [16].

5) REFRESH: (REsponse-aware Frequency-based Summarization with Contextualized Highlights) uses response-aware frequency metrics to highlight key content. It adapts based on context to improve summary relevance [42].

6) SEQ: (Sequence-to-Sequence) models are based on sequence-to-sequence learning approaches that generate summaries by learning from large amounts of text. These models often use encoder-decoder architectures to produce coherent and contextually relevant summaries [43].
TED (Text Extensible Domain) leverages domain-specific knowledge to enhance summarization. By extending the text domain, TED models improve summary quality by incorporating additional contextual information [44].

7) CPSUM: (Soft) is an extractive summarization approach that employs a soft selection mechanism, focusing on selecting important sentences based on their relevance and contribution to the summary [13].

8) CPSUM: (Hard) differs from its soft counterpart by using a hard selection mechanism, which selects sentences more decisively without soft probability weighting [45].

9) BERTEXT: is an extractive summarization method that employs sequence labeling. This approach determines which sentences should be included in the summary by leveraging predictions made by a pre-trained BERT model [8].

10) BART: effectively captures context through its bidirectional encoder and produces high-quality summaries using its autoregressive decoder [1].

C. Evaluation

To evaluate the performance of the summarization approach, the ROUGE (Recall-Oriented Understudy for Gisting Evaluation) metric was used to assess the quality of the generated summaries [19]. ROUGE measures the overlap between the generated summaries and reference summaries across several dimensions including [46]:

ROUGE-1 (R-1): Measures unigram overlap between the generated and reference summaries. This metric evaluates the proportion of unigrams (single words) in the generated summary that are present in the reference summaries [4].

ROUGE-2 (R-2): Assesses bigram overlap, focusing on pairs of consecutive words. This metric helps determine how well the generated summary captures the sequence of word pairs found in the reference summaries [13].

ROUGE-L (R-L): Evaluates the longest common subsequence between the generated and reference summaries [47]. The calculation of the ROUGE-N is shown in Eq. (1).

$$\text{ROUGE-N} = \frac{\sum_{s \in S} \sum_{n \in \text{N-grams}(s)} \text{count}_{\text{match}}(n)}{\sum_{s \in S} \sum_{n \in \text{N-grams}(s)} \text{count}_{\text{ref}}(n)} \quad (1)$$

where:

- S is the set of generated summaries.
- N-grams(s) represents the set of n-grams in summary s.
- $\text{count}_{\text{match}}(n)$ is the count of n-grams n that match between the generated summary and the reference summaries.
- $\text{count}_{\text{ref}}(n)$ is the count of n-grams n in the reference summaries.

D. Implementation

The implementation involved Libraries, the "transformers" library for BART was used, "datasets" for loading the datasets, "sklearn" for clustering and vectorization, and "nltk" for sentence tokenization. A Python script was developed to automate the entire process, from article retrieval and sentence clustering to summary generation and evaluation.

V. Results and Discussion

A. Results

The performance of the proposed BEAR model is evaluated using ROUGE metrics across various summarization models, as detailed in Table III. This table showcases the R-1, R-2, and R-L scores for different models on the CNN/DailyMail dataset, including the BEAR model. Notably, BEAR demonstrates competitive performance with R-1, R-2, and R-L scores of 48.15, 19.23, and 37.03, respectively, surpassing several baseline models.

To facilitate a visual interpretation of these results, Fig. 4 presents a heatmap of the ROUGE scores. This heatmap highlights the comparative performance of BEAR against other models, clearly illustrating that BEAR excels in both R-1 and R-2 metrics. This indicates its superior capability in capturing relevant information and ensuring coherence in summaries.

TABLE III. ROUGE Scores for Different Models on the CNN/DailyMail Dataset

Model	R-1	R-2	R-L
Lead 3	40.01	17.45	36.31
PacSum	40.37	17.92	36.62
FAR	40.42	17.95	36.67
SUMO	41.00	18.40	37.20
PGNet	39.50	17.30	36.40
REFRESH	41.30	18.40	37.50
SEQ	23.24	7.10	22.15
TED	38.73	16.84	36.15
BART	44.16	18.07	35.53
BEAR (proposed model)	**48.15**	**19.23**	**37.03**

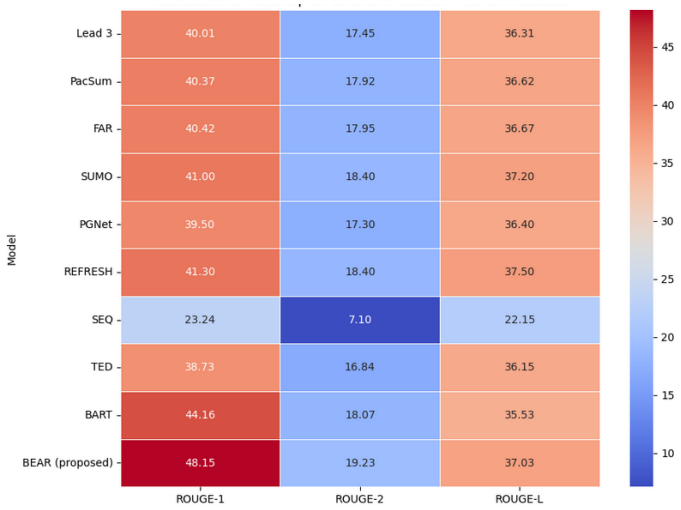

Fig. 4. Heatmap of ROUGE scores for different summarization models on the CNN/DailyMail dataset.

Table IV presents the ROUGE scores for various summarization models evaluated on the XSum dataset. Notably, the proposed BEAR model demonstrates impressive performance, achieving R-1, R-2, and R-L scores of 25.00, 8.57, and 19.44, respectively. Fig. 5 provides a visual representation of these results through a heatmap. In the heatmap, color gradients are used to illustrate the relative performance of each model, with darker shades indicating higher ROUGE scores. This visualization effectively highlights the strengths of the BEAR model compared to other models, underscoring its capability in generating high-quality summaries.

TABLE IV. ROUGE SCORES FOR VARIOUS SUMMARIZATION MODELS ON THE XSUM DATASET

Model	R-1	R-2	R-L
Lead 3	16.30	1.60	11.95
SEQ	20.11	5.23	16.15
CPSUM(Soft)	17.22	2.17	12.71
CPSUM(Hard)	17.29	2.18	12.73
BERTEXT	22.86	4.48	17.16
BEAR (proposed model)	**25.00**	**8.57**	**19.44**

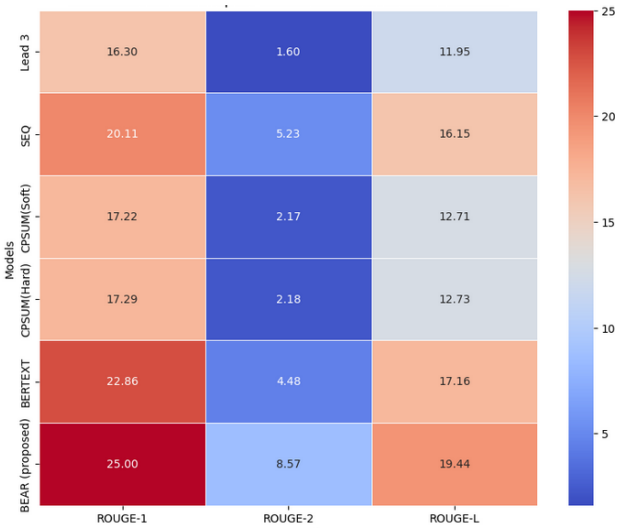

Fig. 5. Heatmap of ROUGE scores for various summarization models on the XSum dataset.

B. Comparative Analysis with Previous Research

To assess the relevance and competitiveness of the BEAR model, its results were compared with those of other state-of-the-art summarization approaches. Table V shows a detailed comparison of ROUGE scores across different models on the CNN/DailyMail and XSUM datasets, highlighting the BEAR model's superior performance.

1) CNN/DailyMail dataset: The BEAR model outperforms several baseline models such as Lead-3, PacSum, and REFRESH in terms of R-1 and R-2 scores, indicating its superior ability to capture essential content. For example, Lead-3 achieved an R-1 score of 40.01, while BEAR obtained 48.15, demonstrating significant improvements compared to BERTSUM, which has been widely used for summarization, BEAR's higher ROUGE scores underscore its effectiveness in integrating clustering-based sentence selection with abstractive summarization.

2) XSum dataset: The BEAR model outperforms models like BERTEXT and SEQ in both R-1 and R-2 scores. The comparative analysis of the proposed BEAR model against other summarization models on the XSum dataset demonstrates its superior performance across all three ROUGE metrics (R-1, R-2, and R-L) key observations include:

3) ROUGE-1 (R-1): BEAR achieved an R-1 score of 25.00, outperforming other models, such as SEQ (20.11) and BERTEXT (22.86), which are commonly used for summarization tasks. This higher score indicates that BEAR can better capture important words and phrases from the original text.

4) ROUGE-2 (R-2): With an R-2 score of 8.57, BEAR substantially surpasses the other models in capturing bigram-level co-occurrences between the generated summaries and the reference summaries. For instance, SEQ and BERTEXT which scored 5.23 and 4.48 respectively, lag behind in capturing contextual relationships that involve pairs of words. The improvement in R-2 reflects BEAR's enhanced ability to generate coherent summaries.

5) ROUGE-L (R-L): BEAR also leads in the ROUGE-L metric with a score of 19.44, demonstrating its strength in maintaining the longest common subsequence between the generated summaries and the references. This indicates that BEAR is more capable of producing summaries that retain the overall meaning and structure of the original content compared to other models like SEQ (16.15) and CPSUM (Soft) (12.71).

Overall, BEAR's results on the XSum dataset show that the model consistently outperforms the other methods across all metrics, validating its capability to generate high-quality summaries for summarization tasks.

C. Role of Clustering and Representative Sentences

Clustering organizes sentences into thematic groups based on their semantic similarity, utilizing TF-IDF and K-means clustering algorithms. This method structures the text into distinct clusters, each representing specific topics or aspects, which helps maintain context and relevance throughout the summarization process. By segmenting the text into these thematic clusters, redundancy is minimized and the focus is placed on selecting the most representative sentences. This reduces repetition and ensures a concise, relevant summary.

Once the clustering is complete, representative sentences from each cluster are selected and serve as the context for the BART model. The BART model then generates the final summary by integrating these representative sentences, this hybrid approach effectively bridges the gap between extractive and abstractive summarization techniques. It ensures that the summary not only captures key points but also maintains fluency and coherence, facilitating smooth transitions between different sections. The combination of clustering and BART helps to create a summary that is both contextually relevant and well-structured.

D. Limitations of the Present Study

While the approach aims to enhance coherence and relevance, there might still be instances where the generated summaries contain redundant or less relevant information if the clustering or similarity measures are not perfectly aligned with the summary objectives.

VI. CONCLUSION

In this paper, a novel framework for text summarization is presented that enhances the quality of generated summaries. The approach integrates a rewrite model with an innovative sentence sampling strategy, resulting in summaries that are not only more relevant but also of higher quality. A method for the rewrite model leverages an effective sentence sampling strategy, enhancing the selection of content for summarization.

TABLE V. STATE-OF-THE-ART COMPARISON FOR TEXT SUMMARIZATION

Model	CNN/DailyMail			XSUM		
	R-1	R-2	R-L	R-1	R-2	R-L
Lead 3	40.01	17.45	36.31	16.30	1.60	11.95
PacSum	40.37	17.92	36.62	-	-	-
FAR	40.42	17.95	36.67	-	-	-
SUMO	41.00	18.40	37.20	-	-	-
PGNet	39.50	17.30	36.40	-	-	-
REFRESH	41.30	18.40	37.50	-	-	-
SEQ	23.24	7.10	22.15	20.11	5.23	16.15
TED	38.73	16.84	36.15	-	-	-
BART	44.16	18.07	35.53	-	-	-
CPSUM (Soft)	-	-	-	17.22	2.17	12.71
CPSUM (Hard)	-	-	-	17.29	2.18	12.73
BERTEXT	-	-	-	22.86	4.48	17.16
BEAR (proposed model)	**48.15**	**19.23**	**37.03**	**25.00**	**8.57**	**19.44**

The framework consistently outperforms existing state-of-the-art baselines across various text summarization tasks. These results underscore the superiority of the approach in delivering more coherent and contextually relevant summaries. Future work will focus on several key areas to further enhance the summarization framework. First, the application of this approach to other languages and domains will be explored, expanding its scope and effectiveness. Additionally, methods to incorporate user feedback into the summarization process will be explored, enabling the generation of more personalized and user-centric summaries.

Hiding Encrypted Images in Audios Based on Cellular Automatas and Discrete Fourier Transform

Jose Alva Cornejo, Esdras D. Vasquez, Jose Calizaya Quispe, Roxana Flores-Quispe, Yuber Velazco-Paredes
Universidad Nacional de San Agustín de Arequipa, Arequipa, Perú

***Abstract*—With the increasing need for secure long-distance communication, protecting sensitive information such as images during transmission remains a significant challenge. This paper proposes a new method for hiding encrypted images inside audio files by integrating Cellular Automata (CA) and the Discrete Fourier Transform (DFT). The primary aim is to enable secure transmission of large encrypted images without altering the audio's perceptual quality. The scheme leverages the cryptographic properties of CA to generate encrypted images, which are then embedded into inaudible frequencies of audio using DFT. Results show that this method successfully hides and recovers images of considerable size, maintaining bit-level integrity of the original images while preserving audio quality. However, the scheme lacks resilience to signal processing attacks, such as compression or filtering, the resulting size of the audio is also bigger. Despite this limitations, the method provides a competitive advantage in payload capacity and efficiency, making it suitable for applications where the transmission of large, sensitive data is necessary but not subject to aggressive signal attacks.**

***Keywords*—Cellular automaton; Fourier Transform; cryptography; synchronization; stenography; embedding**

I. Introduction

Nowadays with the development of information and communication technologies, access to information has become easier and establishing communication in a secure way has become a necessary requirement [1]. As a result, people can easily exchange information and distance is no longer a barrier to communication. However, the safety and security of long-distance communication remains an issue [2], because in many cases, the Internet is being affected by hackers.

For that reason, attempts have been made to provide a cyber security environment to protect the assets of institutions, organizations, and individuals such as encryption systems, watermarking, steganography, fingerprinting, hybrid systems [3].

It is therefore essential to investigate more secure and efficient methods for safeguarding sensitive data, such as images, during transmission over open channels.

In the case of steganographic techniques, many were proposals to provide secure data exchange through an open communication channel. These approaches are mainly hosted under three domains: In spatial domain techniques [4] [5], the data is hidden, and replacement is directly applied to the pixels of the image; Transform Domain Methods hide the messages in significant areas of the cover image to produce more efficient stego-images. It manipulates the image indirectly by various transformation techniques; the most popular of these techniques are: Discrete Cosine Transformation (DCT) and Discrete Wavelet Transformation (DWT); and the third domain considers hybrid domain techniques; which is a type of steganography where spatial and transform domains may be combined. The hybrid approaches also provide some security and capacity enhancements but still are in their beginnings and need more research. [6].

In other cases, Cellular Automata (CA) models have been used for their good cryptographic properties that provide security against attacks and better confusion and diffusion properties [7]. CA models also give a secret key for the encryption which cannot be predicted since it evolves into a chaotic and complex system starting from an initial state [8].

So the question arises How can encryption methods be integrated with a CA cellular automata to hide encrypted images in audio files to improve transmission security? With all that has been seen, it was asked, how can encryption methods be integrated with a well-encryption system like CA with steganography to improve the security of encrypted image transmission?

For that reason, this paper proposes a novel method to increase security in image transmission: A hybrid method to encrypt high quality images using CA and hide them inside audio files using the Discrete Fourier Transform (DFT) based on the methods proposed by Alvarez et al. [9] and Hwai-Tsu and Tung-Tsu [10] for improved security in hiding encrypted images. This method could be of great use in industries that require the protection of sensitive information, such as the financial, military or healthcare sectors, where data integrity and confidentiality are paramount.

The rest of the paper is organized as follows: The review of previous works is presented in Section II, the proposed scheme is described in Section III, where a description of fundamental concepts is made and then the detailed description of each step in encryption and decryption is presented, in Section IV the results are shown along with their respective analysis, the discussion is presented in Section V and it ends with the conclusion in Section VI.

II. Related Work

In recent years, significant efforts have been made to solve the problem of information security in data transmission, such as the work done by Alvarez et al. [9], who have proposed a scheme based on the bidimensional reversible CA with memory. These schemes are cryptographic procedures to share a secret among a set of participants in such a way that only some qualified subsets of these participants can recover the secret. Also, the security of the scheme is studied and it is proved that the protocol is ideal and perfect and also resists the most important statistical attacks. To validate the

protection of the original information, the number of changing pixel rate (NPCR) and the unified averaged changed intensity (UACI) randomness test were used, with scores of 99 and 33 respectively, which would indicate a high level of change in the encrypted image compared to the original. This suggests a robust encryption that is very sensitive to changes in the original image; in other words, a minimal modification in the original image will cause a noticeable difference in the encrypted image, which is positive for the security of the encryption.

Similarly, Hwai-Tsu and Tung-Tsu [10] have proposed a study to introduce an innovative phase modulation (PM) scheme based on the fast Fourier transform (FFT) that facilitates efficient and effective blind audio watermarking. The results reflected the robustness of phase modulation against a variety of common signal processing attacks, and comprehensive and rigorous tests confirmed the PM's robustness against a variety of common signal processing attacks, including resampling, requantization, and low pass filtering. But the FFT–PM was less resistant to attacks that caused severe phase perturbations.

Likewise, Eslami et al. [11] proposed a model using CA and a double authentication mechanism to propose a new threshold image sharing scheme with steganographic properties. That proposed scheme uses 2 bits in each pixel of cover images for embedding data and so a better visual quality for the produced stego images was achieved. Consequently, this study got a Peak Signal-to-Noise Ratio (PSNR) value of 48, showing that the difference between the original image and the compressed or encrypted image is minimal and that the loss of quality is practically imperceptible to the human eye.

Similarly, Hernández et al. [12] proposed a new graphic symmetrical cryptosystem in order to encrypt a colored image defined by pixels and by any number of colors. This cryptosystem is based on a reversible bidimensional CA and uses a pseudo-random bit generator where the session key is the seed used to generate the pseudorandom bit sequence. In consequence, the decrypted image is identical to the original, i.e., no loss of resolution occurs.

On the other hand, Tanwar & Bisla [13] understood that the goal of audio steganographic technique is to embed data in audio cover files that must be robust and resistant to malicious attacks. That paper presents various audio steganographic methods like LSB, echo hiding, spread spectrum etc. Also, merits and demerits of each method are described. Finally, they showed that the low bit coding (LSB) method has a low robustness, echo masking, and phase coding have a low capacity for data embedding; in relation to the spectrum, it has a higher robustness but is vulnerable with respect to the modification of the time scale.

Abdirashid, Solak & Saku [14] argued that image steganography techniques provide better data embedding capability. So, they proposed secure data hiding algorithms based on frequency domain in image steganography. The methods were evaluated according to the criteria of imperceptibility, payload capacity and robustness, where they obtained good results of PSNR of 50 dB and Structural Similarity Index Measure (SSIM), which represents a successful restoration for the same image.

Also noteworthy is the comparison of different types of encryption realized by Louis [15], which tests the DCT and DFT encryption techniques in order to compare which of the two is better where it is seen that even though the images are embedded using bytes complete directly into the Fast Fourier Transform (FFT) transformed dimension, the byte difference is distributed somewhat evenly over the entire image, with small differences of the pixel values. That method is thus harder to detect than embedding methods that directly use the spatial domain.

An interesting paper was realized by Najiya and Renjith [16] who describe a method of compressing the image using wavelet compression and converting it into a bit sequence in order to embed it in the modified cover audio using a secret key, then the audio is encoded with an error correction code to improve its robustness of this technique. Where at the receiver section, the original secret image is reconstructed successfully. The PSNR value of the image in the system is 32.84. This means that the difference between the original image and the altered image is small.

The review of related works shows that many of these methods focus on information protection using different techniques in the spatial domain, transform domain and hybrid domain, this encouraged further research and improvement in this field.

III. Proposed Method

Fig. 1 shows the representation of the proposed method hiding encrypted images by CA in audios based on DFT. And, Fig. 2 shows the process to decrypt the information.

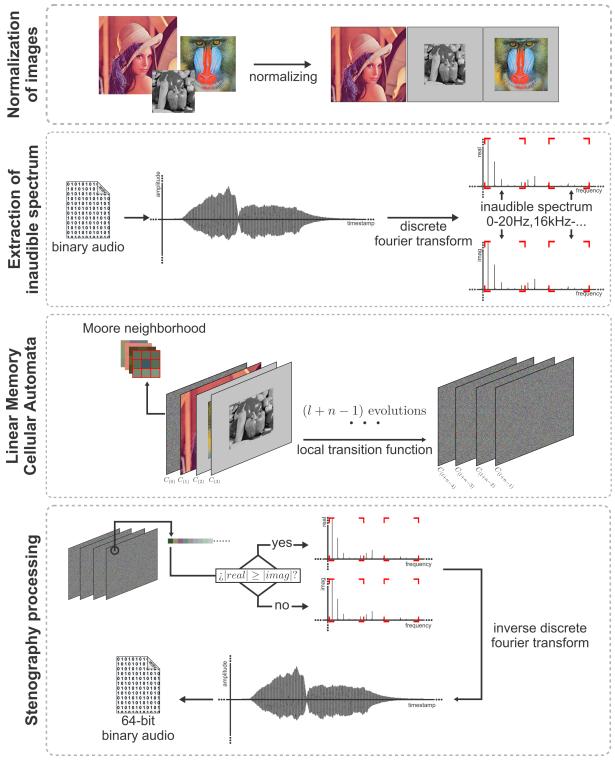

Fig. 1. Encryption of the proposed scheme.

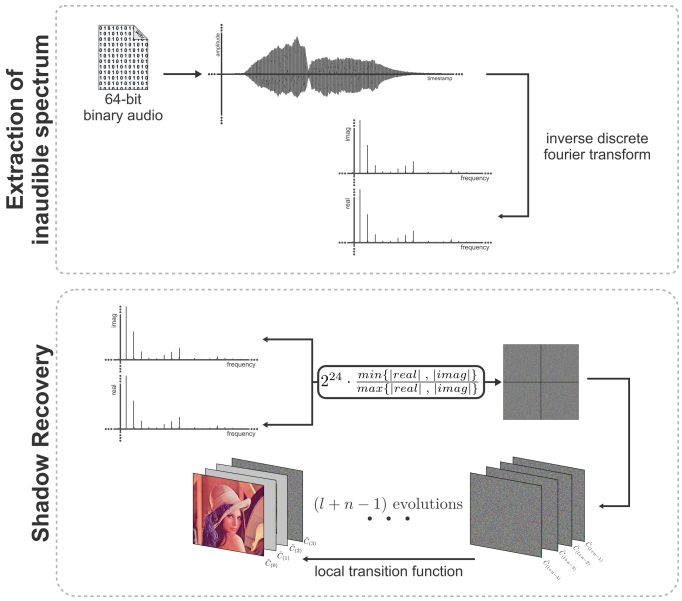

Fig. 2. Decryption of the proposed scheme.

A. Normalization of Images

This first stage is considered essential, because the operation of the CA depends on its environment, i.e. "neighborhood", based on the number of cells given by the number of rows and columns, which is simply feasible for any case. However, the proposal is to hide images by means of these evolutions, that means that the space operated by the CA must be the same in all cases of evolutions, by adding white pixels around each image if necessary.

Therefore, from a set of RGB images of different sizes, they are normalized by adding a padding of white pixels so that they have the same dimensions, Fig. 3 shows an example, not including the borders.

(a) (b) (c) (d)

Fig. 3. Normalized images.

B. Extraction of Inaudible Spectrum

Although the CA gives the necessary images to be able to reverse the process, these images could have essentially noise, which can generate suspicion, therefore, a higher stage of encryption is proposed, which means hiding it inside an audio.

The method supports the reading of different types of audio in wav format $(16-bit\ PCM,\ IEEE\ float)$, internally all processing is done in $64-bit$ float format, so any conversion from an audio with a smaller data format does not result in any alteration of the original audio [17]. Audio recorded at sampling rates greater than or equal to $44100Hz$ are used, because this is the standard used in music CDs and provides good frequency precision [18]. The output audio will be a $64-bit\ IEEE\ float\ .wav$ file.

On the other hand, of all the forms of audio steganography that exist, the decision has been to use the algorithm called "Fast Fourier Transform" or FFT, to hide data in the less perceptible frequencies: from 0 to $20Hz$ and from $16kHz$ [19].

Where, for each audio channel, it will be divided into M segments of length L each one. Using the DFT, each segment frequency is obtained using the Eq. 1.

$$X^{(m)}(k) = \sum_{n=0}^{L-1} x^{(m)}(n) \mathrm{e}^{-\mathrm{i}2\pi k \frac{n}{L}} \tag{1}$$

where $m = \{0 \dots M\}$
$k = \{0, \dots, 20, 16000, 16001, \dots \frac{L}{2}\}$
* Illustrative quantity, take into account the frequency resolution.

However, the nature of the FFT algorithm will return $N/2$ samples from $N = 2^n, n \in \mathbb{R}^+$ samples. Therefore it is set that $L = 65536 = 2^{16}$ to ensure that a wide range of frequencies is obtained. That results by the concept called frequency resolution, which is shown in Eq. 2.

$$\Delta f = \frac{f_s}{N} \tag{2}$$

f_s : Frequency sample rate
N : Number of samples

$$e.g: \ \Delta f = \frac{44100}{65536} \approx 0.67$$
$$\Delta f = \frac{44100}{32768} \approx 1.34$$
$$\Delta f = \frac{44100}{16384} \approx 2.69$$

$\therefore$ More sample gets more resolution

Then the "frequency resolution" is used to put the encrypted data into an array, in this way it can approximate a 1:1 relationship between the indices of an array and frequencies it want to access.

Additionally, a function is used to access a frequency by indices of an array, which is shown in Eq. 3:

$$freqToIndex(freq) = \lfloor \frac{freq}{2^{16}} \rfloor, \quad freq \geq 0 \tag{3}$$

C. Linear Memory Cellular Automata

CA is a computational model that simulates dynamic systems and processes within a concrete space composed of cells. These cells have different states that vary in relation to time due to predefined rules. Each cell of a CA is composed of a dynamic state in relation to its neighboring cells by means of specific rules, which define the state configuration, simulating the evolution of a system over multiple continuous time steps [9].

According to [9], the following elements define a CA:

- State It is the set S of possible values that a cell will have. This paper makes use of RGB images leads to a $S = \mathbb{Z}_{2^{24}}$, it is the minimum value containing all possible values of an RGB pixel.
- Local transition function Function that gives a new state to the cell (i, j) from its neighborhood V_{ij}, using a number ω of 9 bits defined as a rule. It is defined in the following way:
$$s_{ij}^{(t+1)} = F(V_{ij}^{(t)}, ..., V_{ij}^{(t-n)})$$
- Neighborhood It is defined as the set of neighbors of a cell. Therefore, in this paper the Moore neighborhood is used.

Instead of working on a one-dimensional line, two-dimensional CA are organized in a grid or matrix of cells, where each cell can have a particular state, and offers a way to model and understand complexity starting from simple local rules. Their versatility and ability to represent a wide variety of events make them a valuable tool [20].

The change of the evolutions depends on the states previous to these since are based on the $k - th$ order, and each of them defines a new change of states of the CA based on the k previous evolutions. For example, if k takes the value of 3, then the new state in $(t + 1)$, depends on the states of (t), $(t - 1)$ and $(t - 2)$.

Now, the security of the evolutions to be performed in the Linear Memory Cellular Automata (LMCA) depends on an image composed of random pixels, indicating dimensions and other characteristics, see Fig. 4. This will be considered as configuration 0, C_0 while the images to be encrypted will be the images shown in Fig. 3: C_1 C_2 C_3 C_4 respectively. Based on the fact that this has $n = 4$ initial images, along with an initial configuration, the order of the cellular automaton would be 5; which implies that the 5 previous ones will always be used to generate the next one (times), and so on until the number of evolutions [9][21].

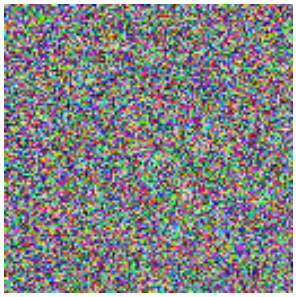

Fig. 4. Configuration C_0.

For each time it have, w is a random number. According to the model of an LMCA, a random number l is necessary, which determines the number of evolutions defined as $\#evo = n + l - 1$, for the present investigation the value of l will be equal to 10 ($l = 10$), the results of which are shown in Fig. 5.

At the moment of making the evolutions, it can be observed how images of what is apparently noise (shadows) are created,

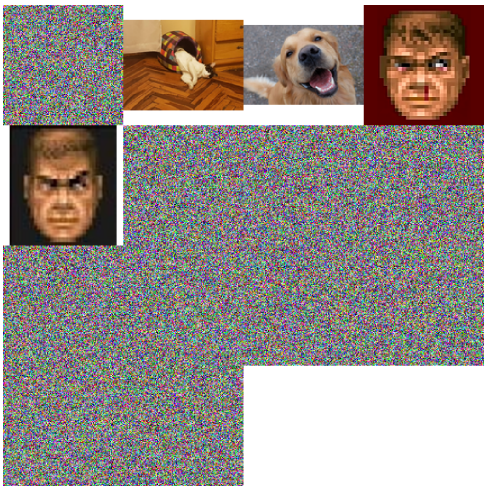

Fig. 5. Evolutions with a value of l=10.

and according to [11], the correlation between shadows is very small, which guarantees that it is not possible to extract relevant information from the original images by having only a fraction of the shadows. The LMCA has a set of times, because it used is a k to k symmetric scheme, the keys for the recovery will be composed by the same number of initial configurations as it had. In the example, the last four noise images would be presented together with the one preceding them. The latter would serve as a public key, while the other four are secret.

D. Stenography Process

It is widely acknowledged that the human auditory system exhibits relatively low sensitivity to variations in phase [22]. For this reason, the key to imperceptible audio primarily involves manipulating the FFT phase. Since each FFT coefficient comprises a real and an imaginary component, this scheme for numerical embedding involves the manipulation of the ratio between the magnitudes of these two components. The component with the largest magnitude was identified as the baseline unit. Consequently, the extent of the other component is modulated based on the intended numeric value, such as a pixel value extracted from a color image. Now, the Eq. 4 is derived from the equation proposed by [10]. This equation allows encrypting an entire RGB color.

$$\begin{aligned}
&\text{if } |\text{Re}\{X^{(m)}(k)\}| \geq |\text{Im}\{X^{(m)}(k)\}| \\
&\quad \hat{X}^{(m)}(k) = \text{Re}\{X^{(m)}(k)\} \\
&\qquad + i{\cdot}sgn(\text{Im}\{X^{(m)}(k)\}) \cdot |\text{Re}\{X^{(m)}(k)\}| \cdot \frac{v(\Delta + k)}{2^{24}} \\
&\text{else} \\
&\quad \hat{X}^{(m)}(k) = sgn(\text{Re}\{X^{(m)}(k)\}) \cdot |\text{Im}\{X^{(m)}(k)\}| \cdot \frac{v(\Delta + k)}{2^{24}} \\
&\qquad + i \cdot \text{Im}\{X^{(m)}(k)\}
\end{aligned} \tag{4}$$

where $v(x)$ refers to the value of the ID array that contains the pixels of an image.
$\Delta = m(L - 16020)$ storage capacity in a block m.

Once the values of each pixel of an image have been positioned inside the inaudible frequencies of an audio, the Inverse Fourier Transform (see Eq. 5) is operated to obtain an audio that will be saved in a 64-bit .wav file in order to safeguard the precision of the mathematical operations and the values of this new audio.

$$\hat{x}^{(m)}(k) = \frac{1}{L}\sum_{n=0}^{L-1} \hat{X}^{(m)}(n)\mathrm{e}^{\mathrm{i}2\pi k\frac{n}{L}} \tag{5}$$

This whole process is shown in Algorithm 1.

Algorithm 1 Encryption

Require: D is a vector of data to encrypt
Require: A is a $m \times n$ matrix where

$$m = \begin{cases} 1 & \text{if audio channel is mono} \\ 2 & \text{if audio channel is stereo} \end{cases}$$

and $n = Length\ of\ audio$

Ensure: fft(...) returns an array in CCs format
  $res \leftarrow A\ m \times n\ matrix\ with\ encrypted\ data$
  $samples \leftarrow 2^{16}$
  $encrypted \leftarrow 0$ ▷ Progress
  for all $signal$ **in** A **do**
    $segment \leftarrow 0$
    while $segment \leq |signal|$ **and** $encrypted \neq |D|$ **do**
      $out \leftarrow$ fft$(signal[segment{:}])$ ▷ out is a vector of $\frac{samples+1}{2}D$
      $out \leftarrow \frac{out}{samples}$ ▷ Normalize
      for $i \leftarrow 1$ **to** $|out| - 1$ **and** $encrypted \neq |D|$ **do**
        if $i = freqToIndex(20.0)$ **then** ▷ See equation 3
          $i \leftarrow freqToIndex(16000.0)$
          continue
        end if
        $x \leftarrow out[i]$
        if $|real(x)| \geq |imag(x)|$ **then** ▷ See equation 4
          $imag(x) \leftarrow sgn(imag(x)) * |real(x)| * \frac{D[encrypted]}{2^{24}}$
        else
          $real(x) \leftarrow sgn(real(x)) * |imag(x)| * \frac{D[encrypted]}{2^{24}}$
        end if
        $encrypted \leftarrow encrypted + 1$
      end for
      $out\_inv \leftarrow$ ifft(out)
      $copy\ out\_inv\ into\ res$
    end while
    $copy\ signal[segment{:}]\ to\ res[signal]$ ▷ Remainder
  end for
  return res

E. Shadow Recovery

Similar to the previous step, the recovery is based on separating the audio stego into segments of 2^{15} audio samples, where in each one the FFT is applied to recuperate the values of the frequencies where the data is saved.

$\tilde{X}^{(m)}(k)$ is define as the sequence of values obtained by using the FFT in a block; the same variables defined in the previous step are shown by Eq. 6.

$$v(\Delta + k) = 2^{24} \cdot \frac{min\{|\mathrm{Re}\{\tilde{X}^{(m)}(k)\}|\ ,\ |\mathrm{Im}\{\tilde{X}^{(m)}(k)\}|\}}{max\{|\mathrm{Re}\{\tilde{X}^{(m)}(k)\}|\ ,\ |\mathrm{Im}\{\tilde{X}^{(m)}(k)\}|\}} \tag{6}$$

After getting the pixel array, they are saved for later use in the CA.

Continuing, the images have been recovered from the audio files and a process identical to the first evolution is developed where the public key will be the configuration 0, and the following shadows are added in the order they were generated, by effecting the number of evolutions with the same value l, the original images are obtained (with their respective padding. See Fig. 6 and 7.

This whole process is shown in Algorithm 2.

Algorithm 2 Decryption

Require: A is a $m \times n$ matrix where

$$m = \begin{cases} 1 & \text{if audio channel is mono} \\ 2 & \text{if audio channel is stereo} \end{cases}$$

and $n = Length\ of\ audio$

Require: $size$: The desired size of the decrypted data
Ensure: fft(...) returns an array in CCs format
  $res \leftarrow$ Array of decrypted data
  $decrypted \leftarrow 0$ ▷ Progress
  for all $signal$ **in** A **do**
    $segment \leftarrow 0$
    while $segment + 2^{16} < |signal|$ **and** $decrypted \neq size$ **do**
      $out \leftarrow$ fft$(signal[segment{:}])$
      $out \leftarrow out/samples$ ▷ Normalize
      for $i \leftarrow 1$ **to** $|out| - 1$ **do**
        if $decrypted = size$ **then**
        end if
        if $i = freqToIndex(20.0) + 1$ **then**
          $i \leftarrow freqToIndex(16000.0)$ **continue**
        end if
        $x \leftarrow out[i]$
        $v \leftarrow \lfloor \frac{min\{|real(x)|,|imag(x)|\}}{max\{|real(x)|,|imag(x)|\}} * 2^{24} \rfloor$ ▷ See Eq. 6
        $res.append(v)$ ▷ Store decrypted value
        $decrypted \leftarrow decrypted + 1$
      end for
    end while
  end for
  return res

IV. Results

A. Random Noise NIST Test Results

To ensure that the secret images are indeed noise, the NIST statistical test suite is used, it consists 15 different tests that measure the randomness of a sequence of bits. For each test a p-value is calculated, which varies from 0 to 1, where 0 indicates that the bits are non random and 1 perfect randomness [23].

To test the first step of the scheme, a large image(4000x3000 pixels) is used to generate the appropriate noise images to hide. For this example, nine evolutions are created; and then, for each images, a binary file composed entirely of the pixel RGB bytes is made.

Each of the nine files passed to the NIST suite contain 288 million bits and are of size 36MB. The results in Table I give them an average p-value of a little under 0.5, which shows good randomness. There were only a couple of failed tests in the earlier evolutions, however, it can be concluded that the secret images to be hidden in an audio file will be very close to random noise.

TABLE I. Results of Randomness Test

Evolution	Average p-value	Passrate
1	0.467008	99.47%
2	0.495432	100.00%
3	0.481725	98.94%
4	0.471555	99.47%
5	0.478481	100.00%
6	0.502455	100.00%
7	0.457972	100.00%
8	0.474596	100.00%
9	0.499604	100.00%

B. Size and Capacity of Audio Files

Because the process of hiding images in audios using the FFT internally uses $64 - bit$ floating numbers, it cannot save the frequency values in audio formats such as $16 - bit$ fixed-point and $32 - bit$ floating-point without losing data in the truncation process, which forces to save $64 - bit$ IEEE wav audios. See Table II to view the comparison of the created audios.

TABLE II. Size Analysis of Created Audios

	Audio1	**Audio2**	**Song1**	**Song2**
Duration	4s	7s	6:23 min	2:49 min
Orig Size	812.6 KiB	1.5 MB	64.5 MB	28.5 MB
64bit Size	3.2 MB	5.8 MB	257.9 MB	114.1 MB
Increase	293.798%	286.667%	299.845%	300.351%
Max Capacity (NxN)	256	330	2153	1434

It can be observed that the created audios are about four times larger, but it allows them to save an RGB image of considerable size, or in the case of smaller images, a set of these.

C. Spectrograms

By performing a spectrogram analysis of both the original audio (see Fig. 8) and the one containing their payload (see Fig. 9), it can be observed how it proceeds according to the proposed method, where only the less audible frequencies have been covered by what amounts to noise.

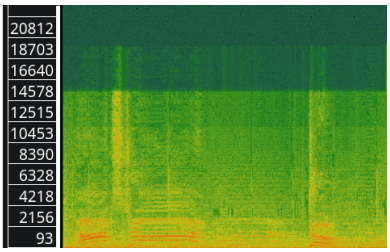

Fig. 8. Spectrogram of original audio.

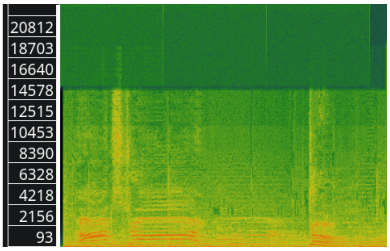

Fig. 9. Spectrogram of stego-audio.

In a second sample only a 128×128 pixel image has been inserted, it can be observed that only a section of the high frequencies is modified, this due to the fragmentation of the audio for the realization of the process, see Fig. 10 and 11.

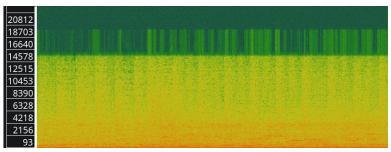

Fig. 10. Spectrogram of second original audio.

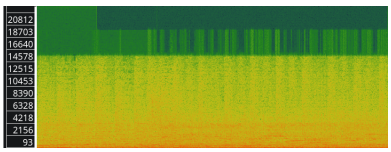

Fig. 11. Spectrogram of second stego-audio.

D. Measuring Similarity to Original Audio

1) Dynamic Time Warping: As a way of measuring how similar the payloaded audio is to the original one, the algorithm

Dynamic Time Warping (DTW) has been used. DTW is a really powerful tool with uses way beyond just measuring differences in audio files, such as speech and sign language recognition, computer vision, animation, data mining, music and signal processing [24]. DTW compares two signals that may or may not be of the same length to find an optimal alignment with minimal cost, to do this a cost matrix is found, by comparing every value of both signals, were the higher the difference between values, the higher the cost. After obtaining the matrix, the optimal warping path is the one with the lowest accumulated cost from traversing from bottom left to top right [25]. Because the signals to be compared are practically of the same length, the alignment path will always be a straight line from bottom to top.

To find a measurement related to the similarity of both audio signals, two comparisons have been decided upon. The first comparison uses DTW on the original audio and the stego audio. The second comparison is performed between the original signal and a noisy signal, which is generated by adding almost imperceptible random noise to the original. This approach provides a baseline for assessing how different the stego signal is.

Fig. 12 and 13 show the cost matrix of both comparisons, where orange tones show a greater cost. The shortest path is always the direct one, as a better way of showing the differences of the comparison, Fig. 14 and 15 shows a slice of the cost matrices, but plotted as a 3d bar chart, the first comparison presents lower values overall and by calculating the distance cost of the optimal warping path. The values obtained are 1528.1893 for the stego audio and 82826.3947 for the noisy signal. This indicates that the stego audio signal is easier to adapt and correct, and thus very similar to the original audio.

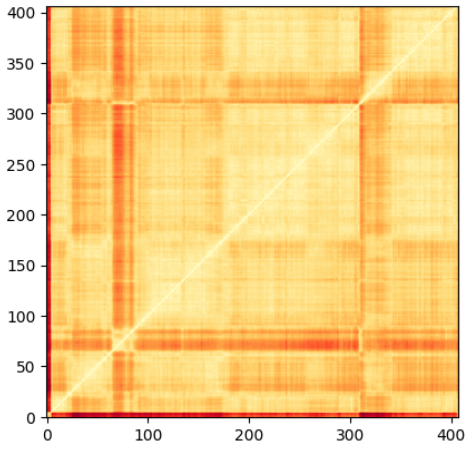

Fig. 12. DTW cost matrix of stego-audio comparison.

2) Error Testing: An evaluation will be made with the Mean Square Error (MSE) and Signal-to-Noise Ratio (SNR) coefficients to see the efficiency of the proposed method, by the use of the Fourier transform to audio.

In the MSE, the error signal $e_i = x_i - y_i$ represents the difference between the original and distorted signals [26], which will be evaluated with respect to audio quality, after performing data hiding within the audio during the transform. See Eq. 7.

$$MSE = \frac{\sum(O - E)^2}{N} \tag{7}$$

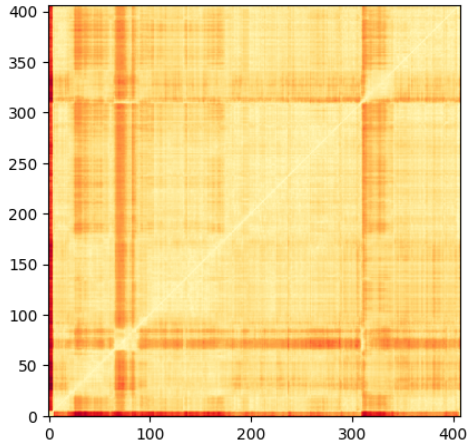

Fig. 13. DTW cost matrix of noisy audio comparison.

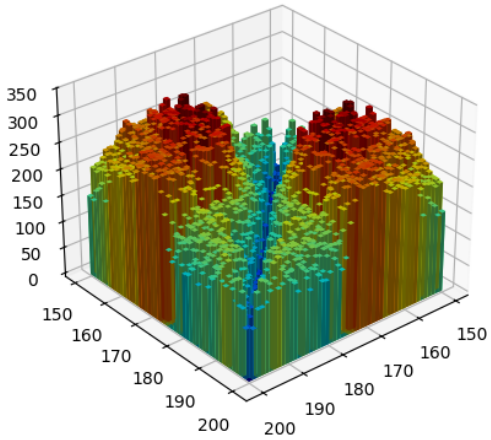

Fig. 14. 3D bar chart of DTW cost matrix of stego-audio comparison.

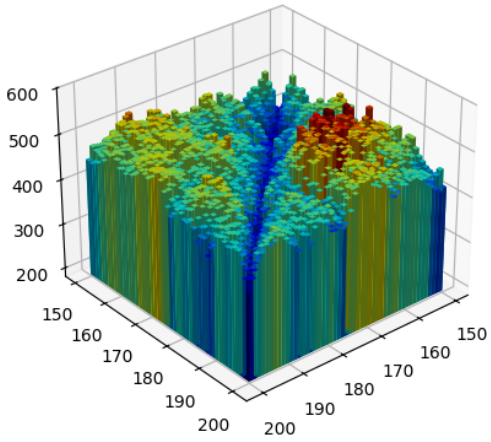

Fig. 15. 3D bar chart of DTW cost matrix of noisy-audio comparison.

On the other hand, SNR reflects the signal-to-noise relation of an audio, usually written as S/N, is an estimate of the robustness of the source signal in relation to the possible noise (unwanted signal) [27], see Eq. 8

$$SNR = 10 * \log_{10}(\frac{O^2}{MSE}) \tag{8}$$

After several comparisons of encrypted and decrypted audios, The resulting values are shown in the Table III.

TABLE III. ANALYSIS OF ORIGINAL AND ENCRYPTED AUDIO

Sample Indices	Original (O)	Encrypted (E)	(O^2)	(O - E)^2
0	0	-0.0048	0.0048000	2.28 $\times 10^{-5}$

208000	0.0054	0.0054	0.0000295	2.8 $\times 10^{-14}$
Total			**0.37908**	**0.00047**

The difference of the amplitude of the original audio minus the encrypted audio is solved for each row of the table and the result elevated to 2.

All the results in column 5 of Table III are summed, and the value of the variable N is equal to the number of samples that exist in the table, in this case 33. Therefore using the Eq. 7

$$MSE = \frac{\sum(O-E)^2}{N}$$
$$MSE = \frac{0.00047}{33}$$
$$MSE = 0.0000142$$

This MSE result affirms that there is a minimum change between the original audio and the encrypted audio because the audio is close to 0, and as explained above, the closer the MSE is to zero, the smaller the average difference will be; therefore, the better the quality of the audio reproduction or processing, so it is reaffirmed that the audio quality is maintained after applying the FFT algorithm to the audio.

The summation of O^2 is in column 4 of Table III, and the value of the MSE is the result obtained previously, therefore using the Eq. 8:

$$SNR = 10 * \log_{10}(\frac{0.37908}{0.0000142})$$
$$SNR = 10 * \log_{10}(26695.77)$$
$$SNR = 10 * 4.43$$
$$SNR = 44.26dB$$

This result of 44.26 dB, reaffirms that the quality of the signal (sound) is preserved, after doing the Transform algorithm, so it deduced that the sound emitted by the audio remains clear and neat after encryption, and that any evident change between the values of the original audio with the encrypted audio is not perceptible or is minimally perceptible.

E. Recovered Images Similarity

By way of a more detailed analysis of the decrypted images in order to ensure pixel equality, MSE and SSIM measurements are used in the comparison of the original image (with some padding) and the one resulting from the encryption and decryption process. See the Table IV.

TABLE IV. IMAGES SIMILARITY MEASUREMENTS

	MSE	SSIM
Cat	0.00	1.00
Dog	0.00	1.00
Doom1	0.00	1.00
Doom2	0.00	1.00

MSE is used, because of its ample use and its simplicity to compare two images [28], every single image recovered by the scheme got a perfect score of 0, which indicates that the squared sum of the errors always equal 0, therefore, every single pixel value of both the recovered images and the original ones are the same.

The use of SSIM helps to evaluate the similarity between original and distorted images after applications in the evaluation of image quality, image recovery, image encryption and data hiding [29]. In effect, a value of 1 was obtained as result, this is evidence that the images still maintain the exact same image quality before and after encryption.

V. DISCUSSION

The use of Cellular Automata in the scheme ensures the security of the sensitive images to be hidden. These images are converted to effectively noise, any attacker that manages to extract the data hidden in the very low and high frequencies would find nothing but useless data.

In this study, an SNR of 44.26 has been obtained using the DFT together with CA. This result is notably superior to that obtained by another research on the embedding of color images in audio signals using residual networks [10]. In that work, the SNR ranged from 18.75 to 25.004, depending on the embedding scheme and the range of FFT indices employed.

An SNR of 44.26 indicates that the audio signal has a significantly higher SNR than the watermarking schemes employed in [10]. This suggests that the method using DFT and CA can insert information into the audio signal with less degradation of the perceived quality, which is crucial in applications where maintaining the fidelity of the original signal is a priority.

The presented scheme shows good payload capacity for the resulting file sizes, a 4 seconds audio file is capable of hiding an image of at most 256x256 dimensions, with a final size of 3.2MB. When comparing it to the scheme proposed by [10], a similar size audio file (4.23MB) of 24.15 seconds of duration, is able to hide an image of 64x64 dimensions. This shows a considerable increase in capacity per MB, albeit with a very reduced resistance to signal processing attacks and compression techniques because of the need to preserve every bit of the secret CA images to be able to decrypt the original images. Because of this, the proposed scheme should probably be used on relatively small audio files, so that the increase in size is not as dramatic and any action that affects the audio file data, such as applying mp3 compression, should be considered destructive to the encrypted information.

VI. Conclusion

Based on the challenge of secure and private information sharing, a new encryption method using CA and Fourier Transform based steganography has been proposed in this research. This method demonstrates the ability to preserve the full integrity of the encrypted images while maintaining an extremely similar quality to the original audio, where the hidden data is no different to noise, supported SNR, MSE and a magnitudes lower optimal warping path length compared to an audio containing an almost imperceptible noise.

Because of the combination of the produced audios file format and the range of frequencies that are embedded with data, the proposed scheme has good payload capacity, albeit with the limitation of the resulting file size and the vulnerability to small changes in the audio file.

Therefore, as possible improvements for future work, different approaches could be explored, such as implementing support for lower and higher color depth images at $24 - bits$, optimizing the Fast Fourier Transform process to use less precision, which would allow us to hide encrypted images in smaller floating point audio formats such as 32 and 24 bits, reducing the audio file size at the expense of data storage capacity.

School of Computing and Data Science, BADYA University, Cairo, Egypt[3]

***Abstract*—Scalability poses a significant challenge in blockchain networks, particularly in optimizing the propagation time of new blocks. This paper introduces an approach, termed "DBPF" - Dynamic Block Propagation Framework for Blockchain Networks, aimed at addressing this challenge. The approach focuses on optimizing neighbor selection during block propagation to mitigate redundancy and enhance network efficiency. By employing informed neighbor selection and leveraging the Brotli lossless compression algorithm to reduce block size, the objective is to optimize network bandwidth and minimize transmission time. The DBPF framework calculates the Minimum Spanning Tree (MST) to ensure efficient communication paths between nodes, while the Brotli compression algorithm reduces the block size to optimize network bandwidth. The core objective of DBPF is to streamline the propagation process by selecting optimal neighbors and eliminating unnecessary data redundancy. Through experimentation and simulation of the block propagation process using(DBPF), we demonstrate a significant reduction in the propagation time of new blocks compared to traditional methods. Comparisons against approaches such as selecting neighbors with the least Round-Trip Time *RTT*, random neighbor selection, and the DONS approach reveal a notable decrease in propagation time up to more than (45%) compared to them based on network type and number of nodes. The effectiveness of (DBPF) in boosting blockchain network efficiency and decreasing propagation time is emphasized by the experimental findings. Additionally, various compression algorithms such as zstandard and zlib were tested during the research. Nevertheless, the results suggest that Brotli produced the most positive outcomes. Through the integration of optimized neighbor selection and effective data compression, DBPF presents a hopeful resolution to the scalability issues confronting blockchain networks. These results showcase the capability of (DBPF) to notably enhance network performance, leading the path toward smoother and more efficient blockchain operations**

Keywords*—Blockchain; scalability; minimum spanning tree; compression; broadcasting; optimized neighbor selection; network bandwidth; transmission time optimization

I. Introduction

Blockchain (BC) technology has revolutionized the way data and financial transactions are shared among network participants BC was initially introduced in 2008, credited to Satoshi Nakamoto [1]. At its core, a blockchain is a decentralized and distributed ledger that securely records transactions across a network of nodes. The value added by blockchain technology lies in its ability to provide transparency, immutability, and trust. By eliminating the need for intermediaries and central authorities, blockchain enables peer-to-peer transactions and data sharing, fostering a new era of decentralized applications and services [2], [3]. This improves its reliability and efficiency compared to traditional data storage systems. The networks within (BC) can securely manage information and protect it from tampering, even in the presence of some malicious nodes, These features are highly valuable and find applications not only in cryptocurrencies but also across a wide range of fields [4]. Therefore, (BC) has many applications in emerging fields such as the internet of things [5], [6], 5G [7] [8], [9], and artificial intelligence, [10], [11].

However, despite its numerous advantages, blockchain faces scalability challenges that hinder its widespread adoption [12]. One of the key scalability issues is the low throughput of blockchain networks, primarily caused by the high propagation time required to disseminate new blocks to all nodes in the network. This delay in block propagation can lead to inconsistencies in the blockchain, impacting transaction finality and network performance. It is evident that Bitcoin's transaction processing capability is limited, allowing for only seven Transactions Per Second (TPS). This stands in stark contrast to widely adopted mainstream payment platforms like PayPal, which achieves a transfer rate of 500 TPS, and Visa, surpassing 4000 TPS [13]. Similarly, **Ethereum**, another prominent cryptocurrency, can handle approximately 15 TPS. Clearly, both **Bitcoin** and **Ethereum** are inadequate when it comes to meeting the demands of large-scale trading scenarios.

The high propagation time in blockchain networks can be attributed to several factors. Firstly, traditional methods used for path selection and neighbor discovery in blockchain networks often result in suboptimal routing paths, leading to longer propagation times and message redundancy. Random Neighbor Selection (RNS) is one such method that may contribute to inefficient block dissemination by selecting neighbors without considering the network topology or optimal paths, where shared data propagates through random paths [14], leading to an inefficient data propagation scheme. This inefficiency arises from the probability of redundancy in the exchanged messages between network nodes. This redundancy arises from cycling in randomly chosen data paths, leading to longer delivery times and reduced consistency. Despite this, most blockchain (BC) systems support Random Neighbor Selection (RNS). Several methods have been proposed to enhance the Neighbor Selection (NS) process locally, addressing the issue of dynamicity. For example, Bi et al. [15] introduced an NS protocol based on network latency, where nodes measure the Round Trip Time (RTT) to their neighboring nodes and prioritize those with the lowest RTT for the NS process. However, none of these methods has presented an optimal NS strategy.

Additionally, the size of blocks and network bandwidth

limitations also play a significant role in increasing propagation time. As block sizes grow, the time required to propagate blocks across the network increases proportionally [16]. Moreover, some blockchain protocols overlook the optimization of network bandwidth usage, further exacerbating propagation delays.

In response to these challenges, this paper proposes a novel solution to enhance blockchain scalability by addressing the inefficiencies in neighbor selection and block size management. Our approach focuses on optimizing neighbor selection for each node in the network (ONS) by calculating the Minimum Spanning Tree (MST) to establish efficient communication paths. Furthermore, we aim to optimize network bandwidth by reducing block size and improving propagation speed by implementing the (Brotli compression) method, a lossless data compression technique that minimizes redundant data within blocks and transactions. By combining optimized neighbor selection and block size reduction through compression, our proposed solution (**DBPF**) seeks to mitigate the propagation time challenges in blockchain networks, ultimately enhancing network scalability and performance.

The contributions of this paper are summarized as follows:

1) The Dynamic Block Propagation Framework (DBPF) addresses blockchain scalability by optimizing neighbor selection through a Minimum Spanning Tree (MST), reducing redundant data propagation, and improving communication efficiency between nodes.
2) DBPF incorporates Brotli lossless compression to reduce the size of the propagated blocks, improving network bandwidth usage and speeding up block dissemination.
3) By leveraging MST-based Optimal Neighbor Selection, DBPF selects neighbors that enable faster and more efficient block propagation, reducing the overall time needed to disseminate blocks across the network.
4) The framework significantly reduces the total propagation time for data exchanged between nodes, ensuring faster and more efficient block distribution.
5) DBPF combines optimized neighbor selection with effective data compression, providing a scalable and efficient solution for large blockchain systems to increase the throughput of the network.

The remaining sections of this paper are structured as follows: Section II analyzes relevant literature, Section III provides the proposed system model for DBPF, Section IV provides a detailed explanation of the proposed DBPF, Section V presents the evaluation of DBPF, and finally, Section VI summarizes the most significant findings and conclusions.

II. Related Work

This section presents several modern network layer scalability solutions, which primarily aim to enhance either the gossip algorithm or reduce block data size. Research studies targeting improvements in the gossip algorithm focus on reducing duplicate data and increasing block propagation speed [17]. These proposed solutions aim to minimize duplication caused by the gossip protocol decrease block propagation time through enhanced gossip mechanisms and reduce the size of the block to accelerate block propagation through network bandwidth. Below are some recent works that represent such solutions.

The authors of "PiChu: Accelerating Block Broadcasting in Blockchain Networks with Pipelining and Chunking" [18] introduce an innovative method to enhance the efficiency and scalability of blockchain networks. PiChu leverages pipelining and chunking techniques to expedite block propagation, significantly reducing the time required to broadcast blocks across the network. The approach involves verifying the block header before dividing the block into smaller segments, which are then processed and forwarded in parallel. This continuous data flow minimizes delays associated with waiting for entire blocks to be verified. The chunking process splits each block into smaller, self-contained chunks that include complete transactions, allowing for incremental verification and faster dissemination. PiChu is particularly effective in scenarios with high transaction volumes and large block sizes, making blockchain networks more robust and scalable. However, PiChu's effectiveness is influenced by the network topology and the connectivity between nodes. The requirement for modifications to existing consensus protocols may also limit its immediate applicability in some blockchain systems. Additionally, the benefits of pipelining and chunking may vary depending on the specific characteristics of the network, and The need for nodes to verify and forward chunks can introduce additional processing overhead.

Baniata and Anaqreh [19] introduced the Dynamic Optimized Neighbor Selection Algorithm (DONS) to enhance P2P network management within blockchain networks. In this approach, a leader peer is selected to manage the network and construct its topology using neighbor lists from regular peers. The leader uses a Minimum Spanning Tree (MST) to identify optimal neighbors, thereby minimizing propagation delay and enhancing transaction throughput. However, when the leader changes, the network topology must be reconstructed, necessitating the collection of neighbor lists anew. As the number of peers increases, the time required to compute the MST also increases, leading to inefficient bandwidth utilization. Furthermore, the unavailability of the leader poses risks of topology loss and incurs overheads associated with leader reselection.

Zhang et al. [20] investigate the dynamics of block propagation in blockchain-based vehicular networks (VANETs) and the impact of node mobility on blockchain consensus mechanisms. The authors propose an analytical model to derive a closed-form expression for single-block propagation time and analyze multi-block competitive propagation to address blockchain forking issues. The model accounts for the dynamic connectivity of moving nodes, introducing opportunistic communication to blockchain consensus. Their findings reveal that higher mobility and more moving vehicles expedite block propagation, thereby reducing consensus time. The study also shows that distinct propagation capabilities of moving nodes help mitigate blockchain forking. However, the model has limitations, such as its reliance on closed-form expressions and the assumption of a single-chain structure. The approach may face limitations in scenarios with highly dynamic topologies and varying node densities, which could affect its overall performance.

The paper "FastChain: Scaling Blockchain System with

Informed Neighbor Selection" by Ke Wang and Hyong S. Kim [21] introduces the FastChain protocol to enhance blockchain scalability by optimizing block propagation times. FastChain operates by leveraging nodes with higher bandwidth capacity to distribute blocks throughout the network. Nodes with limited bandwidth prioritize connections with high-bandwidth nodes and disconnect from those with bandwidth below a specific threshold. This mechanism comprises two essential stages: the bandwidth monitoring phase and the neighbor update phase. During the bandwidth monitoring phase, each node maintains a table containing the recent bandwidth information of its neighboring nodes. In the neighbor update phase, nodes periodically update their connections, disconnecting from those with low bandwidth. This informed neighbor selection policy significantly reduces block propagation time, thereby increasing the effective block rate and improving throughput by 20% to 40%. Despite its advantages, the FastChain protocol introduces additional processing overhead due to the continuous monitoring and updating of neighbor connections. Moreover, reliance on high-bandwidth nodes could lead to centralization risks within the network.

The authors in [22], [23] proposed a score-based neighbor selection protocol for constructing a blockchain network. This protocol assigns higher scores to peers with lower propagation delays compared to those with higher propagation delays. Subsequently, peers with the highest scores are chosen as neighbors. Each miner node evaluates its neighboring nodes based on the time difference between when the block was created and when it was received by the recipient node. After successfully receiving ten blocks, a node updates its list of neighbors. During this update, the node randomly selects new neighbors, including only those with high scores. Neighbor nodes that exhibit faster block transfer rates compared to others are assigned higher scores, indicating superior network communication capabilities. Thus, miners prefer these high-scoring neighbors. This method leads to excessive dependence on the nodes that have the shortest total propagation time, which can reduce node performance.

Wang introduces the Txilm protocol in [24] to tackle the challenge of large data transmissions in blockchain networks. This is achieved through the application of lossy block compression alongside salted short hashing. The protocol operates by pre-sorting transactions based on their identifiers (TXIDs) or other criteria and hashing them using a short hash function combined with a cryptographic salt. This process significantly reduces the data size, resulting in substantial bandwidth savings. The compressed transaction list is broadcast instead of the original transactions, achieving up to 100x bandwidth efficiency. In cases of hash collisions, a second-stage resolution involving Merkle tree recomputation ensures data integrity. While the protocol effectively reduces data transmission sizes and enhances network scalability, it introduces additional computational overhead for collision resolution and depends on the consistent ordering of transactions and mempool size across nodes.

III. The Proposed System Model

To address the scalability and efficiency challenges in blockchain networks, we propose the Dynamic Block Propagation Framework (DBPF). This framework integrates MST-based optimal neighbor selection with Brotli compression for block data, aiming to minimize propagation time and enhance network throughput.

Let $G = (V, E)$ represent the blockchain network, where V is the set of nodes and E is the set of edges. Each edge $(i, j) \in E$ is associated with a weight w_{ij}, indicating the latency or communication cost between nodes i and j. The MST $T = (V, E_T)$ is a subset of E that spans all nodes V with the minimum total edge weight. The MST is computed using Kruskal's algorithm, formulated as:

$$\min \sum_{(i,j)\in E_T} w_{ij}$$

The MST provides the optimal neighbor selection (ONS_i) for each node i.

Let B denote the block containing T transactions. The block size is given by:

$$\|B\| = \sum_{i=1}^{T} \|t_i\|$$

Applying Brotli compression reduces the block size to $C(B)$, with the compression ratio $R = \frac{\|B\|}{C(B)}$. The propagation time P_t for a block B is determined by the compressed block size $C(B)$ and the network bandwidth W:

$$P_t = \frac{C(B)}{W}$$

For the entire network, the total propagation delay Δt considering the MST is given by:

$$\Delta t = \sum_{(i,j)\in E_T} \frac{C(B)}{W_{ij}}$$

where W_{ij} is the bandwidth between nodes i and j.

The overall objective of DBPF is to minimize the total propagation time by integrating MST-based optimal neighbor selection and Brotli compression:

$$\min_{T,C(B)} \Delta t = \min_{T,C(B)} \sum_{(i,j)\in E_T} \frac{C(B)}{W_{ij}}$$

This model demonstrates how DBPF optimizes both the network topology and data propagation processes, thereby enhancing blockchain network efficiency and scalability.

IV. The Proposed Efficient Dynamic Block Propagation Framework (DBPF)

This section introduces the explanation and design of an Efficient Dynamic Block Propagation Framework for Blockchain Networks (DBPF), which incorporates a combination of an efficient algorithm in neighbor selection by obtaining optimal neighbor for each node in the network by constructing a

minimum spanning tree (MST) and block size management by using **Brotli** compression algorithm to optimize network bandwidth. The primary objective of the DBPF protocol is to reduce message propagation time, optimize network bandwidth utilization, elevate overall network performance by leveraging compression techniques on block messages, and optimize blockchain network construction to be a solution for blockchain scalability problems.

To provide a clear understanding of the proposed solution, a diagram in Fig. 1 is presented. This diagram highlights the main components and mechanisms of the solution (DBPF), focusing on optimized neighbor selection and block size reduction through compression.

A. Phase-1: Leader Selection

In the context of the "**DBPF**", the leader Selection process adopts a random selection approach to designate a node as the leader within the blockchain network. This phase encompasses two primary tasks: Network leader selection and leader announcement. The DBPF requires a global view of the BC network. All nodes in BC have equal privileges in the public and permissionless BC network. However, the proposed **DBPF** selects one of these nodes to be the leader node (**LN**) to perform **MST** calculations for all other nodes. **LN** have advantages compared to other nodes in the same (BC) network, allowing it a global view or metadata information of the entire network. Additionally, **LN** collects information from the other nodes within the same network and uses it to generate the **MST** for the entire Network. Thus, each node in the network can select its optimal neighbors (ON) from the generated MST to exchange new blocks or transactions.

1) Step 1: Random selection: The **DBPF** protocol incorporates a random selection process for choosing a **LN**, which offers several notable advantages. Firstly, this approach ensures fairness by giving every node an equal opportunity to be selected as a leader, thereby eliminating potential biases. Secondly, the random selection method promotes unbiased network operations and decentralization, as it prevents the influence of network hierarchies or power dynamics in the leader selection process. This aligns with the core concept of decentralization within the BC ecosystem. Thirdly, in dynamic networks where nodes frequently join or leave, the ability to swiftly transition leadership is crucial. Random selection facilitates rapid leadership transitions without the delays associated with traditional election processes. If a **LN** departs or becomes less effective, a new leader can be randomly chosen, ensuring minimal disruption to network operations. This adaptability is paramount for maintaining the seamless functioning of the network in the face of changing circumstances.

In addition to the previously mentioned advantages, the random selection process in the **DBPF** protocol also enhances the security of the network. By randomly selecting a leader, the protocol introduces an element of unpredictability in the leadership position. Potential attackers or malicious actors are unable to predict or target specific nodes that might have elevated privileges as leaders. This randomness adds an extra layer of security to the network, as it prevents adversaries from exploiting any inherent vulnerabilities associated with predictable leader selection methods.

2) Step 2: Assessment of the Randomly Selected Leader: After a node is randomly selected as a potential leader, it undergoes a critical evaluation process to confirm its suitability. This assessment is vital to ensure that the node meets key criteria necessary for effective leadership. If the selected node meets these criteria, it is confirmed as the leader. If it does not, the random selection process is repeated. This step is designed to minimize the likelihood of choosing an unsuitable node, particularly aiming to avoid light nodes in favor of full nodes for leadership roles.

The first essential criterion is computational strength. The prospective leader node must possess substantial computational power to handle the responsibilities associated with leadership. This includes processing large volumes of data, making rapid and accurate decisions, and managing complex algorithms essential for optimizing the network. High computational capacity ensures that the node can perform its tasks efficiently without bottlenecks. Robust connectivity is another crucial requirement for the leader node. The selected leader must exhibit strong connectivity within the network. This robust connectivity is vital for ensuring efficient communication between the leader and other nodes, facilitating the swift and reliable dissemination of directives and information. Well-connected nodes enhance the overall responsiveness and coordination within the network. Finally, stability and reliability are essential characteristics of a leader node. The node must demonstrate a history of stable and reliable operation. High uptime and consistent availability are crucial, as they indicate the node's capability to maintain its leadership role without causing disruptions. A stable leader node ensures continuity and reliability in the network's functioning. To minimize the frequency of reselection, there is a preference for choosing from full nodes rather than light nodes. Full nodes, typically being more robust in terms of resources and connectivity, are more likely to meet the leadership criteria on the first selection. This approach streamlines the selection process, making it more efficient and reducing the time and resources spent in finding a suitable leader.

3) Step 3: Leadership Redetermination: In cases where the initially selected node does not meet the required criteria, the protocol stipulates a reselection. This process is promptly initiated to ensure that network leadership is established without undue delay.

Finally, The leader announcement proposed by the DBPF framework can be described as follows: Following the leader selection process, the DBPF notifies all nodes in the network about the new leader by sending announcement messages to all of them. Additionally, it informs the new leader of their responsibility for creating the MST for the network and broadcasting it to all nodes within the BC network. this phase algorithm is presented in Algorithm 1.

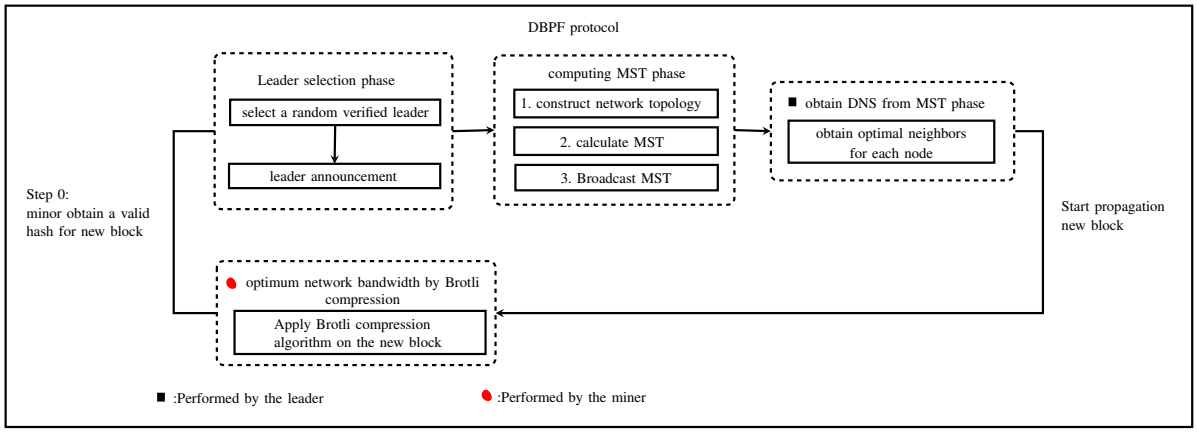

Fig. 1. The main steps involved in the proposed DBPF framework.

Algorithm 1 Leader Selection in DBPF Protocol

Require: Blockchain Network $\mathcal{N}$
Ensure: Selected Leader Node L
Begin
RandomlySelectNode:
  $n \leftarrow$ select a node randomly from $\mathcal{N}$
if $\neg$ isFullNode(n) **then**
    goto step 2 (RandomlySelectNode)
end if
AssessCandidate:
if hasComputationalStrength(n) $\wedge$ hasRobustConnectivity(n) $\wedge$ isStableAndReliable(n) **then**
    $L \leftarrow n$
else
    goto step 2 (RandomlySelectNode)
end if
End

B. Phase-2: Calculate and Dissemination of the Minimum Spanning Tree (MST)

In DBPF protocol, the subsequent phase following the random selection of the leader (L) involves a critical process that lays the foundation for network optimization. Upon phase 1, Each node and miner within the network acknowledges and recognizes the appointed leader (L). Consequently, Phase-2 is triggered and is performed by the leader (*L*) to compute MST for BC network (G) by using Kruskal's Algorithm as follows:

1) Step-1: Collection of Local information (LIs): *L* commences the process by collecting Local information (*LIs*) from all participating nodes (n) in the network (G). *LIs* consist of anonymized data regarding the network's topology, crucial for understanding the current network structure without compromising the privacy of individual nodes.

2) Step-2: Constructing Network Topology(NT): *L* employs the (*LIs*) stored locally to formulate an anonymized representation of the global network topology *NT*, Presented as an Adjacency List [25]. The Adjacency List is a fundamental data structure used to represent graph structures efficiently, particularly suitable for sparse graphs like BC networks, where the number of edges is significantly less than the number of possible edges. In the context of the Dynamic Block Propagation Framework (DBPF), the Adjacency Listis employed to construct the network topology (NT) based on the Local Information (LIs) collected from all participating nodes in the blockchain network. An Adjacency List represents a weighted graph $G = (V, E)$ where V is the set of vertices (nodes) and E is the set of weighted edges (connections with associated weights between nodes). Each vertex in the graph maintains a list of its adjacent vertices along with the weights of the connecting edges. This list captures all nodes directly connected to it by an edge and the corresponding weights, thus providing a compact and efficient way to store and manipulate the network topology.

Formally, for a weighted graph G with vertices $V = \{v_1, v_2, \ldots, v_n\}$ and weighted edges E, the Adjacency List is an array of lists, where the i-th element of the array corresponds to vertex v_i and contains a list of pairs (v_j, w_{ij}) such that there exists a weighted edge $(v_i, v_j) \in E$ with weight w_{ij}.

Example:

Consider a blockchain network with five nodes: $A, B, C, D,$ and E. The weighted connections (edges) between these nodes are as follows: $A - B(2), A - C(3), B - D(4), C - D(1), D - E(5)$. The Adjacency List representation of this weighted network would be:

- $A : \{(B, 2), (C, 3)\}$
- $B : \{(A, 2), (D, 4)\}$
- $C : \{(A, 3), (D, 1)\}$
- $D : \{(B, 4), (C, 1), (E, 5)\}$
- $E : \{(D, 5)\}$

This structure efficiently represents the network, allowing for quick look-up and traversal of adjacent nodes along with the weights of the connecting edges. Fig. 2 illustrates this weighted blockchain network graph.

The Adjacency List offers several advantages in the context of the DBPF. It provides an efficient way to store and access

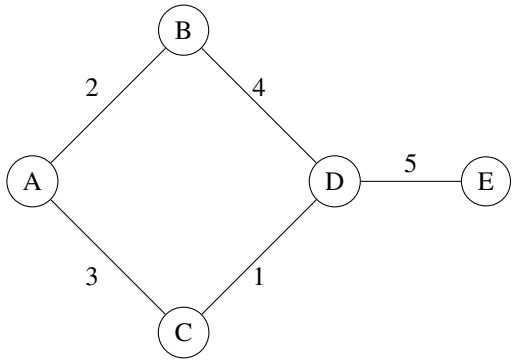

Fig. 2. Example of a weighted blockchain network graph.

the network structure, which is crucial for large blockchain networks with potentially thousands of nodes. As the blockchain network grows, the Adjacency List can handle the increasing number of nodes and edges without significant performance degradation, demonstrating its scalability. Furthermore, the list can be easily updated as new nodes join or leave the network which makes **DBPF** dynamic, ensuring that the representation remains accurate and up-to-date, highlighting its flexibility.

3) Step-3: Computation of the (MST) Using Kruskal's Algorithm:: Following the previous step where the leader node (L) utilized Local Information (LIs) to construct the network topology (NT), the next phase in the Dynamic Block Propagation Framework (DBPF) involves computing the (MST) for the blockchain network (G) using Kruskal's algorithm [26] as shown in Algorithm 2. Let $G = (V, E)$ be the graph where V is the set of vertices and E is the set of edges with weights $w : E \to \mathbb{R}$. The goal is to find a subset $T \subseteq E$ that forms a tree covering all vertices V with the minimum total edge weight:

$$\min \sum_{e \in T} w(e)$$

subject to T forming a connected acyclic subgraph of G.

Kruskal's algorithm sorts the edges E in non-decreasing order by weight and iteratively adds the shortest edge to T, provided it does not form a cycle, using the union-find data structure to manage disjoint sets. This structured approach ensures the MST is computed efficiently, forming a key component of our DBPF for optimizing blockchain network performance. The primary goal is to minimize the total edge weight while preserving network connectivity and avoiding cycles. Kruskal's algorithm processes each edge independently, which is advantageous when the number of edges $|E|$ is much smaller than the number of possible edges $\left(\frac{V(V-1)}{2}\right)$. This reduces the overall computational burden. The computed MST serves as the backbone for block propagation, significantly reducing propagation time and enhancing overall network efficiency. The time complexity of Kruskal's algorithm is $O(E \log E + E \log V)$, making it efficient for the large-scale and sparse nature of blockchain networks.

Algorithm 2 Compute MST using Kruskal's Algorithm

```
Input: Network topology NT = (V, E)
Output: Minimum Spanning Tree (MST)
procedure COMPUTE_MST(NT)
    Convert NT to a dictionary of dictionaries
    Initialize T ← ∅   ▷ Initialize the set for MST edges
    Create a union-find data structure for V
    Extract nodes and edges from NT
    Sort the edges E in non-decreasing order of their weights w(e)
    for each edge e = (u, v, w) in sorted E do
        if FIND(parent, u) ≠ FIND(parent, v) then
            T ← T ∪ {e}   ▷ Add edge to MST
            UNION(parent, rank, u, v)
        end if
    end for
    return T   ▷ The set of edges in the MST
end procedure
```

Example

Consider a blockchain network with five nodes: A, B, C, D, E. The weighted connections (edges) between these nodes are as follows: $A - B(2)$, $A - C(3)$, $B - D(4)$, $C - D(1)$, $D - E(5)$, as shown in Fig. 3.

Edge	Weight
(A, B)	2
(A, C)	3
(B, D)	4
(C, D)	1
(D, E)	5

The steps to compute the MST are as follows:

1) **Initialization**: Nodes: {A, B, C, D, E}; Edges: {(A, B, 2), (A, C, 3), (B, D, 4), (C, D, 1), (D, E, 5)}
2) **Sorting**: Sorted Edges: {(C, D, 1), (A, B, 2), (A, C, 3), (B, D, 4), (D, E, 5)}
3) **Edge Selection**:
   - Add (C, D, 1): No cycle
   - Add (A, B, 2): No cycle
   - Add (A, C, 3): No cycle
   - Skip (B, D, 4): Forms a cycle
   - Add (D, E, 5): No cycle
4) **Result**: MST: {(C, D, 1), (A, B, 2), (A, C, 3), (D, E, 5)} as shown in Fig. 4.

4) Step-4: Optimal Neighbor Selection (ONS):: Following the computation of the Minimum Spanning Tree (MST) by the leader node (L) in the previous step, the subsequent step involves disseminating the MST to all nodes within the blockchain network. This step aims to enable each node to derive its Optimal Neighbor Selection (ONS) from the received MST. Upon receiving the MST, each node runs Algorithm 3 to identify its optimal neighbors. This algorithm examines the MST and selects the most efficient connections based on the weights of the edges. These optimal neighbors are then used by the nodes to efficiently transmit new blocks or transactions across the blockchain network.

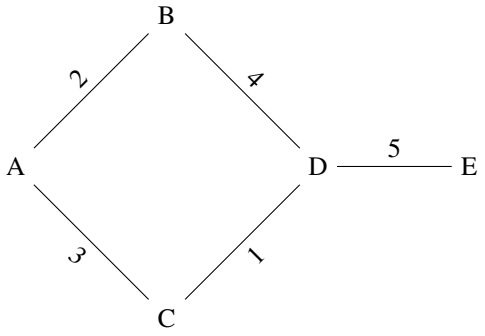

Fig. 3. Example of a weighted blockchain network graph.

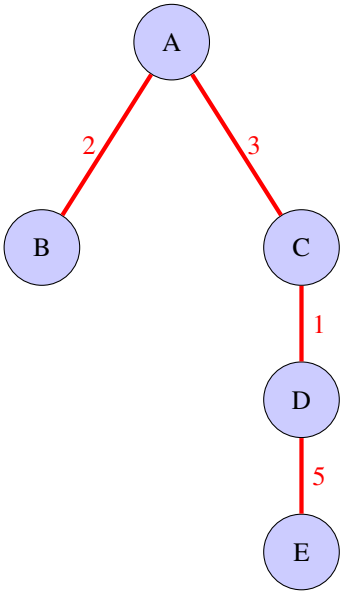

Fig. 4. Minimum spanning tree for the blockchain network.

This process ensures that data sharing is optimized, leveraging the MST to enhance overall network efficiency and performance. By utilizing the MST, the nodes can avoid redundant connections and minimize latency, which is crucial for maintaining the speed and reliability of blockchain operations. The MST-based ONS provides each node with a clear, efficient pathway for data transmission, contributing to the overall scalability and robustness of the blockchain network.

Algorithm 3 Find Optimal Neighbor Selection (ONS)

Require: MST $G = (V, E)$, node identifier node_id
Ensure: Optimal Neighbor Selection (ONS)
ONS $\leftarrow \{\}$ ▷ Initialize the set for ONS
for each $u \in G$ **do**
  if $u ==$ node_id **then**
    for each neighbor $v_j \in G[u]$ **do**
      ONS$[v_j] \leftarrow G[u][v_j]['\text{weight}']$
    end for
    break
  end if
end for
return ONS

C. Phase-3: Optimize Network Bandwidth by Brotli Compression

In this phase of the Dynamic Block Propagation Framework (DBPF), the focus shifts to optimizing network bandwidth and enhancing block propagation speed through the use of the Brotli lossless compression Algorithm [27]. This phase operates in parallel with the leader node's computation of the Minimum Spanning Tree (MST), enabling each node to transmit the compressed block efficiently to its Optimal Neighbors (ON). By doing so, the DBPF aims to reduce the propagation time of newly mined blocks across the network and increase the throughput of the public blockchain which contributes to solving the scalability problem.

The primary objective of compressing the block is to reduce its size ($\|B\|$), thereby minimizing the transmission time (P_t) across the network and optimizing the utilization of network bandwidth (W). This reduction in size aids in the faster propagation of the block to all nodes, addressing scalability issues and enhancing network efficiency.

We selected the Brotli compression algorithm for several reasons. Brotli, developed by Google, offers a high compression ratio and rapid decompression speed, making it particularly well-suited for The nature of blockchain data, which includes repetitive elements such as transaction inputs, outputs, and digital signatures, benefits greatly from Brotli's efficient compression techniques. A blockchain block is composed of two main parts: the header and the body. The header includes critical information necessary for the block's integrity and validation, such as the previous block hash, Merkle root, timestamp, difficulty target, and nonce. The body contains the transaction data, including inputs, outputs, and digital signatures. The block header's attributes are crucial for the validation cycle and maintaining the blockchain's integrity; thus, they are not compressed. Compressing these attributes would complicate validation and introduce security risks. Therefore, only the transaction data in the block body is compressed, preserving the essential information in the block header for seamless and secure validation. This compression process involves identifying redundant or less critical data within the block, applying the Brotli algorithm to reduce the block size, and then propagating the compressed block to neighboring nodes

The compression process involves several key steps. Initially, the miner identifies redundant or less critical data within the block, such as transaction inputs, outputs, digital signatures, and intermediate branches of the Merkle tree. Although the Merkle root must remain uncompressed for validation purposes, other components are suitable for compression. Let B represent a block containing T transactions, with the block size $\|B\|$ given by:

$$\|B\| = \sum_{i=1}^{T} \|t_i\|$$

Applying the Brotli compression algorithm, the block size is reduced to $C(B)$:

$$C(B) = \text{Brotli}(\|B\|)$$

The compression ratio R is defined as:

$$R = \frac{\|B\|}{C(B)}$$

This ratio reflects the effectiveness of the compression while ensuring that critical elements required for block validation, remain intact. Compressed transaction data is decompressed by nodes upon receipt, ensuring the block's integrity and validity are preserved.

When a miner successfully mines a new block B, it is compressed using the Brotli algorithm. This step occurs concurrently with the MST computation by the leader node. The miner then propagates the compressed block $C(B)$ through the optimized network to its neighboring nodes (N) which is calculated in phase 2. Each neighboring node decompresses $C(B)$ upon receipt to validate and add the block to its local blockchain. The propagation time (P_t) as a function of the compressed block size and network bandwidth is given by:

$$P_t = \frac{C(B)}{W}$$

By minimizing $C(B)$ through Brotli compression, the propagation time (P_t) is optimized, leading to enhanced network efficiency. Considering the network as a graph $G = (V, E)$, where V represents nodes and E represents communication links, the objective is to minimize the total propagation delay (Δt) across the network. This delay is influenced by the sum of individual propagation delays between nodes:

$$\Delta t = \sum_{i,j \in E} \frac{C(B)}{W_{ij}}$$

Here, W_{ij} represents the bandwidth between nodes i and j. By effectively compressing block data, DBPF optimizes the total propagation delay, improving the overall efficiency and scalability of the blockchain network.

By combining these two phases—optimized neighbor selection and enhanced network bandwidth—into a single framework called the Dynamic Block Propagation Framework (DBPF), we can significantly increase the throughput of blockchain networks. The DBPF leverages an MST-based optimal neighbor selection to establish efficient communication paths, alongside Brotli compression to reduce block sizes and transmission times. This dual approach not only minimizes propagation time but also enhances overall network efficiency. As we will demonstrate in the next evaluation section, DBPF outperforms many other methods in terms of scalability and performance in public blockchain networks.

V. Experiments and Results

This section provides a comprehensive overview of the experiments and assessments carried out to evaluate the Dynamic Block Propagation Framework (DBPF). It includes a discussion of the network datasets utilized, the performance metrics employed, and the detailed experiments executed. The network data was generated through a simulator that creates random network topologies using the Barabási-Albert(BA) model [28]. This model is well-suited for simulating real-world networks such as the Internet, social networks, and the World Wide Web.

To validate our analysis in real-world scenarios, we varied the network size and the average number of neighbors per miner. The simulation involves generating a random blockchain network where a miner node is randomly chosen as the source node for a data block. This source node disseminates the block to its neighboring nodes, which in turn propagate it to their neighbors, creating a cascading dissemination effect. The simulation ends once the block has reached all nodes in the network.

The experiments were run on a DELL PC equipped with an Intel(R) Core(TM) i5-10210U CPU (8 cores, 2.11 GHz), 8 GB DDR4-SDRAM, and a 500 GB SSD, running Windows 10 OS. We evaluated the experimental results using the Total Propagation Time (TP) metric in microseconds (μs), which measures the time it takes for a block sent from a randomly selected miner node to reach all nodes in the network.

Our experiments aim to demonstrate that the DBPF solution significantly enhances network performance by reducing the propagation time of new blocks, thereby improving the scalability and efficiency of blockchain networks.

The experiments are categorized as follows:

Experiment 1:

This experiment compares the performance of DBPF in terms of Total Propagation Time (TP) and the number of exchanged blocks (NB), against other algorithms such as Dynamic Optimized Neighbor Selection (DONS), Round-Trip Time (RTT), and Random Neighbor Selection (RNS). DONS is designed to optimize the propagation delay by selecting the most efficient paths based on delay metrics. RTT selects neighbors based on the minimum round-trip time, aiming to reduce latency in block propagation. RNS, on the other hand, randomly selects neighbors without considering network topology or path efficiency.The experiments were conducted using a network simulator based on the Barabási-Albert (BA) model to generate random network topologies. Two configurations were tested: networks with an average of 7 neighbors per node and networks with an average of 15 neighbors per node. The network bandwidth was assumed to be 10,000 bits per second. In each experiment, a randomly selected miner propagated a new block, and the propagation time and number of exchanged blocks were recorded.

The results demonstrate that DBPF significantly outperforms DONS, RTT, and RNS in both configurations. For networks with seven neighbors per node, DBPF achieved a total propagation time of 105.89 ms for 50 nodes, compared to 268.89 ms for DONS, 2124.58 ms for RTT, and 7489.9 ms for RNS. This trend continued as the network size increased to 100 and 450 nodes, with DBPF maintaining the lowest propagation times. Similarly, for networks with 15 neighbors per node, DBPF's propagation time remained consistently lower than the other algorithms. For example, with 450 nodes, DBPF achieved 156.95 ms compared to 840.50 ms for DONS, 19918.79 ms

TABLE I. PERFORMANCE OF DBPF AGAINST DONS, RTT, AND RNS

Nodes	Avg. Neighbors	Total Propagation Time (ms)			
		DBPF	DONS	RTT	RNS
50	7	105.89	268.89	2124.58	7489.9
100	7	263.37	721.72	5790.9	21089.09
450	7	326.42	1089.54	34805.4	162987.06
50	15	109.97	301.84	2152.55	14527.94
100	15	94.97	361.81	3271.19	21095.96
450	15	156.95	840.50	19918.79	125417.10

for RTT, and 125417.10 ms for RNS. The minimal increase in propagation time with DBPF highlights its efficiency and scalability. Additionally, DBPF maintained the lowest number of exchanged blocks as there is no any redundant block sent within the propagation process, indicating superior bandwidth utilization and network performance.

Based on the results in Table I, the insights derived from the experimental results underscore the superior performance of the Dynamic Block Propagation Framework (DBPF) in terms of propagation time and bandwidth efficiency compared to DONS, RTT, and RNS. As the number of nodes increased from 50 to 450, the propagation time for DBPF showed a minimal increase, highlighting its scalability and efficiency. For instance, DBPF's propagation time increased by only 220.53 ms (from 105.89 ms to 326.42 ms) for networks with seven neighbors per node, whereas RTT's time surged by 32680.82 ms (from 2124.58 ms to 34805.4 ms), and RNS's time skyrocketed by 155497.16 ms (from 7489.9 ms to 162987.06 ms). This demonstrates DBPF's superior scalability and efficiency in larger networks.

Compared to DONS, DBPF also showed significant improvements. For networks with seven neighbors per node, DBPF reduced the propagation time by 60.61% for 50 nodes, 63.52% for 100 nodes, and 70.05% for 450 nodes. Similar trends were observed for networks with 15 neighbors per node. This significant reduction in propagation time showcases the effectiveness of DBPF in optimizing network performance and achieving fast propagation of new blocks to all nodes.

The performance of the proposed DBPF algorithm was compared with DONS, RTT, and RNS algorithms across two experimental setups. The total propagation time for each algorithm as the number of nodes increases is shown in Fig. 5.

In Experiment 1 (Fig. 5a), with an average of seven neighbors per node, DBPF significantly outperforms the other algorithms. For instance, with 450 nodes, DBPF achieves a propagation time of 326.42 ms, whereas DONS, RTT, and RNS require 1089.54 ms, 34805.4 ms, and 162987.06 ms, respectively.

In Experiment 2 (Fig. 5b), with an average of 15 neighbors per node, DBPF again demonstrates superior performance. With 450 nodes, DBPF has a propagation time of 156.95 ms, compared to DONS at 840.50 ms, RTT at 19918.79 ms, and RNS at 125417.10 ms.

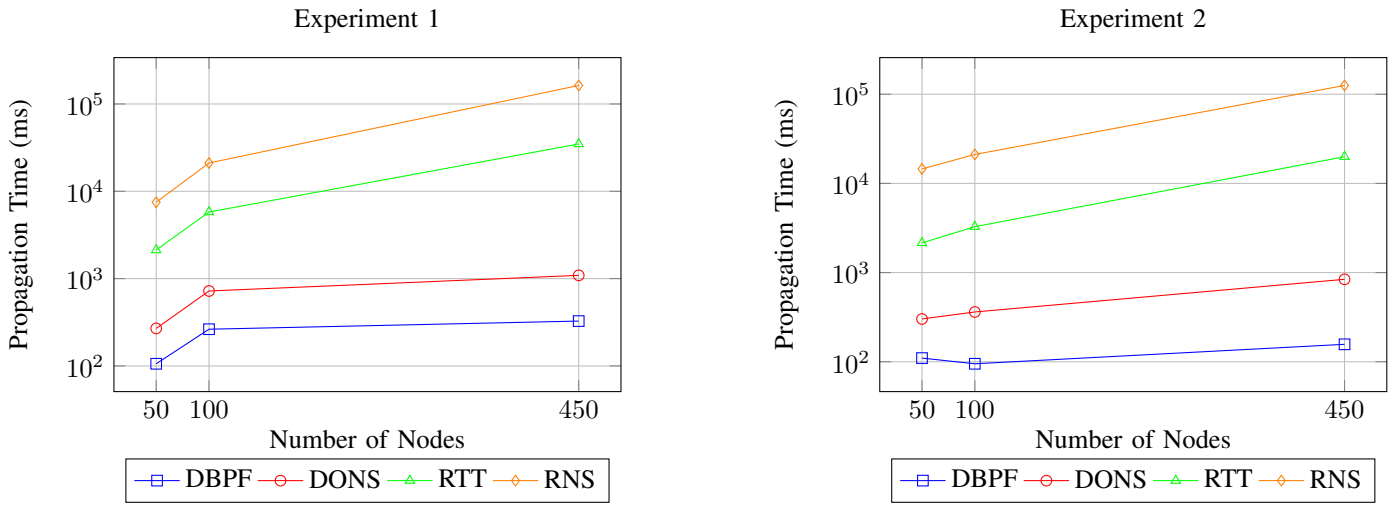
Experiment 2:

This experiment aims to demonstrate the robustness and efficiency of the Dynamic Block Propagation Framework (DBPF) under varying network bandwidth conditions, simulating realistic blockchain network scenarios under the Barabási-Albert (BA) model. Unlike previous experiments with constant bandwidth, this experiment introduces random bandwidth variations between nodes to assess DBPF's performance in more dynamic environments. The network configurations for this experiment include two cycles: Cycle 1 with an average number of neighbors per node set to 8 and Cycle 2 with an average number of neighbors per node set to 15. For each cycle, three different network sizes are tested: 30, 70, and 180 nodes. For each configuration, a random network topology is generated, and random bandwidth values are assigned to each pair of nodes to mimic real-world conditions where network bandwidth can vary. The total propagation time (PT) and the number of exchanged blocks (NB) are measured for DBPF, DONS, RTT, and RNS algorithms. The primary objective is to verify DBPF's efficiency in environments with fluctuating bandwidth and to compare its performance against other well-known algorithms (DONS, RTT, RNS). By simulating realistic network conditions, we aim to highlight DBPF's adaptability and robustness in maintaining low propagation times and efficient block propagation, even when network bandwidth varies significantly. The results from these experiments are presented in Table II.

The results of the second experiment, conducted under varied bandwidth conditions, provide a comprehensive evaluation of the performance of the Dynamic Block Propagation Framework (DBPF) compared to DONS, RTT, and RNS. The experiments were conducted on two different average neighbor settings (8 and 15) with randomly generated bandwidth values to simulate realistic network conditions. The bandwidth values for the first set of experiments ranged from 1000 to 10000 Bps, while the second set ranged from 5000 to 100000 Bps.

The experiments clearly demonstrate the impact of bandwidth variability on propagation time across different algorithms. In scenarios with lower average neighbors (8), DBPF consistently outperformed other methods. For instance, with 70 nodes, DBPF achieved a propagation time of 140.46 ms compared to DONS (647.99 ms), RTT (5406.97 ms), and RNS (16553.99 ms). This indicates that DBPF is highly efficient in utilizing available bandwidth, leading to reduced propagation times.

In scenarios with higher average neighbors (15), DBPF continued to show superior performance. With 30 nodes, DBPF recorded a propagation time of 93.91 ms, significantly lower than DONS (154.92 ms), RTT (1121.16 ms), and RNS (4998.62 ms). This trend persisted with 70 nodes and 180 nodes, where DBPF consistently demonstrated lower propagation times, highlighting its robustness in handling varying network conditions and higher node densities.



(a) Avg. Neighbors = 7

(b) Avg. Neighbors = 15

Fig. 5. Comparison of total propagation time for different algorithms in two experimental setups

TABLE II. PERFORMANCE OF DBPF, DONS, RTT, AND RNS UNDER VARIED BANDWIDTH CONDITIONS (BA MODEL)

Model	Nodes	Avg. Neighbors	Total Propagation Time (ms)			
			DBPF	DONS	RTT	RNS
BA	30	8	160.26	630.43	1609.75	10345.17
BA	70	8	140.46	647.99	5406.97	16553.99
BA	180	8	219.80	865.98	18618.33	63783.90
BA	30	15	93.91	154.92	1121.16	4998.62
BA	70	15	111.12	167.33	2084.82	10820.95
BA	180	15	130.91	217.12	5694.26	44358.25

To quantitatively assess the performance improvement of DBPF, we calculate the percentage reduction in propagation time compared to DONS. For instance, with 180 nodes and 8 average neighbors, DBPF achieved a propagation time of 219.80 ms, while DONS recorded 865.98 ms. The percentage improvement is calculated as follows:

$$\text{Percentage Improvement} = \left(\frac{\text{DONS Time} - \text{DBPF Time}}{\text{DONS Time}}\right) \times 100$$

$$\text{Percentage Improvement} = \left(\frac{865.98 - 219.80}{865.98}\right) \times 100 \approx 74.61\%$$

Similarly, with 30 nodes and 15 average neighbors, DBPF showed a 39.38% improvement over DONS. These substantial improvements demonstrate the efficiency of DBPF in minimizing propagation time, and enhancing overall network performance.

Let T_{DBPF} and T_{DONS} represent the propagation times of DBPF and DONS, respectively. The percentage improvement $P_{\text{improvement}}$ can be expressed as:

$$P_{\text{improvement}} = \left(\frac{T_{\text{DONS}} - T_{\text{DBPF}}}{T_{\text{DONS}}}\right) \times 100$$

The experiments also showed significant differences in the number of exchanged blocks (NB) across different methods. For instance, DBPF required no redundant block exchanges compared to RTT and RNS, reflecting its efficiency in reducing network load and overhead

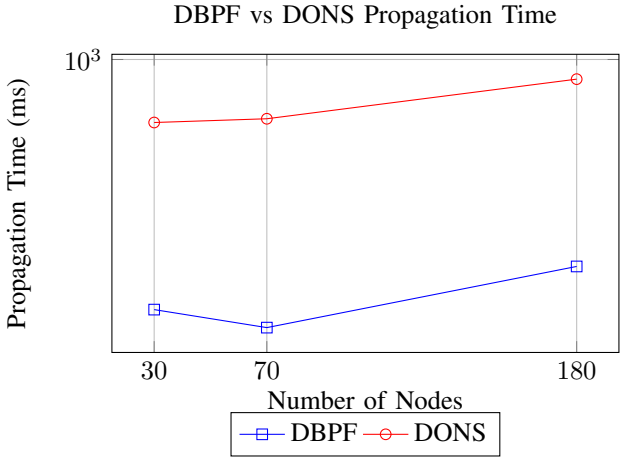


Fig. 6. Comparison of propagation time between DBPF and DONS.

These results underscore the effectiveness of DBPF in optimizing network performance, even under varying and challenging bandwidth conditions. The framework's ability to reduce propagation time significantly while maintaining low overhead highlights its potential for enhancing the scalability and efficiency of blockchain networks. As shown in Fig. 6, the DBPF algorithm consistently outperforms DONS across various network sizes and bandwidth conditions.

Experiment 3:

In this experiment, we investigate the efficiency of the Dynamic Block Propagation Framework (DBPF) implemented with different compression algorithms, specifically focusing on Brotli compression. The goal is to evaluate the performance of DBPF using Brotli in comparison with other widely-used compression techniques, zlib [29] and zstandard [30], under identical network conditions and the same block size. The Barabási-Albert (BA) model is employed to simulate realistic network environments.

The experiment consists of two cycles. In the first cycle, the number of nodes is set to 100 and 280, with an average number of neighbors per node fixed at 18. The bandwidth is kept constant at 10,000 bps to maintain a controlled environment. In the second cycle, the number of nodes is increased to 280 and 450, with the same average number of neighbors per node, but the bandwidth is randomly generated within the range of 1,000 to 10,000 bps to simulate dynamic network conditions.

The primary objective is to compare the performance of DBPF using Brotli, zlib, and zstandard compression algorithms. Zlib, a widely used compression library, provides a good balance between speed and compression ratio and is often utilized for data storage and transmission. Zstandard, developed by Facebook, offers high compression efficiency and fast decompression speeds, making it ideal for large-scale data compression tasks.

Metrics used to evaluate performance include total propagation time (ms). The hypothesis is that Brotli compression will outperform zlib and zstandard in reducing propagation time and optimizing network efficiency, demonstrating the robustness and scalability of the DBPF framework. The results from this experiment aim to provide a comprehensive analysis of the most efficient compression technique for enhancing blockchain network performance.

As it is shown in Table III, the results of this experiment highlight the effectiveness of the DBPF framework, particularly when using the Brotli compression algorithm. The propagation times for DBPF-Brotli were consistently lower than those for DONS and the other compression algorithms across all tested configurations. For instance, with 100 nodes and a fixed bandwidth of 10,000 bps, DBPF-Brotli achieved a propagation time of 105.65 ms, significantly outperforming DONS, which recorded 496.73 ms. Even when compared with other compression algorithms, DBPF-Brotli maintained its superiority, with DBPF-Zlib at 107.32 ms and DBPF-Zstandard at 216.80 ms. As the number of nodes increased to 280, DBPF-Brotli continued to show excellent performance, recording a propagation time of 91.45 ms, while DONS and DBPF-Zstandard recorded 627.63 ms and 297.06 ms, respectively. This trend was also observed when the bandwidth was randomly generated within the range of 1,000 to 10,000 bps. With 280 nodes, DBPF-Brotli achieved a propagation time of 163.32 ms, compared to DONS at 1496.8 ms, DBPF-Zlib at 171.27 ms, and DBPF-Zstandard at 189.71 ms. When examining the performance with 450 nodes under random bandwidth conditions, DBPF-Brotli again demonstrated superior performance with a propagation time of 99.65 ms. In contrast, DONS recorded 842.38 ms, DBPF-Zlib recorded 101.23 ms, and DBPF-Zstandard recorded 105.75 ms.

VI. Conclusion

The Dynamic Block Propagation Framework (DBPF) introduced in this study addresses key challenges in blockchain networks, such as limited transaction throughput, large blockchain sizes, scalability issues, and consensus protocol limitations. By integrating optimal neighbor selection (ONS) and advanced data compression techniques, specifically utilizing the Minimum Spanning Tree (MST) computation for efficient communication paths and the Brotli compression algorithm for data reduction, DBPF significantly enhances the performance of blockchain networks. Extensive experiments conducted using the Barabási-Albert (BA) model under various network conditions demonstrated the superiority of DBPF over existing methods. The outcomes of the presented research demonstrated a notable enhancement in block propagation across networks of diverse sizes, outperforming current state-of-the-art approaches. In networks with 180 nodes and 8 average neighbors, DBPF achieved up to a 74.61% improvement in propagation time compared to DONS. Further, DBPF outperformed RTT and RNS by 88.20% and 99.65%, respectively, under the same conditions. These results highlight the effectiveness of DBPF in reducing propagation time and enhancing overall network throughput. Additional experiments under varied bandwidth conditions confirmed the robustness and adaptability of DBPF. The framework maintained superior performance with both fixed and randomly generated bandwidths, demonstrating its flexibility in real-world scenarios. Evaluations with different compression algorithms, including Brotli, zlib, and zstandard, further underscored the efficiency of DBPF. Notably, DBPF using Brotli consistently outperformed other methods, validating the benefits of combining optimal neighbor selection with advanced compression techniques.

In summary, the DBPF framework offers a scalable and efficient solution for blockchain networks, significantly reducing block propagation time and increasing network throughput. These findings underscore the potential of DBPF to address inherent scalability challenges in blockchain technology, paving the way for more robust and efficient blockchain operations.

While the current study demonstrates the effectiveness of DBPF, several areas for future research can further enhance the framework's capabilities. Firstly, exploring the integration of DBPF with emerging consensus algorithms such as Proof of Stake (PoS) or Delegated Proof of Stake (DPoS) could provide insights into optimizing blockchain performance under different consensus mechanisms. future work could focus on implementing adaptive compression techniques that dynamically select the most suitable algorithm based on real-time network conditions and data characteristics.

Higher Normal School, Department of Computer Science, University Cadi Ayyad, Marrakech, Morocco[3]

***Abstract*—Skin cancer is one of the most prevalent types of cancer worldwide, and its early detection is crucial for improving patient outcomes. Artificial Intelligence (AI) has shown significant promise in assisting dermatologists with accurate and efficient diagnosis through automated skin disease classification. This systematic review aims to provide a comprehensive overview of the various AI techniques employed for skin disease classification, focusing on their effectiveness across different datasets and methodologies. A total of 220 articles were initially identified from databases such as Scopus and IEEE Xplore. After removing duplicates and conducting a title and abstract screening, 213 studies were assessed for eligibility based on predefined criteria such as study relevance, clarity of results, and innovative AI approaches. Following full-text review, 56 studies were included in the final analysis. These studies were categorized based on the AI techniques used, including Convolutional Neural Networks (CNNs), Transformer-based models, hybrid models combining CNNs with other techniques, Generative Adversarial Networks (GANs), and ensemble learning approaches. The review highlights that the ISIC dataset and its variations are the most commonly used data sources, owing to their extensive and diverse collection of dermoscopic images. The results indicate that CNN-based models remain the most widely adopted and effective approach for skin disease classification, with several hybrid and Transformer-based models also demonstrating high accuracy and specificity. Despite the advancements, challenges such as dataset variability, the need for more diverse training data, and the lack of interpretability in AI models persist. This review provides insights into current trends and identifies future directions for research, emphasizing the importance of integrating AI into clinical practice for improved skin disease management.**

I. Introduction

Skin diseases encompass a broad spectrum of conditions that affect the skin, which is the largest organ of the human body. These conditions can vary greatly in severity and presentation, ranging from benign issues like acne to life-threatening diseases such as melanoma. Accurate diagnosis, classification, and segmentation of skin diseases are critical as they directly influence treatment plans, patient outcomes, and overall healthcare efficiency. Misdiagnosis or delayed diagnosis can lead to severe consequences, including unnecessary treatments or the progression of the disease to more advanced stages [1], [2].

Common skin diseases that are frequently the focus of classification and segmentation efforts in medical research include melanoma, psoriasis, and eczema. Melanoma, in particular, is a malignant tumor of melanocytes and is one of the most serious forms of skin cancer due to its high potential for metastasis [3]. Psoriasis is a chronic inflammatory skin condition characterized by the rapid growth of skin cells, leading to thick, red, scaly patches [4]. Eczema, also known as atopic dermatitis, is a chronic condition that causes inflamed, itchy, cracked, and rough skin [5].

Traditionally, the diagnosis of skin diseases has relied heavily on clinical examinations performed by dermatologists. This process typically involves visual inspection, often aided by tools like dermoscopy, which provides magnified images of the skin, allowing for better visualization of structures beneath the skin surface [6]. In cases where the visual inspection is inconclusive, a biopsy may be performed, wherein a sample of the skin is taken for histopathological examination under a microscope [7].

While these traditional methods are well-established and widely used, they are not without limitations. Human error is a significant concern, as the accuracy of diagnosis can vary depending on the dermatologist's experience and expertise. Studies have shown variability in diagnostic accuracy, even among experienced dermatologists [8]. Additionally, the manual segmentation of skin lesions, which is crucial for treatment planning, is time-consuming and labor-intensive. This process often involves delineating the borders of the lesion manually, which is not only subjective but also prone to variability [9].

Given these challenges, there is a growing interest in the application of artificial intelligence (AI) to improve the accuracy, efficiency, and consistency of skin disease diagnosis and segmentation. A significant body of research has emerged that integrates AI techniques into the detection and segmentation of skin diseases, demonstrating promising results in enhancing diagnostic processes. This paper proposes a systematic review focusing on the use of AI for the classification and segmentation of skin diseases, aiming to consolidate current findings, identify prevailing methodologies, and highlight existing knowledge gaps within this rapidly evolving field. By systematically analyzing the literature, this review will provide

valuable insights into the effectiveness of AI in dermatology, outline the strengths and limitations of current approaches, and suggest potential avenues for future research.

The remainder of this paper is organized as follows: The Theoretical Background section provides a comprehensive overview of the foundational concepts and existing literature related to AI-driven skin disease classification. This is followed by the Methodology section, where the criteria and procedures used to select and analyze the studies are detailed. The Results section presents the findings from the systematic review, including bibliometric analyses and the evaluation of methodologies. In the Discussion section, the implications of the findings are explored, and the strengths and limitations of current approaches are assessed. Finally, the paper concludes with Final Considerations, summarizing the key takeaways and suggesting directions for future research in this rapidly evolving field.

II. Theoretical Background

A. From Classic to Modern Dermatology

Dermatology has undergone a profound transformation from its early days of visual inspection and basic histopathological analysis to the incorporation of advanced imaging technologies and digital tools. Traditionally, dermatologists relied heavily on their clinical expertise, using simple tools like magnifying glasses to examine skin lesions, and performing biopsies followed by histopathological analysis to diagnose complex conditions. Histopathological images, derived from these biopsies, provided detailed views of skin tissue at the cellular level, becoming a cornerstone of accurate diagnosis, particularly for skin cancers [10].

Over time, the limitations of these conventional methods, including their invasiveness and the potential for diagnostic variability, drove the development of more sophisticated tools. The advent of dermoscopy revolutionized non-invasive examination by enabling magnified visualization of subsurface skin structures, greatly enhancing the accuracy of initial assessments [11]. This was followed by the introduction of digital dermoscopy, confocal microscopy, optical coherence tomography (OCT), and multispectral imaging, each offering unique insights into different aspects of skin anatomy and pathology [12], [13]. These technological advancements have not only improved traditional diagnostic practices but have also set the stage for the integration of artificial intelligence, which leverages these diverse imaging modalities to further revolutionize dermatological care.

These diverse imaging modalities—ranging from high-resolution dermoscopic images to detailed histopathological and confocal microscopy images—have provided a wealth of data that is now being harnessed by artificial intelligence (AI) to further advance the field. AI systems, trained on these extensive image datasets, are capable of analyzing and interpreting complex patterns within the skin, leading to more precise and efficient diagnoses [14], [15]. This integration of AI with a wide variety of imaging techniques is not only enhancing diagnostic performance but also paving the way for more personalized and effective treatment strategies in dermatology.

B. Artificial Intelligence and Skin Disease Classification

Building on the advancements in imaging technologies, the integration of artificial intelligence into dermatology marks a significant leap forward in skin disease classification. AI, through machine learning and deep learning algorithms, leverages the vast array of imaging data—from clinical and dermoscopic images to histopathological and confocal microscopy images—to identify subtle patterns and features that might escape human detection. This capability allows AI to offer unprecedented accuracy and efficiency in the diagnosis and classification of skin conditions, setting the stage for more personalized and precise dermatological care [16].

Artificial Intelligence (AI) is a broad field that includes machine learning (ML) and deep learning (DL), both of which have become crucial in healthcare, particularly in dermatology. ML involves algorithms that learn from data to make predictions, while DL, a more advanced subset, uses multi-layered neural networks to automatically extract features from complex datasets. These AI techniques are particularly well-suited for analyzing skin images, enabling more accurate and efficient diagnosis of dermatological conditions by identifying patterns that may be difficult for human clinicians to detect [17], [14], [16].

Machine learning (ML) initially made significant strides in dermatology by enabling the automated classification of skin lesions based on manually extracted features. Techniques such as support vector machines (SVMs), decision trees, and random forests were effectively used to analyze images and identify patterns that distinguish between benign and malignant conditions [14]. One notable success was the use of SVMs in melanoma detection, where these models achieved high accuracy by focusing on key features like color, texture, and shape [16]. Despite these advancements, ML models often required extensive feature engineering, relying on expert knowledge to select the most relevant attributes. This limitation, combined with the models' relatively shallow architecture, made it challenging to handle the complex and high-dimensional data typical in dermatology, which paved the way for the adoption of deep learning (DL).

Machine learning was the first wave of AI to make a substantial impact in dermatology. By training algorithms on datasets of labeled skin images, ML models have been able to assist in diagnosing various skin conditions. For example, support vector machines (SVMs), decision trees, and ensemble methods like random forests have been utilized to classify skin lesions based on features extracted manually or through basic automated processes [14]. These models improved diagnostic consistency and reduced human error, particularly in distinguishing between benign and malignant lesions. However, the effectiveness of ML in dermatology was often limited by the need for extensive feature engineering and the relatively shallow nature of these models, which struggled to capture the complexity of high-dimensional image data.

The introduction of deep learning marked a significant leap forward for AI in dermatology. Deep learning, particularly through convolutional neural networks (CNNs), overcame many of the limitations of traditional ML models by automatically learning hierarchical features directly from raw image data. CNNs, with their ability to process and analyze

large amounts of image data, have been particularly effective in dermatology, where they are used to classify skin diseases with unprecedented accuracy [17]. These models have been trained on vast datasets of clinical, dermoscopic, and histopathological images, enabling them to recognize subtle patterns and features that might be missed by human clinicians or simpler algorithms.

As AI continues to evolve, its applications in dermatology are expected to expand, addressing current challenges such as model interpretability and data bias, while opening new avenues for personalized and accessible skin care.

III. Related Work

The application of machine learning (ML) and deep learning (DL) techniques in the classification of skin diseases has garnered significant attention in recent years, leading to the development of various models aimed at improving diagnostic accuracy and efficiency. Traditional ML methods such as Support Vector Machines (SVM), Random Forests (RF), and k-Nearest Neighbors (k-NN) have been extensively utilized for skin disease classification tasks. For instance, [14] employed SVM in conjunction with handcrafted features for melanoma detection, achieving competitive performance against dermatologists. However, these approaches are often limited by their dependence on feature engineering, which can be both time-consuming and reliant on domain expertise.

With the advent of DL, particularly Convolutional Neural Networks (CNNs), there has been a paradigm shift in the approach to skin disease classification. CNNs have the inherent ability to automatically learn hierarchical feature representations from raw image data, eliminating the need for manual feature extraction.

Over the past decade, several systematic reviews have been conducted to assess the efficacy of machine learning (ML) and deep learning (DL) techniques in the classification of skin diseases. These reviews have provided valuable insights into the trends, challenges, and future directions in this rapidly evolving field. The author in [18] conducted one of the early comprehensive reviews, focusing on the application of CNNs in dermatology. This review highlighted the increasing adoption of deep learning models over traditional machine learning approaches due to their superior accuracy and ability to process raw image data without extensive preprocessing.

Further advancing the field, [19] provided a thorough review of dermatological image analysis using both machine learning and deep learning techniques. The review emphasized the significant advancements in CNN architectures, such as ResNet, AlexNet, VGG.., and their impact on improving diagnostic accuracy for various skin conditions, including common cases and rare ones. However, the authors also noted the limitations related to the interpretability of these models and the challenges posed by imbalanced datasets.

[20] conducted a meta-analysis focused specifically on the performance comparison between human dermatologists and DL models. Their review concluded that DL models, particularly those based on CNNs, have reached a level of performance comparable to that of expert dermatologists, especially in the detection of malignant melanoma. This finding was corroborated by the review conducted by [21], which compared multiple DL models and found that ensemble methods often outperform individual models in terms of accuracy and robustness.

A more recent review by [22] explored the integration of advanced techniques such as transfer learning and generative adversarial networks (GANs) into dermatological applications. The authors highlighted that while these techniques offer promising avenues to overcome the challenges of limited labeled data and improve model generalizability, there is still a need for more standardized evaluation protocols and larger, more diverse datasets to fully realize their potential.

In addition to these, [23] reviewed the ethical and regulatory considerations associated with the deployment of ML and DL models in clinical settings. Their work underscores the importance of ensuring model transparency, patient data privacy, and the need for rigorous clinical validation before these models can be widely adopted in practice.

These reviews collectively illustrate the rapid advancements and the ongoing challenges in applying ML and DL techniques to skin disease classification. They provide a foundation for future research, particularly in addressing issues related to model interpretability, dataset bias, and the ethical implications of AI in dermatology.

In contrast, this systematic review aims to fill a specific gap in the literature by focusing on the progression from traditional ML techniques to advanced DL models. Process was to systematically search, extract, and analyze studies that detail the exact methodologies and techniques used in both ML and DL for skin disease classification. This approach allows us to map the evolution of these techniques, highlighting how deep learning, particularly CNNs, Transformers, and hybrid models, has been increasingly adopted and refined over time.

A notable particularity of this review is the attention given to hybrid models that combine both machine learning and deep learning techniques. This focus is crucial, as hybrid models represent a significant trend in the literature, often outperforming their pure ML or DL counterparts by leveraging the strengths of both approaches. These models' architectures and performances were meticulously documented, thereby offering insights into their potential for future research and clinical applications, by tracing the trajectory from early adoption phases to the more recent innovations, such as Vision Transformers (ViTs) and Generative Adversarial Networks (GANs), providing a clear picture of the technological advancements and their impact on classification performance.

This systematic review stands out in its detailed exploration of the transition from ML to DL in skin disease classification. It not only contributes to the existing body of knowledge but also serves as a valuable resource for researchers aiming to further advance the field.

IV. Methodology

A. Aim and Scope Definition

The primary objective of this study is to systematically review and synthesize the existing literature on the application of artificial intelligence (AI), including machine learning (ML)

and deep learning (DL), in the classification of skin diseases. The study aims to explore how these AI techniques have been utilized in analyzing various types of dermatological images, including clinical, dermoscopic, and histopathological images, to enhance diagnostic accuracy and efficiency. The scope of the review includes original research articles, and review papers published in peer-reviewed journals. The study focuses on skin diseases such as melanoma, psoriasis, and acne, with no specific geographical or linguistic restrictions, although only English-language publications are included.

B. Data Collection

1) Retrieval database: The literature for this systematic review was retrieved from several databases known for their comprehensive coverage of medical and technological research. The primary databases used include IEEE Xplore and Scopus. These databases were selected due to their relevance to the fields of dermatology, artificial intelligence, and medical imaging, ensuring that a broad range of studies could be captured.

2) Keyword selection strategy: A strategic keyword selection process was employed to identify relevant studies. Keywords were chosen to reflect the core concepts of the study: artificial intelligence, machine learning, deep learning, and skin disease classification. Specific search terms included combinations of the following: "AI in dermatology", "deep learning", "machine learning", "classification". Boolean operators (AND, OR, NOT) were used to refine the search and ensure comprehensive coverage of the literature.

Research query for scopus = (TITLE-ABS-KEY ("skin diseases" OR "dermatological disorders" OR "skin conditions") AND ("machine learning" OR "deep learning") AND ("classification") AND TITLE-ABS-KEY ("segmentation") AND PUBYEAR ¿ 2020 AND PUBYEAR ¡ 2024 AND [LIMIT-TO (LANGUAGE, "English")

Research query for IEEE Xplore = ("All Metadata": "skin diseases" OR "All Metadata": "dermatological disorders" OR "All Metadata": "skin conditions" OR "All Metadata": "skin lesions") AND ("All Metadata": "machine learning" OR "All Metadata": "deep learning") AND ("All Metadata": "classification") NOT ("All Metadata": "segmentation")] (Table I).

C. Inclusion and Exclusion Criteria

1) Inclusion criteria: To ensure the relevance and quality of the included studies, the following inclusion criteria were applied:

- The study focuses on the application of AI (ML or DL) in the classification of skin diseases.
- The study is published in a peer-reviewed journal.
- The study provides sufficient data for analysis, including details of the AI methods used and the types of images analyzed.
- The study is written in English.

TABLE I. RESEARCH QUESTIONS OF THE STUDY

No.	Research Question (RQ)
RQ1	What are the most commonly used artificial intelligence models for the classification of skin diseases?
RQ2	How effective are these AI models in accurately classifying various skin diseases?
RQ3	How do AI-based methods for skin disease classification compare to traditional diagnostic methods ?
RQ4	What datasets are commonly used to train and validate AI models for skin disease classification, and what are their characteristics?
RQ5	What are the potential clinical implications of integrating AI models into the diagnosis and treatment planning of skin diseases?
RQ6	What are the main challenges and limitations associated with the use of AI models in the classification of skin diseases?
RQ7	What future research directions are needed to improve the performance and clinical applicability of AI models in skin disease classification?

2) Exclusion criteria: Studies were excluded based on the following criteria:

- The study does not focus on dermatology or AI applications in skin disease classification.
- The study is a conference abstract, editorial, letter, or opinion piece with no original research data.
- The study lacks methodological rigor, as determined by the quality assessment process.
- The study does not utilize one of the following datasets: "ISIC", "HAM10000", "PH2", "Dermnet" or "Derm7pt".
- The study is about the segmentation of skin diseases.
- The study is not available in English.

In this systematic review, a total of 220 articles were initially identified through comprehensive database searches in Scopus and IEEE Xplore. After the removal of 7 duplicate articles, 213 unique records remained for screening.

The initial screening process led to no exclusions at this stage. All 213 records were then assessed for eligibility. Subsequently, 109 articles were excluded due to various reasons, such as lack of clear results reporting (11 articles), non-novel approaches (11 articles), irrelevant content (15 articles), or falling out of the scope of the review (14 articles). This left 104 articles for further retrieval attempts, out of which 48 were not retrieved. Ultimately, 56 articles were included in the final review and deemed suitable for qualitative synthesis (Fig. 1).

3) Software tools: The data analysis was performed using a combination of software tools, including Microsoft Excel for data management and descriptive analysis, R for statistical analysis, and Bibliometrix with Biblioshiny package for qualitative analysis. These tools were chosen based on their functionality, ease of use, and ability to handle large datasets effectively.

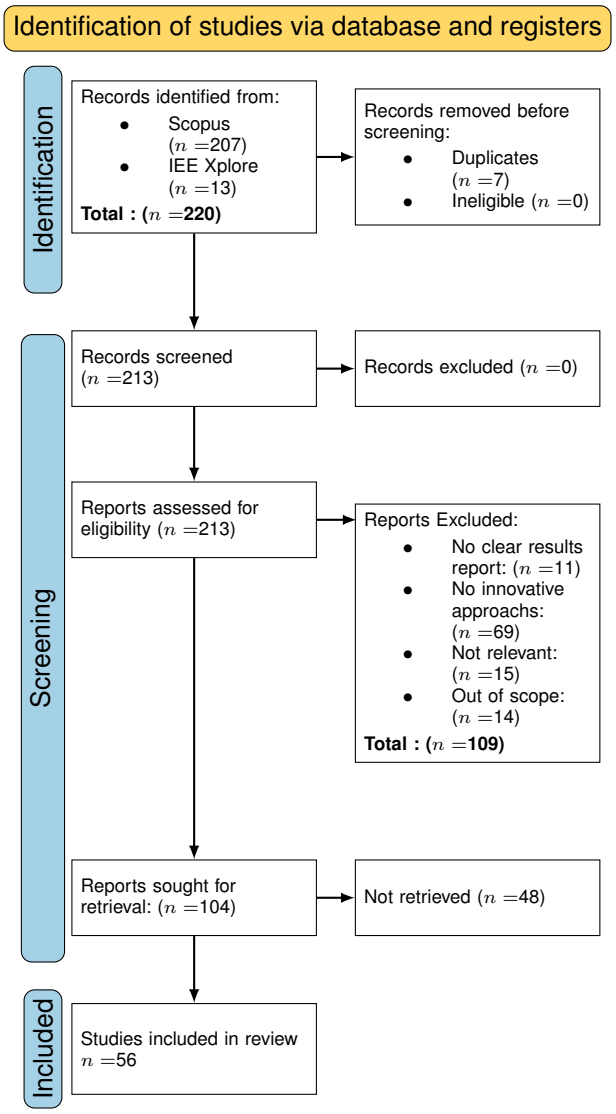

Fig. 1. Prisma diagram.

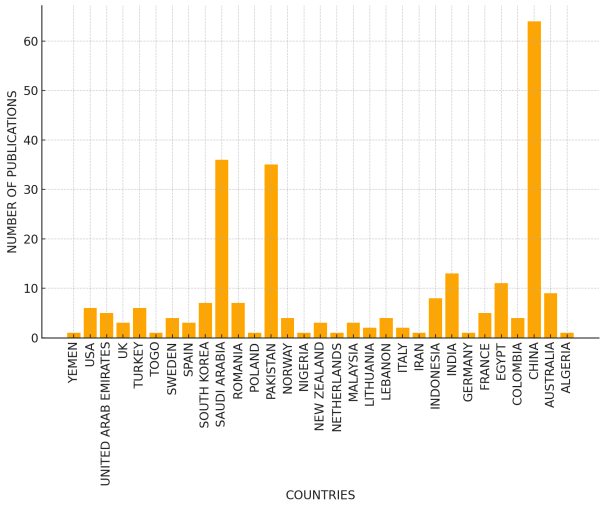

Fig. 2. Distribution of selected papers by countries.

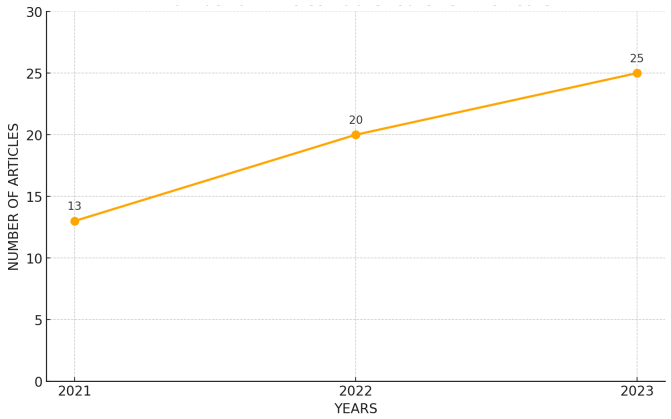

Fig. 3. Number of articles by years of publication.

V. Results

Retained articles related to the classification of skin diseases using machine learning and deep learning tools were published across 31 different countries.

Fig. 2 illustrates the distribution of included works by countries of publication. The countries representing the origin of the greatest number of publications are China with 64 articles, followed by Pakistan with 35 articles, and Saudi Arabia with 36 articles. Additionally, India and Indonesia contributed significantly with 13 and 8 articles, respectively. Together, China, Pakistan, Saudi Arabia, India, and Indonesia account for over 80% of the papers included in this study, with a total of 56 papers.

Considering publication dates of selected articles, a large part of the retained documents was published during the period 2020 to 2023, with a total of 45 papers. Fig. 3 below represents the curve of the publication's evolution per years between 2021 and 2023.

The bibliometric analysis also includes a thematic map in Fig. 4, which offers a visual representation of the key research themes within the field of AI-driven skin disease classification. The map categorizes themes based on their relevance (centrality) and development degree (density), providing a clear overview of the research landscape. This analysis highlights "deep learning" and "dermatology" as highly relevant but still developing themes, suggesting ongoing growth in these areas. Conversely, "human melanoma" appears as a well-established motor theme, indicating its foundational role in the field. Emerging or declining themes such as "optimization algorithms" are also identified, pointing to areas where future research may be necessary.

To further explore the thematic connections within the literature, Fig. 5 presents a co-occurrence network of keywords. This visualization highlights the central themes in AI-driven skin disease classification, with "deep learning" and "skin cancer" emerging as the most connected and frequent terms. The network also reveals the relationships between various methodologies, such as "convolutional neural networks" and "transfer learning", underscoring their significance in this research domain.

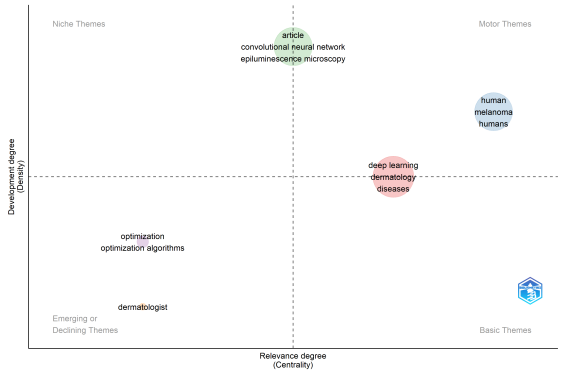

Fig. 4. Thematic map of research in AI-driven skin disease classification.

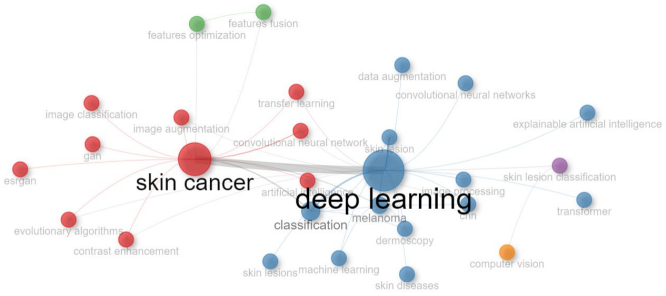

Fig. 5. Co-occurrence network of keywords in AI-driven skin disease classification literature. This network visualizes the relationships between key terms, with larger nodes indicating more frequently occurring keywords. The network highlights the centrality of terms like "deep learning" and "skin cancer", revealing their strong connections with related concepts such as "image augmentation", "transfer learning", and "convolutional neural networks".

RQ1: What are the most commonly used artificial intelligence models for the classification of skin diseases?

The qualitative analyse of the obtained results from the researches papers provided, indicates that Convolutional Neural Networks (CNNs) are the most frequently employed AI models for skin disease classification. CNNs appear in various forms, including standalone models, hybrid approaches (e.g. CNN combined with SVM, XGBoost, or Random Forest), and enhanced architectures (e.g. Inception-V3, EfficientNets). Additionally, Transformer-based models and Vision Transformers (ViTs) are increasingly utilized, reflecting a shift towards more complex, attention-based architectures. Hybrid models integrating multiple techniques, such as CNNs with transformers or Extreme Learning Machines (ELM), are also prevalent, suggesting an ongoing effort to enhance model performance through combining strengths of different methods.

RQ2: How effective are these AI models in accurately classifying various skin diseases?

The reviewed studies report high accuracy rates across different AI models, with CNN-based approaches often achieving accuracy levels above 90%. Specific examples include:

- A deep learning-based auto-encoder with an accuracy of 98.7%.
- A CNN combined with XGBoost and SVM showing 97.85% accuracy.
- Hybrid CNN-ELM models achieving up to 96.7% accuracy.

Sensitivity and specificity metrics are also robust, frequently exceeding 90%. For example, the sensitivity for CNN models ranges from 88.3% to 98.46%, while specificity ranges from 90% to 100%. These results indicate that AI models, particularly CNNs and hybrid approaches, are effective in accurately classifying skin diseases, often outperforming traditional diagnostic approaches.

RQ3: How do AI-based methods for skin disease classification compare to traditional diagnostic methods?

The analyse of the provided researches reveals that deep learning-based methods, particularly Convolutional Neural Networks (CNNs), consistently outperform traditional machine learning techniques in skin disease classification across various metrics. Deep learning models achieve higher accuracy, often exceeding 94%, with some models reaching up to 96.83% ([24], [25]). In contrast, traditional machine learning methods, including Support Vector Machines (SVM) and Random Forests, typically demonstrate accuracy within the 90% to 97% range.

Sensitivity and specificity are also higher in deep learning models. For instance, [26] reports a sensitivity of 98% and specificity of 98.1% using a Lightweight CNN with dynamic-sized kernels and ReLU/leaky ReLU activations, while machine learning approaches generally show slightly lower performance in these metrics.

Moreover, deep learning models benefit from data augmentation techniques, such as Generative Adversarial Networks (GANs), which enhance their generalization capabilities, especially in imbalanced datasets ([27]). Traditional machine learning methods, although effective, often require more extensive feature engineering and do not leverage data augmentation as effectively as deep learning approaches.

Hybrid models that combine deep learning with machine learning methods, such as CNNs with SVM or Random-Forest offer a balanced approach, leveraging the strengths of both techniques ([28], [29]). However, these hybrids still typically fall short of purely deep learning-based methods in terms of overall performance.

In terms of model interpretability, traditional machine learning models, particularly decision trees, provide more straightforward explanations. However, the integration of Explainable AI (XAI) techniques with CNNs has begun to address the "black box" nature of deep learning models, enhancing their transparency ([30]).

While machine learning models still hold value in scenarios requiring interpretability, deep learning approaches, particularly when augmented with hybrid techniques, represent the most effective tools for skin disease diagnostics.

RQ4: What datasets are commonly used to train and validate AI models for skin disease classification, and what are their characteristics?

Several datasets emerge as commonly utilized benchmarks for training and validation purposes for skin disease classification task. The following are the key datasets frequently employed in these studies, along with their characteristics:

- ISIC (International Skin Imaging Collaboration): This dataset is a comprehensive repository of dermoscopic images that has been widely adopted due to its diversity and scale [31]. The ISIC dataset includes several variations, such as ISIC2018, ISIC2019, ISIC2020, ISIC2017, and ISIC2008, each corresponding to different years of challenge submissions. These variations contain images that differ in terms of disease types, resolutions, and annotations, providing a robust foundation for model development (Fig. 6).
- HAM10000: The HAM10000 dataset [32] contains a large collection of dermatoscopic images with an emphasis on the most common pigmented skin lesions. It is particularly valued for its balanced representation of multiple classes of skin diseases, making it a reliable resource for training classifiers that need to generalize across various conditions.
- PH2: Although smaller, the PH2 dataset is a key resource that provides high-quality dermoscopic images specifically curated for the assessment of melanocytic and non-melanocytic skin lesions [33]. Its limited class diversity is counterbalanced by the precise annotations and image quality, making it ideal for specialized classification tasks.
- Derm7pt: This dataset focuses on a seven-point checklist system for melanoma detection, providing a structured approach to training models in clinical decision-making scenarios [34].
- PAD-UFES-20: This dataset includes images collected from a specific demographic, aiding in the development of models that are more inclusive and adaptable to different population groups [35].

Fig. 7 summarizes the usage distribution of these datasets across the reviewed studies, highlighting the dominance of the ISIC and its variants, followed by the widespread adoption of HAM10000 and other datasets.

RQ5: What are the potential clinical implications of integrating AI models into the diagnosis and treatment planning of skin diseases?

The high accuracy and specificity of AI models indicate significant potential for their integration into clinical practice. AI can assist dermatologists in diagnosing skin diseases more quickly and accurately, reducing the time required for analysis and potentially improving patient outcomes. Moreover, the precision of AI models could help in early detection of malignant lesions, leading to more timely interventions. However, the clinical integration of these models also requires careful consideration of ethical implications, including patient consent, data privacy, and the potential for algorithmic bias. The integration of AI into treatment planning could also extend to personalized medicine, where AI-driven insights help tailor treatment strategies to individual patient profiles.

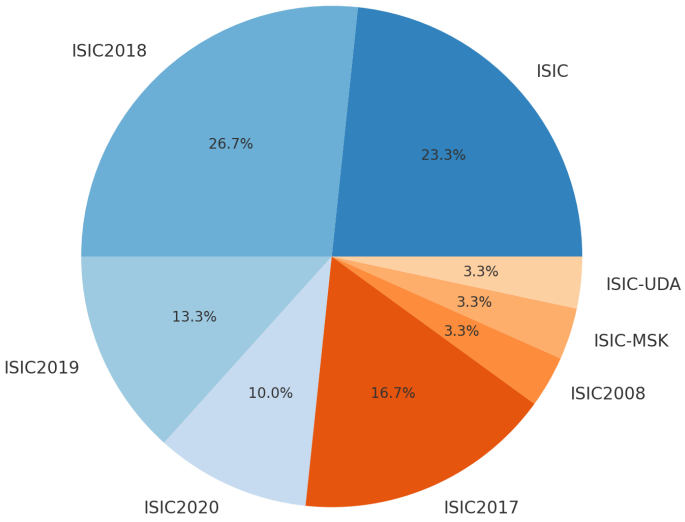

Fig. 6. Usage distribution of ISIC dataset variants across studies.

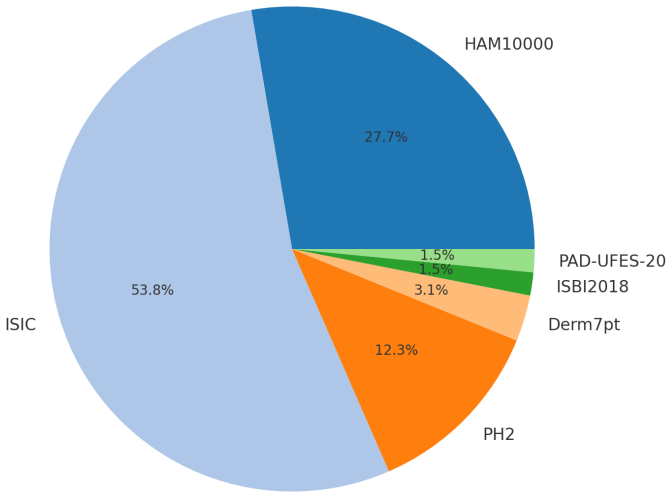

Fig. 7. Percentage of Dataset Usage in the Selected Studies.

RQ6: What are the main challenges and limitations associated with the use of AI models in the classification of skin diseases?

Despite the promising results, several challenges and limitations persist. One significant challenge is the generalizability of AI models across different populations and clinical settings. Most models are trained on specific datasets, which may not fully represent the diversity of skin types and conditions found in the broader population. Data quality and annotation is another concern; the accuracy of AI models heavily depends

on the quality of the input data, and misannotations or inconsistencies can lead to reduced model performance. Moreover, computational complexity and the need for high-end hardware for training and deploying complex models like transformers could limit their accessibility in resource-constrained environments. Additionally, there is a need for explainability in AI models to ensure that clinicians can trust and understand the decisions made by these systems. Finally, there is limited research on how these models can be effectively integrated into real-world clinical workflows. Understanding the challenges of AI adoption in everyday clinical practice, including clinician trust, usability, and workflow compatibility, is essential for the successful implementation of AI in dermatology [36].

RQ7: What future research directions are needed to improve the performance and clinical applicability of AI models in skin disease classification?

Future research in AI for skin disease classification should prioritize several key areas to enhance both performance and clinical applicability. First, increasing dataset diversity and size is critical for improving model generalization, particularly for underrepresented skin conditions and demographic groups, ensuring broader applicability across diverse populations. Second, cross-validation in varied clinical settings is necessary to assess the robustness and consistency of AI models, which is essential for their practical integration into healthcare environments. Third, improving the explainability of AI models is vital for building trust among healthcare providers, enabling transparent and verifiable diagnoses that can encourage clinical adoption.

Additionally, research should focus on reducing the computational complexity of AI models, making them more accessible and deployable, especially in resource-limited settings. The development of multi-modal diagnostic systems that integrate visual data with patient-specific information, such as demographics and medical history, is another crucial area. These systems could enhance diagnostic accuracy and lead to more personalized treatments.

Moreover, most current research focuses on static images and one-time predictions. There is a gap in studies that investigate the application of AI in longitudinal analyses, where the progression of skin diseases is tracked over time. Such studies are crucial for developing AI tools that can not only diagnose but also monitor disease progression and treatment response [37], [38].

VI. Discussion

The analysis of methodologies employed across the studies included in this systematic review reveals distinct patterns in the application of various AI techniques for skin disease classification. To provide a more nuanced understanding of the approaches utilized by different researchers, the studies have been categorized based on the general technique employed, including Machine Learning techniques (e.g. XGBoost, SVM), Generative Adversarial Networks (GANs), Ensemble Learning approaches, Multi-modal methods, Transformer-based models, and Hybrid models combining Convolutional Neural Networks (CNNs) with other techniques.

The following sections summarize the methodologies applied within each of these categories, highlighting the specific strategies used in feature extraction, model training, and validation. This organization elucidates the strengths and limitations inherent to each approach, offering a clearer perspective on the current state of AI-driven skin disease classification. By structuring the analysis in this manner, a direct comparison between different techniques is facilitated, providing insights into potential future directions for research in this rapidly evolving field.

A. Studies Using Generative Adversarial Networks (GANs)

Generative Adversarial Networks (GANs) have been explored for their ability to generate synthetic data and improve classification tasks in skin disease detection.

Two notable studies have employed Generative Adversarial Networks (GANs) to enhance skin lesion classification. Abdelhalim et al. [39] combined GANs with Convolutional Neural Networks (CNNs) in their study, utilizing the ISIC dataset. In this approach, GANs were employed to generate synthetic dermoscopic images, which were subsequently used to train the CNN. This method effectively improved the model's robustness by augmenting the training data.

Similarly, Su et al. [27] adopted a GAN-CNN hybrid model for skin lesion classification. In their study, the GAN was used to generate additional training samples, while the CNN handled the classification task. This methodology was validated using the HAM10000 dataset, and the results demonstrated improved accuracy, attributed to the enriched dataset provided by the GAN.

B. Studies Using Ensemble Learning Approaches

Ensemble learning approaches combine multiple models to improve classification accuracy and robustness. The following table provides an overview of studies that utilized ensemble learning techniques in skin disease classification.

Several studies have utilized ensemble learning approaches to enhance the classification of skin lesions. Popescu et al. [40] proposed an ensemble learning methodology that involved combining multiple models to classify skin lesions using the ISIC dataset. In this approach, different base models were trained separately, and their predictions were subsequently combined through majority voting or weighted averaging, leading to higher accuracy.

Similarly, Thurnhofer-Hemsi et al. [41] applied an ensemble approach to improve the accuracy of skin lesion classification on the HAM10000 dataset. This method focused on reducing the variance and bias inherent in single models by integrating the strengths of multiple classifiers, ultimately enhancing the overall classification performance.

C. Studies Using Multi-modal Approaches

Multi-modal techniques have been explored in several studies to enhance the accuracy of skin disease classification by integrating various data sources. Fu et al. [42] utilized a graph nodes-based approach that incorporated multi-modal data from different sources, including the 7-point checklist, ISIC2017, and ISIC2018 datasets. This methodology focused on combining different types of data to improve the classification of skin lesions.

Zhang et al. [43] introduced TFormer, a throughout fusion transformer model for multi-modal skin disease classification. The transformer model served as the feature extraction backbone, fusing both image and metadata, which significantly enhanced the accuracy of classification.

Roge et al. [28] employed a deep ensemble learning approach that integrated demographic information with image data to improve classification performance. This study combined the use of a demographic machine with standard imaging techniques, leading to superior results in classification accuracy.

Cai et al. [44] applied a multi-modal transformer model that fused images and metadata, leveraging the strengths of Vision Transformer (ViT) in handling multi-modal data. This approach provided a notable boost in classification accuracy by effectively combining different data sources.

Nguyen et al. [45] utilized a combination of deep learning models (DenseNet) and traditional machine learning algorithms (SVM) to classify skin lesions on imbalanced datasets. By incorporating both image data and patient metadata, this approach improved model robustness and accuracy.

Yin et al. [46] introduced the MetaNet module, which employs multi-modal data from both images and metadata to enhance skin tumor classification. The comprehensive analysis enabled by this multi-modal approach resulted in improved classification performance.

D. Studies Using Transformer-Based Models

Transformer-based models, originally developed for natural language processing, have been adapted for image classification tasks due to their ability to capture long-range dependencies in data.

Several studies have explored the use of Transformer-based models for skin lesion classification, showcasing the versatility and effectiveness of this approach. Ding et al. [47] employed a Vision Transformer (ViT) model on the ISIC2018, ISIC2017, and PH2 datasets. The methodology capitalized on the Transformer's ability to process image patches, which provided an effective solution for skin lesion classification.

Zhang et al. [43] proposed a Transformer-based model tailored for the Derm7pt dataset. Their approach emphasized the model's capability to learn global contextual information, which is crucial for accurately classifying skin lesions.

Abbas et al. [48] utilized a Transformer-based model to classify dermoscopic images from the ISIC dataset. The study highlighted the use of self-attention mechanisms inherent in Transformers, which allowed the model to capture intricate patterns in the images, thereby improving classification performance.

Cai et al. [44] applied a Vision Transformer (ViT) to the ISIC2018 dataset, focusing on the model's ability to process images in a patch-wise manner. Their study demonstrated the effectiveness of the Transformer architecture in handling large-scale image data, resulting in enhanced classification accuracy.

Yang et al. [49] also employed a Transformer-based model, specifically for the HAM10000 dataset. This study leveraged the self-attention mechanism of the Transformer to capture the intricate details of skin lesions, thereby improving classification accuracy.

Aladhadh et al. [50] used a Transformer-based model to classify images from the HAM10000 dataset. Their focus was on enhancing the model's sensitivity and specificity by taking advantage of the deep attention mechanisms inherent in Transformer architectures.

E. Studies Using Hybrid Models (CNN with Other Techniques)

Hybrid models that combine CNNs with other techniques, such as machine learning algorithms or other deep learning methods, have shown potential in improving classification accuracy.

Hybrid models that combine Convolutional Neural Networks (CNNs) with other techniques have been widely explored for improving the classification of skin lesions. Ma et al. [24] proposed a hybrid approach that integrated CNN with Random Forest for the classification of skin lesions using the HAM10000 dataset. In this study, the CNN was responsible for deep feature extraction, which were then classified by the Random Forest, combining the strengths of both methods.

Similarly, Roge et al. [28] developed a CNN-Random Forest hybrid model for the ISIC dataset (HAM10000). Their methodology also involved using CNN for initial feature extraction, followed by Random Forest for final classification, which enhanced both the accuracy and robustness of the model.

Nie et al. [51] explored a hybrid model that combined CNN with Transformer architecture, specifically for skin lesion classification using the ISIC2018 dataset. In this study, the CNN component handled initial feature extraction, while the Transformer captured global dependencies in the image data, leading to improved classification performance.

Li et al. [52] also utilized a hybrid CNN-SVM approach for the ISIC2019 dataset. In this study, the CNN was used for initial feature extraction, with SVM refining the classification process to enhance the accuracy of multi-class skin lesion classification.

Tahir et al. [29] proposed a hybrid model that combined CNN with XGBoost and Support Vector Machine (SVM) for classifying skin lesions in the ISIC2017 dataset. The CNN was utilized to extract relevant features, with XGBoost and SVM models performing the classification, leveraging the strengths of both deep learning and traditional machine learning techniques.

Khan et al [53] proposes a fully automated system for multiclass skin lesion localization and classification using deep learning. To address class imbalance in the HAM10000, ISBI2018, and ISBI2019 datasets, the approach fine-tunes a pre-trained DarkNet19 model and fuses visualized images using a High-Frequency approach with a Multilayered Feed-Forward Neural Network (HFaFFNN). Two additional models, DarkNet-53 and NasNet-Mobile, are trained using transfer learning on localized lesion images. Features are fused using the parallel max entropy correlation (PMEC) technique, and the entropy-kurtosis controlled whale optimization (EKWO) algorithm selects the most discriminant features. The model

achieves accuracies of 95.8%, 97.1%, and 85.35% on the HAM10000, ISBI2018, and ISBI2019 datasets, respectively. Zhou et Arandian. [54] introduce a new computer-aided skin cancer diagnosis method that combines deep learning with the Wildebeest Herd Optimization (WHO) algorithm. Inception CNN is used for feature extraction, followed by the WHO algorithm for feature selection to reduce analysis complexity. The method was tested on the ISIC-2008 dataset and compared with three other algorithms, demonstrating superior results.

Annaby et al. [55] proposes a melanoma detection approach that combines graph-theoretic representations with conventional image features to improve detection performance. Superpixels from dermoscopic images are used as graph nodes, and edges connect adjacent superpixels based on feature descriptor distances. Features are extracted from both weighted and unweighted graph models in the vertex and spectral domains, as well as from color, geometry, and texture. Various classifiers were trained on these feature combinations using ISIC datasets. The proposed system demonstrated significant improvements in accuracy, AUC, specificity, and sensitivity in detecting melanoma. Saeed et al. [56] employed a hybrid model that combined CNN with SVM for the classification of skin lesions using the ISIC2019 and ISIC2020 datasets. In this approach, the CNN handled feature extraction, while the SVM classifier provided enhanced decision boundaries, leading to improved model performance.

Afza et al. [57] introduced a hybrid CNN-Extreme Learning Machine (ELM) model for skin lesion classification using the ISIC dataset (HAM10000 and ISIC2018). In this study, CNN was used for feature extraction, while the ELM classifier processed these features, achieving high accuracy and specificity.

Nivedha et al. [58]focuses on melanoma detection using a novel computer-aided method combining the African Gorilla Troops Optimizer (AGTO) algorithm and Faster Region Convolutional Neural Networks (Faster R-CNN). The AGTO algorithm selects the most valuable features, and Faster R-CNN performs the classification. Applied to the ISIC-2020 skin cancer dataset, the proposed model achieves an accuracy of 98.55%, outperforming four existing approaches.

Damarla et al. [59] proposes an automated skin cancer classification system using a Deep Convolutional Neural Network (DCNN) for multiclass classification of dermoscopy images. The system employs transfer learning for feature extraction, followed by feature selection using metaheuristic algorithms like Particle Swarm Optimization (PSO), Ant Colony Optimization (ACO), and Gorilla Troop Optimization (GTO). A two-level classification is then applied to optimize and reduce features. Tested on the HAM10000 dataset, the model achieved 93.58% accuracy, outperforming state-of-the-art techniques and showing high scalability.

Finally, Attique Khan et al. [60] developed a two-stream deep neural network framework for multiclass skin cancer classification. The first stream uses a fusion-based contrast enhancement technique and DenseNet201 to extract and optimize features, while the second stream extracts features from a fine-tuned MobileNetV2. The most discriminant features from both streams are fused using a novel multimax correlation method and classified with an extreme learning machine. The classification of skin lesions was done using a mixed datasets (HAM10000, ISBI2018, ISIC2019).

F. Studies Using CNN-Based Models

Convolutional Neural Networks (CNNs) are a popular choice for image classification tasks due to their ability to automatically learn and extract features from images. The following table summarizes studies that employed CNN-based models for skin disease classification.

Numerous studies have explored the use of Convolutional Neural Networks (CNNs) for the classification of skin lesions, showcasing the versatility and effectiveness of these models. Alassaf et al. [25] utilized a deep learning-based Auto-Encoder model on the ISIC dataset, focusing on unsupervised feature learning. The model was trained to classify skin lesions based on these features, achieving high accuracy and specificity.

Abayomi et al. [61] proposes a novel data augmentation technique based on the covariant Synthetic Minority Oversampling Technique (SMOTE) to address data scarcity and class imbalance in melanoma detection. The augmented images, generated from the PH² dataset, are used to train the SqueezeNet deep learning model. In binary classification, the model achieved 92.18% accuracy, 80.77% sensitivity, and 95.1% specificity. In multiclass classification, it improved melanoma detection with 89.2% sensitivity and 96.2% specificity for atypical nevus detection, outperforming state-of-the-art methods.

Akram et al. [62] employed a CNN to classify dermoscopic images from the PH2, ISIC-MSK, and ISIC-UDA datasets. Their methodology centered on using CNN architectures for feature extraction and classification, resulting in high accuracy and sensitivity.

Calderon et al. [63] presents a bilinear CNN approach for classifying seven skin lesion types with high accuracy and low computational cost. The framework includes data augmentation to address class imbalance, transfer learning, and fine-tuning using ResNet50 and VGG16 architectures. Tested on the HAM10000 dataset, the model achieved a 2.7% improvement over the state-of-the-art.

Khan et al. [64] enhanced a deep learning architecture with the Entropy-NDOEM algorithm for multiclass skin lesion classification. The process used include contrast enhancement, fine-tuning EfficientNetB0 and DarkNet19, feature extraction and selection using Entropy-NDOELM, feature fusion, and classification using an extreme learning machine with diverse datasets such as HAM10000, ISIC2018, and ISIC2019 datasets. The overall methodology leads to an overall improvement in model performance.

Rasel et al. [65] presents in their study, a deep learning-based system using a Convolutional Neural Network (CNN) for melanoma detection to improve early diagnosis. The research focuses on how different nonlinear activation functions affect CNN performance on limited dermoscopic image datasets. The proposed model, using the parameterized Leaky ReLU function, achieved 97.5% accuracy, 98% precision, and 98% sensitivity in classifying skin lesions into three classes. Experiments were conducted on the PH2 and ISIC datasets,

demonstrating that this approach outperforms other activation functions for melanoma recognition.

Foahom et al. in their study [66] addresse the challenge of class imbalance in skin lesion (SL) detection by proposing an end-to-end decoupled training method for long-tailed skin lesion classification. The approach utilizes a novel loss function (Lf) for initial training to improve feature representation and a weighted variant of Lf to enhance robustness against class imbalance. Tested on the ISIC 2018 dataset, the model outperformed existing methods for SL detection by at least 2%, demonstrating its effectiveness in handling class imbalance.

Aldhyani et al. [26] proposes a lightweight deep learning model using dynamic-sized kernels for the accurate classification of skin lesions. The model incorporates both ReLU and leaky ReLU activation functions to enhance performance while maintaining a low number of trainable parameters. Tested on the HAM10000 dataset, the model achieved an impressive accuracy of 97.85%, outperforming several state-of-the-art models. The results demonstrate the model's efficiency in classifying various types of skin lesions.

Shen et al. [67] proposes a high-performance data augmentation strategy designed to improve skin cancer classification accuracy, particularly for use in low-resource settings. The strategy, which can be combined with any model in a plug-and-play mode, optimizes data augmentation with minimal computational cost. Using EfficientNets as a baseline, the model achieved strong performance on multiple datasets, including a BACC of 0.853 on HAM10000 and an AUC of 0.909 on ISIC 2017.

Kaur et al. [68] proposes an automated melanoma classifier using a deep convolutional neural network (DCNN) to classify malignant and benign melanoma from dermoscopic images. The DCNN is designed to efficiently extract features across multiple layers, optimizing filter selection, network depth, and hyperparameters to create a lightweight, less complex model. Tested on the ISIC 2016, 2017, and 2020 datasets, the model achieved accuracies of 81.41%, 88.23%, and 90.42%, respectively, outperforming other state-of-the-art methods and offering an efficient solution for melanoma diagnosis.

Dillshad et al. [69] focused on optimizing a CNN model for the classification of skin lesions in the HAM10000 dataset. The methodology based on a variance-controlled Marine Predator methodology optimizes feature selection and achieves high sensitivity and specificity in detecting various types of skin lesions.

Nugroho et al. [70] applied a CNN using the Inception-V3 architecture to the ISIC2019 dataset. Their approach emphasized feature extraction using the Inception-V3 model, followed by classification, which led to high accuracy in skin lesion detection. Mehmood et al. [71] proposed SBXception, a modified deep learning model based on the Xception architecture, designed for efficient skin lesion classification using the HAM10000 dataset. This methodology aim to enhance the original Xception model by making it shallower (reducing depth) and broader (increasing width), leading to fewer parameters and faster training times, achieving a high accuracy of 96.97% on the test set.

Mukadam et al. [72] used a CNN model to classify images from the HAM10000 dataset, with a focus on improving the CNN architecture to enhance accuracy and specificity in skin lesion classification.

Dahou et al. [73] proposes a robust skin cancer detection framework using a pre-trained MobileNetV3 architecture for feature extraction. The extracted features are optimized through a modified Hunger Games Search (HGS) algorithm, combining Particle Swarm Optimization and Dynamic-Opposite Learning (DOLHGS), to select the most relevant features. The model was tested on the ISIC-2016 and PH2 datasets and has improved classification accuracy across these datasets.

Finally, Supriyanto et al. [74] developed a CNN-based model for the classification of skin lesions using the HAM10000 dataset. The study focused on refining the CNN architecture to improve the sensitivity and specificity of the classification results.

G. Studies Using Machine Learning Techniques

Machine learning techniques such as XGBoost and SVM have been widely used for skin disease classification due to their robustness in handling complex datasets. The following table summarizes studies that employed these techniques, highlighting their methodologies.

Various studies have utilized machine learning techniques to improve the classification of skin lesions, often integrating multiple approaches to enhance performance. Khater et al. [75] employed XGBoost on selected features derived from dermoscopic images in the PH2 dataset. Their methodology focused on enhancing feature extraction through preprocessing and used explainable AI techniques, as SHAP to ensure the interpretability of the results, leading to improved classification accuracy.

Ahmed et al. [76] integrated Convolutional Neural Networks (CNNs) with Support Vector Machine (SVM) and Artificial Neural Network (ANN) models to analyze dermoscopic images from the HAM10000 and PH2 datasets. Their approach utilized MobileNet and ResNet101 architectures for feature extraction, followed by classification with SVM and ANN, achieving high accuracy across multiple metrics.

Ilkin et al. [77] proposed a combination of SVM with feature extraction from mixed datasets, including PH2 and ISIC. Their study focused on optimizing the feature set prior to SVM classification, aiming to improve the model's ability to differentiate between various skin lesion classes.

Finally, Pitchiah et al. [78] introduced a hybrid model combining K-Nearest Neighbors (KNN) with Random Forest and SVM. This model was validated on the PH2 dataset and aimed to balance sensitivity and precision by using ensemble methods to enhance classification performance.

These methodologies explanations serve as a focal point for the discussion. The detailed breakdown presented here assists researchers and practitioners in the identification of prevailing trends and gaps in the literature, and understanding which methodologies are most promising for clinical application and where further innovation may be required.

TABLE II. SUMMARY OF TECHNIQUES AND PERFORMANCE IN SYSTEMATIC REVIEW STUDIES

Ref.	Year	Technique	Data Type	Classes Number	Performance
[25]	2023	Deep learning-based Auto-Encoder	Image dataset (ISIC)	7	Accuracy: 96.83%, Sensitivity: 96.57%, Specificity: 97.83%
[76]	2023	CNN combined with SVM/ANN	HAM10000	7	HAM10000: Accuracy: 98.4%, Sensitivity: 94.46%, Specificity: 99.43%, AUC: 97.53%
			PH2	3	PH2 : Accuracy: 100%, Sensitivity: 100%, Specificity: 100%, AUC: 100%
[24]	2023	CNN integrated with Random Forest	HAM10000	7	Accuracy: 94.96%, Sensitivity: 93.74%, Specificity: 93.16%, F1-score: 93.24%
[75]	2023	XGBoost applied to selected features	PH2	3	Accuracy: 94%, AUC: 99.47%
[64]	2023	CNN enhanced with ELM (Extreme Learning Machine)	HAM10000	7	Accuracy : 95.7%
			ISIC2018	7	Accuracy : 96.3%
			ISIC2019	8	Accuracy : 94.8%
[47]	2023	Vision Transformer (ViT) model	ISIC2018	8	Accuracy: 93.2%, Specificity: 92.2%, AUC: 97.7%
			ISIC2017	2	Accuracy: 89.5%, Specificity: 94.7%, AUC: 96.2%
			PH2	2	Accuracy: 91.4%, Specificity: 88.5%, AUC: 96.3
[62]	2023	Deep models with entropy-controlled optimization for feature selection	PH2	3	Accuracy: 98.89%, Specificity: 98.9%, Sensivity: 98%
			ISIC-MSK	Various	Accuracy: 99.01%, Specificity: 99.4%, Sensivity: 98.5%
			ISIC-UDA	3	Accuracy: 99.09%, Specificity: 99.4%, Sensivity: 98.6%
[43]	2023	Transformer-based model	Image dataset (Derm7pt)	2	Accuracy: 80.03%
[51]	2023	Hybrid CNN and Transformer model	Image dataset (ISIC2018)	7	F1 score: 87.37%, Sensitivity: 88.13%, Specificity: 88.29%
[29]	2023	DSCC_Net model with SMOTE Tomek	ISIC2020, Derm-IS, HAM10000	Various	Accuracy: 94.17%, Sensitivity: 94.28%, Specificity: 93.76%, F1-score: 93.93%
[58]	2023	Region-based CNN (RCNN)	Image dataset (ISIC2020)	2	Accuracy: 98.55%, Sensitivity: 96.92%, Specificity: 98.11%, Precision: 98.34%
[48]	2023	Transformer-based model	Image dataset (Personalized ISIC)	9	Accuracy: 95.6%, Sensitivity: 96.7%, Specificity: 95%
[69]	2023	Optimization-aided deep learning with MobileNetV2, NasNet, and Marine Predator	Image dataset (HAM10000)	7	Accuracy: 94.4%, Sensitivity: 94.4%, Specificity: 94.4%
[70]	2023	Convolutional Neural Network (CNN) using Inception-V3	ISIC dataset (ISIC2019)	7	Accuracy: 96.4%, AUC: 0.98
[28]	2023	Hybrid CNN with Random Forest	HAM10000	7	AUC: 87.6%
[72]	2023	Custom CNN with ESRGAN preprocessing	HAM10000	7	Accuracy: 98.9%
[73]	2023	CNN with Hunger Games Search	PH2	3	Accuracy: 96.43%
			ISIC2016	2	Accuracy: 88.19%
[44]	2023	Multi-modal Vision Transformer (ViT) model	ISIC dataset (ISIC2018)	7	Accuracy: 93.81%, Sensitivity: 90.14%, Specificity: 98.36%, F1-score: 90.13 %

Ref.	Year	Technique	Data Type	Classes Number	Performance
[49]	2023	Transformer-based model	HAM10000	7	Accuracy: 94.1%
[56]	2023	Hybrid CNN with SVM	ISIC2019	8	Accuracy: 96%
			ISIC2020	2	Accuracy: 92%
[71]	2023	SbXception: an enhanced Xception architecture	HAM10000	7	Accuracy: 96.97%, Sensitivity: 95.43%, Specificity: 85.34%
[74]	2023	Two-stage image augmentation with GAN and CNN models	HAM10000	7	Accuracy: 96.9%, Sensitivity: 96.87%, Specificity: 97.07%, F1-score: 96.97%
[52]	2022	Hybrid CNN with SVM	ISIC dataset (ISIC2019)	8	Accuracy: 98.76%, Sensitivity: 98.4%, Specificity: 99.81%
[59]	2022	A deep learning system using transfer learning and meta-heuristic optimization	HAM10000	7	Accuracy: 93.58%
[67]	2022	Convolutional Neural Network (CNN) using EfficientNets	HAM10000	7	Accuracy: 95.8%, Sensitivity: 85.3%, Specificity: 97.9%, AUC: 0.975
[45]	2022	Convolutional Neural Network with Soft-attention	HAM10000	7	Accuracy: 90%, Sensitivity: 81%, FA-score: 81%, AUC: 0.99
[63]	2021	Convolutional Neural Network (CNN) using bilinear approach	HAM10000	7	Accuracy: 93.21%, Sensitivity: 93%, Specificity: 92.92% , AUC: 0.98
[61]	2021	Convolutional Neural Network using SMOTE Oversampling Technique	Image dataset (PH2)	3	Accuracy: 92.18%, Sensitivity: 80.77%, Specificity: 95.1%, F1-score: 80.84%
[55]	2021	Graph nodes in CNN architecture	ISIC datasets	7	Accuracy: 97.4%, Sensitivity: 100%, Specificity: 95.16%, AUC: 99.91%
[68]	2022	Deep Convolutional Neural Network (DCNN)	ISIC2016	2	Accuracy: 81.41%
			ISIC2017	2	Accuracy: 88.23%
			ISIC2020	2	Accuracy: 90.42%
[65]	2022	Convolutional Neural Network (CNN) Leaky ReLU function	Mixed dataset (PH2, ISIC)	2,7	Accuracy: 97.5%, Precision: 98.0%, Sensitivity: 98.0%
[77]	2021	Support Vector Machine (SVM)	PH2	3	Accuracy: 97.5%, Sensitivity: 93.75%, Specificity: 100%, AUC: 97%
			ISIC	3	Accuracy: 97.56%, Sensitivity: 97.94%, Specificity: 97.07%, AUC: 98%
[57]	2022	Hybrid CNN-ELM (Extreme Learning Machine)	HAM1000	7	Accuracy: 93.4%, Precision: 93.10%
			ISIC2018	7	Accuracy: 94.36%, Precision: 94.08%
[46]	2022	Hybrid CNN with DenseNet-169	Mixed dataset (PAD-UFES-20, ISIC 2019)	7	Accuracy: 81.4%
[66]	2022	Convolutional Neural Network (CNN)	ISIC dataset (ISIC2018)	7	B.Accuracy: 88%
[54]	2021	CNN combined with Meta-Heuristic methods	ISIC dataset (ISIC2008)	Not defined	Accuracy: 96%, Sensitivity: 96%, Specificity: 95%
[26]	2022	Lightweight CNN with dynamic-sized kernels and ReLU/leaky ReLU activations	HAM10000	7	Accuracy: 97.8%, Sensitivity: 98%, Specificity: 98.1%, F1-score: 98%
[39]	2021	GAN combined with CNN	ISIC dataset (ISIC2018)	7	Accuracy: 70.1%
[78]	2022	K-Nearest Neighbors (KNN) combined with Random Forest (RF) and SVM	Image dataset (PH2)	3	Accuracy: 94.81%

Ref.	Year	Technique	Data Type	Classes Number	Performance
[53]	2021	CNN with PMEC feature fusion and EKWO optimization	HAM10000	7	Accuracy: 95.8%
			ISIC2018	7	Accuracy: 97.1%
			ISBI2019	8	Accuracy: 85.35%
[79]	2022	Convolutional Neural Network (CNN)	HAM10000	7	Accuracy: 91%, F1-score: 88.1%, ROC-AUC: 95%
[50]	2022	Transformer-based model	HAM10000	7	Accuracy: 96.14%, Sensitivity: 96.5%, Specificity: 96%, F1-score:97%
[80]	2021	CNN combined with Machine Learning (ML) techniques	HAM10000	7	Accuracy: 91.7%
[30]	2022	Explainable AI (XAI) approach using CNN	ISIC dataset (ISIC2019)	8	Accuracy: 94.47%, Sensitivity: 94.01%, Specificity: 93.57%, F1-score: 94.45%
[81]	2021	Neural Network (NN)	ISIC dataset (ISIC2017)	2	Precision: 94%, Sensitivity: 93%, Specificity: 91%
[82]	2021	Feedforward Neural Network combined with Artificial Neural Network	ISIC2018	7	Accuracy: 90%, Sensitivity: 89.37%, Specificity: 97.84%
			PH2	3	Accuracy: 95.8%, Sensitivity: 95.64%, Specificity: 98.21%
[83]	2023	CLCM-net model with layer-wise weight constraints	ISIC2018	7	Accuracy: 94.42%
			ISIC2019	8	Accuracy: 95.8%
			Combined dataset	-	Accuracy: 93%
[84]	2022	Capsule Network	HAM10000	7	Accuracy: 96.49%
[85]	2021	Neural Network (NN)	7-Point	2	Accuracy: 95.42%, Sensitivity: 98.01%, Specificity: 94.4%
			Med-Node	2	Accuracy: 94.71%, Sensitivity: 96.42%, Specificity: 87.5%
			PH2	3	Accuracy: 94.88%, Sensitivity: 100%, Specificity: 85.62%
[60]	2022	Two-stream neural network with feature fusion and ELM	HAM10000	7	Accuracy: 96.5%
			ISBI2018	7	Accuracy: 98%
			ISIC2019	8	Accuracy: 89%
[40]	2022	Ensemble Learning approach	HAM10000	7	Validation Accuracy: 86.71%
[86]	2022	StochasticProgressive Instance Learning	ISIC2017	2	Accuracy: 88%, AUC: 98.3
			ISIC2018	7	Accuracy: 89.4%, AUC: 92.9
[42]	2022	Graph nodes-based approach	7-point	2	AUC: 83.6%
[87]	2021	CNN combined with ANN	ISIC dataset	5	Balanced Accuracy: 92.34%, Sensitivity: 87.10%, Specificity: 94.19% , AUC-ROC: 97.10%
[41]	2021	Ensemble Learning approach	HAM10000	7	Accuracy: 83.5%, Sensitivity: 65.6%, Specificity: 95.4%
[27]	2024	Generative Adversarial Network (GAN) with CNN	HAM10000	7	Accuracy: 98.23%, Sensitivity: 88.85%, Specificity: 98.34%, F1-score:89.48

The varying performance of AI models across different datasets can be attributed to the unique characteristics of each dataset, such as size, number of classes, image diversity, and data quality. Larger datasets like ISIC2018 and ISIC2019, which contain thousands of high-resolution dermoscopic images, generally allow AI models to perform well due to the availability of diverse training data. However, the number of classes also plays a crucial role. For example, studies using ISIC2019, which contains 8 classes, reported lower accuracy (e.g. [64] achieved 94.8% accuracy) compared to ISIC2018 (96.3% accuracy), which has fewer classes and is less complex. The increased difficulty in distinguishing between more skin disease types likely accounts for this discrepancy. Conversely, smaller datasets like PH2, with only 200 images and 3 classes, often result in higher accuracy within the dataset, as seen in [62] with an accuracy of 98.89%. However, such models may struggle with generalizability when applied to larger, more complex datasets. Similarly, HAM10000 provides a diverse dataset with 7 classes, leading to good overall performance in most models (e.g., 95.7% accuracy in [64]), although class imbalance in some categories can affect results. Models tested on clinical image datasets like Derm7pt, which include more background noise and variability in image conditions, often report lower performance compared to dermoscopic datasets, as these models must handle more variability in input data. This analysis suggests that certain algorithms, particularly CNNs and hybrid models, are better suited to high-quality, diverse dermoscopic datasets, while challenges like class imbalance, dataset size, and image quality play a significant role in the comparative results across different datasets.

The systematic review of recent studies on AI models for skin disease classification, as detailed in Table II and categorized in the paragraphs above, reveals several critical trends, patterns, and challenges that underscore the current state of research in this domain. To provide a nuanced understanding of these approaches, Fig. 8 presents the distribution of the AI techniques utilized across the studies. This figure highlights the prevalence of different methodologies, offering insights into the current state of AI-driven skin disease classification.

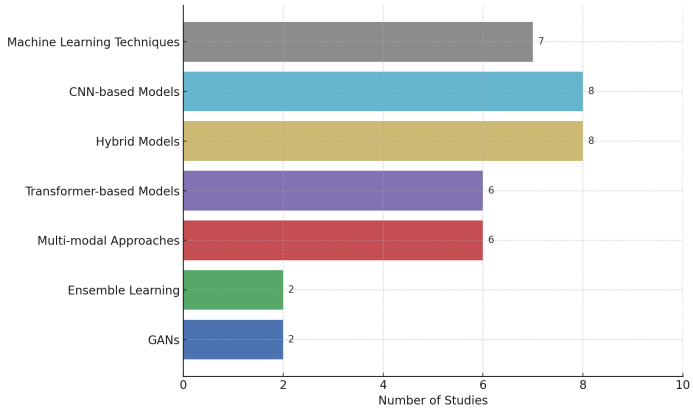

Fig. 8. Trends in AI techniques for skin disease classification (2021-2023).

A significant trend observed across the reviewed literature is the dominance of Convolutional Neural Networks (CNNs) and their variations, including hybrid models combining CNNs with other machine learning techniques such as Support Vector Machines (SVMs), Extreme Learning Machines (ELMs), and Random Forests. This reflects the strong performance of CNNs in image recognition tasks, which are central to dermatological diagnosis. To further analyze the methodologies within CNN-based models and their variations, Fig. 9 presents the usage frequency of various pre-trained CNN models across the studies. This figure provides a clear overview of which pre-trained models are most commonly employed in skin disease classification.

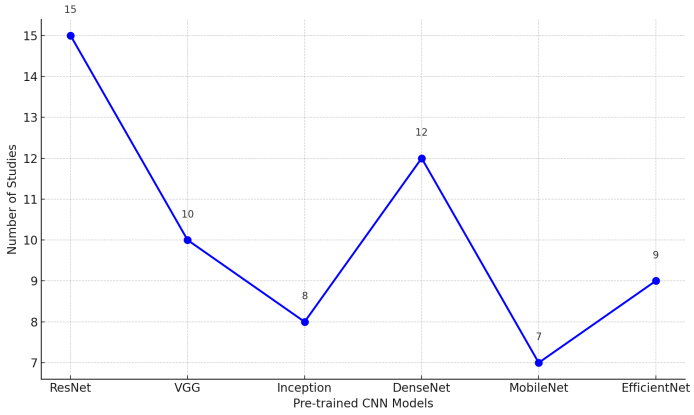

Fig. 9. Usage frequency of Pre-trained CNN models in skin disease classification studies.

More recently, the emergence of Transformer-based models and Vision Transformers (ViTs) suggests a growing interest in leveraging these advanced architectures, which have demonstrated exceptional performance in natural language processing and are now being adapted for medical imaging.

The reviewed studies span from 2021 to 2023, indicating a rapid evolution of techniques over a relatively short period. Early studies primarily focused on straightforward CNN architectures, while later studies have increasingly explored more complex hybrid models and the integration of transformers. This evolution suggests a shift towards more sophisticated, multi-faceted approaches aimed at improving model accuracy and generalization across diverse datasets. Fig. 10 illustrates the increasing trend in the use of Hybrid Models and Transformers over time.

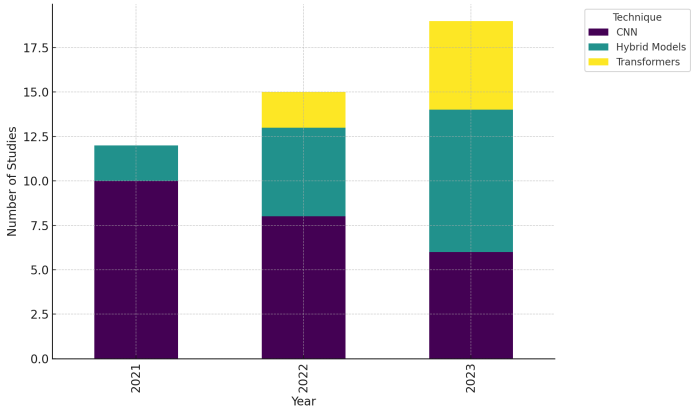

Fig. 10. Trends in AI techniques for skin disease classification (2021-2023).

Additionally, there is a noticeable increase in the application of Auto-Encoders, Generative Adversarial Networks (GANs), and ensemble methods, reflecting the ongoing effort to enhance model robustness and address challenges such as data scarcity and imbalance. The development of GANs combined with CNNs, as seen in recent studies, highlights a trend towards generating synthetic data to improve training outcomes, which is particularly valuable in medical fields where annotated data can be limited.

The predominant use of datasets such as HAM10000, ISIC (International Skin Imaging Collaboration), and PH2 across the studies indicates a reliance on these well-established, publicly available image datasets. The consistent use of these datasets underscores their role as benchmarks in the field. However, it also highlights a potential limitation in terms of dataset diversity, as most studies focus on the same data sources, which may not fully represent the variety of skin conditions encountered in clinical practice.

In terms of class distribution, most studies focus on classifying a limited number of conditions, with a particular emphasis on melanoma and non-melanoma skin cancers. This trend reflects the clinical importance of accurately diagnosing these conditions but also points to a gap in research focused on rarer or less visually distinct skin diseases, which are underrepresented in current models.

The reported performance metrics, including accuracy, sensitivity, specificity, and precision, show high variability across studies, with accuracy ranging from 88.19% to 98.7%. This variability can be attributed to differences in model complexity, data preprocessing methods, and the inherent difficulty of the classification tasks. Notably, hybrid models and those incorporating transformers generally report higher performance, suggesting that these more complex models may offer advantages in handling the nuances of skin disease classification. Fig. 11 provides a comparative analysis of the performance distribution across different model types.

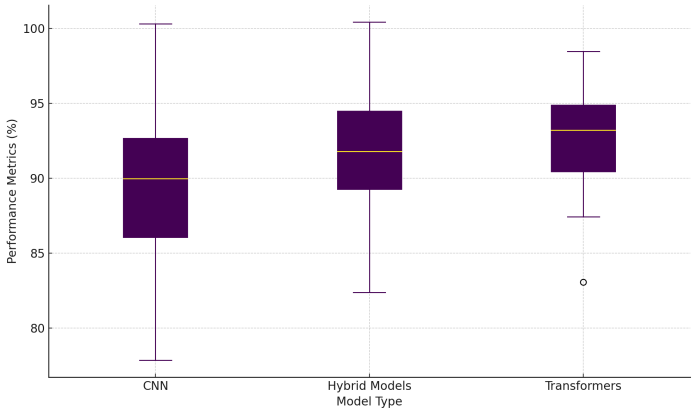

Fig. 11. Performance distribution across different models.

However, it is important to note that high performance on well-curated datasets does not necessarily translate to clinical effectiveness. The consistent reporting of high specificity across models is encouraging, as it suggests a strong ability to correctly identify negative cases, which is critical in avoiding unnecessary interventions. Nonetheless, the lower sensitivity scores reported in some studies, particularly those involving simpler CNN architectures, indicate a potential risk of missed diagnoses, which could have serious clinical implications.

Despite the progress made, several challenges remain. The reliance on a few datasets raises concerns about the generalizability of these models to broader, more diverse patient populations. Additionally, while the integration of multimodal data (e.g., combining images with patient history) is increasingly being recognized as essential for improving diagnostic accuracy, few studies have fully implemented this approach.

Moreover, the computational complexity of advanced models such as transformers and GANs may limit their deployment in resource-constrained settings, highlighting the need for research focused on optimizing these models for real-world clinical environments. Fig. 12 compares the performance metrics of hybrid models versus pure deep learning models, emphasizing the potential advantages of hybrid approaches.

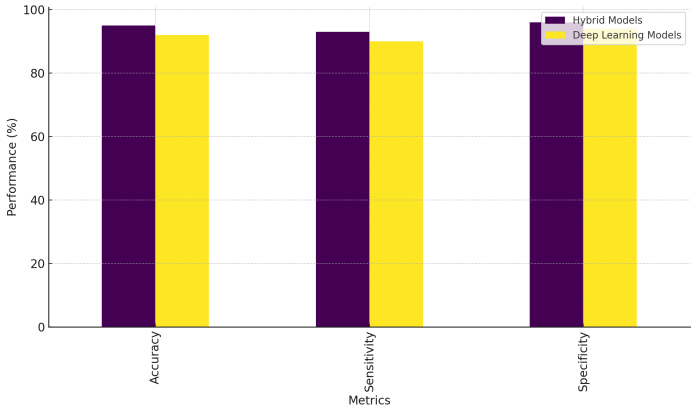

Fig. 12. Performance comparison: Hybrid models vs pure deep learning.

The general metrics commonly used to evaluate the performance of AI models in skin disease classification include Accuracy, Sensitivity, Specificity, Precision, F1-Score, and Area Under the Curve (AUC). These metrics are crucial in assessing the effectiveness of the models in correctly identifying and classifying skin conditions.

1. Accuracy: The proportion of correctly classified instances (both true positives and true negatives) among the total number of instances.

$$\text{Accuracy} = \frac{TP + TN}{TP + TN + FP + FN}$$

2. Sensitivity (Recall or True Positive Rate): The proportion of actual positives that are correctly identified by the model.

$$\text{Sensitivity} = \frac{TP}{TP + FN}$$

3. Specificity (True Negative Rate): The proportion of actual negatives that are correctly identified by the model.

$$\text{Specificity} = \frac{TN}{TN + FP}$$

4. Precision (Positive Predictive Value): The proportion of positive predictions that are actually correct.

$$\text{Precision} = \frac{TP}{TP + FP}$$

5. F1-Score: The harmonic mean of Precision and Sensitivity, providing a balance between the two.

$$F1\text{-Score} = 2 \times \frac{\text{Precision} \times \text{Sensitivity}}{\text{Precision} + \text{Sensitivity}}$$

6. Area Under the Curve (AUC): The area under the Receiver Operating Characteristic (ROC) curve, representing the model's ability to discriminate between classes.

$$\text{AUC} = \int_0^1 \text{TPR}(\text{FPR}^{-1}(x))\, dx$$

VII. Conclusion

This systematic review provides a focused analysis of AI methodologies in skin disease classification, highlighting the growing adoption of advanced techniques like GANs, Transformer models, and multi-modal approaches. While CNNs remain a dominant tool, their performance is often enhanced by hybrid and ensemble learning methods, demonstrating a trend towards more complex model architectures.

However, this review also identifies several key challenges that need to be addressed. The lack of standardization across studies and the limited application of multi-modal approaches restrict the generalizability of current models. Additionally, the datasets used in most studies lack diversity in terms of patient demographics, including under-representation of different skin tones and rare skin diseases, which limits the models' applicability across broader populations. Moreover, the explainability of AI models remains a critical barrier to their integration into clinical practice. Ensuring that AI-driven diagnostic tools provide transparent and interpretable outputs for clinicians is crucial for their adoption in real-world settings.

Future research should prioritize the development of standardized protocols and benchmarking methods to enable meaningful comparisons between different AI models. The creation of more diverse and representative datasets is essential to improve the generalization of AI models and their applicability in real-world clinical environments. Furthermore, addressing the ethical implications of AI use in dermatology is vital, particularly in relation to bias mitigation, ensuring that AI technologies perform equitably across all patient groups. There is also a growing need to investigate advanced techniques such as federated learning, which could enhance collaboration between institutions while preserving patient privacy, thereby improving model generalizability without compromising data security.

Finally, real-world validation through clinical trials and large-scale implementation studies is necessary to evaluate the practical utility and reliability of AI-driven skin disease classification tools. Collaboration between AI researchers and clinicians will be crucial in translating these models from research into clinical practice.

***Abstract*—Forest fires are a major environmental hazard that can have significant impacts on human lives. Early detection and swift action are crucial for controlling such situations and minimizing damage. However, the automatic tools based on local sensors in meteorological stations are often insufficient for detecting fires immediately. Machine learning offers a promising solution to forecast forest fires and reduce their rapid spread. In recent state-of-the-art solutions, only one or two techniques have been utilized for prediction. In this research, we investigate several methods for forest fire area prediction, including Long Short Term Memory (LSTM), Auto Regressive Integrated Moving Average (ARIMA), and Support Vector Regression (SVR). Our aim is to identify the most effective and optimal method for predicting forest fires. After comparing our results with other artificial intelligence and machine learning techniques applied to the same dataset, we found that the LSTM approach outperforms the ARIMA and SVR predictors by more than 92%. Our findings also indicate that the LSTM algorithm has a lower estimation error when compared to other predictors, thus providing more accurate forecasts.**

***Keywords*—Machine Learning; Forest Fire; LSTM; ARIMA; SVR**

I. Introduction

Forests play a crucial role in the earth's ecosystem and environmental sustainability. Wildland fires, commonly known as forest fires, are among the deadliest disasters that pose a threat to forest preservation, causing ecological devastation and casualties [1], [2]. In recent decades, human activities have caused the number of forest and land fires to significantly increase [3]. The 2019 wildfire in southeast Australia is an example of the devastating impact of forest fires, destroying over 11.2 million hectares of forest and leading to the extinction of numerous creatures [4], [5]. Detecting and controlling forest fires is becoming increasingly challenging. Rapid detection is essential to effective control. Detection techniques typically include smoke detection, satellite monitoring, and local perception (such as data analysis). While satellite monitoring is costly and subject to delays, smoke detection requires expensive equipment and maintenance. Data analysis, in contrast, is a less expensive and more accessible method for detecting and analysing forest fires [6], [7].

Human carelessness and natural factors like lightning are the two primary causes of forest fires. Recent studies have indicated that forest fires and climate change are related [8]. Inconsistencies in weather patterns, such as irregular rainfall, wind patterns, temperature swings, and precipitation, have contributed to an increase in forest fires in recent years [9]. The amount of money spent by the government to fight forest fires has also increased. Ecologists have employed several methods to understand how the forest landscape is changing, and statistical models have proven to be useful in examining how the patterns of forest fires are evolving for a particular location. However, current technologies cannot accurately predict the site of forest fires based on past data and environmental circumstances. Detecting forest fires early can help contain and reduce the scope of a disaster, and such solutions can aid firefighters in their efforts.

Artificial intelligence has emerged as a promising tool for predicting wildland fires with high accuracy [10], [11]. Neural networks (NN) are commonly used to forecast the occurrence of wildland fires and can reduce false alarms with the aid of infrared data [12]. Support vector machines (SVM) have also proven to be effective in increasing the accuracy and effectiveness of wildland fire predictions [13], [14]. Random Forest (RF) [15], [16] is considered to be a technique that performs quite well in these scenarios and its hybrid with SVM that is Random vector forest regression (RVFR) has also been studied to bring better results [17]. Additionally, data mining techniques such as logistic regression [18], [19], decision tree (DT) [15], and fuzzy logic [16] have been used to develop wildland fire prediction models. These techniques can help authorities detect forest fires early, allowing for more efficient and effective containment efforts.

Forest fires can cause significant losses to nature, the environment, and property. To prevent these losses, it is essential to have accurate and timely forest fire prediction systems in place. However, relying solely on automatic tools based on local sensors in meteorological stations may not be enough to instantly detect fires. Therefore, studying and selecting a suitable model for forest fire prediction can play a vital role in preventing fires from occurring or spreading. By accurately predicting forest fires, authorities can take proactive measures to ensure the safety of people, property, and the environment.

The main objective of this research is to identify the factors that contribute to the rapid spread of forest fires, including wind speed, humidity, temperature, precipitation, FFMC (Fine Fuel Moisture Code), DMC (Duff Moisture Code), DC

*Corresponding authors.

(Drought Code), and ISI (Initial Spread Index). The aim is to develop a predictive model that can assist authorities in assessing the long-term impacts of climate change. Furthermore, the study compares the outcomes with other machine learning and artificial intelligence techniques that were previously applied to the same dataset and reported in the literature. However, it is worth noting that only a limited number of techniques were utilized in the state-of-the-art solutions. Therefore, this research aims to fill this gap by applying various machine learning algorithms and selecting the best prediction model. By doing so, it can contribute to the development of a more accurate and effective forest fire prediction model that can help prevent losses due to forest fires.

This study is focused on addressing the following research questions:

- RQ1: What are the current state-of-the-art techniques and models used for predicting wild fires, as reported in the literature?
- RQ2: Which specific features or variables are most influential in accurately predicting the spread of forest fires?
- RQ3: Based on a thorough review of previous literature, what are the most suitable models that can be trained for our specific dataset?
- RQ4: What methods can be employed to improve the accuracy of the prediction model, such as reducing the root mean square error or mean absolute error?

The rest of the paper is structured in the following way: Section II provides a comprehensive literature review. Sections III and IV elaborate on the methodology and results, respectively. Finally, the paper concludes with a summary of findings and future research directions in the last section.

II. Literature Review

Numerous studies and research have been conducted to predict forest fires and minimize their damage.

Cortez et al. [14] proposed data mining algorithms, including support vector machine (SVM) and random forest, which utilized four different features (spatial, temporal, weather attributes, and FWI* component) to predict the burned area of a forest. However, this proposed solution based on SVM can only predict small fires and has a low accuracy rate for large fires.

Elshewy et al. [20] proposed three machine learning algorithms, which were applied to a dataset of 517 entries and 13 features per entry. The algorithms were tested in two scenarios: one with the entire dataset used for training and testing, and the other with 70% of the attributes used for training and 30% for testing. It was concluded that linear regression had the highest accuracy score of 0.99, surpassing the other two algorithms.

In their study, Nebot et al. [21] utilized fuzzy logic models to predict the burned area of forest fires. The authors employed two powerful fuzzy systems, the Adaptive Neuro-Fuzzy Inference System (ANFIS) and Fuzzy Inductive Reasoning (FIR), to model burned sections of fires in Portugal. To validate their models, a 10-fold cross-validation method was used, involving model identification and validation repeated 10 times. The authors created 100 FIR and 100 ANFIS models to test the generalization performance of these hybrid fuzzy models. The FIR models exhibited the highest predictive power and the lowest MAE and RMSE errors when compared to all other models.

In their study, Al Janabi et al. [22] explored the use of soft computing algorithms for predicting forest fires. They collected over 500 entries for Montesinho Natural Park (MNP) in Portugal, which included 12 spatial and temporal parameters, a fire weather indicator, and burned area. To extract significant insights from the data, the researchers utilized Principle Component Analysis and Particle Swarm Optimization techniques. They employed five strategies simultaneously to compare and select the optimal solution. The SVM strategy with minimal estimating error was found to be the most successful approach.

Liang et al. [23] investigated the use of meteorological variables, including temperature, humidity, and precipitation, in combination with various predictive models for a fire-prone region in Alberta, Canada. The data was obtained from the National Fire Database of Canada. To estimate the size of forest fires, the researchers employed Back Propagation Neural Networks (BPNN), Recurrent Neural Networks (RNN), and Long Short Term Memory Models. The LSTM model exhibited the highest performance with an accuracy rate of 90.9%.

Zhang et al. [24] developed a Convolutional Neural Network (CNN) with a complex architecture for predicting forest fire susceptibility in Yunnan Province, China. The researchers manually assembled pictures to study the effects of various parameters. To optimize the model, they employed multicollinearity analysis and the Information Gain Ratio (IGR) approach. The model architecture was inspired by Google's AlexNet [25] and categorized photos into different classes. The CNN model exhibited a strong predictive potential with an AUC of 0.86.

Long Short-Term Memory (LSTM) algorithm has been extensively used to address time series prediction problems due to its high accuracy and speed [26]. The LSTM model is particularly advantageous in predicting trends, making it well-suited for predicting wildland fire burned areas. However, the complexity of factors and computations involved has limited the potential of the LSTM model in this domain. Therefore, further exploration and development of an enhanced LSTM model is necessary to improve the accuracy and applicability of predicting burned regions in wildland fires.

Li and Huang [27] proposed a modified model based on the Long Short-Term Memory (LSTM) network with multiple input layers and an attention mechanism module to predict the burned regions in wildland fires. The study used the Montesinho dataset and drew some interesting conclusions. First, to reduce computational complexity and interference, correlation analysis was used to identify potential related elements, and unnecessary factors were removed. This helped determine the various causes of wildfire speed. Second, a Multi-AM-LSTM

*Fire Weather Index (FWI) system was introduced in 1970s. It only required readings of four meteorological observations (i.e. temperature, relative humidity, rain and wind).

model was developed to learn effective features and predict burned areas. The proposed model achieved an impressive accuracy rate of over 96%. Comparison with other models showed that LSTM with an attention mechanism is particularly effective in this context.

George E. [11] proposed a novel mechanism for predicting forest fire risk using only meteorological data, independent of weather forecasting systems. The study utilized support vector machines to achieve a high accuracy rate of up to 96% for August in a two-class prediction of fire risk. The findings demonstrate the potential of this approach to accurately predict forest fire risk, which can aid in preventing and mitigating the damage caused by wildfires.

In their study, Richa.S et al [28] employed a variety of machine learning techniques to test eight classification models using the Cortez Morais dataset, which includes 517 instances and 13 attributes. The algorithms were evaluated using several metrics, including precision, recall, f-score, accuracy, and Area Under the Curve (AUC). The Boosted Decision Tree model achieved an accuracy of 72%, which outperformed the neural network model by 6%, the 2 Class Bayes machine by 14%, and the remaining five algorithms by 3%. These results suggest that the Boosted Decision Tree model may be a promising approach for predicting forest fires based on the Cortez Morais dataset.

Ahmed Al Janabi's study [20] utilized particle swarm optimization (PSO) to segment fire zones and principal component analysis (PCA) to identify key patterns or clusters. The study then employed five soft computing (SC) techniques based on neural networks in parallel to determine the best method for predicting forest fires with accuracy and optimality. The performance of these predictors was evaluated using five quality metrics, including information gain, relative absolute error, mean absolute error, and root mean squared error (RMSE). The results indicated that the SVM technique outperformed RBF, MPNN, PNN, and CCN predictors in terms of both effectiveness and efficiency. These findings suggest that the SVM technique may be a promising approach for predicting forest fires based on PSO and PCA segmentation.

In recent years, several projects have investigated the application of various fire detection methodologies and technologies. For instance, a study by ZQ et al. [6] presented an overview of the different forest fire detection methods that have been introduced, including wireless sensor networks, optical sensors, digital cameras, and satellite imaging. Similarly, Gibson et al. [5] explored the use of statistical methods in predicting forest fires while considering the various factors and challenges associated with it. Hong et al. [29] examined the use of different sensors, such as temperature, smoke, flames, and flammable materials, in fire detection systems.

David et al. [25] proposed an efficient machine learning method for predicting total burned areas for specific wildfire episodes with high accuracy. The transparent open box (TOB) algorithm does not rely on regression, correlation, or statistical distribution assumptions, nor does it use any hidden layers or complex calculations. This method can provide valuable insights to aid in mitigating specific burn events as they occur, resulting in various short- and long-term benefits. Furthermore, the proposed strategy can be adapted to anticipate and analyze data from other agricultural systems that rely on complex relationships between meteorological and environmental factors, in addition to regression and correlation-based approaches.

III. Methodology

This section provides a comprehensive overview of the dataset utilized in the study, along with the preprocessing steps taken to predict fire and details of the models used. First, we will discuss the dataset in detail, followed by a description of the preprocessing techniques employed to ensure the accuracy and reliability of the predictions. Finally, we will delve into the specific models utilized in this research, highlighting their strengths and limitations in predicting fire occurrences.

The workflow for our study is presented in Fig. 1. The diagram outlines the various steps taken to analyze the dataset, preprocess the data, and develop and evaluate the models used in the study. Each step in the workflow is described in detail in the subsequent sections.

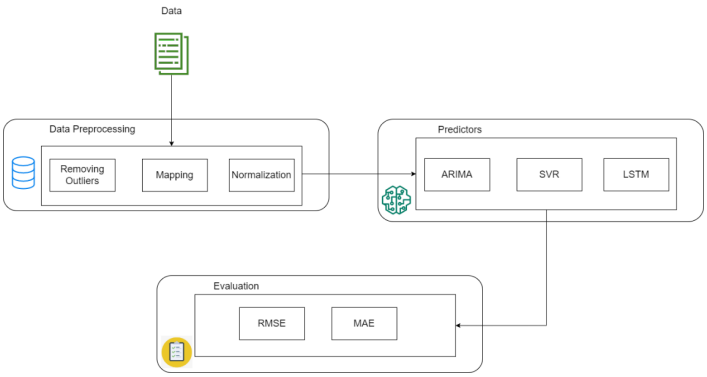

Fig. 1. Workflow process.

A. Dataset

The dataset used in this research was sourced from the UCI machine learning repository, consisting of 517 unique entries recorded at various periods between January 2003 and December 2020. The dataset comprises 12 attributes categorized into three groups: weather conditions, fire weather index (FWI), and geographical and temporal components, with the overall burned area serving as the output feature. The data was collected from two sources, as described in [7]. The first source recorded details such as date, time, location within a 9-by-9 grid, vegetation type, FWI elements, and burned area each time a forest fire occurred. The FWI, a Canadian system for categorizing fire hazard that was used to indicate the intensity of the fire. The second source consisted of weather measurements taken every 30 minutes by a meteorological station. The two databases were combined to create a single dataset. Table I provides a detailed explanation of each attribute.

B. Data Exploration

The dataset contains 517 rows of data. To gain insights into the distribution of the numerical variables, we created boxplots for each variable. Upon analysis, we identified the presence of outliers in some of the variables. The boxplots of these variables are presented in Fig. 2.

TABLE I. DESCRIPTION OF DATASET

Attributes	Description
Spatial Attribute	
X	Coordinates on x-axsis (1-9)
Y	Coordinates on y-axsis (1-9)
Temporal Attributes	
Month	January to December months start
Day	Day starts with Monday and ends on Sunday
Intensity of Weather Attributes	
FFMC	FFMS code in digits
DMC	DMC code in digits
DC	DC code in digits
ISI	ISI code in digits
Weather Attributes	
Temperature	Temperature in degree Celsius
RH	RH in percentage
Rain	Rain in mm
Wind	Relative humidity in percentage
Target	
Area	Total area burnt in hectare

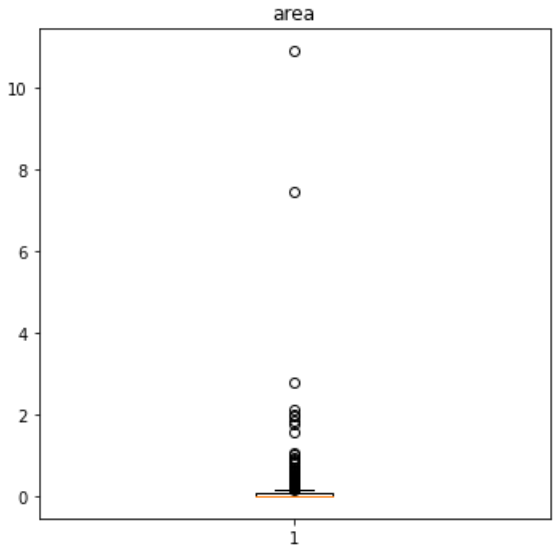

Fig. 2. BoxPlot of area.

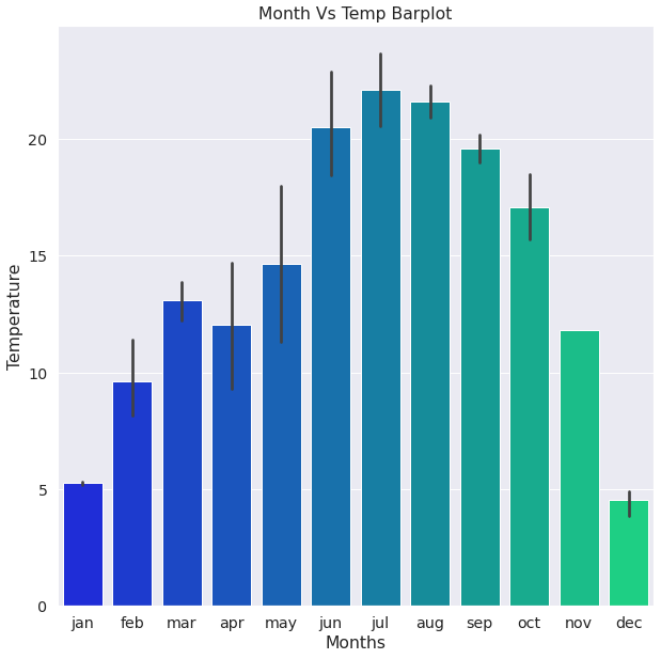

Fig. 3. Month vs Temperature.

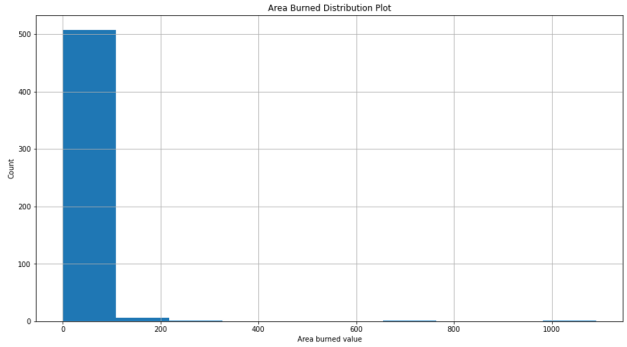

Fig. 4. Area distribution.

Our target variable is the "Area" variable which also has a significant number of outliers. However, we have decided to remove only the top 10% of outliers from the right side of the data. After removing these outliers, we were left with a total of 515 rows, down from the initial 517 rows.

The graph in Fig. 3 highlights that the months of June, July, August and September experience the highest temperatures. This phenomenon is primarily due to the summer season, resulting in high temperatures and increased humidity levels. As September concludes, the temperature starts to decline gradually.

1) Target transformation: The variable "area" has a highly skewed distribution that is positively skewed towards 0, as shown in Fig. 4. Modeling such a skewed distribution during training impacts the model performance. Ideally, the variable should have a normal distribution. To transform "area" into a normal distribution range, we performed a log transformation as shown in Fig. 5.

2) Mapping: To apply different models to our dataset, we needed to convert our categorical variables into numeric variables. Specifically, we mapped the "month" attribute to its corresponding month number and the "day" attribute to its corresponding day number, with Sunday being the first day. Additionally, we utilized one-hot encoding to apply LSTM to our dataset.

3) Normalization: The feature values in the dataset exhibited a wide range, potentially leading to increased computing complexity and inaccurate predictions. Thus, normalization is necessary to assign equal weight to each variable. This involves utilizing the Min-Max Scaling technique to quantify the variables, linearly transforming the original variable ranges to new ranges.

$$Z = \frac{x_i - min(x)_i}{max(x)_i - min(x)_i} \quad (1)$$

In Eq. 1, Z is the output value, x_i is the value of the

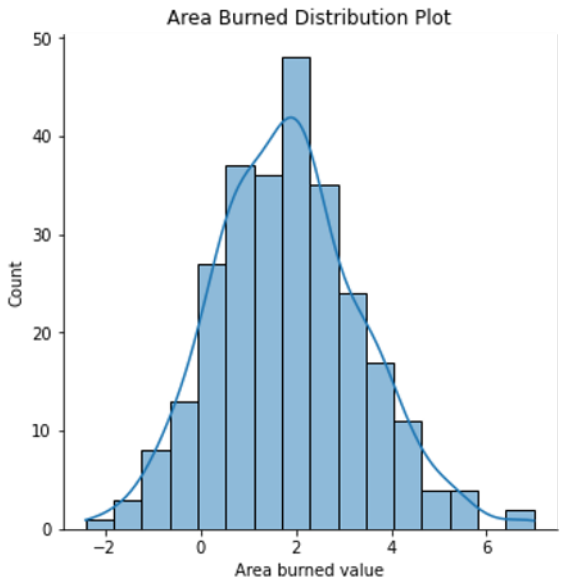

Fig. 5. Transformed area distribution.

variables, max and min denote the minimum and maximum values of each variable, respectively.

C. Feature Selection

Feature selection is a technique employed to improve accuracy in the machine learning process. Additionally, it enhances the predictive ability of algorithms by choosing the most essential variables while excluding redundant and irrelevant ones. In this research we applied two techniques: the Mutual Information (MI) and correlation analysis.

D. Mutual Information

MI is a measure of the amount of information that one random variable can provide about another random variable. It is often used for dimension reduction [30].

A formal way to express the mutual information between two random variables X and Y is as follows:

$$I(X,Y) = H(X) - H(X \mid Y) \tag{2}$$

Where $I(X,Y)$ is the mutual information for X and Y, $H(X)$ is the entropy for X and $H(X \mid Y)$ is the conditional entropy for X given Y.

Fig. 6 displays the results of applying the MI to our features and target. It indicates that the month has a great mutual information with the target feature "area". Besides, the temp attribute is showing some mutual information with the target. Thus, the events of fire have a relation with temperature.

E. Correlation Analysis

Correlation analysis is used to check which are the most important variables in the data set. The correlation between these characteristics is applied using the following equation:

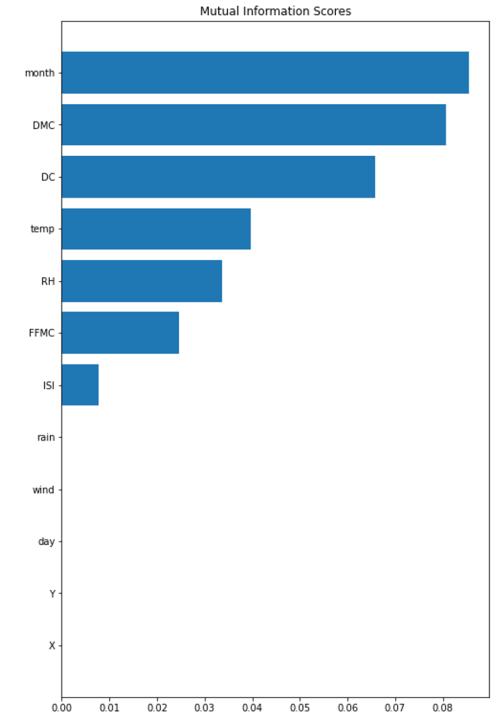

Fig. 6. The Mutual inclusion between the features and the target.

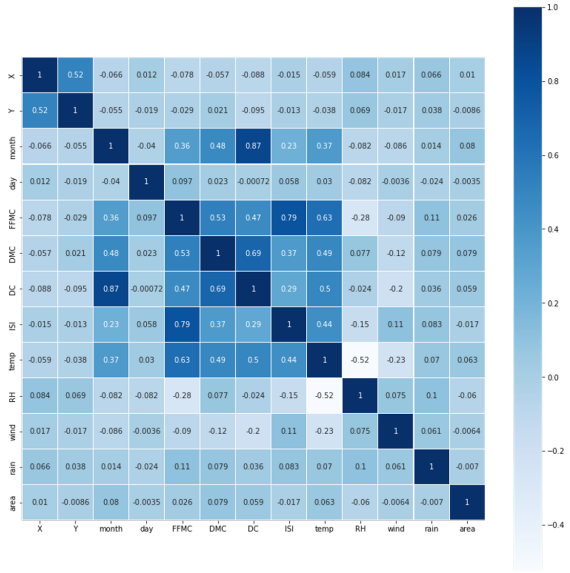

Fig. 7. Correlation analysis.

$$r = \frac{n\sum xy - \sum x \sum y}{\sqrt{[n\sum x^2 (\sum x)^2][n\sum y^2 (\sum y)^2]}} \tag{3}$$

where n represents total observation and $-1 < r < 1$, the positive sign $(+)$ means positive correlation and negative sign $(-)$ means negative relationship between variables.

Fig. 7 indicates that 5 features have some correlation with the target which are: Month, DC, DMC, RH, Temp, ISI.

F. Predictors

In the following discussion, we will examine the predictors utilized for forecasting the area.

1) Long short term memory: Particular types of recurrent neural networks can be trained to identify long-term dependencies in data. As such, we utilized an LSTM network to address prediction problems using a dataset sourced from UCI Machine Learning respiratory. The LSTM network incorporates a cell state through which information is passed, and the addition or removal of information is regulated by input gates, forget gates, and output gates. To gain insight into the functioning of the LSTM network and how the gates acquire pertinent information, refer to Fig. 8[†].

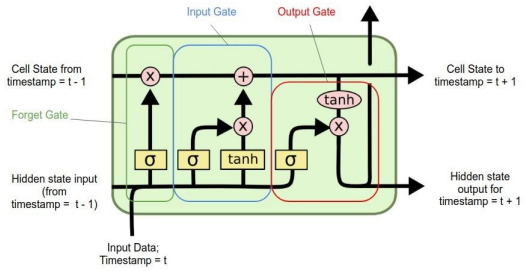

Fig. 8. LSTM network.

a) Forget gate: The forget gate plays a crucial role in determining which information should be kept or removed from the cell state. This gate processes both current input and relevant information using a sigmoid function, resulting in values that fall between 0 and 1. A value of 1 indicates that the information is to be retained, while a value of 0 indicates that it should be forgotten.

b) Input gate: The input gate is responsible for deciding which data to preserve in the cell state. This gate processes both input and hidden state information through a hyperbolic tangent (tanh) function. The resulting output is multiplied by a sigmoid function to determine whether to keep or discard the information. If the sigmoid output approaches 1, the information is retained, whereas a sigmoid output approaching 0 results in the information being discarded.

c) Output gate: The output gate plays a critical role in determining the final output of the cell state. This gate filters the cell state output to produce a refined version of the information that should be included in the final output.

2) ARIMA: ARIMA, short for AutoRegressive Integrated Moving Average, is a widely-used model in time series data analysis. It utilizes historical values of a time series to forecast future values. However, external factors can also have an impact on the time series and serve as accurate predictors of future values. This is where the SARIMAX model comes into play, by introducing an exogenous variable X. In statistics, predictors or input variables are referred to as exogenous, while the target variable is referred to as endogenous. The SARIMAX model enhances the $SARIMA(p,d,q)(P,D,Q)_m$ model by incorporating the effects of exogenous variables, producing more accurate forecasts [31]. The parameters p,d,q are trend elements which refer to autoregressive order, difference order and moving average order respectively. Similarly, the parameters P,D,Q are seasonal elements refering to autoregressive order, difference order and moving average order. The parameter m indicates seasonal length.

In Eq. 4, we may easily add any number of exogenous variables X_t to the $SARIMA(p,d,q)(P,D,Q)_m$ model to reflect the present value Y_t.

$$Y_t = SARIMA(p,d,q)(P,D,Q)_m + \sum_{i=1}^{n} \beta_i x_t^i \qquad (4)$$

Eq. 4 indicates that the SARIMA model is a linear combination of the historical values of a time series and the corresponding error terms. The SARIMAX model, an extension of SARIMA, incorporates exogenous variables, transforming it into a more comprehensive linear model. This extension allows to model the relationship between the time series and external factors in a more accurate and effective manner, thereby yielding improved forecasting results.

3) Support Vector Regression SVR: Support Vector Regression (SVR) is an extension of the Support Vector Machine (SVM) algorithm, designed to handle regression problems in both linear and nonlinear domains. While SVM is primarily used for classification tasks with categorical variables, SVR is tailored for continuous variable prediction. This fundamental distinction enables SVR to model complex relationships between variables and generate accurate predictions from continuous datasets.

Despite a few minor differences, SVR operates on the same fundamental principles as SVM. Both algorithms aim to locate a curve that fits the given data points. However, as a regression procedure, SVR utilizes this curve to match the vector to the point of the curve, rather than as a decision boundary. This matching process is facilitated by the use of support vectors, which helps to identify the closest match between the data points and the function used to represent them.

IV. Results

This section presents the results of three models that were developed to predict forest fire areas based on historical data. By analyzing the performance of each model, we can gain insights into the effectiveness of their respective methodologies and techniques. Through these evaluations, we aim to identify the most accurate and reliable model that can be used to predict forest fire areas with the highest level of confidence.

A. LSTM

LSTM has been widely used to address time series prediction problems due to its high accuracy and speed. Here, we explain the development of the prediction model using LSTM.

[†]Figure from: https://colah.github.io/posts/2015-08-Understanding-LSTMs/

1) Data Splitting: After preprocessing our data for use in LSTM, we were left with 514 rows and 30 features out of a total of 517 rows. To predict the fire area for the next day, we implemented a window length of 10. During the training phase, we utilized 80% of data, incorporating all features, and reserved 20% rows for testing. This model will be used to forecast the fire area for the next 38 days.

2) Model Training: Several models have been trained with different parameters as shown in Table II.

TABLE II. TRAINED LSTM MODELS

Model No.	Layers	1^{st} Layer Neurons	2^{nd} Layer Neurons	3^{rd}Layer Neurons
1	1	100		
2	1	50		
3	2	50	55	
4	3	100	100	55

All models utilize the ReLU activation function. Additionally, we have included a dense layer with eight neurons, as illustrated in Fig. 9. To optimize our model, we employed the Adam optimizer with default settings for the learning rate (lr=0.001) and weight decay (0.9). During training, we used a batch size of 25 and conducted 50 epochs to ensure that our models are able to learn from the data effectively.

Fig. 9 illustrates the second model summary, which consists of a total of 78,368 parameters, all of which have been trained.

```
Model: "Forest_fire_Prediction_Model"
_________________________________________________________________
 Layer (type)                Output Shape              Param #
=================================================================
 LSTM_Hidden_Layer_1 (LSTM)  (None, 10, 100)           43600

 LSTM_Hidden_Layer_2 (LSTM)  (None, 55)                34320

 output_layer (Dense)        (None, 8)                 448

=================================================================
Total params: 78,368
Trainable params: 78,368
Non-trainable params: 0
_________________________________________________________________
```

Fig. 9. Model 2 summary.

To fine-tune the hyperparameters, we utilized the validation set. The hyperparameters for the proposed bidirectional LSTM models are presented in Table III.

TABLE III. HYPERPARAMETER OF LSTM

Hyperparameter	Values
Activation Function	ReLU
Number of LSTM layer	1,2,3,4
Dropout	Yes
Regularization	Yes
Optimizer	Adam
Learning rate	0.001
Batch size	25
Epochs	50

Loss indicates the performance of the model whether it is able to predict accurately or not. If loss is zero then it is accurate. Fig. 10 displays the loss with respect to the number of epochs for all the trained models. As shown in the figure, the loss decreases as the number of epochs increases. Besides, Models 3 and 4 demonstrate a better convergence between the training and validation losses.

Fig. 11 explains the ground truth or the actual area versus the predicted area for the models. We have predicted occurrence of forest fire area for thirty eight (38) days.

B. ARIMA

ARIMA is an extensively used model for analysis of time series data. It utilizes historical values of a time series to forecast future values. In this section, we explain how we prepared the data for creating a model using ARIMA and explain our findings.

1) Data Splitting: After preprocessing, we were left with 515 out of 517 rows and 13 features for ARIMA analysis. We trained the model on 477 days of data using all features, and reserved 38 rows for testing. The ARIMA model forecasted the area of fire for the next 38 days, as illustrated in Fig. 12.

2) SARIMAX summary: The SARIMAX model is utilized when an exogenous variable 'X' is included. In statistics, the term *exogenous* is used to describe predictors or input variables, while *endogenous* refers to the target variable- what we aim to predict. For ARIMA training, we determine the values of (P, D, Q). To determine these values for our dataset, we used the auto arima built-in function from the pdarima library, resulting in P=0, Q=1, and D=4. We also attempted to predict forest fire occurrences for the next 38 days, and Fig. 13 displays the SARIMAX model's results.

C. SVR

In SVR, we began with a total of 517 rows. After preprocessing, we were left with 515 rows and 13 features. For training, we used 477 days of data, including all features. The remaining 38 rows were used for testing. The model is designed to forecast the area of fire for the next 38 days. We utilized a linear kernel with C=1 and gamma of 2e-5 for the SVR. The SVR model forecasted the area of fire for the next 38 days, as illustrated in Fig. 14.

D. Overall Comparison of Models

To assess the model's effectiveness, we employ the RMSE (root mean square error) metric defined in Eq. 5. These error measurements are widely used in the field of data analysis and are valuable tools for determining the accuracy of a model's predictions. By analyzing the RMSE, we can gain insight into the model's strengths and weaknesses and identify areas for improvement.

$$RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}|y_i - \hat{y}_i|^2} \tag{5}$$

Based on the data presented in Table IV, it is evident that the ARIMA and SVR models have the highest RMSE error. Therefore, we can conclude with confidence that LSTM can be utilized for predicting fires in this dataset or other similar datasets. Indeed, it outperforms the two other method by more than 92%.

(b) 2^{nd} Model

(c) 3^{rd} Model

(d) 4^{th} Model

Fig. 10. Training loss for 4 LSTM models.

TABLE IV. COMPARING THE PERFORMANCE OF THE TESTED MODELS

Model	RMSE
ARIMA	16.59
LSTM 1	1.219
LSTM 2	1.233
LSTM 3	**1.15**
LSTM 4	1.16
SVR	18.82

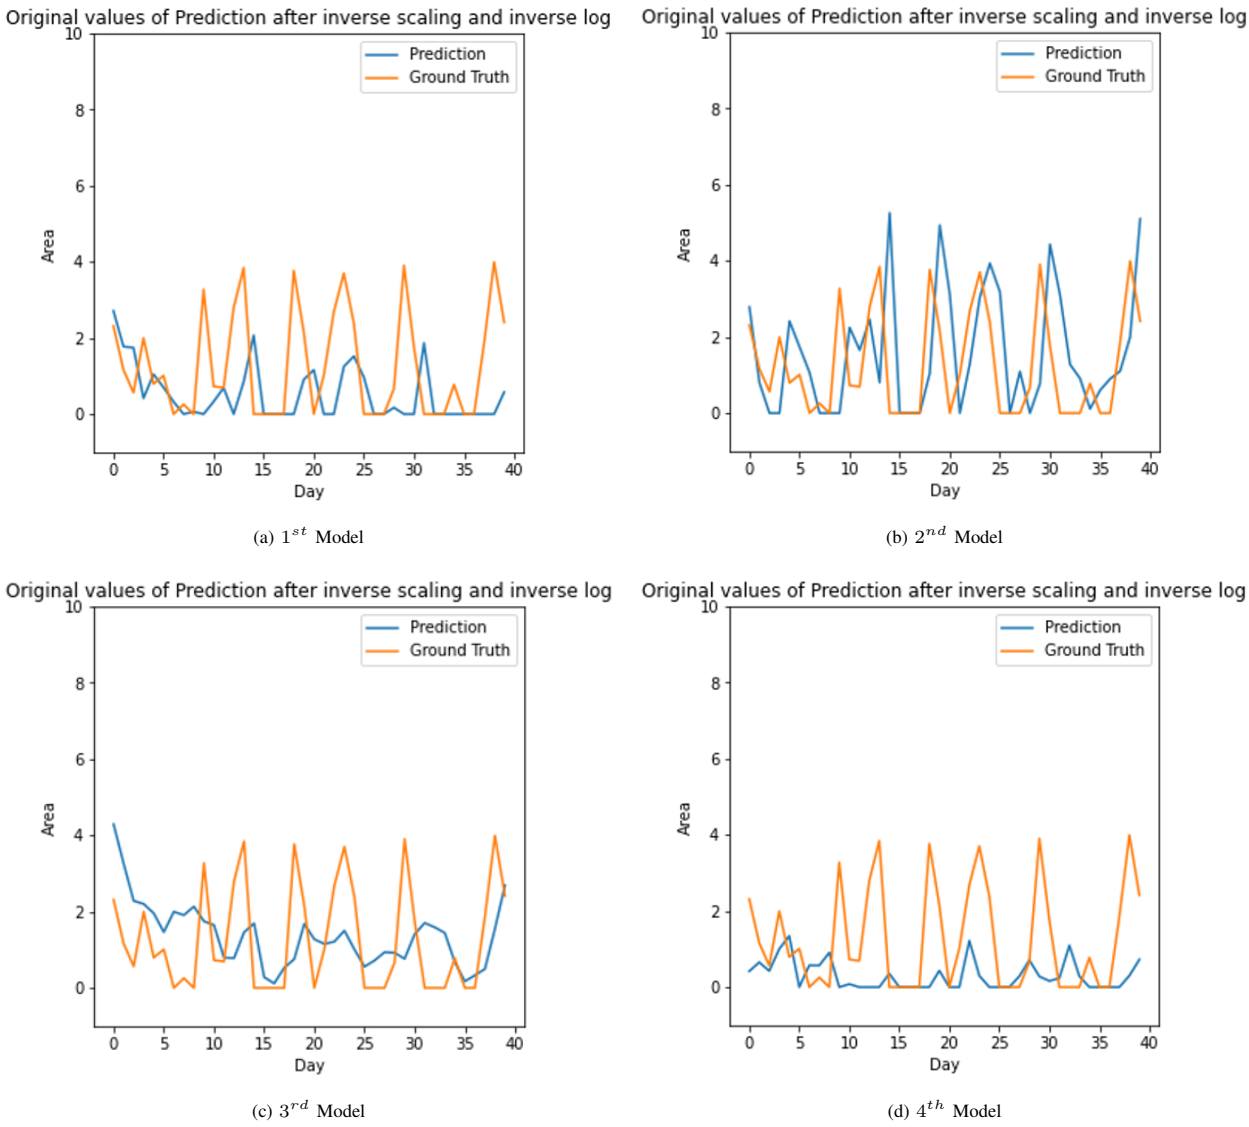
E. Discussion

To determine the predictive accuracy of artificial intelligence and machine-learning models, it is essential to compare their outcomes with those of other similar models. This is why this section showcases the results of previously published research that was conducted on the same datasets. For this comparison, we use the RMSE error, which is depicted in Eq. 5. By comparing these errors with those of other models, we can assess the effectiveness of our own model.

Several models have been applied and evaluated on the same datasets in the literature [7], [22], [21], [32]. Table V summarizes the assessment metric results of these models, along with the errors produced by LSTM, SVR, and ARIMA (shown at the bottom of the table). These datasets have shown promising results for both statistical models and other machine learning techniques. In this study, we have utilized comparable data from previous research to evaluate the performance of our models.

V. CONCLUSION AND FUTURE WORK

The aim of this study was to create an effective machine learning algorithm for predicting the spread of fire in hazardous incidents. This would enable workers to take immediate action, thereby reducing economic and natural losses. The study utilized data on forest fires from Portugal's Montesinho Natural



(a) 1^{st} Model

(b) 2^{nd} Model

(c) 3^{rd} Model

(d) 4^{th} Model

Fig. 11. Prediction of the 4 LSTM models.

Park, which is accessible through the UCI machine-learning repository. After thorough research, the study identified the most suitable machine learning and statistical models, including Long Short Term Memory (LSTM), Auto Regressive Integrated Moving Average (ARIMA), and Support Vector Regression (SVR). The study evaluated the models using the Root Mean Square Error (RMSE), and found that LSTM was the most effective model, producing the best results with an RMSE of 1.15.

The prediction results of LSTM, SVR, and ARIMA were compared to those published in the literature [7], [22], [21], [32]. The methodologies used in these papers included various types and structures of neural networks (NN), Support Vector Machines (SVMs), Decision Trees (DTs), Multiple Regression (MR), Random Forest (RF), Transparent Open-Box (TOB) Network, Radial Basis Function (RBF), Standard Genetic Programming Decision Trees (ST-GP), Linear Regression (LR), Adaptive Neuro-Fuzzy Inference System (ANFIS), Probabilistic Neural Networks (PNN), and Finite Impulse Response (FIR). Using the same data, the comparison aimed to evaluate the performance of the aforementioned methods and to identify the most accurate model for prediction.

The results indicate that the top-performing LSTM models exhibited the lowest RMSE error, as well as the highest predictive accuracy compared to all other models. To enhance accuracy in the future, we can make necessary parameter adjustments and augment data sources by incorporating various factors, such as forest vegetation, cover, types of trees, and Buildup Index. By integrating geographic information system (GIS) data and satellite imagery, we can further optimize this model and achieve even greater precision. This approach can significantly enhance our ability to analyze and understand forest dynamics and provide valuable insights for forest management and conservation efforts.

***Abstract*—Optical Character Recognition (OCR) holds immense practical value in the realm of handwritten document analysis, given its widespread use in various human transactions. This scientific process enables the conversion of diverse documents or images into analyzable, editable, and searchable data. In this paper, we present a novel approach that combines transfer learning and Arabic OCR technology to digitize ancient handwritten scripts. Our method aims to preserve and enhance accessibility to extensive collections of historically significant materials, including fragile manuscripts and rare books. Through a comprehensive examination of the challenges encountered in digitizing Arabic handwritten texts, we propose a transfer learning-based framework that leverages pre-trained models to overcome the scarcity of labeled data for training OCR systems. The experimental results demonstrate a remarkable improvement in the recognition accuracy of Arabic handwritten texts, thereby offering a highly promising solution for the digitization of historical documents. Our work enables the digitization of large collections of ancient historical materials, including manuscripts and rare books characterized by delicate physical conditions. The proposed approach signifies a significant step towards preserving our cultural heritage and facilitating advanced research in historical document analysis.**

Keywords*—Optical character recognition; transfer learning; Arabic OCR; image processing; classification; convolutional neural network

I. Introduction

Around 1.8 billion people in the world speak the Arabic language. Arabic writing is unique and semi-cursive in both printed and handwritten forms. Arabic OCR systems are of two types, online and offline, aiming to convert Arabic text images into machine-readable words. Online systems use special equipment like a pen and tablet, while offline systems use scanners. There are open issues in Arabic OCR, such as generalization ability, the use of deep learning, lack of standard taxonomy, large-scale evaluation, and reproducible research [1], [2], [3].

The method used to process the documents or images to extract text is represented as OCR. These images or documents be in different forms, like scanned or digitized. This process helps extract text from these documents in an editable form for a machine to edit it. This process exists in two types, i.e. online and offline. In an online OCR system, real-time text recognition will be performed like writing on digital notebooks [4]. Whereas, written documents or images taken from some written sources are used in the offline OCR system [5]. As we focus on Arabic and dealing with handwritten documents or images, it comes in both offline and online types. Therefore, recognizing the text more accurately is the issue because the Arabic language has unique and challenging characteristics compared to other languages [6]. Its characters come in different shapes concerning their position in words, increasing the difficulty level for recognition, and when the document is of low quality or in different writing styles, fonts, cursive nature, and quality documents [7].

Some available tools help extract and recognize the Arabic text from the documents, like Tesseract [8], OCR Space [9], OmniPage [10], easy-OCR [11] and others. From all these, Tesseract gives a better result, but it needs more training and data to recognize handwritten Arabic text with high character, word, and overall text accuracy. By keeping this point in mind, we decided to use the transfer learning method on Tesseract to achieve a high recognition rate for offline handwritten Arabic text. It needs more training datasets, including ground truth, images, and box files. For this purpose, we write a script that makes images of the ground truth to fast forward the process and then makes the box files, and then these files are used together for transfer learning.

OCR can be used in many fields of life where it makes work easy, efficient, and digital. Hospitals process patient and insurance company files on the computer to make a digitized record as these kinds of records are handwritten, which is why OCR needs handwritten documents as well and uses them in many more fields [12], [13], [14].

A. Problem Formulation

Many OCR systems are available for different languages with different features, like unilingual or multilingual OCR systems. Much research is done in English and other Germanic languages, especially in noncursive scripts, because these are easier to be processed by the OCR systems. However, scripts like Arabic are challenging to recognize due to their cursive nature, the appearance of Arabic letters in different shapes in different words as shown in Table I, and diacritics that come above or below the Arabic word or letter. It changes the meaning of words as they are just minor signs, as shown in Table II. Arabic script is written from right to left, and some writing

styles change the appearance of the words, like in Fig. 1. Due to these complexities, Arabic OCR is a challenging research area that needs more consideration. Limited publicly available datasets exist for research purposes, and different techniques are available. However, each technique has pros and cons that limit character and word accuracy in the preprocessing and segmentation phases [15], [16].

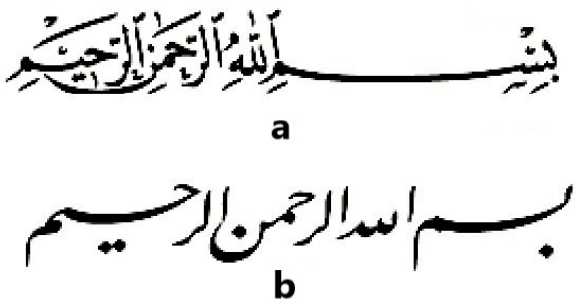

Fig. 1. Arabic sentence in two different writing styles, i.e. (a) Nask and (b) Nastaliq.

Table I. Arabic Letters and their Different Shapes based on the Position in a Word

Isolated Form	Initial Form	Middle Form	End Form
ا	ا	ـا	ـا

B. Problem Motivation

The digitization of historical documents stands as a critical endeavor in the preservation and dissemination of our global cultural heritage. These documents, ranging from ancient manuscripts to letters and administrative records, encapsulate not only the factual history but also the intellectual, social, and cultural dynamics of past societies. Digitization offers a bulwark against the relentless march of time, safeguarding these irreplaceable insights from the ravages of physical degradation, environmental hazards, and the obscurity of inaccessibility. Moreover, it democratizes access to knowledge, transcending geographical and temporal barriers to make these treasures universally accessible, fostering a broader understanding and appreciation of human history. In the realm of Arabic historical documents, which are rich in linguistic and cultural nuances, digitization is not merely a technical challenge but a crucial step towards preserving a significant part of the world's intangible cultural heritage. Thus, our research is motivated by the imperative to advance Optical Character Recognition (OCR) technologies, specifically tailored to Arabic script, to facilitate the efficient and accurate digitization of these documents, ensuring their preservation and accessibility for future generations.

Table II. Position of Arabic Diacritics in the Script Changes the Meaning and Sound of the Words

Diacritics Type	Diacritics Shape
Fathah	◌َ
Kasrah	◌ِ
Dammah	◌ُ
Alif Khanjariyah	◌ٰ
Sukūn	◌ْ
Tanwin	◌ً ◌ٌ ◌ٍ
Shaddah	◌ّ

The motivation for this research paper on Arabic handwritten OCR stems from the challenges associated with recognizing and digitizing handwritten Arabic documents. While there are existing OCR systems for recognizing printed Arabic text, there has been less research on developing accurate models for recognizing handwritten Arabic characters and numbers. This is problematic because handwritten documents are important cultural artifacts that need to be preserved, but they are at risk of being lost if not digitized. Furthermore, the lack of publicly available datasets for Arabic handwritten OCR makes it difficult for researchers to develop and evaluate new models. Therefore, this paper aims to contribute to the field of Arabic handwritten OCR by presenting a new dataset and an accurate OCR model that can be used to preserve and make accessible handwritten Arabic documents.

We make the following contributions to significantly advance the state-of-the-art in Optical Character Recognition (OCR) for Arabic handwritten texts:

1) We present an enhanced OCR accuracy for Arabic handwritten texts through the novel application of transfer learning techniques to the Tesseract OCR engine, substantially reducing common recognition errors.
2) Our work includes the compilation and preparation of a comprehensive dataset, which comprises high-resolution `.tiff` images, `.box` files, `ground truth` files, and `dictionary files`. This dataset not only supports our model's training but also serves as a resource for the broader research community.
3) We introduce a robust framework for evaluating OCR accuracy, utilizing Character Error Rate (CER) and Word Error Rate (WER) as the principal metrics. This framework facilitates a thorough quantitative analysis and validation of our approach.
4) Through detailed **visual demonstrations of our**

model's efficacy, we provide clear evidence of our methodology's effectiveness and its practical implications for Arabic text digitization.

These contributions underscore the novelty and significance of our work, showcasing its potential to significantly impact the OCR field by enhancing the recognition accuracy of Arabic handwritten texts and promoting the digitization and preservation of historical documents.

II. Related Work

The exploration of Optical Character Recognition (OCR) technologies, especially in the realm of Arabic handwritten texts, reveals a landscape marked by both advancements and persistent challenges. While the strides in OCR methodologies have paved the way for notable achievements, the unique intricacies of Arabic script—ranging from its cursive nature to the prevalence of diacritics—pose specific hurdles that remain inadequately addressed. This gap not only underscores the necessity for innovative approaches but also serves as the cornerstone of our motivation. Our investigation into the related work illuminates the breadth of strategies previously employed, yet simultaneously highlights a critical void in the application of advanced machine learning techniques, such as transfer learning, to the nuances of Arabic handwriting recognition. It is this intersection of opportunity and challenge that our research aims to navigate, propelled by the conviction that enhancing OCR accuracy for Arabic texts not only contributes to the technological domain but also fosters the preservation and accessibility of cultural heritage. As such, our work seeks not only to bridge the existing gaps identified through our review but to set a new benchmark for accuracy and efficiency in the recognition of Arabic handwritten documents.

The Arabic language has complexities for developing OCR systems due to its cursive nature and morphological structure. Applied approaches and methods in this area are compared and show the best-performing approach. This study shows that the hidden Markov model (HMM) gives an accuracy of 95.6%. As the survey is working on handwritten characters recognition of Arabic, it shows the recognition by an automatic capitalization of OCR using the hidden Markov model [17].

Arabic text recognition system faces many challenges due to its cursive nature, different shapes of characters, diacritics, and writing styles [7], [18]. Handwritten text recognition comes in two formats, i.e. document (manuscripts) and online (tablets) [19]. A proper pipeline is required to overcome the challenges and get a high recognition rate [20]. Urdu and Arabic are the same, i.e. Urdu uses all of the Arabic characters. Recent advances discuss state-of-the-art research about Urdu and Arabic Naskh and Nastaliq scripts. It has also discussed the dataset and its different forms, i.e. printed, scanned, and handwritten, and the pipeline used to process the data, i.e. preprocessing, segmentation, classification, recognition, and post-processing to get better text recognition [21], [22], [23].

As mentioned above, most researchers also work on Arabic and use transfer learning. However, they only concentrated on characters and numbers, which are easier to recognize through transfer learning on models like Alex-Net and Google-Net. Moreover, they are already trained on the image of different objects and give high recognition on a single letter or number images [24].

The authors of [25] discuss the challenges of handwritten Arabic text classification and recognition and evaluate the different deep learning models, i.e. ResNet50, ResNet101, VGG16, VGG19, AlexNet, GoogleNet, and ResNet18 using transfer learning techniques. To overcome the challenges, use handwritten images of text written by a native or non-native person. The dataset consists of 22 subjects equally written by native and non-native writers. After using different models, results show that GoogleNet is the model that achieves 93.2% accuracy on the native dataset and 95.2% on the non-native dataset.

Sahlol et al. [26] describe a hybrid machine-learning approach for handwritten Arabic character recognition using optical character recognition (OCR) systems. This approach combines neighborhood rough sets with a binary whale optimization algorithm for feature selection. The proposed method outperformed state-of-the-art and deep neural networks regarding recognition rate and computational time. However, some misclassified failure cases occurred due to the context of appearance.

Authors of [27] present a new model for Arabic document information retrieval (ADIR) using OCR services. They used datasets written by 60 writers containing 16,800 Arabic letters and applied them to preprocess techniques such as binarization, noise removal, skew correction, and page and zone segmentation. They discussed the challenges of segmentation and recognition for Arabic script, particularly with cursive writing and compound graphemes. The Arabic document information retrieval (ADIR) system achieved a classification success rate of 100% for test images. The paper also describes the service description for ADIR, which includes the user interface (UI) and a server address for communication between clients and services.

Rahal et al. [28] discussed the difficulties of automatic Arabic text recognition due to the language's cursive nature, character similarities, large vocabulary, and the use of multiple font sizes. This paper proposed a novel hybrid network that combines Hidden Markov Models (HMMs) and a Bag-of-Feature (BoF) framework, which is based on a deep Sparse Auto-Encoder (SAE) for feature extraction. The system eliminates the need for preprocessing stages like baseline estimation and slant normalization. Instead, the SAE automatically selects the best weights for visual words for each local descriptor while concurrently learning the best dictionary, making it suitable for irregular, variable-size, mixed-font, high- and low-resolution documents. The system was tested on four different datasets and performed well on each one.

Zanona et al. [29] present a model for recognizing handwritten Arabic characters that use preprocessing functions and contour analysis to produce a vector for recognition by a neural network. The system was tested on private data and achieved 98% accuracy on the complete dataset and 99.4% precision. The classification system uses a segmentation operation [30] and a multilayer feed-forward neural network (FFNN). In another research, an Arabic handwritten text recognition system was designed that extracts and recognizes single-line text and converts that extracted or predicted text into individual words

and their characters, achieving an 83% recognition rate.

Many advanced systems, like Mathpix, Digital Ink API, ML Kit Text, Read-Ink, MyScript, GoodNotes, and Mazec, were developed in the last decade to resolve challenges in handwritten text recognition. Multiple methods and techniques are used for this purpose, like dynamic time warping, hidden Markov models, and artificial neural networks, which use a pipeline to process the data correctly. These methods use the data and enhance the recognition rate, which shows impressive results [31].

Some systems are used for the Arabic text OCR, i.e. Tesseract, Textract, and Document AI. These OCR systems work for different languages, like English and Arabic. In this research, historical documents are used, and these documents are multilingual and contain English and Arabic text. The English dataset contains historical text from books that scan with various fonts. In contrast, the Arabic dataset contains articles from online resources in a single widely used font. The author found that Textract and Tesseract performed slightly better on gray-scale test images than on color versions, but Tesseract was more sensitive to noise than the other two engines. It shows that Document AI and Textract give better results than Tesseract. However, Document AI and Textract have higher noise in their images even after applying noise removal technique in it [32], which recommends self-training or transfer learning to the Tesseract, it will be able to give better results than others.

Most of the researchers work in Arabic handwritten OCR. However, they mostly used characters, digits, or other individuals in their experiments and showed better results as shown in Table III.

Authors in [35] proposed a technique based on text area detection and text recognition using pre-trained OCR systems, i.e. Tesseract, KerasOCR, and EasyOCR. This system deals with engineering documents, and a high recognition rate is significant. For this purpose, transfer learning is used, which helps to increase the word recognition rate and increase the overall text recognition rate as well.

III. Methodology

This section describes the methodology of our proposed work. We provide a descriptive analysis of our datasets. We have explained our transfer learning approach and each step of the experimentation.

A. Dataset

As datasets play an important role in training models, a more extensive dataset helps train the model more accurately, and the model can learn quickly. For deep and machine learning models, larger datasets are required, but due to handwritten text, data preparation is a tough job as first need to generate round truth. Handwritten text against ground truth and its image and box files generation to pass the model for text extraction, recognition, and further processing. Due to these challenges, the availability of a public dataset is very low. Moreover, every model requires a large amount of data to do its excellent training; by considering this problem, we moved toward transfer learning, and we know that for transfer learning models, a larger dataset is not an issue, and this technique helps the model to get better training even on smaller datasets.

Urdu and Arabic have many similarities, i.e. both are written from right to left, all of the Arabic characters are used in Arabic, but Urdu has just extra characters, their digits have the same shapes, their writing styles are also common, and Urdu borrows a large amount of vocabulary from Arabic that is about 30%.

Due to these similarities, the Urdu dataset can also be used for Arabic text. Bhatti et al. [36] presents an Urdu dataset based on the Urdu handwritten digits dataset and experiments using deep learning techniques and achieving a high accuracy rate.

An Urdu handwritten dataset is proposed by [37], which is based on Nastaliq handwritten text, i.e. UNHD, and used a bidirectional LSTM classifier and this dataset is written by 500 writers on A4 size paper as shown in Table IV that will be available on request. The address of the dataset link is attached [1].

Mostafa et al. [38] proposed a dataset that is based on text images shown in Fig. 2 with their ground truth as well. The dataset contains 270 million words and 1.6 billion characters. 12 fonts are used in the dataset, and the used text font size is 13.

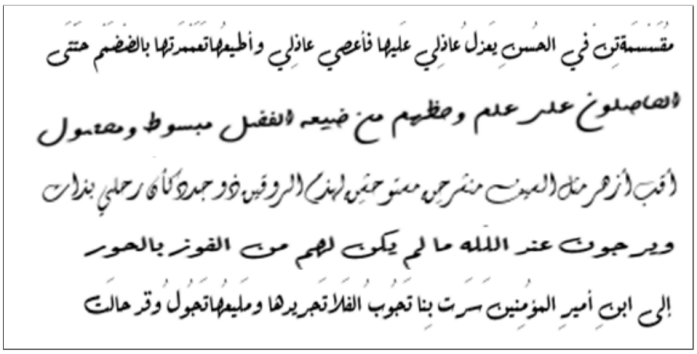

Fig. 2. Dataset sample of arabic text image that contains text with diacritics.

The authors of [39] proposed a handwritten dataset that is taken from different handwritten documents. A description of the dataset is shown in Table V and a sample image of the dataset is shown in Fig. 3.

Dataset selection:

For dataset selection, we find the Arabic text and then write a Python script that tests a script that gives the relative frequency of characters present in the text, and then we compare the relative frequency to that relative frequency [40], [41], as shown in the Table VI to avoid biases, this frequency distribution helps to use the characters in same quantity and position as they are used in normal text writing. Also, we test the script on each file separately to check their frequency. We then gave the text files to different people to write the handwritten text, and then we scanned that text and evaluated the handwritten dataset.

Table III. Previous Arabic Handwritten Text Research Focused on Character Recognition, Digit Recognition, Hijja Recognition, and Word Recognition using Image-based Data for Model Training

Paper	Model	Dataset	Accuracy
Albhattah [33]	Hybrid CNN with finetune	AHCD (characters and Hijja)	98%
	CNN with finetune	AHCD (characters)	92.4%
Alghyaline [34]	Deep CNN	APTI (words)	76.30%
	CNN-RNN	Alif dataset (words)	85.98%
	Deep CNN	HMBD (characters)	92.88%

Table IV. Description of the Urdu Nastaliq Handwritten Dataset, adaptable for Arabic Due to its Derivation from the Arabic Script

Urdu Nastaliq Handwritten Dataset	Description
Writers	500
Text lines	10,000
Words	312,000
Characters	1,872,000
Words written by a writer	624

Table V. Description of the Handwritten Dataset Extracted from Handwritten Documents

No. of Pages	No. of Lines	No. of Words	No. of Chars
1,000	18,000	35,000	252,000

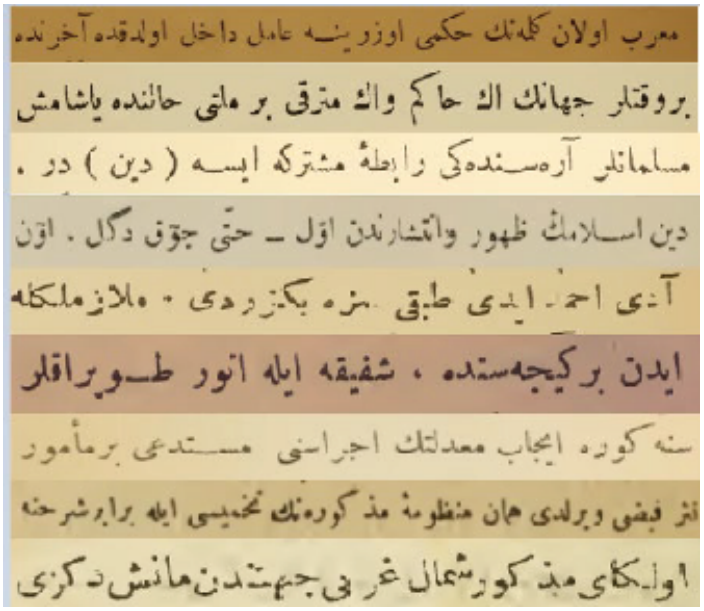

Fig. 3. Sample image of the handwritten dataset that is taken from the various Arabic handwritten documents.

1) Publicly Available Datasets: Some handwritten datasets are reported [2], but those datasets contain images of words because most researchers work on individual character and number recognition of Arabic. They used these datasets for pre-trained object image recognition models like ImageNet and AlexNet [19]. A description of these kinds of datasets is shown in Table VII.

Arabic MNIST dataset is also available, but it is also for individual characters and numbers. This database is split into training and testing datasets for Arabic characters and numbers, consisting of 60,000 images for training and 10,000 images for testing purposes of characters and the same for numbers; this dataset is available [3]. Furthermore, another dataset is available that is written by the contribution of 60 writers and contains 168,00 character images, and these images were scanned on 300dpi resolution [42].

Table VI. Comparison of Arabic Characters Frequency in the Selected Text and Overall Frequency of Arabic Characters

Characters	Frequency in selected text	Frequency in Arabic Language
ا	15.00%	14.61%
ل	14.13%	11.64%
م	6.56%	6.49%
ي	6.38%	7.25%
و	5.64%	5.40%
ن	5.41%	4.76%
ت	4.39%	4.58%
ع	4.15%	3.27%
ر	3.54%	4.53%
ب	2.70%	3.38%

Table VII. Description of Handwritten Images of Arabic Words Dataset used in Pre-trained Models

Statistics	AlexU-W	IFN/ENIT
Images	25,114	32,492
Training images	20,114	26,459
Testing images	5,029	6,033
Unique words	109	937
Maximum PAWS	3	10

A gold-standard dataset is available on GitHub [4], which contains Arabic books, their ground truth, images, and box files. That is much enough to train any model, text images based on one-line text, and a description of the gold standard set is shown in Table VIII. Some publicly available datasets of Arabic handwritten text, words, characters, and digits are also available, as shown in Table IX.

Table VIII. EDA of Arabic Gold-Standard Dataset Derived from Literature Books

Book	Pages	Lines	Words	Chars
IbnFaqihHamadhani.al-Buldan	79	1466	16909	92730

Table IX. Publicly Available Datasets Focus Primarily on Arabic Ligatures and Digits

Dataset	Type of content
IFN/ENIT [43]	Handwritten Words
HACDB [44]	Handwritten Characters
KHATT [45]	Handwritten Text lines
SmartATID [46]	Printed & Handwritten Pages
Degraded historical [47]	Handwritten documents
Numeral [48]	Handwritten Digits
AHDBIFTR [49]	Handwritten images
ARABASE [50]	Handwritten Text
CENPARMI [51]	Handwritten subwords & digits

25,000 entries, which contain ground truth, images, box, and "lstmf" files, which is a complete set of the required dataset for training the Tesseract transfer learning, and these images consist of one-line text, and in a raw format that will be preprocessed in the preprocessing stage of Tesseract pipeline, as shown in Table X.

Table X. EDA of Datasets used for Evaluating Handwritten Arabic Text in Our Experiments

Dataset	Words	Char	Lines	Digits	Punc.
Printed lines	3,592	19,802	307	29	370
Words and lines	71,365	374,516	14,606	5,592	6,451
IbnFaqihHamadhani	104,845	577,392	15,296	1,713	9,948
Ancient Arabic	700	3,160	100	-	-

B. Transfer Learning using Tesseract

Tesseract is an open-source engine for Optical Character Recognition used to recognize text from images. It consists of the following steps to process the image from its raw shape to make it able to be used for OCR, i.e. preprocessing, Converting Image to Box file, Converting Box files to "lstmf" file.

While using the Tesseract base model, firstly, we passed the handwritten image to the model to check its accuracy and try to find the problem in the base model. After passing images in PNG or JPG, we write a script that takes all the images from the folder individually, passes them from the model, extracts text from the images, and saves them in a text file in another folder. After this, we pass both ground truth and extracted or predicted text files and find accuracy. For evaluation, we write a script using Levenshtein distance to find the character error rate (CER) and word error rate (WER) and then find the average CER and WER and their accuracy as the base model is trained on editable or computer-typed text. Therefore, we prepare the data for model [5] some dictionary files, the dataset contains ".tiff" files and ground truth and passed this data to the Tesseract for transfer learning purpose and consider starting point to the base model. After transfer learning, repeat the test for evaluation and get the results with more accuracy, CER and WER, as shown in Fig. 4.

The methodology depicted in Fig. 4 commences with the meticulous preparation of training data, a pivotal phase for the effective employment of transfer learning on the Tesseract OCR engine. This stage encompasses the assembly of high-resolution `.tiff` images of Arabic handwritten texts, alongside their corresponding `.box` files which delineate bounding boxes around each character, and `ground truth` files containing the verbatim text. Furthermore, `dictionary files` are curated to guide the model towards recognizing the expected lexical items. Subsequent to the data preparation, the Tesseract base model undergoes augmentation through transfer learning, enabling it to adapt to the nuances of Arabic handwritten text. This adaptation is facilitated by training the model with the prepared dataset, thereby enhancing its capability to accurately recognize Arabic characters and words. The retrained model is then evaluated against a set of unseen data to ascertain its accuracy, employing metrics such as the Character Error Rate (CER) and Word Error Rate (WER) derived through Levenshtein distance calculations. These metrics serve as indicators of the model's proficiency in character and word recognition, with lower CER and WER values signifying superior performance. This comprehensive approach underscores the efficacy of transfer learning in refining the Tesseract model's recognition accuracy for Arabic handwritten texts.

Preprocessing: In this step, Tesseract takes an image for preprocessing and improves the image quality by resizing the image into a standard size, converting the image into gray-scale, and applying filters to remove noise from the image like thresholding, erosion, blur.

Converting image into Box file: In this step, it converts the preprocessed image into a box file with plain text containing coordinates of the bounding boxes around each character or word of text present in an image. The following command is used to make a box file against the image. "Tesseract image.png output -l ara makebox". In this command, "image.png" is an image that needs to be recognized, and 'output' is the file that gets the recognized text and saves it, while "ara" is for language; here, we are using Arabic, and we used the keyword for it, same "eng" is for the English language.

Converting box file to "lstmf": This step takes the box file created in the previous step and makes a binary file containing the training data for Tesseract. This process contains the following steps like "tesseract image.png output -l ara box.train", Which will create "lstmf" files with the name of "ara.traineddata" in the same directory.

Evaluation: For evaluating, we need to compare the recognized text with the ground truth to get accuracy. For this purpose, we can use the following steps to get a better evaluation, i.e. CER, WER, and Overall accuracy. A higher accuracy, lower CER, and BER represent good results. CER gives the percentage of incorrectly recognized characters. It can be calculated simply by dividing the number of incorrect characters by the number of characters in the ground truth, as shown in Eq. (1) below.

$$\text{CER} = \frac{\text{Number of incorrect characters}}{\text{Total number of characters}} \tag{1}$$

WER gives the percentage of incorrectly recognized words. It can be calculated simply by dividing the number of incorrect words by the total number of words in the ground truth, as shown in Eq. (2) below.

$$\text{WER} = \frac{\text{Number of incorrect words}}{\text{Total number of words}} \tag{2}$$

[5] https://github.com/Shreeshrii/tesstrain-JSTORArabic/tree/master/data/

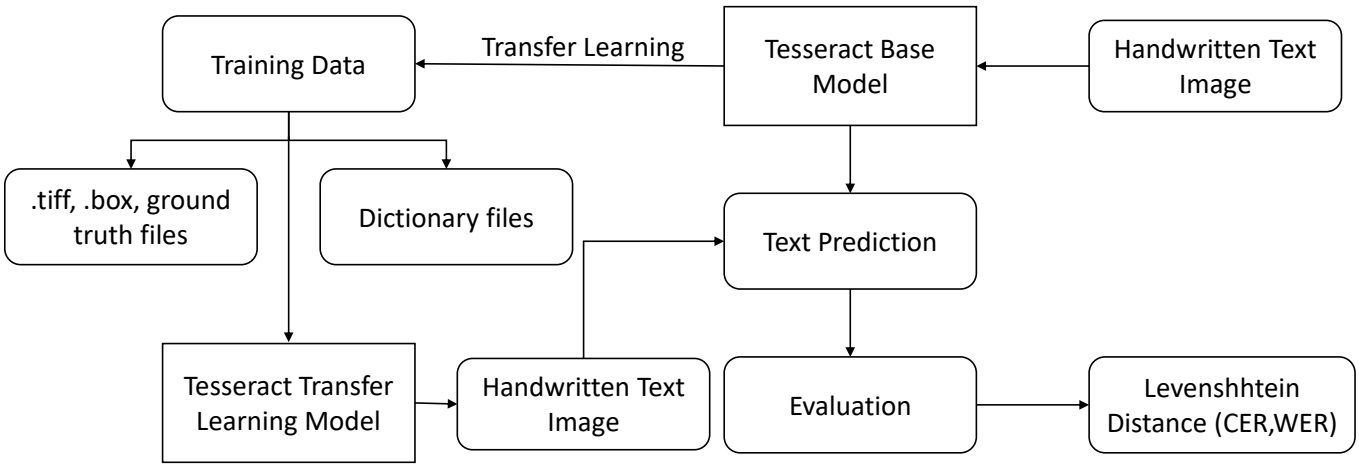

Fig. 4. Tesseract base-model, transfer learning process and evaluation methods.

Overall accuracy gives the percentage of correctly recognized words and characters. It can be calculated by dividing the number of correct words and characters by the total number of words and characters in the ground truth, as shown in Eq. (3) below.

$$\text{Accuracy} = \frac{\text{No. of correct } \{\text{words + characters}\}}{\text{Total no. of } \{\text{words + characters}\}} \quad (3)$$

IV. Results

The experiments were conducted on a Windows Dell laptop with an Intel(R) Core(TM) i7-6600U CPU @ 2.60GHz, 16GB DDR4 RAM, 512GB SSD storage, and an Intel® HD Graphics 520. The laptop ran Windows 10 and was connected to a stable power source throughout the experiments. The experiments were conducted in a controlled environment to minimize external factors that could affect the results. Additionally, Ubuntu 22.04.1 LTS was installed using WSL to run the Tesseract experiment.

In the next section, evaluation metrics, i.e. CER and WER, are discussed, and the overall accuracy of the predicted text against ground truth is described with the results. Then, a discussion of the results and experiments is presented.

A. Evaluation Metrics

After transfer learning of Tesseract, we evaluate the model. For this purpose, firstly, give handwritten text image files to the model that generates box and "lstmf" file and then gives the predicted text of all images. Then, this predicted text compares with ground truth, which is also available in a text file. As mentioned above, the dataset is split into 80% for the training and 20% for testing. Furthermore, we used two types of evaluation, i.e. our evaluation that gives us the overall accuracy of the experiment, CER and WER. For more detail, we use an open-source evaluation tool named "OCREVALUATION", which compares ground truth and the predicted text that elaborates more openly, as shown in Fig. 5. This sample image has two sections: one represents the ground truth on the left, and the other is about the predicted text. The ground truth section represents the characters or words by different colors that are predicted wrong in the predicted text section.

The base model gives an overall accuracy of 23.30%, an average CER of 31.57%, and an average WER of 65.95% on handwritten text images of the Arabic language. However, after transfer learning, it gives an overall accuracy of 87.89% and gives the average CER of 14.02% and average WER of 41.39%, which is relatively better, also shown in Table XI. It also depends on the size of the dataset, and the total time taken by the training is 21 hours. Then, evaluate the second dataset, which contains 5526 images of text that are also based on 1 line text. For these images, we also have ground truth for evaluation purposes and then generate "lstmf" and box files for each image and the ground truth file. After evaluation, we get a character error rate (CER) of 14.85%, a word error rate (WER) of 40.30%, and achieve an overall accuracy of 85.53% also shown in Table XI.

Table XI. Comparison of Tesseract base Model with our Transfer Learning-based Model for Arabic Handwritten Text Recognition

Model	CER	WER	Accuracy%
Tesseract Base Model	31.57%	65.95%	23.30%
Transfer Learning (Dataset 1)	14.02%	41.39%	87.89%
Transfer Learning (Dataset 2)	14.85%	40.30%	85.53%

To check the accuracy of the printed text of this retrained model, we test a dataset that contains a total of 6118 files, which are divided into image and ground truth files, and that took about 5 hours to evaluate. It achieves an accuracy of 94.94%, character error rate, and word error rate based on order dependent and independent are shown in Table XII.

Table XII. Arabic Printed Images Text Recognition with Order Dependent and Order Independent

Features	Stats
Number of files	3,059
CER (order independent)	5.62%
WER(order independent)	19.08%
CER (order dependent)	5.55%
WER(order dependent)	17.85%

Fig. 5. Spotting differences between ground truth (gt.txt) and predicted (ara.OCR.txt) arabic handwritten text.

B. Results and Discussion

For this problem, we have chosen the open-source OCR engine Tesseract as the base model and applied the transfer learning approach to get better Arabic handwritten text recognition results. Firstly, we tested the base model to know its results on Arabic text; we decided to evaluate the computer-generated Arabic text first. After evaluation, we found an average CER of 14.02% and an average WER of 41.39% and got an overall accuracy of about 87.89%. Then, we tested the handwritten images on the base model and got bad results, giving an average CER of 31.57%, WER of 65.95%, and accuracy of 23.30%.

Some challenges while recognizing text are that Arabic handwriting can vary significantly between individuals, making it difficult for Tesseract to recognize characters accurately. This variation can be due to factors such as writing style, speed of writing, and individual handwriting quirks. Arabic script includes diacritical marks, which are symbols that indicate vowel sounds. These marks can be challenging for Tesseract to recognize accurately, especially when small or poorly written.

Handwritten text may contain noise or distortion due to uneven ink distribution, smudging, or poor image quality. This can make it difficult for Tesseract to recognize characters accurately. Handwritten text may be oriented or aligned in various ways, making it challenging for Tesseract to recognize the correct characters or words. Additionally, training Tesseract with a more extensive and diverse dataset of Arabic handwriting may improve its accuracy.

After this, we apply the transfer learning approach and train the model by giving handwritten images and their ground truth. After 21 hours of training, the transfer learning gives outstanding results, with CER being 14.02%, WER being 41.39%, and overall accuracy of 87.89%, which is impressive. Then, evaluate the second dataset, which contains 5526 images of text that are also based on 1 line text. After evaluation, we get a character error rate (CER) of 14.85%, a word error rate (WER) of 40.30%, and achieve an overall accuracy of 85.53%.

V. Conclusion

In conclusion, our paper has presented an effective OCR method for handwritten Arabic text recognition using a transfer learning approach with Tesseract. Our evaluation results show a significant improvement in word and character recognition accuracy compared to previous models. The applied transfer learning technique achieved an average CER of 14.02% and an average WER of 41.39% and got an overall accuracy of about 87.89%. Then we decided to test the handwritten images on the base model to get the comparison result with the retrained model by using the transfer learning technique, giving an average CER of 31.57%, WER of 65.95%, and accuracy of 23.30%. These findings suggest that transfer learning can be a valuable technique for improving OCR accuracy in challenging languages such as Arabic and may provide a promising direction for future research in this field. Overall, our work demonstrates the potential of leveraging existing knowledge and models to improve the performance of OCR systems.

A Secure Scheme to Counter the Man in the Middle Attacks in SDN Networks-Based Domain Name System

Frank Manuel Vuide Pangop[1], Miguel Landry Foko Sindjoung[2], Mthulisi Velempini[3]
IUT-FV of Bandjoun, University of Dschang, Bandjoun, Cameroon[1]
Department of Computer Science, University of Limpopo, Mankweng, South Africa[2,3]

***Abstract*—Internet and computer networks are vulnerable to cyber-attacks which compromise the services they provide to facilitate the management of data and users. The domain name system (DNS) is the Internet service that translates domain names and computer IP addresses and IPs to domain names. DNS is sometimes a victim of attacks that are difficult to detect and prevent because they are not only very stealthy but also conceal its proper functioning. Among the attacks that DNS is subject to, there are man-in-the-middle (MITM) attacks. Traditional networks that centralize all network functions in a single device complicate the detection and protection of systems against these attacks challenging. Software-defined networking (SDN) is a technology that is widely used to address many traditional network problems such as security and network architectures. Therefore, in this paper, we propose a scheme designed to detect and block man-in-the-middle attacks based on a newly defined architecture. The effectiveness of our secured solution is evaluated in an SDN architecture where an Address Resolution Protocol spoofing MITM attack is generated for the evaluation purpose. The results of our simulations show that we can effectively detect the attack and the performance evaluation of our approach shows that the proposed solution is effective in terms of security, implementation cost and resource consumption. We then recommend the use of our proposed solution to address the MITM attacks in SDN networks-based Domain Name System.**

***Keywords*—Cyber security; domain name system; man in the middle attack; software defined networking**

I. Introduction

Cybersecurity protects computer systems from malicious attacks. Cybersecurity [1] is the set of measures and practices which protect computer systems, networks, data and users against attacks, intrusions and online threats. Interestingly, human error counts for 50-80 % of network outages [2] due to misconfigurations made by administrators when configuring a network. These attacks also affect the domain name system (DNS).

The DNS is a hierarchical, distributed system for associating domain names with IP addresses. DNS is also vulnerable to attacks [3]. New forms of attacks that are stealthy and sophisticated [4] are difficult to address in traditional networks. The use of new technologies, such as software-defined networking (SDN) is a new networking paradigm that facilitates network management and administration by providing an interface to control network infrastructure such as switches which can be employed to address the security problem.

DNS servers are victims of several attacks because of their role and visibility on the Internet. Some of the common attacks are amplification and DoS attacks, botnets and attacks using DNS, DNS Zone transfer attacks, and DNS manipulation. DNS manipulation compromises DNS resolvers responsible for manipulating DNS responses [5]. In recent years, several researchers have focused on finding ways to counter DNS manipulation that uses active measurements to profile open resolvers. In this paper, we focus on DNS manipulation, more precisely on the man-in-the-middle (MITM) attack.

The MITM attack is an interference where an attacker eavesdrops, intercepts, or manipulates communication between two or more parties to steal information. In DNS, the attacker manipulates DNS servers or cache to redirect users to fraudulent sites to steal information or download the malware [6]. The attacker using a MITM attack intercepts communication on the communication channel and pretends to be a receiver to the sender and the sender to a receiver. This can be possible following two scenarios: firstly, communication between the two entities is not secure, in other words, the start of the communication is not preceded by an authentication; secondly, the two parties communicate over an insecure communication channel, such as public Wi-Fi or an unencrypted network. So, an attacker can intercept and manipulate the messages.

It is, therefore, necessary to find effective mechanisms to prevent and detect MITM attacks in DNS to ensure the security and confidentiality of users' communications. This involves implementing protection mechanisms such as encryption of communications, mutual authentication, Intrusion Detection System/Intrusion Prevention System (IDS/IPS), and the use of protocols such as Secure Socket Layer/Transport Layer Security (SSL/TLS). In this article, we propose a solution to detect and block MITM attacks on DNS servers based on a new SDN architecture.

The rest of this paper is organized as follows: in Section II, we present the related work. We then present our proposed scheme to address the MITM attacks in SDN networks-based DNS in Section III. Thereafter, we present the simulation results and analysis in Section IV. Finally, we conclude the paper in Section V.

This work is based on the research supported by the National Research Foundation of South Africa (Grant Numbers: 141918).

II. State of the Art

In the literature, many solutions have been proposed to counter security attacks in SDN architecture. In this section, we review some of the related works.

In study [7], Sungmin et al., proposed a new security extension named Topoguard to the existing OpenFlow controllers to provide automatic and real-time detection of network topology poisoning attacks in an SDN architecture. Their solution is premised on the poisoned network visibility and the upper-layer OpenFlow controller, services/applications may be misled, leading to hijacking, denial of service or MITM attacks. Topoguard is based on SDN/OpenFlow topology service security analysis for vulnerability identification. Sungmin et al. have proposed a network topology poisoning attack to exploit the vulnerabilities their solution has identified. Moreover, they investigated the defence space and proposed an automatic mitigation approach against network poisoning attacks and a prototype defence system.

In study [8], Cheng et al. investigated the potential threats that the OpenFlow control channel may face from the MITM attacks. They proposed an attack model in an IoT-Fog architecture and they also demonstrated the consequences of these attacks. Based on the previous demonstration, Cheng et al. [8] proposed a lightweight countermeasure based on Bloom filters. Anass et al. [9] proposed a Context-Based Node Acceptance (CBNA) framework to mitigate the MITM threats based on the authentication of new nodes using OpenFlow switches in a software-defined network. The CNBA framework takes place when new nodes attempt to connect to the controller for the first time and make a decision based on the response time of nodes.

Sahri et al. [10] proposed a collaborative SDN authentication (CAuth) which blocks the spoofed packet while authenticating the legitimate packet when establishing communications between a client and the DNS server within an SDN architecture. Their solution allows authentication of the two entities wishing to communicate with each other (client and DNS). The authentication is made between the client controller and the DNS server controller. When the DNS server controller receives the query packet, it sends an authentication packet to the clients that initiate the communication; when the DNS server controller receives an authentication from the client, it replies with the DNS reply to the client. During this exchange, the switch flow table is updated from a match check with the incoming packet to detect the attacking packets. This method can discriminate legitimate packets from attacking ones. Moreover. it can block the attacks before they reach the DNS server, but it consumes a lot of bandwidth. Main focus in this paper will be on the MITM attacks

III. The Proposed Scheme to Address the MITM Attacks in DNS based on SDNs

In this section, we present our contribution to counter the MITM attacks in DNS based on SDN networks. We present a SDN architecture (Section III-A) within which our proposed secure MITM attacks algorithm (Section III-B) is executed.

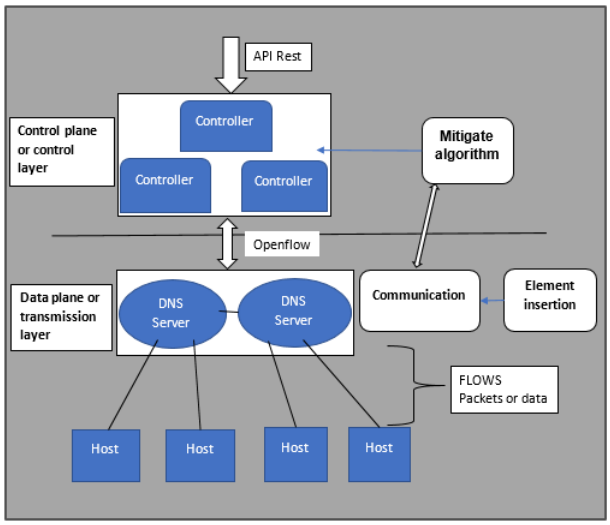

Fig. 1. The proposed architecture.

A. The Proposed Architecture

The proposed architecture is organised into two main layers: the infrastructure layer and the control layer. These two layers are linked by a communication interface which promotes interaction between them. The proposed architecture is shown in Fig. 1 and includes some modules at each layer. The communication interface acts as a bridge between the infrastructure and the control layers. Its main role is to ensure data transfer from one layer to another. The roles of each layer are discussed below:

1) The infrastructure layer: The infrastructure layer is responsible for collecting and transmitting data to the post traffic layer in the network for analysis. The data collection is done according to the rules defined by the control layer. Importantly, this layer has the various network equipment that are DNS server and hosts as shown in Fig. 1. The following modules are incorporated in the infrastructure layer:

- The communication module: It is used to establish communication rules between the DNS server of the infrastructure layer and the controller in the control layer through the communication interface. The collected data is transmitted to the control layer, otherwise, no verification will be made at that layer for attack detection.
- The element insertion module: It is responsible for filtering the data stream collected from the parameters defined by the controller. If these parameters are not defined, then all the network data flow is sent to the control layer, resulting in the increase of the workload in the controller and consequently, the analysis of some incoming data may be ignored, causing a security risk in the network.

2) The control layer: This layer is responsible for overall network monitoring. In other words, it allows the management and control of the flow of data transmitted in the network. This layer works through the controller. The controller fulfils or applies all the functions of the control layer and serves as a

bridge between the applications and the infrastructure layer. Our proposed algorithm (Algorithm 1) which mitigates the MITM attacks is executed in this control layer.

B. The Proposed Algorithm

To detect the MITM attacks in DNS based on SDN network, we propose Algorithm 1 named MITM attack detection (MitAL). MitAL works as follows: Firstly, the rules for DNS-controller communication are established. After the traffic is generated, the transmitted packets are captured and sent to the controller for analysis. If the packet is of ARP type then an attack is detected. If the MAC address of the packet is not the expected one or there is no corresponding MAC address in the MAC-IP table, it is classified as malicious. The MAC address received with the incoming packet is considered as MAC address of a malicious node. Therefore, a notification is sent to all the DNS servers of the network to block all communications from the host with the detected malicious MAC address. Moreover, if the packet is of IP type then an attack is detected if the IP address is valid and the three following conditions are satisfied:

1) The IP address of the node is external to the logical network
2) The response time is greater than the defined threshold value, and
3) The received IP address is not the expected one.

In the previous scenario, a notification is sent to all the DNS servers of the network to block all the communications from the host with the detected malicious IP address.

Algorithm 1: MitAL:MITM attack detection

```
Input: Thr: Threshold in milliseconds, ip_to_mac = ():
       MAC-IP address table;
Capture packets after generating network traffic;
Retrieve information (types) about each incoming
  packet;
For each packet P Do
    If ARP packet Then
        Extract (src_mac, src_ip) of packet;
        If ip_to_mac[P.src_ip] != P.src_mac Then
            Block all the communications from the host
              with MAC address src_mac
    Else
        If IP packet Then
            Extract (src_ip, dst_ip) of packet;
            If src_ip is valid Then
                time ← Calculate response_time();
                mask ← Check if is_external (src_ip) to
                  network;
                source ← Check if src_ip !=
                  expected(src_ip);
                If (time ≥ Thr) and mask and source Then
                    Block all the communications from
                      the host with ip address src_ip
```

To evaluate the effectiveness of our scheme, we perform some simulations where we compare our algorithm to those presented by authors in studies [9] and [10]. The generated results are presented in Section IV.

IV. Simulations and Analysis

This section presents the results of our simulations. These simulations were performed using Mininet* as a network emulator because it creates a network of virtual hosts, switches, controllers and links, and therefore it can be used to build SDN. As a network security tool for analysing, penetration testing and protocol analysis, we have used Ettercap†. Ettercap is a comprehensive suite of tools that allows users to sniff, intercept, and manipulate network traffic in real time. It was used in our simulations to generate the MITM attacks. Wireshark‡ was also used to capture and analyse network traffic in real time. It can support a range of protocols and various capture interfaces. Table I summarizes the details of the used simulation environment and Fig. 2 shows testbed environment.

TABLE I. Simulation Environment

Tool	Version
OS	Ubuntu 22.04 LTS
Python	3.10
Mininet	2.3.0
Ettercap	0.8.3.1
Wireshark	3.6.2
Ryu controller	4.34

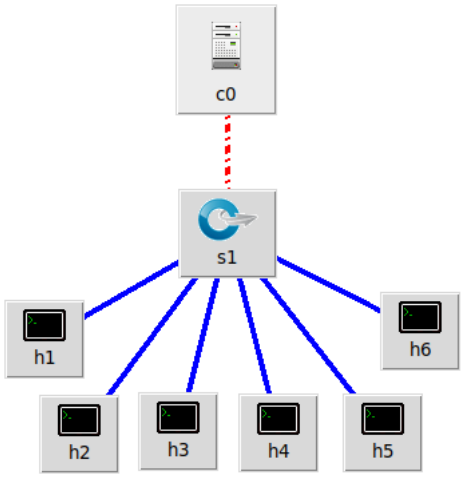

Fig. 2. Testbed environment.

We have used the Mininet generator to create SDN network topology on Ubuntu 22.04 LTS installed on a laptop with an intel core i3 processor, RAM - 4GB, Hard disk - 30GB. We used the Ryu controller for network management and monitoring (We justify the choice of the controller in Section IV-A). The SDN network set-up includes a Ryu controller, one open vSwitches (s1) acting as DNS server, and six end-hosts (h1-h6). The non-malicious hosts are h3 and h4, and the malicious host is h1. To generate normal traffic between non-malicious hosts, we used iperf3 and ping command and we generated an attack (ARP spoofing - MITM attack) traffic using Ettercap. The use of Wireshark assisted us in retrieving more details or information about the attack.

‡https://www.wireshark.org

A. Choosing the Suitable Controller for our Simulations

To choose the suitable controller to be used in our simulations, We evaluated three existing controllers designed for mininet environments: Ryu, Pox and Floodlight. The evaluation was inspired by the work presented in study [11]. The parameters used for comparison are presented in Table II.

The evaluation was done by generating traffic and varying the number of switches from 5 to 100 in order to obtain accurate results. During this time, data related to bandwidth and latency were collected and the resulting graphs are presented in Fig. 3(a) and Fig. 3(b). The evaluated controllers are Ryu, Pox and Floodlight. In Fig. 3(a), we observed that overall, the Pox controller consumes more bandwidth compared to the Ryu and Floodlight controllers, especially when the number of switches is less than 64. At the same time, the Ryu controller consumes more bandwidth than Floodlight. However, in Fig. 3(b), we observed that the latency is overall the best when using the Ryu controller compared to the Pox (medium) and Floodlight (Bad) controllers. In conclusion, among the evaluated controllers, Ryu is moderate in bandwidth consumption and the best for latency. For this reason, it was selected and used in our simulations.

B. Attack Detection using Flow Table

After traffic is generated by an attacker, the protocol stores any information about each incoming packet according to different fields defined in the flux table. By inspecting this table and the contained information, we were able to detect the presence of a MITM attacker in the communication between the two non-malicious hosts as illustrated in Fig. 4. It shows the contents of the flow table before and after attack generation. Before the attack, normal traffic between the non-malicious hosts is observed without interference in their communications. After the attack is launched, the attacker initiates, intercepts and manipulates the communication between the legitimate hosts by impersonating one of the two entities according to the sent packet. The highlighted green and red areas respectively represent the non-malicious and the attacking hosts.

C. Capturing Network Traffic using Wireshark

We used wireshark for overall network capture and analysis to detect the attack and to have more details and information about the attack. Fig. 5 illustrates a wireshark capture of all traffic generated in the network. We can observe normal communication between network hosts using the ICMP protocol. An example of attack traffic is observed by the area highlighted in red where we note a host which initiates communication between the two non-malicious nodes to intercept and manipulate the traffic. We also observe that the protocol used is modified in ARP since in the ARP spoofing attack, the size and the information on the packets are modified.

Fig 6(a) and 6(b) illustrate the content of a request and a response sent from the attacking host; when communicating with a non-malicious host. They show the request and reply content from the attacker. Each of these messages contains a header and a body specific to it. The header allows to see some information about the message in transit. That is, the detection of an attacking host is effective, both in packet transmission and reception.

D. Performance Based on Bandwidth and Latency

Bandwidth is used to determine a network's ability to transfer information/packets over a defined period. Generally expressed in Mbits/sec (can also be expressed in Kbits/s or Gbits/sec), in our work, we expressed it in Gbits/sec. Latency in a network is the time it takes for an entire data packet to be sent from one point to another. It is measured in milliseconds (ms) and can be influenced by various factors such as the distance between the two points, the quality of the connection, and the number of hops between the points. To compare our algorithm according to bandwidth and latency in the network, we simulated an exchange of packets and collected the associated data to represent it in graphs illustrated in Fig. 7(a) and 7(b).

Fig. 7(a) depicts the comparative bandwidth results of our algorithm (MitAL) and the work of Anass et al.[9] (CBNA). The results show that: for five (5) switches the CBNA consumes less bandwidth than MitAL, however, for $n = [10, 20, 32, 64, 100]$ where n is the number of switches, MitAL consumes less bandwidth than CBNA. From this comparison, we can conclude that our algorithm minimises the bandwidth consumption.

Fig. 7(b) shows the latency between our algorithm (MitAL) and the work of CBNA framework of Anass Sebbar et al. [9]. The graph obtained from the collected data illustrates that for $n = [5, 10, 32, 100]$ where n is the number of switches, the latency occurred by MitAL is better than that of CBNA. This comparison show that our algorithm minimises the latency since in most of the considered points our algorithm achieved better performances.

E. Traffic without Protection vs. Traffic with MitAL

Fig. 8 shows the comparison between the network traffic without protection and the traffic with our proposed solution (MitAL). We can observe and conclude that when the network is not protected and the attack is generated, the packet transmission time is high which means that the latency is high. Unlike with our algorithm and the associated security protocols, we observe that this time is considerably reduced. This shows the effectiveness of our protocol.

F. Detection Rate by Number of Generated Attacks

To evaluate the performance of our algorithm, we used the attack detection rate parameter. This rate is determined from the number of generated attacks, and it shows the performance in terms of detection when the MITM attack generated from different sources. It is computed using evaluation metrics such as throughput, available bandwidth when the attack is generated, and analysis of network communications to determine healthy packets from the number of packets exchanged, attacked and lost (percentage).

We have compared MitAL to the solution by Anass et al. (CBNA) [9] and that of Sahri et al. (CAuth) [10]. The comparison graph is provided in Fig. 9. When analysing that figure, we can conclude that our solution outperforms CBNA and CAuth when the number of generated attacks increases until it reaches 60. From that point, the detection rate is still better for MitAL compared to CAuth, but less than that of CBNA, which is quite satisfactory.

Attack detected and Prevent to port : 1
```

Fig. 10. System response to block attacker.

G. Discussion

In the previous sections, we presented results that we generated through simulations. The results show that the detection of malicious nodes is efficient. Secondly, the results provide detailed information about the attacks (the MAC addresses, the protocol used, and the data contained in the packets). Once an attack is detected, the protocol displays information about the attacking node and builds a flow rule to block its communication in the network by blocking its connection port as shown in Fig. 10.

As presented in Table III, our proposed MitAL protocol for DNS servers in an SDN architecture aims to address MITM attacks like CBNA [9] unlike CAuth [10] that address the IP Spoofing attacks. The secure methods used by MitAl are authentication, latency and cryptographics keys while CBNA

only uses latency and CAuth uses authentication. Furthermore, CAuth and CBNA are based on TLS as a security protocol while MitAl uses both TLS and SSL. Finally, it should be noted that MitAL has a detection rate of 86%, which is higher than the 82% of CBNA and the 75% of CAuth protocols.

V. Conclusion

The DNS is the victim of many kinds of attacks that are difficult to detect and prevent. Among these attacks, are MITM attacks. MITM attacks cause several problems in real-life networks such as tampering, integrity violation and exposure or divulging of confidential or user data. In this paper, we proposed a scheme which is based on SDN architecture. The scheme detects and blocks the MITM attacks on DNS servers. We first presented our designed SDN architecture then we proposed an algorithm that is implemented by the SDN controller to guarantee the security of communications between different trusted hosts of the network, and finally, we presented the simulations results we generated through simulations. The results show that our secure algorithm is effective and efficient in detecting MITM attacks. A comparison with other existing algorithms shows that our proposed solution is superior. We therefore recommend our proposed algorithm (MitAL) as a suitable candidate for use to mitigate the effects of MITM attacks on the DNS server. Despite our results being satisfactory, we believe that the use of Machine Learning techniques can significantly improve the efficiency of our solution. This aspect will be explored in detail in future

***Abstract*—Edge Computing (EC) provides computational and storage resources close to data-generating devices, and reduces end-to-end latency for communications between end-devices and the remote servers. In smart cities (SC) for example, thousands of applications are running on edge servers, and it becomes crucial to manage resource allocation and load balancing to improve data transmission throughput and reduce latency. Kubernetes (k8s) is a widely used container orchestration platform that is commonly employed for the efficient management of containerized applications in SC. However, it does not integrate well with certain EC requirements such as network-related metrics and the heterogeneity of EC clusters. Furthermore, requests are equally distributed across all replicas of an application, which may increase the time taken for processing, since in the EC environment, nodes are geographically dispersed. Several existing studies have investigated this problem, unfortunately, the proposed solutions consume a lot of node's resources in the cluster. To the best of our knowledge, none of studies considered the cluster heterogeneity when deploying applications that have different resource requirements. To address this issue, this paper proposes a new technique to deploy applications on edge servers by extending Kubernetes scheduler, and an approach to manage requests among the different nodes. The simulation results show that our solution generates better results than some of the state-of-the-art works in terms of latency.**

***Keywords*—Latency; Kubernetes; edge computing; Internet of Things; load-balancing**

I. Introduction

The fusion of Internet of Things (IoT) and edge computing has revolutionized distributed computing, enabling real-time data processing and analysis at the network edge in metropolitan cities [1, 11]. Various technologies are enhancing urban life. Numerous fundamental departments of cities such as transportation, power plants, information systems, crime detection traffic monitoring, etc. are equipped with sensors to gather data on community services. The endeavour to construct a smart city entails an increasing number of sensors and a growing volume of traffic. This evolution also impacts applications operating within smart city-related frameworks. Thus, thousands of applications are running in real-time on nodes at the edge layer. So they need to be organised well and orchestrated to serve efficiently each activity sector. Kubernetes (k8s), a leading container orchestration platform, has extended its reach to the edge, offering sophisticated tools for managing containerized applications in this decentralized environment [15, 3]. However, orchestrating containers on heterogeneous edge clusters poses significant challenges. Edge nodes come in diverse forms, ranging from resource-constrained sensors to powerful edge servers, each with distinct processing capabilities and network connectivity. Also, the edge layer is made up of several heterogeneous machines forming a cluster. Some machines are much more powerful than others; consequently, certain processes, such as artificial intelligence training, need to be run on much more powerful machines, while certain processes, such as saving and collecting multimedia data, can be run on less powerful machines.

Despite heterogeneity, smart deployment of applications and efficient utilization of computing resources require the distribution of incoming requests across machines within the cluster. These tasks fall under the kube-scheduler which is the component in charge of application deployment on nodes in a Kubernetes cluster, and under the ingress controller and kube-proxy components, which play a significant role in balancing the workload and optimizing performance across heterogeneous edge nodes. Several existing works designed to improve latency and throughput in edge computing-based IoT networks using Kubernetes as a container orchestration tool have been proposed in the literature. However, some of the proposed techniques designed to extend the default kube-scheduler consume a fair amount of energy due to the workload on nodes [12, 9]. Others use custom orchestrators running in containers in the same cluster [20, 7], which consumes the hardware resources of machines whose main aim is to respond as quickly as possible to end-user requests. Some use strategies to distribute requests fairly among the nodes in the cluster using the kube-proxy component. This does not guarantee a significant reduction in latency given that they do not consider some node hardware resources during the load-balancing process [14]. In this paper, to address the latency problem in an Edge computing-based IoT network using Kubernetes for container orchestration, we first introduce a solution to deploy applications on edge nodes depending on the resources required by these applications to run smoothly on the cluster nodes. Secondly, we propose an approach to manage load-balancing and distribute the requests among the nodes of the cluster while considering hardware resources available on cluster nodes. Thus, the contribution of this paper is summarized as follows

This work is based on the research supported by the National Research Foundation of South Africa (Grant Numbers: 141918)

- We show how the default kube-scheduler can be extended to evaluate and provide a score to applications and deploy them on edge nodes in an efficient way while considering the type of nodes and the available resources.
- We explore the complexities of container orchestration at the edge using Kubernetes, emphasizing the importance of accommodating cluster heterogeneity and implementing request distribution mechanisms for better load-balancing.

The remainder of this paper is organized as follows: Section II reviews the related works. Section III presents our approach to addressing the latency problem, while in Section IV we present the simulation results and discuss the performance of the proposed approach. Finally, Section V concludes the paper and discusses the perspectives of our proposal.

II. Literature Review

This section aims to present the works that are related to our study. We start by presenting kubernetes in Section II-A, then, the state of the art on works that use Kubernetes as orchestrators to reduce the latency in Section II-B.

A. What is on Kubernetes?

Kubernetes is a prominent open-source platform designed to streamline the deployment, management, and scaling of containerized applications. A Kubernetes cluster comprises of master nodes (or control planes) and worker nodes. Applications are run in units called pods, that serve as Kubernetes, the smallest execution units [16]. The control plane manages the worker nodes and the pods within the cluster. In production environments, the control plane operates across multiple computers, and a cluster generally encompasses multiple nodes, ensuring fault tolerance and high availability. Fig. 1 shows the kubernetes cluster architecture.

The control plane components are responsible for making overarching decisions regarding the cluster, such as scheduling, identifying and reacting to cluster events, such as initiating a new pod when necessary. These components have the flexibility to operate on any machine within the cluster. However, to streamline operations, setup scripts commonly initiate all control plane components on a single machine, and also avoid executing user containers on a machine. The control pane has four main components: (1) **kube-apiserver** is a key component also known as API server for the Kubernetes control plane that serves as an interface for the Kubernetes API and acts as its primary gateway. (2) **etcd** is a database within which Kubernetes information like metadata, current state and desired states are stored. (3) **kube-scheduler** is the control plane component that monitors created pods without assigned nodes and selects suitable nodes for their execution. Finally, (4) **kube-controller-manager** is the control plane component responsible for executing controller processes.

The worker nodes are responsible for the applications (pods) that are running in the cluster. They mainly have three components that run on every worker node, with the main role of maintaining the running pods and providing the Kubernetes runtime environment. (1) **kubelet** is a node-level agent that helps to ensure the operational status of containers within pods. (2) **kube-proxy** operates as a network proxy and serves as a fundamental component of the Kubernetes service framework. Finally, (3) **Container runtime** is an essential element that enables Kubernetes to efficiently run containers.

In a Kubernetes cluster, relying on the IP address of an application pod for access can be challenging due to the pod's IP changing upon restart. To ensure application reachability, a layer of abstraction known as a service is employed to expose groups of application pods to clients. Each service is assigned a virtual IP address, called ClusterIP, which remains unchanged unless recreated, thus guaranteeing application reachability within the cluster. However, ClusterIP is only accessible within the cluster. To enable access from outside the cluster, services can be configured with NodePort or LoadBalancer. With NodePort, a static port is opened on each node, allowing access through nodeIP:port from inside or outside the cluster. LoadBalancer leverages the cloud provider's load-balancing mechanisms to externally expose the service. Traffic accessing an application is routed to its pods and monitored by the service, with routing decisions based on kube-proxy modes such as userspace, iptables, and IPVS.

By default, kube-proxy operates in userspace mode, utilizing a round-robin algorithm for traffic distribution. Alternatively, iptables mode randomly selects a pod for traffic handling. For large-scale applications, IPVS offers more efficient routing algorithms including round-robin, least connection, destination hashing, source hashing, shortest expected delay, and never enqueued. Another important component in Kubernetes is the horizontal pod autoscaler (HPA), which is in charge of creating automatically new pods of an application if the existing pods are overloaded, or deleting some of them if the application is not being used.

B. Overview of Works using Kubernetes as Orchestrator

Many recent studies have focused on the integration of Kubernetes for load-balancing management in edge computing-based IoT networks. Although Kubernetes has some limitations in edge computing-based IoT networks, the works presented in study [4, 19] show that it remains a promising candidate for managing load balancing and improving latency and throughput. Cilic et al. [5] found that Kubernetes and its distributions hold promise in facilitating efficient scheduling across edge network resources. Nevertheless, several challenges remain to be addressed to optimize these tools for the dynamic and distributed execution environment inherent in edge computing. In research [10], Han et al. introduced Kais, a learning-based scheduling framework for such edge-cloud systems to improve the long-term throughput rate of request processing. Unfortunately, in their work, some nodes have a high workload, while others are under-utilised. Goethals et al. [8] proposed FLEDGE, A container orchestrator compatible with kubernetes, leveraging Virtual Kubelets, primarily targeting container orchestration on resource-constrained edge devices. They did not integrate the fact that edge nodes are most of the time heterogeneous, and in their implementation, they also did not consider the distribution of user requests among the nodes, which does not allow them to achieve better results in terms of latency and bandwidth. Phuc et al. [16] proposed an extension of the default HPA whose role is to offer the

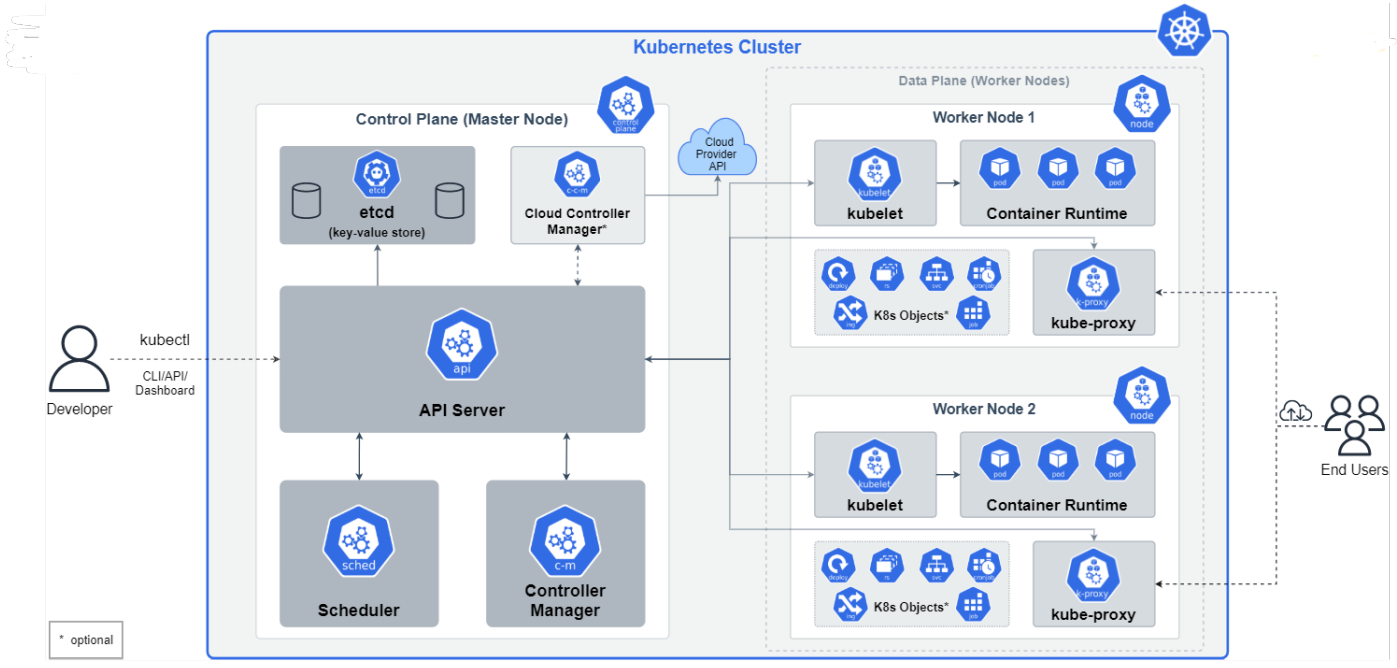

Fig. 1. Kubernetes cluster architecture [2].

resource autoscaling capability. However, the HPA allocates pods to worker nodes without considering the resource demand imbalances in edge computing environments. Authors in [16] considered upscaling and downscaling actions based on network traffic information from nodes to enhance the load-balancing of IoT services in the edge computing infrastructure. Their solution increased throughput and response time between edge nodes, but it doesn't guarantee that a pod that required a lot of resources will be executed on a worker node having the requirements to run that kind of application; therefore, if a particular pod is running on the wrong node, it can increase energy consumption and end-users requests can take too much time to be executed, resulting in high latency. In study [13], the authors studied KubeEdge, which is an open-source platform based on Kubernetes, that aims to orchestrate containerized IoT application services in IoT edge computing environments. In study [6], authors proposed a multi-application hierarchical autoscaling framework tailored for Kubernetes edge clusters. A mechanism based on applications nominates optimal deployment choices through workload prediction and various criteria to ensure application performance while minimizing infrastructure provider costs. This strategy achieves significant improvement in the average allocated resources and energy consumption but it doesn't operate during the first deployment of the application on the servers. Nguyen et al. in study [14], proposed a scheme named Resource Adaptive Proxy (RAP) that considers metrics like latency between worker nodes, Central Processing Unit (CPU) and Random Access Memory (RAM) on worker nodes in order to efficiently distribute the end users requests among the worker nodes. Unfortunately, RAP algorithm does not monitor other cluster resources such as graphics processing units and storage. Rac et al. in STUDY [18] introduce a methodology aimed at reducing the operational costs of applications across the edge-to-cloud computing continuum. Authors in study [17] proposed EdgeOptimizer, a solution that serves as an online testbed for verifying kubernetes-based algorithms, offering detailed configuration options to facilitate cluster management. Unfortunately, their solution does not evaluate the hardware resources consumed by the applications running on their most complex use cases in order to efficiently schedule their deployments in Kubernetes clusters in an edge computing environment.

So far, several works that aim to integrate Kubernetes distributions for container orchestration in edge computing-based IoT networks have been presented. The purpose of doing that is to reduce the latency by managing the load-balancing in edge computing-based IoT networks when considering all the requirements of the edge computing environment. Unfortunately, despite the effectiveness of these solutions, there are still some limitations that need to be addressed while considering Kubernetes for container orchestration in edge computing-based IoT networks.

Edge nodes are heterogeneous and some of them can run faster, some resource-constrained applications than others, and it is therefore important to schedule application deployments by considering the best nodes on which they will efficiently run. Secondly, since Kubernetes and recent works do not integrate network-related metrics and resources like Graphical Processing Unit (GPU) and storage for load-balancing properly. It is important to enhance them and propose solutions to achieve better latency and throughput. Finally, default Ingress-Controller and Kube-proxy components distribute evenly end-users requests among the pods without considering the available hardware resources on the worker nodes. In this work, we address these issues and propose a solution that schedules deployment of containerized applications on worker nodes efficiently, and secondly manages load-balancing by distributing requests among the worker nodes while considering hardware metrics and effective locations of the pods on the worker nodes.

III. Contribution

This section presents our contribution for enhancing latency between end-users and edge layer in edge computing-based IoT networks deployed in smart cities using Kubernetes for container orchestration. The strategy we are proposing consists, on the one hand, extension of the default kube-scheduler installed on the master, to enable it to deploy pods while taking into account the minimum hardware resources required to run those pods and the types of machines in the cluster having these hardware resources. On the other hand, enhancing the default Kubernetes load-balancing algorithms and integrating other metrics with CPU and RAM to manage the workload on the edge layer nodes.

A. Assumptions and Notation

The following assumptions are done for this work:

- There are several edge nodes geographically dispersed in a smart city, and thousands of applications are running on them;
- All applications are containerised using docker, and Kubernetes is used for container orchestration;
- The master node has powerful resources and can launch virtual machines for a sandbox environment, which is a dynamic area where developers can play with codes without fear of disrupting the larger system and where they can test their solutions;
- The worker nodes in the cluster are heterogeneous;
- It is possible to evaluate the hardware resources consumed by a running container and assign a score to that container depending on the resources it consumes;
- It is also possible to evaluate a machine and assign it a score according to its resources;

In Table I, we have a list of notations that will be used to describe our solution

B. Kube-scheduler Awareness

We propose an extension to the default kube-scheduler installed on the master node. In Section II-A, we have described the behaviour of the default kube-scheduler and at the end of Section II, we highlighted some of the limitations of this component. To address these limitations, we propose the integration of a robot installed on the master node, that can evaluate the hardware resources consumed by a running container and decide on what kind of nodes it can be deployed. So, to put our proposed solution into practice, developers will have to expose test endpoints for the most resource-intensive use cases in their applications before they are deployed on the cluster. Thus, before the deployment of containers on the cluster, the kube-scheduler performs the following operations:

- When the kube-scheduler receives a new container for deployment purposes on the cluster, it first deploys it in the sandbox environment (virtual machines running on the master node);
- Once the said application is deployed in the sandbox environment, the robot starts and simultaneously tests all the endpoints exposed by the container. The idea is to overload this application as much as possible and monitor the resources it requires when it is running at full speed;
- A score S is given to a container based on the resources it needs when running at maximum speed :
  - If $S \geq T_{appHGPU}$, then the kube-scheduler will consider only nodes having high GPU and high CPU capacity for the deployment of the new container;
  - If $T_{appLGPU} \leq S \leq T_{appHGPU}$, then the kube-scheduler will only consider nodes having low GPU and high CPU capacity for the new container deployment;
  - If $T_{appHCPU} \leq S \leq T_{appLGPU}$, then the kube-scheduler will only consider nodes having acceptable CPU and high GPU capacity for the new container deployment;
  - If $T_{appLCPU} \leq S \leq T_{appHCPU}$, then the kube-scheduler will only consider nodes having acceptable CPU and low GPU capacity for the new container deployment;
- After the score S is assigned to an application, its deployment is faster and easily done because only some nodes will be considered depending on that score;
- Otherwise, all the nodes likely to host a pod are overloaded, the new pod will be deployed on the worker in the higher level.

Since thousands of applications are running at the same time on edge nodes in a smart city, it is important not to over-use or under-use the nodes by choosing which application to run on what kind of node, so that this node will execute user requests with the highest possible speed compared to the other nodes on the network. The parameters that we used to evaluate the score of an application are RAM, CPU, GPU, network bandwidth between nodes's components and storage (HDD or SDD). Each parameter is assigned a weight W: then the weight for the amount of RAM used by an application is W_{RAM}, for the amount of CPU used is W_{CPU}, for storage memory is W_{Stor}, for the GPU is W_{GPU} and for bandwidth is W_{BW}. Also, we define N_i as the amount of hardware resource i consumed by a running application: so, let N_{RAM} be the amount of RAM used by a running application, N_{CPU} the amount of CPU used by the same running application, N_{Stor} the amount of data stored by that application during its execution, N_{GPU} the amount of GPU used and N_{BW} be the amount of bandwidth used by that application. Since the measurement units of each parameter differ, their values have to be normalized. Thus, the score S of a running application is given by:

$$S = \frac{W_{RAM} \times N_{RAM}}{max_{RAM}} + \frac{W_{CPU} \times N_{CPU}}{max_{CPU}} + \frac{W_{Stor} \times N_{Stor}}{max_{Stor}} + \frac{W_{GPU} \times N_{GPU}}{max_{GPU}} + \frac{W_{BW} \times N_{BW}}{max_{BW}} \quad (1)$$

where max_{RAM} is the highest value of RAM memory among all the nodes in the cluster, max_{CPU} is the highest value of CPU among all the nodes in the cluster, max_{Stor} is the highest

TABLE I. NOTATIONS

Notation	Explanation
CPU	Central Processing Unit
GPU	Graphical processing unit
RAM	Random Access Memory
N_i	Amount of hardware resource i consumed by a running application
$T_{appHGPU}$	Threshold value for an application to be launched on nodes having high GPU capacities and high CPU capacities
$T_{appLGPU}$	Threshold value for an application to be launched on nodes having low GPU capacities and high CPU capacities
$T_{appLCPU}$	Threshold value of an application to be launched on nodes having acceptable CPU capacities and low GPU capacities
$T_{appHCPU}$	Threshold value of an application to be launched on nodes having acceptable CPU capacities and high GPU capacities

value of storage memory among all the nodes in the cluster, max_{GPU} is the highest value of GPU among all the nodes in the cluster and max_{BW} is the highest value bandwidth among all the nodes in the cluster.

Algorithm III.1 shows the different stages executed by the Kube-Scheduler before new containers deployment on worker nodes.

Algorithm III.1: Kube-scheduler awareness

Input: *App*: a containerized application to deploy on the cluster

Begin
- Reception of the container (*App*) to deploy on the cluster ;
- Deploy container *App* in the sandbox environment on Master ;
- Evaluate the score S of container *App* using equation 1 ;
- **if** $S \geq T_{appHGPU}$ **then**
  - only consider nodes having high GPU and high CPU capacity for the deployment of *App*;
- **if** $T_{appLGPU} \leq S \leq T_{appHGPU}$ **then**
  - only consider nodes having low GPU and high CPU capacity for the deployment of *App* ;
- **if** $T_{appHCPU} \leq S \leq T_{appLGPU}$ **then**
  - only consider nodes having acceptable CPU and high GPU capacity for the deployment of *App* ;
- **if** $T_{appLCPU} \leq S \leq T_{appHCPU}$ **then**
  - only consider nodes having acceptable CPU and low GPU capacity for the deployment of *App* ;
- Deploy container *App* on the selected list of nodes ;

C. Load-balancing Awareness

In smart cities, end users send thousands of requests to the edge layer of an edge computing-based IoT network. Default load-balancing algorithms implemented on kube-proxy are userspace, iptable and ipvs, which are not suitable in the edge computing environment. In this section, we propose to use RAP protocol [14] where we integrate other metrics like storage and GPU in the nodes evaluation process considering that the number of nodes for the redirection of requests is reduced since custom applications are running on custom nodes. When a request arrives at a node, it performs the following operations:

- If the current node is running the target pod and has sufficient hardware resources, it executes locally the request and sends the response to the user;
- Otherwise, if it is not running the target pod, it sends the later to the node having the best score [14] and that is running the target pod. The redirection is done faster than in [14] because only a few nodes will be considered for the redirection.

So in this approach, user requests are performed mainly local on the node that receives the request, reducing the risk of latency during request redirection. In addition, in the case of redirection, the selection algorithm runs faster because the list of nodes to be considered is reduced since only some nodes run particular applications. In Fig. 2 the default kube-scheduler and HPA deploy applications on worker nodes without considering the minimum requirements of that application. For example, the best nodes that can run App1 are worker 3 and worker 4 but since they are already running an instance of App1, the next instance of App1 is deployed on worker 1 which will not process requests faster on App1 because of its hardware resources. Also, the default userspace algorithm implemented on kube-proxy component for load-balancing distributes requests evenly among the worker nodes. Thus, when worker 4 receives request number 6 to be executed by App1, it forwards it to worker 1 since App1 on worker 1 is only performing request number 3. So in addition to the delay between worker nodes 1 and 4 (7ms), you need to add the time required by worker 1 to perform requests on App1 which is not negligible.

In Fig. 3, pods are deployed on the best nodes that can perform user requests faster. For example, App1 is deployed on worker nodes 3 and 4. Also, user requests are executed locally most of the time, and are only redirected if the pod receiving the request is overloaded or if the node receiving the request is not running the target pod; for example, request number 4 on worker 4 to App2 (in orange) is redirected on worker 1. Therefore, as shown in Fig. 3, the HPA can delete the second instance of App2 on worker 1, and the two instances of App3 on worker 2 since they are not used; this will contribute to free resources on these nodes.

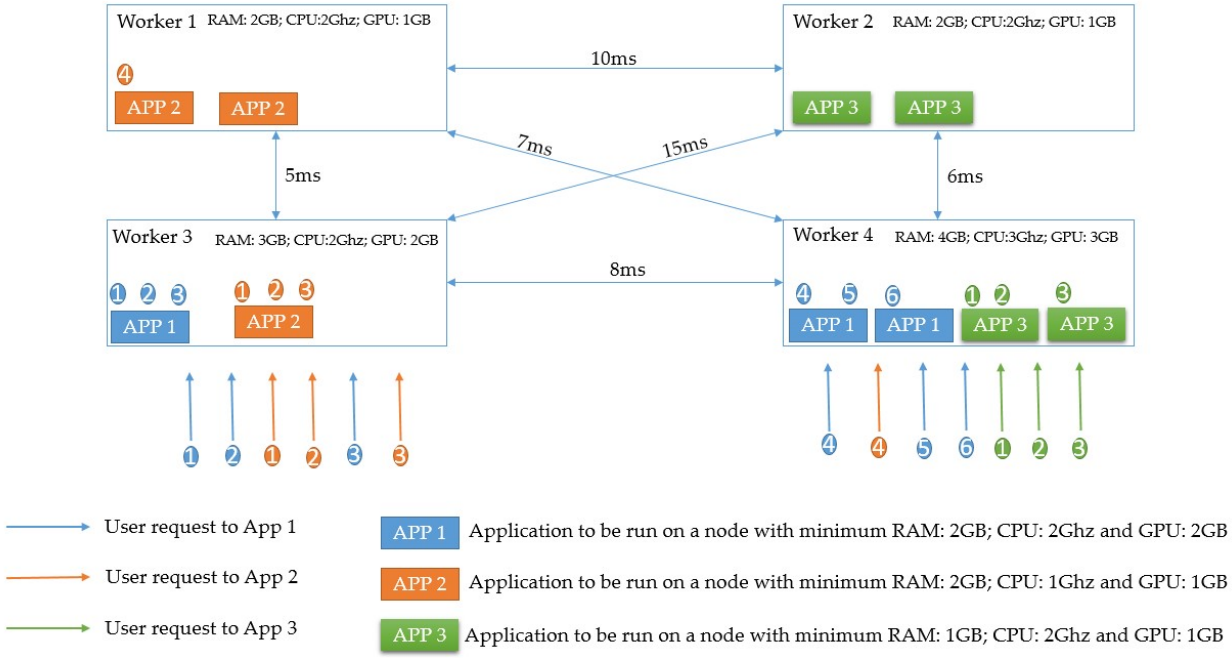

Fig. 3. Our extended kube-scheduler and load-balancing algorithm.

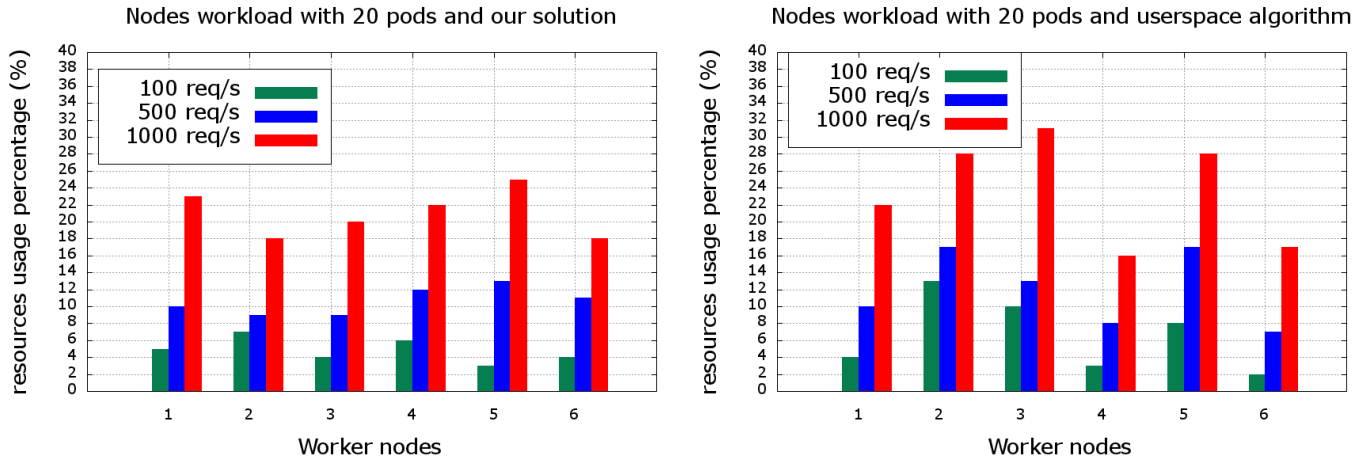
IV. Simulations and Results

In this section, we present the results of our simulations.We installed microk8s V1.26 which is a lightweight distribution of Kubernetes on a cluster with one master node and 6 worker nodes. The characteristics of each node are given in Table II. Also, requests to our Kubernetes cluster have been simulated with the Apache HTTP Server Benchmarking (AB) tool, which is a utility that tests the performance of a server. It has been designed to give an idea of the level of performance of an installation. In particular, it allows one to determine the number of requests an installation can process per second.

A. Workload on Worker Nodes

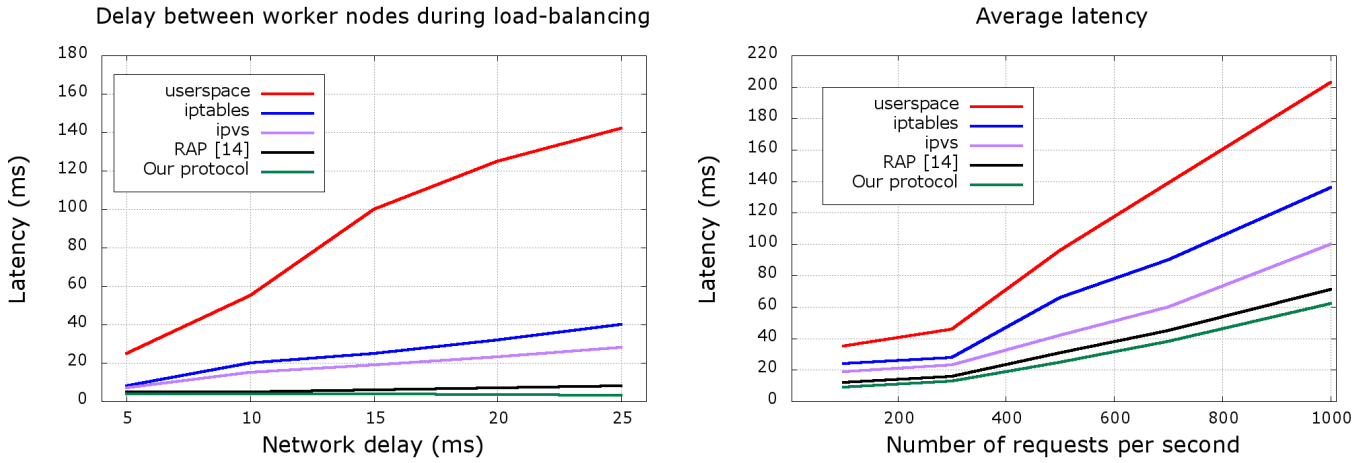
Fig. 4 shows the evaluation of the workload on each worker node when there are 100, 500 and 1000 requests per second (req/s) arriving at the cluster with 20 pods. Fig. 4a shows the results when nodes implement our load-balancing algorithm. All the pods are distributed among the worker nodes while considering their resources. The workload is well distributed among the nodes and there are no cases where some nodes are over-used while others are under-used. Fig 4a shows that when 500 req/s are arriving on the cluster, worker 1 uses 10% of its resources, worker 2 uses 9% of its resources, worker 3



(a) Workload on worker nodes with our approach

(b) Workload on worker nodes with userspace algorithm

Fig. 4. Evaluation of workload on worker nodes.



(a) Latency between worker nodes

(b) End users requests latency

Fig. 5. Latency evaluation.

TABLE II. NODES CHARACTERISTICS

Node	Hard drive type	Number of CPU	disc storage (GB)	RAM (GB)	CPU (Ghz)	GPU
Master	SSD	5	250	8	3.5	4
Worker 1	SSD	2	120	3	2.5	2
Worker 2	SSD	3	150	2	1.8	3
Worker 3	SSD	2	100	3	2.8	1
Worker 4	SSD	4	180	2	3.0	2
Worker 5	SSD	2	150	4	2.0	2
Worker 6	SSD	3	100	2	3.1	2

uses 9%, worker 4 uses 12%, worker 5 uses 13% and worker 6 uses 11% of its resources. However, Fig. 4b shows the results when the default userspace algorithm is implemented. It shows that, when 500 req/s are arriving on the cluster, worker 1 uses 10% of its resources, worker 2 uses 17% of its resources, worker 3 uses 13%, worker 4 uses 8%, worker 5 uses 17% and worker 6 uses 7%. Fig. 4b shows that, even if the requests are evenly distributed among the worker nodes, some pods are not deployed on the appropriate worker nodes; and therefore, these nodes are overused. These evaluations have been made while executing the most resource-intensive use cases of each pod. That is, with the use of our proposed solution, pods are deployed on the most suitable nodes in the cluster so that even if they are in demand, they can perform operations and deliver responses faster.

Results shown in Fig. 4 are supported by those presented in Table III, which shows the comparison between our protocol

TABLE III. EVALUATION OF STANDARD DEVIATION

Protocol	100 req/s	500 req/s	1000 req/s
Our protocol	1.37	1.49	2.59
userspace algorithm	3.97	4	5.73

and the default userspace algorithm in terms of the standard deviation of the workload on worker nodes. The standard deviation with our protocol is 1.37 when there are 100 req/s, while the one of the userspace algorithms is 3.97. When there are 500 req/s, the standard deviation with our protocol is 1.49 while the one of userspace is 4; and when there are 1000 req/s, the standard deviation with our protocol is 2.59 while the one of userspace is 5.73. These results show that the workload on worker nodes when using our protocol does not vary a lot compared to the cases with userspace.

B. Evaluation of Delay Between Worker Nodes During Load-balancing and Its Impact on Latency

Fig. 5a shows the evolution of the latency when the network delay between two worker nodes increases. Since in edge computing, worker nodes are geographically dispersed, the latency between worker nodes plays a key role in load-balancing management. Our protocol was compared to the RAP protocol [14] and the default routing decisions implemented in kube-proxy such as userspace, iptables and ipvs. Fig. 5a shows that userspace is the worst because of its round-robin algorithm and its performance varies from 25ms to 140ms; iptable which varies from 8ms to 40ms is better than userspace because while performing its random algorithm it often selects the closest node to transfer requests; ipvs which is tailored for large scale applications perform better than userspace and iptable. RAP protocol [14] is better than all the default routing decisions implemented in kube-proxy because it executes as many as possible requests locally on the node that received the request, and forwards them only if the local node has no capacity; moreover, the forwarding of a request takes into consideration the hardware resource on the other nodes and the delay between them. Our protocol is the best because our routing algorithm is not only based on the one proposed by [14], but also takes less time because the workload is reduced, thanks to the scheduler distributed pods while considering the scores and the nodes on which they can be deployed. Thus for load-balancing purposes, only a few worker nodes are considered in the routing algorithm.

We also evaluated the average latency of our solution when the cluster receives 100 to 1000 requests per second and compared the obtained results with userspace, iptables, ipvs and RAP [14] as presented in Fig. 5b. While latency with userspace varies from 35ms to 203ms, it varies from 24ms to 136ms in iptables, from 19ms to 100ms with ipvs, from 12ms to 71 ms in RAP, and finally from 9ms to 62ms in our solution. Our solution is the best because of two main reasons, the pods are distributed on suitable nodes which perform user requests faster and secondly, it is based on RAP protocol [14] for load-balancing algorithm. Fig. 4a shows that the workload is well distributed among the nodes even when several pods are running, and Fig. 5a shows that even if the delay between worker nodes increases, the latency for load-balancing management between those nodes is still weak. So, the fusion of these results helps to show that the network latency of our solution is the best.

V. CONCLUSION

This paper presents our approach to enhance latency in an edge computing-based IoT network with Kubernetes as the container orchestrator. This approach extends the default kube-scheduler component deploys pods on the best nodes in the cluster, and then distributes requests among the worker nodes to manage load-balancing. The results show that this approach is promising and better than other approaches in terms of latency. In future work, we plan to examine throughput and a politic for moving containers from one node to another when necessary to increase latency. We also plan to reduce latency by deploying pods according to the geographical regions in which they are used effectively, using machine learning techniques.

***Abstract*—Microgrids are crucial for ensuring reliable electricity in remote areas, but integrating renewable sources like photovoltaic (PV) systems presents challenges due to supply intermittency and demand fluctuations. Demand-side management (DSM) addresses these issues by adjusting consumption patterns. This article explores a DSM strategy combining load shifting (shifting demand to periods of high PV generation), peak clipping (limiting maximum load), and valley filling (redistributing load during low-demand periods). Implemented in MATLAB and tested on a PV-battery microgrid, the strategy significantly reduces peak demand, improves the peak-to-average demand ratio (PAR), and enhances system stability and flexibility, particularly with the inclusion of deferrable loads.**

***Keywords*—Demand side management; microgrid; load shifting; peak clipping; valley fill**

I. Introduction

In recent decennials, an evolution in conventional power grid structure has taken place due to uncertain distributed renewable generation (URG) and advanced communication and control technologies [1], [2]. The increased utilization of deep penetration URGs and the improvement of demand-side resources (DSR) development have been seen as two important technological advances for supporting the sustainable expansion of today's energy infrastructure, enabled by the objective of total cost reduction [3]. A microgrid (MG) that can be incorporated with various URGs, advanced energy storage systems (ESS), and DSRs represents a sustainable way to deliver renewable, clean electricity as a vital part of the power transformation of conventional electricity production systems [4].

Microgrids (MGs) are stand-alone systems that support the integration of distributed power resources (DERs) and renewable energies for both reliability and profitability [4]. They are important components of intelligent energy transmission and distribution networks that regulate the electrical system's resilience under unfavorable conditions.

The various solutions for supplying rural areas with electricity are extensions of the national grid, autonomous systems, or microgrids [5]. Microgrids, or small electrical networks, have become a major solution because they can function independently. They are essential to developing an electrical infrastructure built around locally available renewable energy technologies at considerably reduced costs. In addition, they can accelerate access to electricity in areas where it is impossible to extend the grid in the short or long term.

To ensure that the electrical system becomes more reliable and robust, the peak demand is considered as opposed to the average demand. As a result, environmental resources are being wasted and production systems are being under-used. Rapid-response power generators (e.g. gas and oil-fired units), employed to satisfy the demand peak, not only cost a lot of money, they also generate high levels of carbon emissions. As a response, various packages were presented to help users shape their energy use profiles. These programs aim to make efficient use of the generation available so that new transmission and generation infrastructure is installed as little as possible. Such programs, referred to as demand-side management (DSM) programs, are designed to program consumption or reduce it [6].

A DSM program provides support for power grid functionalities in various areas, such as electricity market control, infrastructure maintenance, and management of decentralized energy resources [7]. In electricity markets, it informs the load controller about the latest load schedule and possible load reduction capabilities for each time step of the next day. Using this procedure, it schedules the load according to the objectives of interest associated with the power distribution systems [8], [9]. The load shapes indicate industrial or residential consumers' daily or seasonal electricity demands between peak hours (PHs) and off-peak hours (OPHs). These shapes can be modified by six techniques [9], [10]: peak clipping, valley filling, load shifting, strategic conservation, strategic load growth, and flexible load shape.

Both peak clipping and valley filling are techniques for controlling loads directly. While peak shaving is concerned with peak load reduction, valley filling takes into consideration load shaping on off-peak loads. The best and widely employed method of managing load in today's electricity networks is load shifting. It involves shifting the load from the PH to the OPH. In the case of conservation strategy [10], demand reduction methods are used at the customer's end to obtain optimal charging patterns. If the load requirement is greater, the daily response is optimized using distributed energy resource load augmentation techniques [11], [12].

The principal aims of the DSM are to remodel a load profile and regulate the highest and lowest day-to-day power requirements to make the most of power sources and prevent the need to construct new generation power plants. This may result in the consumption of electricity. Many DSM technologies are designed to maximize efficiency to avoid or reduce the need to build more power plants. Further reasons to implement DSM techniques include social relations and environmental considerations, by modifying customers' power consumption patterns at peak and off-peak times to conserve power [13].

In this paper, three DSM methods were applied for a microgrid of model photovoltaic solar panels with real measured demand as well as radiance data to show the benefits of energy efficiency which is currently lacking on the island of Djerba, Tunisia. A model system was simulated in the MATLAB software using the DSM load-carrying capability. The principal research contributions of this work are summarized in detail below.

- The DSM methods of load shifting, load capping, and valley filling were applied on a microgrid model of the island of Djerba, Tunisia.
- Substantial power consumption savings can be realized through corresponding generation and load demand requirements without deep-discharging of battery storage.
- The global load profile is enhanced by exploiting available renewable energy resources to a large extent, thus minimizing total reliance on the storage system.

The remaining sections in this paper are structured in the following way. In Section II, we describe the configuration of the microgrid, in Section III we present the DSM method and its features, and in Section IV we present the DSM problem. Section V presents the detailed results and discussion, while Section VI concludes the paper.

II. Configuration of a Microgrid System

A schematic representation of the proposed microgrid system is shown in Fig. 1. This system comprises three different groups of units. The first includes energy production units with photovoltaic panels. The second is comprised of energy consumption units, principally residential electrical loads. The third is dedicated to energy storage, as represented by a typical battery bank.

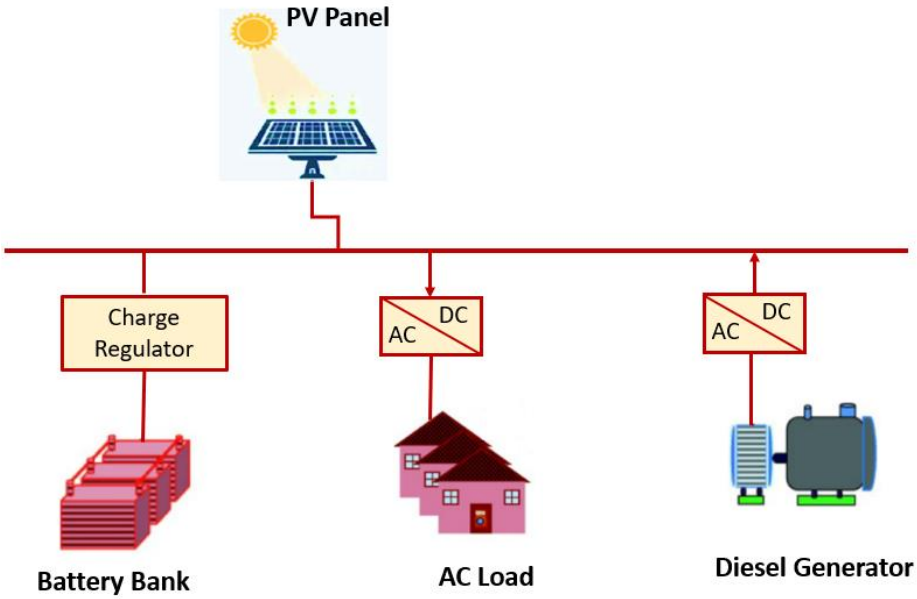

Fig. 1. Schematic representation of the proposed microgrid system.

III. Demand Side Management

Demand side management (DSM), also known as energy demand management, consists of implementing strategies and procedures to improve the efficiency of an energy system on the supply and demand side. It enables us to manage, control, influence, and generally minimize power consumption, giving us a better perspective on the potential of renewable energy systems, or making effective use of those systems that have been installed. Such strategies can provide substantial financial advantages to energy end-users and reduce carbon emissions. The measures aimed at reducing energy consumption do not necessarily have to be costly, and can often even be provided free of charge, making them easy to implement in development regions [14]. According to the [15] definition of demand-side management, DSM comprises three main concepts: demand response, energy efficiency, and energy conservation.

The demand response (DR) approach involves modifying customer electricity consumption, shifting load from periods of peak demand to off-peak times, and using active demand pricing strategies: by modifying electricity prices over time (when it's off-peak, it's less expensive) or through inducement payments, these offer customers an incentive to reduce their demand for energy at a particular period of the day. DR is usually linked to advanced energy metering technologies that provide information to end-users on their consumption of energy.

DSM can be implemented in several ways, and Fig. 2 shows several categorizations of DSM with associated load shapes. Peak clipping aims at reducing demand during peak hours. Utilities achieve this control by incentivizing customers not to consume power during peak hours, directly controlling loads, or setting up higher prices. The method is helpful in cases with no possibility of setting up or installing new power plants [16]. Valley filling focuses on raising usage during periods of very low electricity profile to keep demand and supply balanced, avoiding the startup and ramp-up costs of generators [17]. Load growth is more common when using electric vehicles, where customers are encouraged to increase usage up to a certain threshold for grid stability [18]. Load shifting gives consumers options to shift their usage pattern to off-peak hours based on cheap tariffs.

It is the combination of load clipping and valley filling [19], [20]. Flexible load shaping is when consumers are flexible enough to shift their loads to different low-usage slots. Usually, customers willing to participate in this are identified and incentivized for their participation [16]. Energy efficiency is when the overall load profile is lowered throughout the day by using more energy-efficient devices or through cyclic operation [21].

A demand curve is formed by various DSM technologies [21], as illustrated in Fig. 2, additionally, but without limitation:

- Load shifting: The main objective of load shifting is the transfer of load from peak to off-peak hours.
- Conservation: The best-known approach to reduce global consumption of electricity, and not only at peak periods.
- Peak clipping: The main aim of this strategy is to reduce demand at peak times (e.g. 7 p.m.). Energy consumption is reduced by the control of equipment that can be switched off, like air conditioners or heaters, by the customer or the electricity supplier.
- Valley fill: Under valley fill, the demand for load increases in off-peak hours and reduces during peak hours.
- Load growth: Unlike the conservation approach, with load expansion, the overall amount of electricity sold (off-peak and on-peak) increases.
- Load Shape Flexibility: With this technique, the utilities have the power to discontinue loading as required, and without notifying the customer. Changes in the quality or quantity of service are generally described as flexible load shapes.

Practically all the DSM programs are designed and implemented to optimize the use of existing power plants. Another crucial objective is to avoid, defer, or delay the construction of much-needed new power plants (both renewable and conventional).

A. Demand Response

These programs are recent developments in demand-side management, involving consumers' participation in improving their energy consumption patterns in response to instantaneous price variations [21]. They are seen as an effective solution to some of the problems of deregulated power systems.

Demand response enables industrial, commercial, and residential customers to optimize their electricity consumption to obtain reasonable prices and improve grid reliability. In other words, it can modify electrical energy consumption to reduce peak loads and shift consumption to off-peak hours [22]. Demand response methods generally fall into two categories: electricity price-based programs and incentive-based programs. Fig. 3 illustrates this classification.

In this article, among the various demand management programs, the load shifting program has been used to reduce peak load and increase load during periods of low demand (i.e. peak load reduction and load trough filling). There are also restrictions on time-of-use shifting for each of the loads.

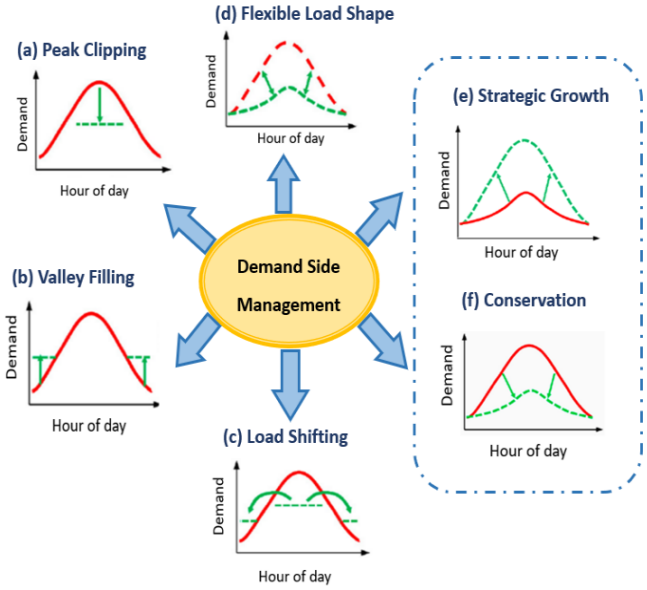

Fig. 2. Classification strategies for demand-side management.

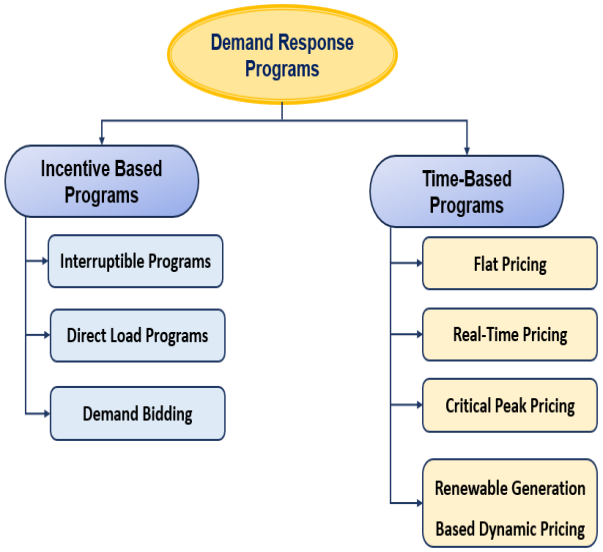

Fig. 3. Different types of demand response programs.

To illustrate the process of implementing the Demand Side Management (DSM) method, the following pseudo-algorithm describes the key steps in the approach used:

Algorithm 1: Pseudo-code of the DSM proposed algorithm

Step 1
Enter data, including renewable energy production (solar irradiance), load demands, system parameters (PV area, yield), and threshold values for demand-side management (DSM).
Step 2
Calculate hourly energy production using input data and system parameters.
Step 3
Initialize load curve for DSM operations (load shifting and peak shaving).
Step 4
Identify periods with significant energy production.
Determine the time of maximum energy production.
Step 5
For each period of the load curve:
If the load exceeds the DSM threshold:
Calculate excess load above a threshold.
Reduce the load to a threshold level.
Redistribute excess load to adjacent periods with sufficient energy production (Load Shifting).
Step 6
For each period of the modified load curve:
If the load still exceeds the threshold:
Limit load to threshold level using Peak Clipping.
Step 7
Apply the Valley Fill method:
Identify periods of low demand (valleys) in the load curve.
Redistribute non-critical load from high-demand periods (after Load Shifting and Peak Clipping) to these low-demand periods to smooth the load curve.
Step 8
Repeat steps 5, 6, and 7 until the load curve is optimized.
Step 9
Return the optimized load curve and analyze the results.
End

IV. Problematic Demand Management System

For a microgrid system that includes the use of photovoltaic (PV) generation, optimization of power consumption is a crucial factor in reducing costs and maximizing the utilization of renewable resources. Two strategies commonly used to meet this objective are demand-side management (DSM):

- Peak Clipping: The purpose of this strategy is to reduce the maximum power requirement by clipping and reducing loads above a specific level.
- Load Shifting: With this approach, loads are shifted during peak periods to periods when photovoltaic generation is most available, thus minimizing dependence on conventional sources.
- Valley Fill: In this method, the loads in periods when demand is low are increased to fill the valley of demand, thus leveling out demand and optimizing the use of available resources, thereby minimizing variations and dependence on traditional sources of energy.

A. System Modeling Equations

1) Power generated by the photovoltaic system: The output generated by the photovoltaic panels, P_{PV} (t), is given in the equation below:

$$P_{PV}(t) = \eta_{PV} \times A_{PV} \times I_{rr}(t) \quad (1)$$

Where:

η_{PV}: representing the efficiency of the photovoltaic panels.

A_{PV}: represents the overall area of the panels in m2.

$I_{rr}(t)$: represents the solar radiation in W/m2 at the time t.

2) Peak clipping strategy: The peak reduction is achieved by setting a maximal limit P_{seuil} above which the load output is restricted:

$$P_{load\_clipped}(t) = \min(P_{load}(t), P_{seuil}) \quad (2)$$

Where:

$P_{load}(t)$: is the initial load at the current time.

P_{seuil}: is the limit value selected.

3) Load shifting strategy: The load shift consists of shifting the surplus charge from the peak times to the times when the photovoltaic generation is highest. If at a given time t, the $P_{load}(t)$ load is above the limit, the $P_{exces}(t)$ surplus is determined as described below:

$$P_{exces}(t) = P_{load}(t) - P_{seuil} \quad (3)$$

This excess is allocated to the hours of most significant PV generation (defined as more than 50% of the maximum PV generation):

$$P_{load\_shifted}(h) = P_{load\_shifted}(h) + \frac{P_{exces}(t)}{N_{PV}} \quad (4)$$

Where:

h: denotes a time selected for redistribution.

N_{PV}: is the total number of hours selected for redistribution.

4) Valley-filling strategy: A valley fill approach involves the redistribution of under-utilized capacity at times of low demand (off-peak hours) to cover the valleys in the load curve. If the load $P_{load}(t)$ is less than a predetermined level at a given time t, the load deficit $P_{deficit}(t)$ is calculated in the following equation:

$$P_{deficit}(t) = P_{seuil} - P_{load}(t) \quad (5)$$

To smooth demand, this deficitis then assigned to the periods of lowest photovoltaic production (defined as less than 50% of peak photovoltaic output):

$$P_{load\_filled}(h) = P_{load\_filled}(h) + \frac{P_{deficit}(t)}{N_{low\_PV}} \quad (6)$$

Where:

h: represents a period selected for the redistribution.

N_{low_PV}: represents the number of total hours selected for the redistribution when the photovoltaic output is low.

5) Mathematical formulation of optimization: The general objective of the problem is to minimize the peak loads and maximize the utilization of renewable energy. The problem can be expressed in the following terms:

$$\min\left(\max P_{load\_final}(t)\right) \quad (7)$$

With the constraints below for peak clipping:

$$P_{load\_final}(t) \leq P_{seuil} \quad (8)$$

Excess load is redistributed in a balanced manner during load shifting, with consideration of PV generation. This approach ensures that load adjustments align with solar energy production, optimizing efficiency and reducing reliance on non-renewable sources

V. Results and Discussion

A. Basic Case

This study utilized a dataset from a microgrid located on the island of Djerba in Tunisia, with a maximum solar power capacity of 889.128 kW. This remote microgrid is designed to supply power to the island's communities, contributing to the region's energy independence and sustainability. The analysis was conducted over a week during which irradiance measurements were taken, to assess the load profile and irradiance patterns to evaluate the solar power generation of the system. Fig. 4 illustrates the power consumption over this period, Fig. 5 presents the irradiance data, and Fig. 6 represents the photovoltaic system's power output. Comparing these results with similar studies in microgrid systems reveals consistent trends in power production and consumption patterns, particularly in remote island contexts. Studies conducted in other island communities show similar variability in solar irradiance and load profiles. However, our findings suggest that the Djerba microgrid demonstrates higher efficiency in converting solar energy, likely due to optimized PV system design and favorable climatic conditions. This has important consequences for isolated microgrid design and operations, underlining the necessity for an enhanced energy control strategy. In comparison to earlier research, this study underscores the potential for enhancing load-shifting techniques and optimizing storage systems, which could further reduce reliance on backup generators and improve overall energy efficiency in isolated microgrids.

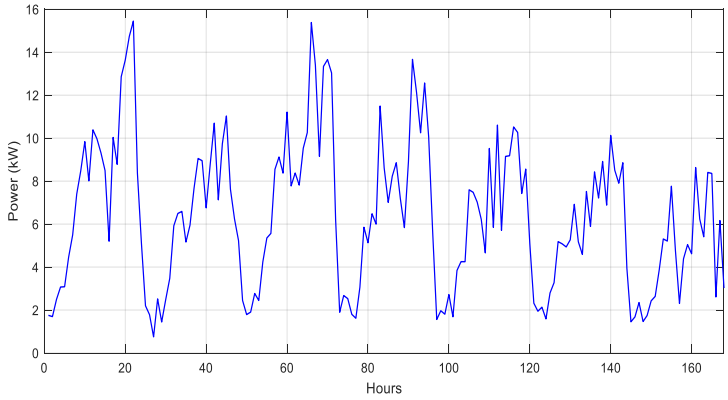

Fig. 4. Weekly load power analysis.

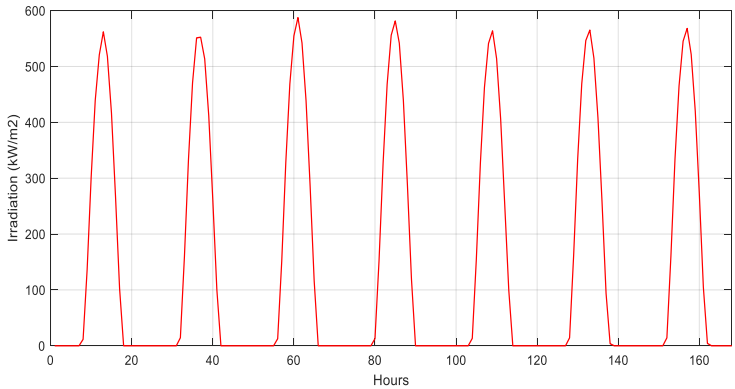

Fig. 5. Weekly analysis of solar irradiation levels.

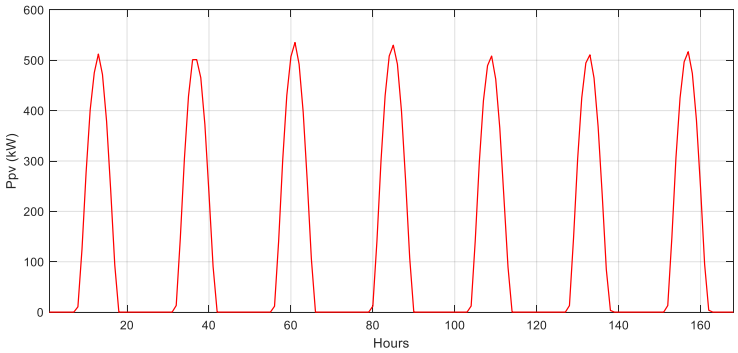

Fig. 6. Weekly performance analysis of photovoltaic power system.

B. *Effect of Peak Clipping*

A controller or switching equipment carries out the peak clipping process. The consumption is continuously supervised and when it rises to levels that give reason for concern, the controller can switch off specific loads to minimize the demand. The loads that can be disconnected are ranked in order of priority, and classified as transferable and non-transferable.

Fig. 7 illustrates the impact that peak clipping has on the hourly load. The blue curve shows the initial load, with significant daily fluctuations. The second curve represents the load after peak shaving, with load values restricted to a 10-kW threshold. The peak clipping process limits the peak consumption to a specified threshold, thereby preventing system surges and stabilizing the energy demand. It effectively holds the load below a monitored level, thus minimizing the potential for power system instability and overloading.

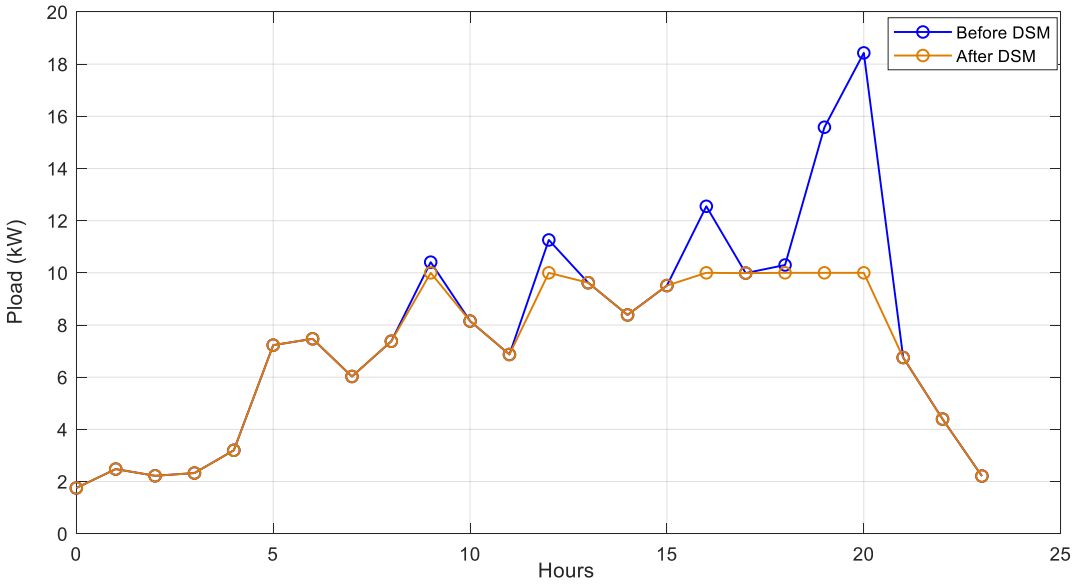

Fig. 7. Impact of peak clipping DSM on load profile.

C. *Effect of Load Shifting*

Fig. 8 presents an example of demand-side management (DSM) implementation through load shifting. An analysis of the results indicates that load shifting has been strategically applied over 24 hours, with most operations scheduled during peak solar irradiation to minimize the need for energy storage. By aligning load utilization with times of highest production, the system maintains a sufficient margin to supply critical loads during peak demand periods, thereby enhancing system stability and preventing overloads. The impact of load shifting on hourly load is illustrated in Fig. 8. The initial load, shown in blue, reveals significant peaks during high-demand periods, while the second curve represents the load after implementing load shifting, where consumption peaks have been effectively smoothed out. This method redistributes surplus load to hours of higher photovoltaic production, resulting in a more uniform demand distribution. Comparative analysis with similar studies shows that load shifting is a widely recognized strategy for optimizing energy consumption in microgrids, demonstrating its effectiveness in reducing peak loads and alleviating pressure on the power supply system. Our findings corroborate previous research, highlighting that load shifting not only enhances system reliability but also supports sustainability efforts by maximizing the utilization of renewable energy resources.

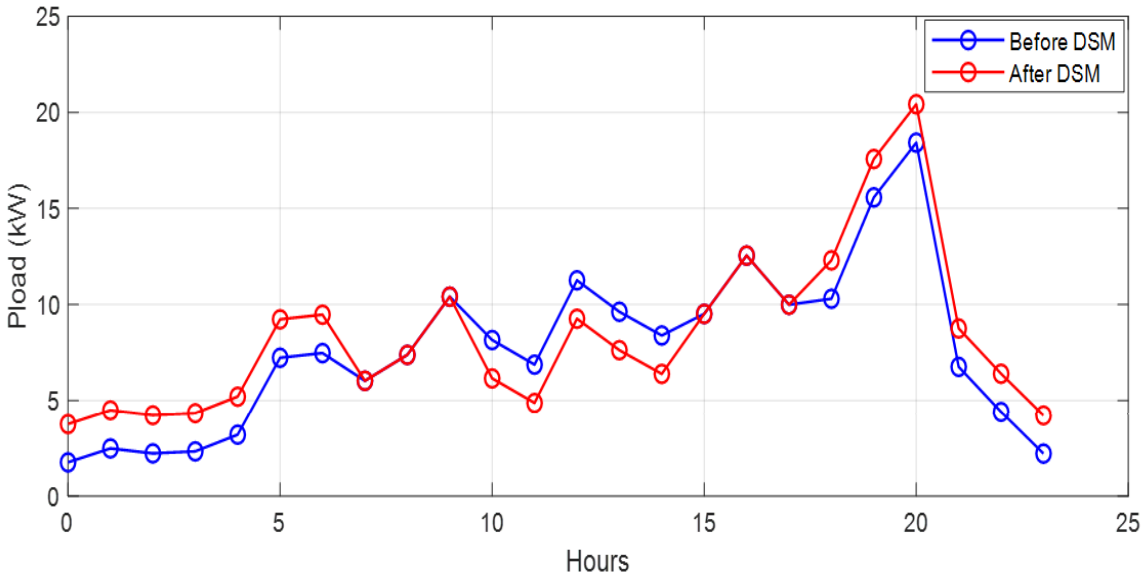

Fig. 8. Impact of Load Shifting DSM on 24-Hour Load Profile.

D. *Effect of Valley Fill*

The Valley Fill approach is implemented in the form of an intentional increase in load during times of reduced demand, usually monitored by an appropriate controller or energy management system. As consumption falls to a critical level, a controller may enable supplementary loads, prioritized based on their ability to transfer loads without affecting the global system. The loads that can be shifted are increased to compensate for any dips in the power curve.

Fig. 9 shows the effect of the Valley Fill method on the load per hour. The initial blue curve represents the load, characterized by steep peaks and troughs during certain periods of the day. The other curve shows the load after Valley Fill has been applied, with the troughs filled to smooth demand. This stabilizes power demand by preventing excess fluctuations, thus reducing the risk of under-utilizing the available energy resources and improving global system efficiency.

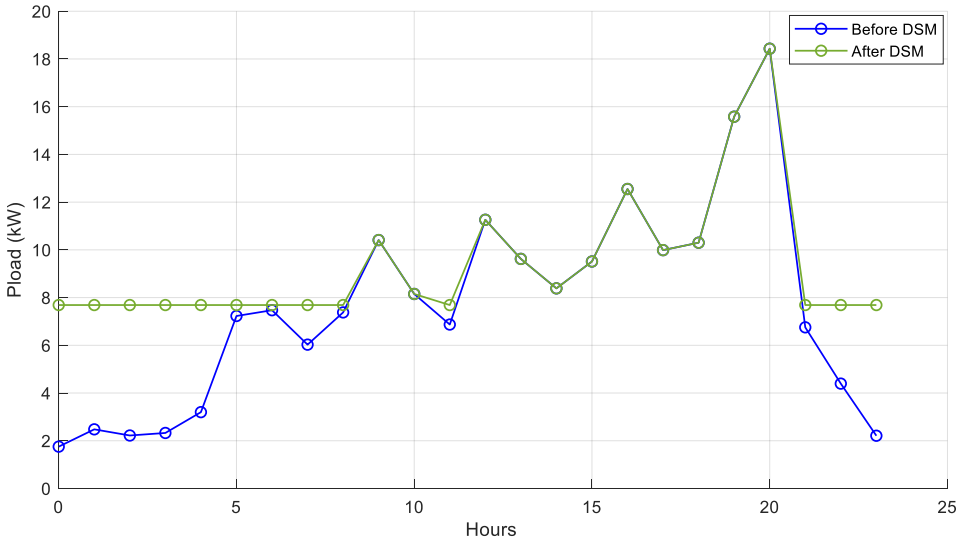

Fig. 9. Load Profile Analysis Before and After Valley Fill DSM.

Shifting reduces power demand and inconvenience in peak hours by switching surplus demand away from the system. Load shifting enables off-peak hours to be rescheduled with a smaller energy consumption reduction, as illustrated in Fig. 10.

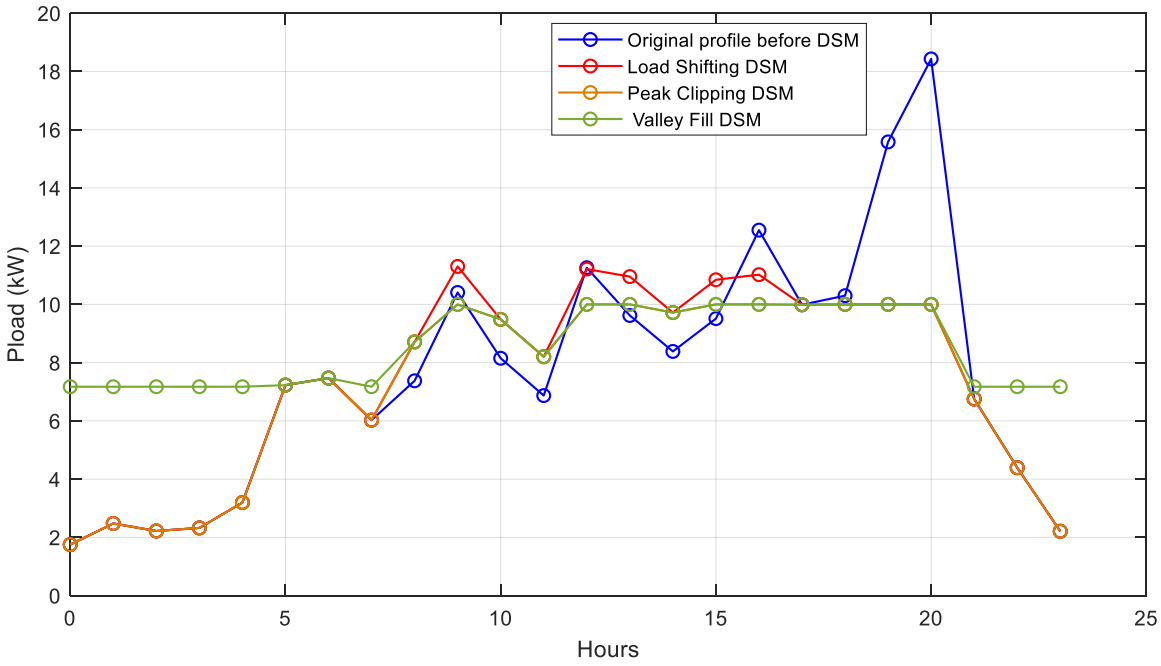

Fig. 10. The impact of DSM strategies on load profile: load shifting, peak clipping, and valley fill.

VI. Conclusion

This study examines energy management in a solar-powered microgrid using the Demand Side Management (DSM) method. The DSM approach was applied to a 24-hour solar microgrid on the island of Djerba, Tunisia, utilizing data from NASA. The results show that after implementing DSM strategies, the load profile aligned more closely with solar generation, as much of the energy demand was shifted to periods of higher solar output. This approach provides a framework for achieving more resilient isolated microgrids by optimizing the use of renewable energy. Additionally, reducing energy consumption in the microgrid enhances system stability and offers cost savings. By improving the balance between load and generation, the method also reduces the need for extensive storage capacity, especially during periods of low solar power availability.

***Abstract*—There is an exponential growth of opinions on online platforms, and the rapid rise in communication technologies generates a significant need to analyze opinions in online social networks (OSN). However, these opinions are unstructured, rendering knowledge extraction from opinions complex and challenging to implement. Although existing opinions mining systems are applied in several applications, limited research is available to handle code-mixed opinions of a non-structured nature where there is a switching of lexicons in languages within a single opinion structure. The challenge lies in interpreting complex opinions in multimedia networks owing to their unstructured nature, volume, and lexical structure. This paper presents a novel ensemble approach using machine learning and natural language processing to interpret code mixed opinions efficiently. Firstly, the opinions are extracted from the input corpus and preprocessed using proposed Extended Feature Vectors (EFV). Subsequently, the opinion mining system is implemented using a novel approach using weighted code mixed opinion mining framework (WCM-OMF) for multiclass classification. The proposed WCM-OMF model achieves an accuracy of 79.11% and 72% for the benchmark datasets, which is a significant improvement over existing Hierarchical LSTM, Random Forest, and SVM models and state-of-the-art-methods. The proposed solution can be implemented in opinion detection of other business sectors beneficial in obtaining actionable insights for efficient decision-making in enterprises and Business Intelligence (BI).**

Keywords*—Opinion mining; Machine learning; weighted ensemble; code mixed; Natural Language Processing; Business Intelligence; Online Social Networks

I. Introduction

With the advent of information and communication technologies, there is an exponential volume of user-generated content [1] available online. However, this data is primarily in the unstructured format in the form of opinions [2-4], suggestions, and forum posts. A further significant chunk of opinions generated are code-mixed. Code mixing is the alternating between two or more languages in a single opinion text source. This renders opinion mining complex to implement and interpret.

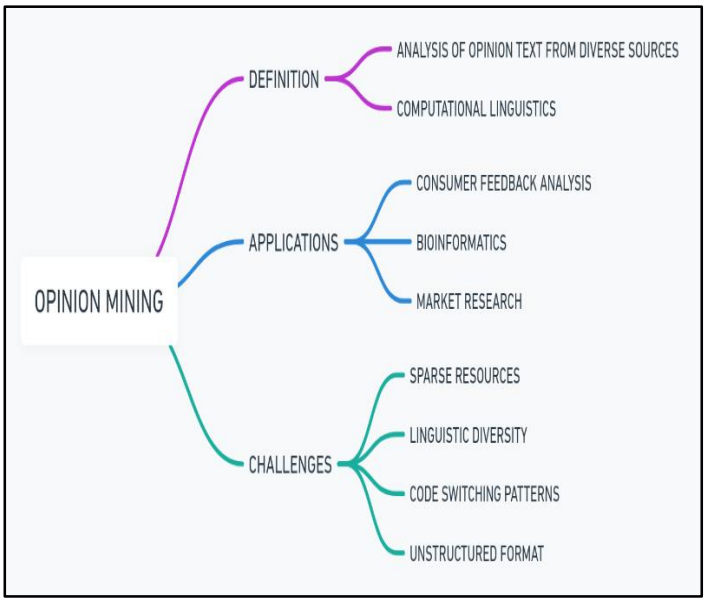

Fig. 1. Opinion mining trends and challenges.

Fig. 1 illustrates the opinion mining trends and challenges in various industrial sectors. The research specifically benefits multilingual cultures [5, 6] wherein multiple users convey the same expression differently despite belonging to the same regional area. Although there are studies related to opinion mining and opinion extraction, there is limited research on handling code-switching issues in opinion corpus. Also, existing studies focus more on mono-lingual input and overlook the lexical nuances of code mixed opinions. Given the aforementioned issue, we have developed a novel weighted code mixed opinion mining framework (WCM-OMF) for handling the code switching challenge. The proposed solution is the design and development of an ensemble method combining natural language processing and machine learning techniques. Compared to the existing systems, the proposed method achieves better results, improving model accuracy and F1 score metrics.

A. Applications of Opinion Mining

Opinion Mining is essential for achieving Business Intelligence in enterprises of several sectors as described in this subsection:

1) Consumer feedback analysis is one of the primary applications of opinion mining [7]. The extraction of consumer opinions and feedback is significant for enhancing the quality of products and services.

2) Manufacturing: Identifying opinions towards a product or service during a specific timeframe is highly valuable for firms, demonstrating the practical benefits of opinion mining in manufacturing.

3) Political analysis: Opinion mining of users about a political candidate [9, 10] or government policy can aid in understanding the public stance on a topic.

4) Risk analysis: Effective opinion mining can help prevent or mitigate risks and significant disasters in public sector companies.

B. Challenges of Opinion Detection

Existing Opinion Detection systems primarily focus on monolingual input. However, there is a vast amount of data in form of code-mixed lexicons. Detecting these opinions poses several challenges, as listed below:

1) Code-switch: The process of alternating between different lexicons in the intrasentential text [5] or opinion renders opinion detection and analysis complex to implement.

2) Lack of standardized datasets: The lack of standardized datasets [6] for machine learning used for interpreting code-mixed data can lower the performance of machine learning models.

3) Unstructured format: Online users utilize non-standardized formats while conveying information [2, 7] that can include abbreviations, special characters, commas, slang, and lexical resources not included in standard machine learning libraries required for interpreting these opinions. This non-colloquial opinion usage makes opinion interpretation complex to implement.

4) Low resource lexicons: Certain opinion corpus categories have low resource availability [9], especially for the lexicon database of languages that are scarcely available.

5) Healthcare domain: Applications in Bioinformatics [8] include techniques for analyzing unstructured clinical data and extracting patient feedback. It can lead to significant insights, especially those that can be overlooked by clinical practitioners.

6) Dialects: Opinions cannot be distinguished from one dialect [10] to another within the same language.

Table I illustrates sample instances of code mixed opinions, translated opinions using API services, and actual interpretation of the Opinion. As observed, there is a variation in actual meaning through accurate interpretation compared to direct translation owing to lexical nuances of code mixed opinions. In order to overcome this challenge, we propose the design and implementation of a Code mixed opinion mining framework using an Adaptive Lemma-based weighted approach and machine learning for multi-class classification.

TABLE I. SAMPLE CODE MIXED OPINION CORPUS

Sr No	Code Mixed Opinion	Translated Opinion	Actual Opinion Interpretation
O1	Online parksha toh ache hain but yaar cheating ko rokna thoda sa mushkil ho jaata hai	Online parking are very good, but it is a bit difficult to stop cheating	Online exams are good friend, but stopping cheating becomes a bit difficult
O2	Ningal ivide thanne irikku	You stay here	Please remain here
O3	Woh kal se gym ja raha hai gr8	He is going to the gym from tomorrow gr8	He's starting gym tomorrow, great.
O4	Enikku oru sambhavam undu parayan.	I have an event to tell.	I have a story to tell you

C. Research Contributions

The major contributions of this research are highlighted below:

1) Design and implementation of novel weighted code mixed algorithm for feature engineering in opinion mining.

2) Efficient handling of code switching problems in code mixed data input.

3) Implementation of multiclass classification using an ensemble of machine learning and natural language processing techniques.

4) We conduct a rigorous performance analysis with state-of-the-art techniques on benchmark datasets to compare the proposed model efficacy for code mixed opinions.

The rest of this research is structured as follows: In Section II, we discuss the background of the literature. Section III describes the proposed solution architecture. The results of the performance analysis and the comparative analysis of related studies are compared in Section IV. Discussion and conclusion are given in Section V and Section VI respectively.

II. LITERATURE REVIEW

In this section, we review the relevant literature and existing opinion mining systems related to our study and research objective. The Intelligent Multi Lexicon Opinion Mining (IMLOM) implementation taxonomy is summarized below and categorized as machine learning, deep learning, and hybrid techniques.

A. Supervised IMLOM Learning

For supervised IMLOM, researchers have adopted conventional machine learning techniques, namely Support Vector Machine (SVM), Naïve Bayes (NB), and Logistic Regression [11], for the Algerian social platform. Other studies also use machine learning approaches. Multimedia network

studies use ML [12] for various domains, like the work done on the climate change crisis [13-14], which highlights the priority levels of different region users and their regional dialects.

B. Unsupervised IMLOM Learning

For unsupervised IMLOM studies, it is observed that authors use deep learning in various application domains. For instance, medical domain analysis for gaining perspective regarding vaccinations [15] being mandatory post-COVID through a survey questionnaire on a sample population selected.

In study [16], deep clustering with embedding was used for document vector recommendations. Deep learning techniques have been applied in further studies with promising results [17-19].

Other studies used Graph Neural Network (GNN) [20], Long Short Term Memory (LSTM) [21], and stacked layering of LSTM. LSTM and stacking mechanism are utilized for the deep learning phase, combining machine and manual translation. Researchers have also employed Convolution Neural Network (CNN) [22] with efficient model development and lingual error analysis.

C. Ensemble IMLOM Learning

Various approaches are adopted for hybridization with variations in preprocessing and classification combinations. In [23], authors use sentence-level embedding combined with the Transformer approach. In study [24], authors hybridize bio-inspired optimization algorithms with recurrent neural networks (RNN) for political corpus. Other popular combinations include CNN, LSTM, Bidirectional LSTM (BiLSTM) feature extraction, and transformer approach [25-29]. Both quantitative and qualitative analyses are conducted to synthesize data effectively. The authors in [30] use the augmentation technique to perform further the LDA-based topic modeling approach and Multilingual bidirectional and Auto-Regressive transformers (mBART), achieving a 71% accuracy level and highlighting the challenge of handling informal text.

Researchers in study [31] achieved significant results by employing the traditional J48 machine learning approach on self-developed data from the extracted contents, applying several linguistic features to analyze the model. Study in [32] implements deep learning methods, and dual datasets are used for cross-pair mapping. However, testing a model trained on one system in another domain yields lower accuracy using source-to-target language mapping. In study [33], the authors highlight the need for a training corpus for Dravidian language content classification into multiple classes. The authors in [34] demonstrated target entity extraction successfully through decisions based on neighboring information. However, the performance was limited by the capabilities of CNN. Alternatively, the shallow neural network [35] is for Spanish input and achieves an F1 score of 0.48. In study [36], the authors preprocess the data corpus and then generate the vectorized using the pre-trained model for emotion detection in online text. Efficiency was lower for heterogeneous content than for the standard English language. Studies in [32, 37 38, 41] utilize LSTM and combinations of other deep learning techniques, including CNN and BiLSTM. Total of five languages, with approximately. 42K social media opinions [39]. The various contexts of words are tackled using a stacked version of the word embedding implementation [40]. Also, a discussion of several research groups currently working on this topic of offensive text in multilingual settings is highlighted [41]. Researchers in [42] proposed a novel method using a combination of deep learning techniques in a stacked format and compared it to standardized machine learning methodologies, including SVM, KNN, and logistic regression. The authors in [43] use Artificial Intelligence for heterogeneous datasets, implementing machine translation using the BART method on Hungarian European content. The study in [44] classifies opinions, employing deep learning techniques to explore opinions towards access to education. We investigate the research papers, and after rigorous analysis of the paper title, abstract, methodology, and conclusion, the initial list is filtered to the most relevant studies.

It is imperative to implement efficient opinion mining frameworks for handling linguistic variability, code-switching, and unstructured format to leverage this vast digital information available, code mixed in the unstructured format, enabling accurate decision making.

III. Proposed Methodology

This section presents the benchmark datasets extracted, data statistics, and the proposed workflow.

A. Dataset Statistics

This section describes the datasets utilized for the experimental evaluation of the proposed work, as explained in Table II. Here, we employ two Benchmark datasets, Bohra et al. [45] and Joshi et al. [46], specifically curated for the problem statement identified as having Filtered data points 4575 and 3879, respectively. These benchmark datasets from the ACL data repository have been further validated through quantitative validation using the Cohens Kappa ITA score. The Bohra dataset has a Kappa score of 0.92, and the Joshi dataset score is 0.64, making it suitable for the proposed framework statistical and qualitative performance validation.

TABLE II. Dataset Statistics for Experimentation

Statistic	Bohra Dataset	Joshi Dataset
Total Data Points Collected	112718	4981
Filtered Data Points	4575	3879
Positive Class Data Points	1661 (Offensive Speech Opinions)	1358
Neutral Class Data Points	Not Available	1939
Negative Class Data Points	2914 (Normal Speech Opinions)	582
Inter Annotator Agreement (Cohen's Kappa)	0.982	0.64

B. Proposed Opinion Mining Framework

In this section, the design and implementation of the proposed technique WCM-OM are explained in detail. Through an extensive literature analysis, we present the comprehensive Intelligent Code Mixed Opinion Mining framework. The majority of the existing frameworks rely solely on a single language or medium, resulting in a significant loss of relevant information. The proposed framework implements a fusion ensemble of statistical features and linguistic features of code

mixed opinions from the input corpus database. Also, we implement data preprocessing for code-switched data to effectively handle the issue of frequent code-switching in an intra-sentential opinion. Fig. 2 illustrates the conceptual framework of the proposed framework. It consists of six significant modules: data acquisition, corpus extraction, data preprocessing for code-switched data, improved feature engineering module using Adaptive lemma-based vector space modeling, hybrid opinion model development, and opinion detection through multi-class classification.

The detailed components are as follows:

1) Data extraction and retrieval: At the initial stage, we retrieve online data content from heterogeneous web sources and unstructured data platforms from their respective programming APIs.

2) Opinion preprocessing: In the next phase, subtasks of NLP, including Stemming, Lemmatization, and irrelevant Noise Removal, are executed. Other subtasks may be required as per the application domain.

3) Lexicon identification: The step for detecting lexicon programmatically is crucial for efficient machine learning and deep learning model implementation. The translation and transliteration involve conversion from 1 lingual and structural format to another, enabling efficient execution of the detection phase given the heterogeneity of opinions.

4) Feature engineering: This phase comprises of feature extraction, transformation, and subsequent vectorization, is executed by employing NLP in several diversified opinion classes.

5) Evaluation: The WCM-OMF model is evaluated using standardized performance indicators depending upon subtasks for measuring the effectiveness of training and test evaluation.

The efficacy of the proposed solution is demonstrated through the comparative analysis of the proposed solution with the existing solution on benchmark dataset 1 (BD1) using standardized performance metrics. These steps are explained in detail in later sections. Further, the proposed weighted ensemble opinion mining framework (WCM-OMF) has been designed and implemented.

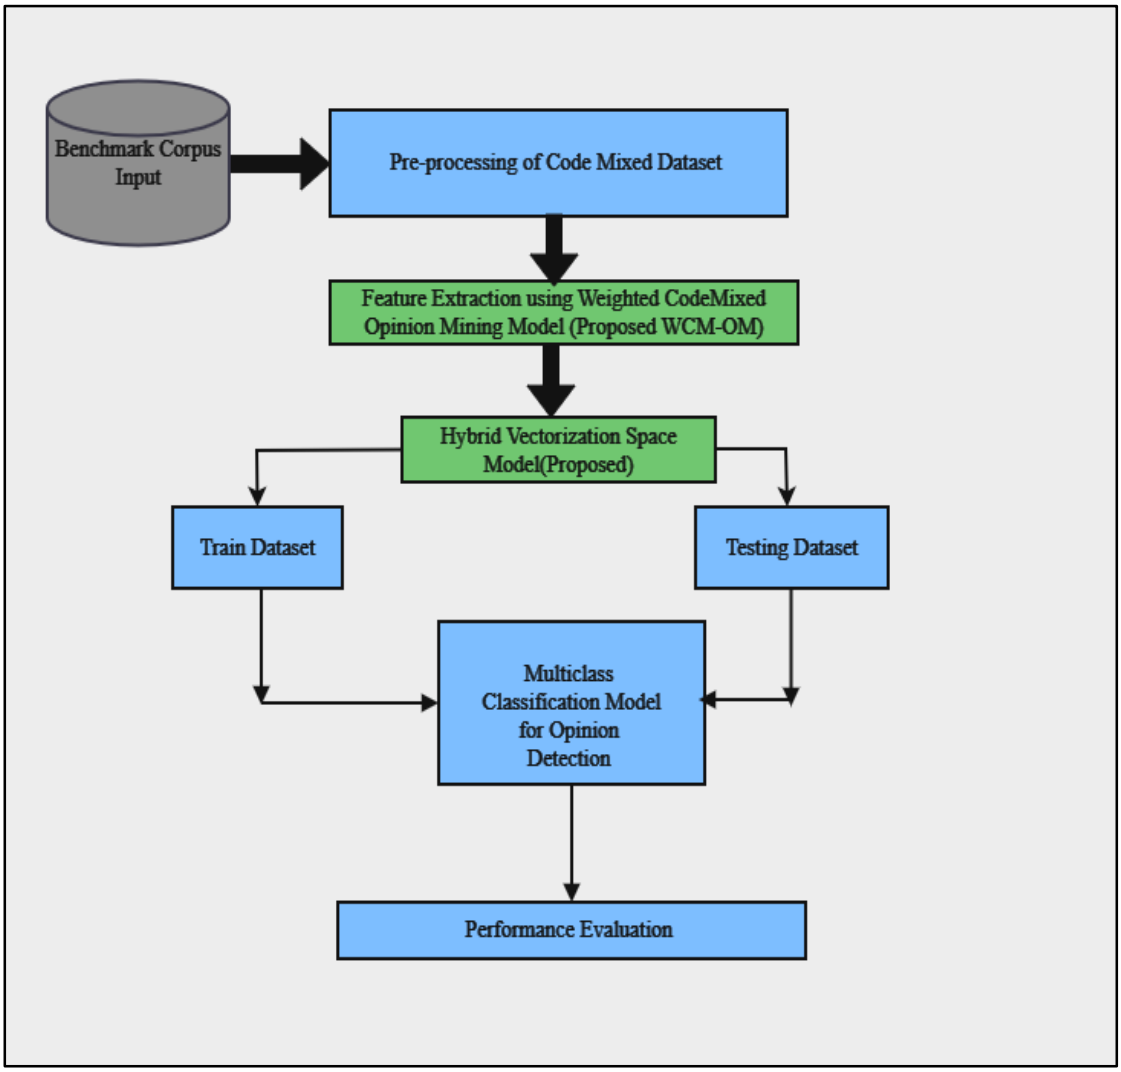

Fig. 2. Proposed opinion mining model conceptual framework.

The proposed solution assigns weights based on the following:

1) The Adaptive Bilingual Influence Weighting (ABIW)

2) The number of code-switches in the initial sentence of the opinion.

We observe that a comprehensive and holistic approach to opinion detection requires the consideration of various factors, and the current state of opinion interpretation requires further improvement consisting of the following key components:

- N: the number of tokens in a segment,
- $LangScore_i$: score indicating the relevance of the language of the i-th token,
- σ : normalization function.

Fig. 3 explains the stepwise analysis of the Proposed Solution Flowchart for the WCM-OM framework. In this architecture, the yellow highlighted cells represent the contributions of the proposed solution.

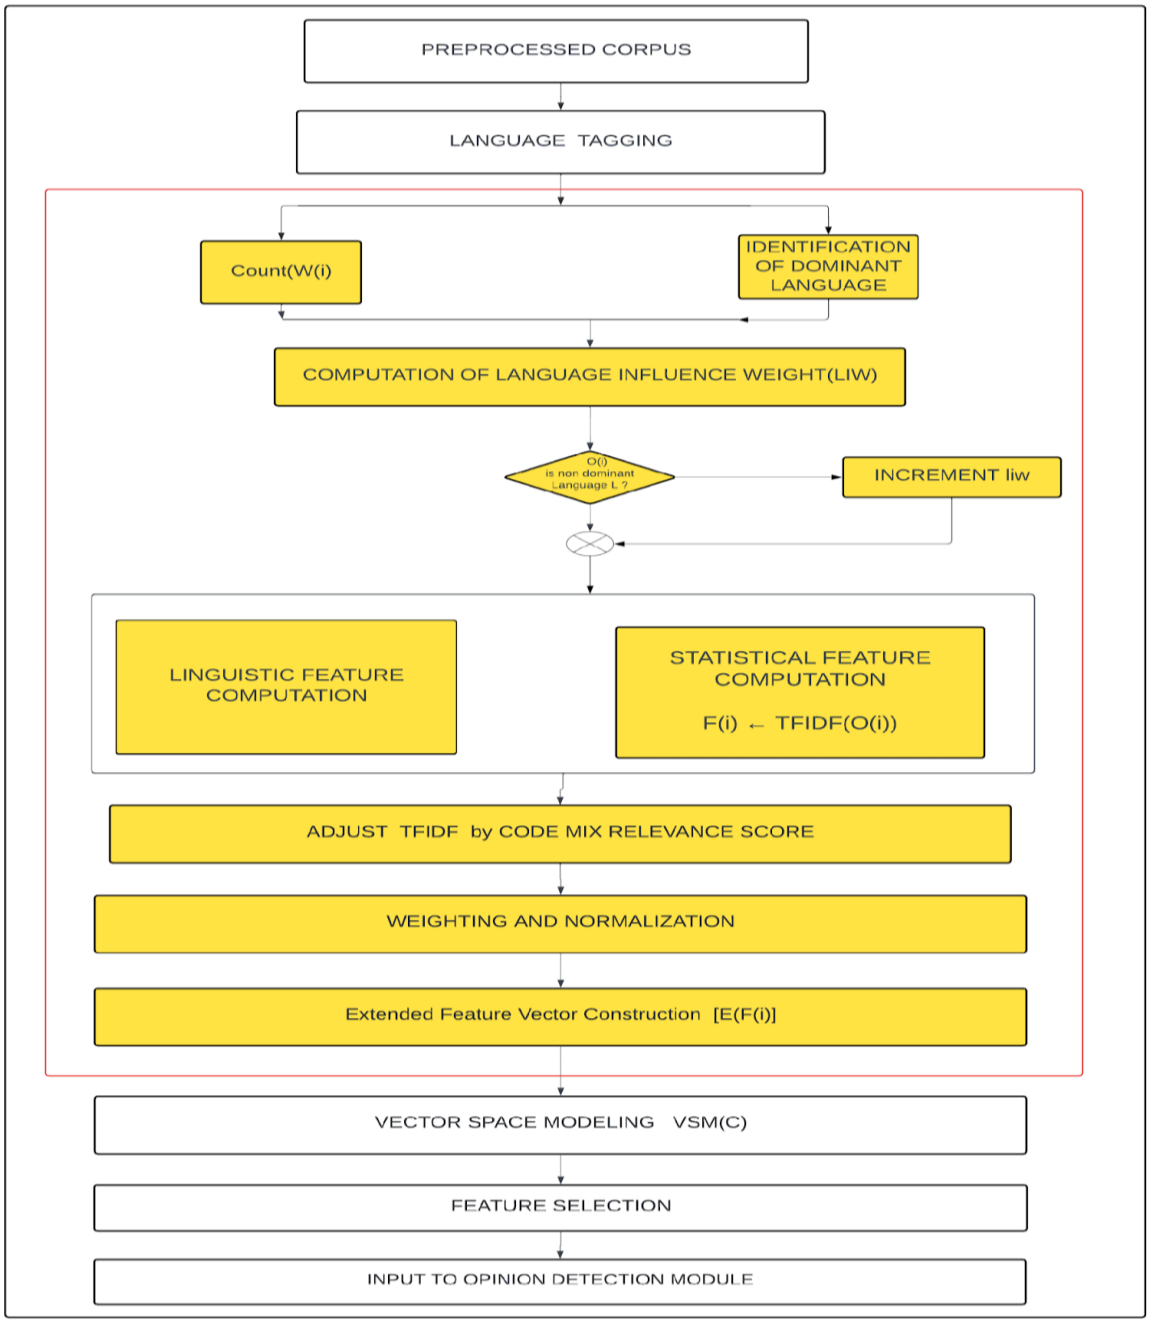

Fig. 3. Proposed WCM-OMF solution flowchart.

Firstly, the preprocessed output from the data extraction module functions as input for WCM-OMF. Thereafter, a language tagging module separates the opinion into parts of speech and tags each sub-block. Subsequently, the ABWI lemma is implemented using Language Influence Weighting (LIW) methods, a proposed metric designed to capture the influence of various lexical contexts in the code-mixed input. ABIW quantifies the extent to which the code-mixed input language contributes to the overall context. Following this, the linguistic feature is computed and combined with the statistical feature to obtain an EFV novel hybrid score. The code-mixed relevance score adjusts the TF-IDF score to get a new score. Weighting and normalization are applied to obtain the final feature vector EF.

C. Proposed Mining Method Mathematical Formulation

The equations and mathematical formulation are described in this section:

$$TF(t,\ o) = \frac{Number\ of\ times\ term\ t\ appears\ in\ a\ opinion\ o}{Total\ terms\ in\ \ opinion\ o} \quad (1)$$

$$IDF(t,\ O) = log\ \left(\frac{Overall\ opinion\ count}{Number\ of\ opinion\ with\ term\ t\ in\ it}\right) \quad (2)$$

$$\text{TF-IDF} = \text{TF (t, o)} * \text{IDF (t, O)} \quad (3)$$

Eq. (1) and Eq. (2) explain the computation of term frequency and inverse document frequencies Eq. (3) is the multiplication of term frequency, and the logarithm of opinion count to frequency ratio.

- EFV: Extended Feature Vector.
- TF-IDF: Term Frequency –Inverse Document Frequency.
- ABIW: Adaptive Bilingual Influence Weighting.

WCM_OMF is implemented to solve the code-switching problem in single opinion text (intra–sentential). For this purpose, lemma ABIW is devised as explained below.

Adaptive Bilingual Influence Weighting (ABIW)

The proposed lemma is explained in Eq. (4) that is used to dynamically adjust the influence of each language based on the opinion.

$$\text{ABIW} = \sigma\left(\frac{1}{N} * \Sigma(i = 1\ to\ N) LangScore_i\right) \quad (4)$$

Where

- W_{Lang} : weighting factor for each language in the bilingual code mixed text.
- $Model_m$: Trained model m.

Adaptive Bilingual Influence Weighting (ABIW), the language influence weighting method (LIW), is a metric designed to capture the influence of different languages in the code-mixed text. It quantifies the extent to which each language contributes to the overall content.

The weighting factor is computed for each opinion instance using a language identification function in combination with a weighting parameter. This result is added to the feature vector module, capturing the linguistic feature weights.

Further, we implement vector space modeling on the extended feature vector for the feature selection process. Eq. (5) computes the final feature vector, which is then used as modified feature vectors for multiclass opinion classification and subsequent opinion detection.

$$CMRS(O(i)) = \sum_{i=0}^{n} LF(O(i)) + STF(O(i)) \quad (5)$$

$CMRS$: Code Mixed Relevancy Score

$O(i)$: i th Opinion where i Є [1, 2, 3…n] and n is the Total count of opinions

STF –Statistical Features Set

LF- Linguistic Feature Set

Algorithm Weighted Code mixed Opinion Mining Framework (WCM_OMF)

Input Parameters:

D: Dataset with two columns,

T: Opinion text (T) and class (C),

Where T_i is the i^{th} text instance and C_i is the corresponding class label.

Algorithm : Weighted Code mixed Opinion Mining Framework(WCM_OMF)

Input: Corpus (C), Total number of samples (n).

Output : Optimized representation of Documents

Preprocessing

For each text T_i in D, preprocess the text to create a normalized text T_i'

$$T_i' \leftarrow preprocess_{text(T_i)}$$

Language Influence Weight (LIW):

Computation of LIW for each text T_i' using language id function L and weighting parameter α

$$LIW_i \leftarrow calculate_{\{liw\}(T_i', \alpha)}$$

Feature Engineering:

LIW module output conversion of T_i' into a feature vector F_i using TF-IDF

$F_i \leftarrow TFIDF(T_i')$

Combine feature vector F_i with LIW_i to create an extended feature vector EF_i

$$EF_i \leftarrow [F_i;\ LIW_i]$$

Dataset Preparation:

Class balancing module implementation ADASYN balancing on D_{train} to get D'_{train}

Training:

Train each model m in M on $D'_{\{train\}}$ using the optimized hyperparameters HP^*_m

$$Model_m \leftarrow Train(m, HP^*_m, D'_{train})$$

Development of ensemble model E from all trained models in M.

$$E \leftarrow Ensemble(M)$$

Prediction and Evaluation:

Predict classes for D_{test} using ensemble model E to get predictions P

$$P \leftarrow Predict(E, D_{test})$$

End

The proposed WCM_OMF Opinion Feature Engineering solution implements the computation of an Extended Feature Vector (EFV) instead of FV in existing systems for feature engineering opinion detection. Further, the resultant output is then inputted for embedding and classification, enabling a deeper linguistic context that assists in distinguishing opinions in different language segments.

IV Experimental Results

In this section, we present the experimental results of the proposed methodologies for code mixed data input.

Table III indicates that the proposed weighted code-mixed opinion analysis solution significantly improves opinion classification accuracy by incorporating both Hindi and English text features. The proposed solution employs a novel weighted strategy for code-switching. Quantitative and qualitative analyses are conducted for efficient data synthesis and validation. The proposed unique feature assigns higher weights for code-mixed lexicons during the opinion mining process, boosting the overall model performance. After using the k-fold cross-validation technique, the unique weighting technique's performance is further validated by performance metrics and compared to current frameworks.

Fig. 4 demonstrates the efficacy of the proposed solution for Benchmark Dataset 1 using Accuracy and Recall rate as evaluation metrics. The proposed model outperforms the existing systems SVM, Random Forest, sub-word LSTM, and Hierarchical LSTM with attention to phonetic words.

TABLE III. Comparative Analysis of Existing and Proposed Frameworks Existing Systems on Benchmark Dataset 1

Methodology	Accuracy	Recall	F1-score
Support Vector Machine Model	70.7	31.3	0.429
Random Forest Model [45]	65.1	19.3	0.292
Sub-word LSTM model [45]	69.8	36.5	0.458
Hierarchical LSTM model + attention on phonemic sub-words [47]	66.6	45.1	0.487
WCM-OMF (Proposed weighted code mixed approach)	**79**	**79.11**	**0.79102**

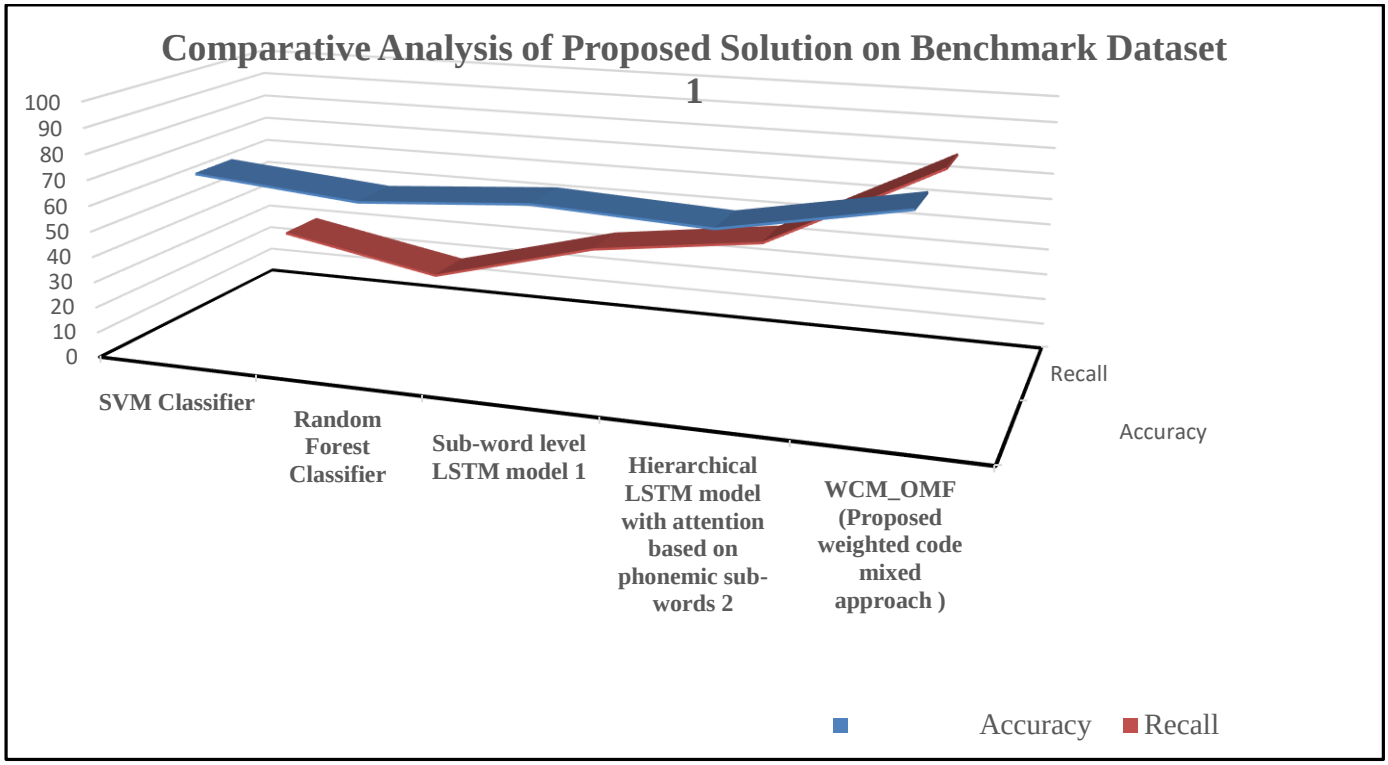

Fig. 4. Performance comparison of existing and proposed frameworks on benchmark Dataset 2.

TABLE IV. COMPARATIVE ANALYSIS OF EXISTING AND PROPOSED FRAMEWORKS ON BENCHMARK DATASET 2

Methodology	Authors	Accuracy	F1-score
BSVM (Unigram)	Wang, Manning[48]	59.15%	0.5335
NBSVM (Uni + Bigram)	Wang, Manning[48]	62.50%	0.5375
MNB (Unigram)	Wang, Manning[48]	66.75%	0.6143
MNB (Uni + Bigram)	Wang, Manning[48]	66.36%	0.6046
MNB (TFIDF)	Wang, Manning[48]	53.53%	0.4783
SVM (Unigram)	Pang and Lee[49]	57.60%	0.5232
SVM (Uni+Bigram)	Pang and Lee[49]	52.96%	0.3773
Lexicon Lookup	Sharma et al.[50]	51.15%	0.252
LSTM Model 1	Joshi et al[46]	59.80%	0.511
LSTM Model 2	Joshi et al[46]	59.70%	0.658
WCM_OMF (Proposed weighted code mixed approach)	**Proposed**	**72.55%**	**0.7208**

Results demonstrate that the proposed weighted approach to handle code-switching gives significantly better results than existing opinion mining frameworks, achieving an accuracy of 79% using comparative analysis evaluated on benchmark dataset 1. Table IV results show that the proposed weighted approach for handling code-switching performs significantly better than the existing opinion mining frameworks.

The overall accuracy achieved for the proposed system is 72.55%, and the F1 score is 0.72. The proposed method considers relevant factors during the process of grouping language-based text.

V. DISCUSSION

In this section, we discuss the results of the proposed solutions and the lemma developed. As observed in Fig. 5, the proposed solution WCM-OMF is designed and implemented to assign weights based on the ABIW lemma and the number of code switches in intra-sentential opinion. The steps for WCM (Weighted code mixing metric) are explained in detail and are primarily implemented to handle the unstructured nature of opinion input. Results show that the proposed WCM-OMF performs significantly better, achieving an F1 score of 0.72, which is a 6% improvement over the existing method on the benchmark dataset.

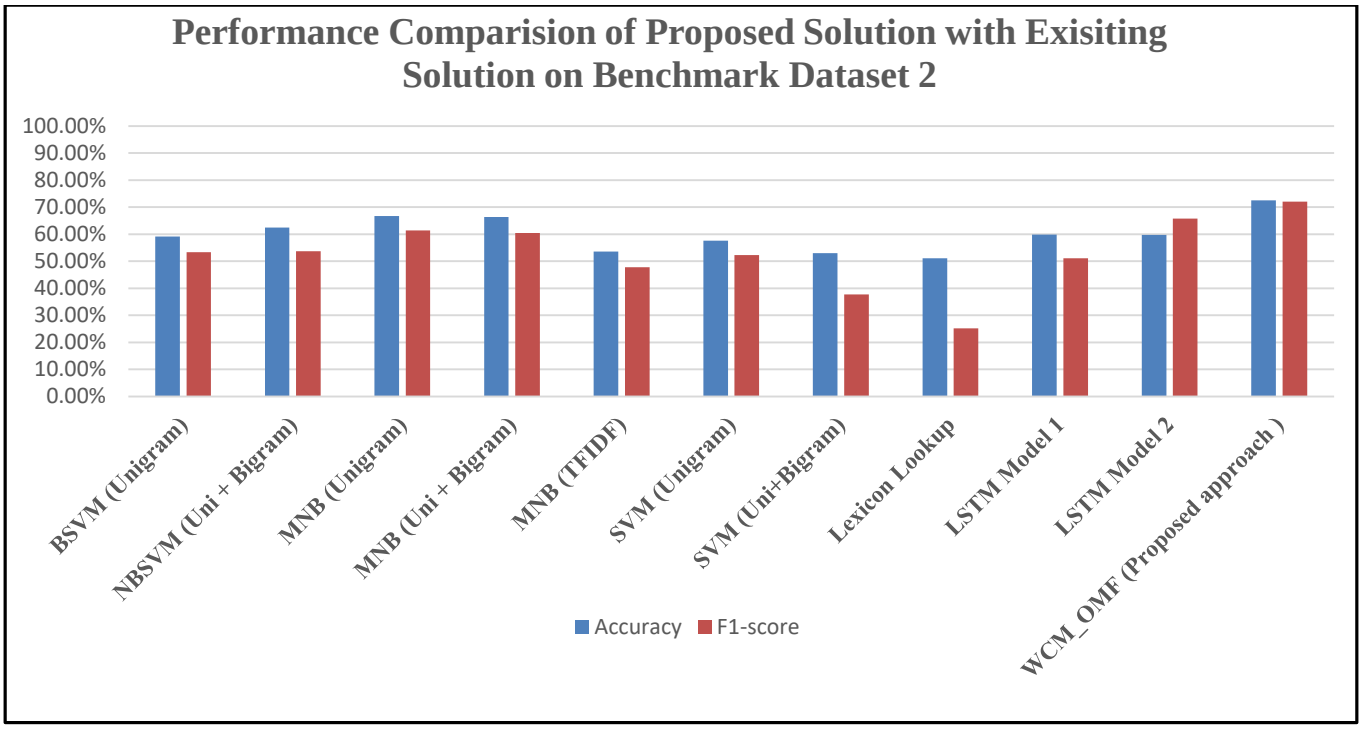

Fig. 5. Performance comparison of the proposed solution on benchmark Dataset 2.

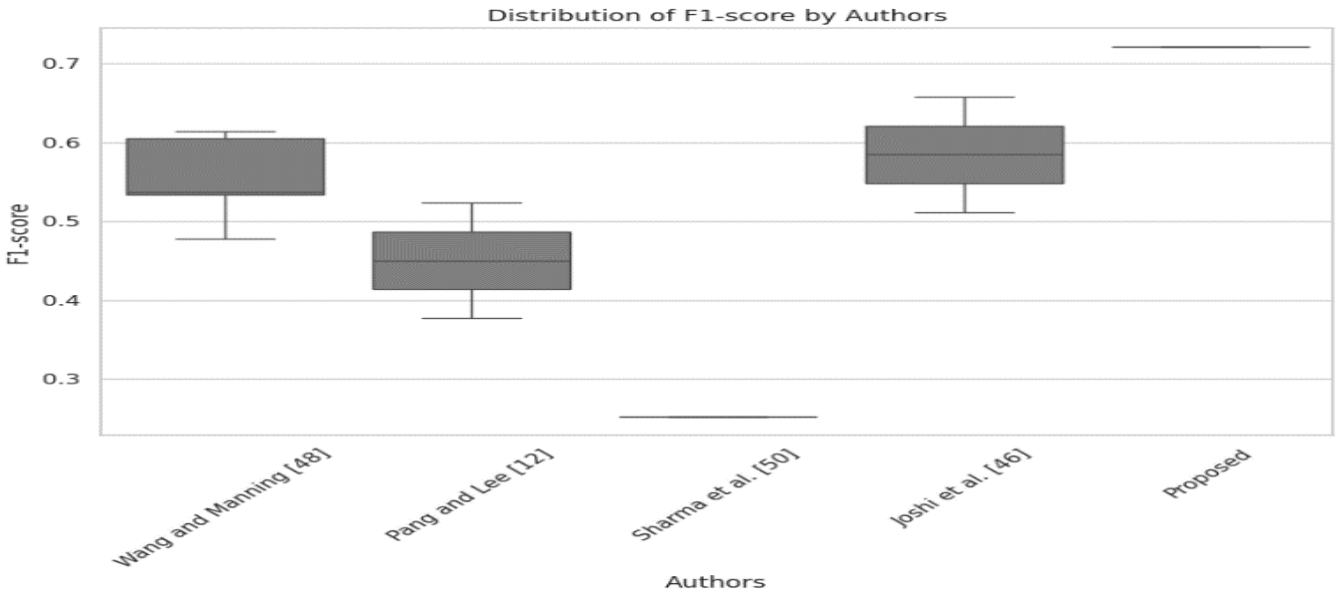

Fig. 6. Box Plot representation of F1 score distribution of proposed and existing systems.

As demonstrated in Fig. 6, the box plot represents the accuracy and F1 score distribution across several existing state-of-the-art models. As observed, the proposed model demonstrates a superior performance, as evidenced by the grouping of median data points. Opinion mining helps in the detection of patterns, improves decisions, and customizes strategy-based data extracted [51], leading to Business Intelligence [52].

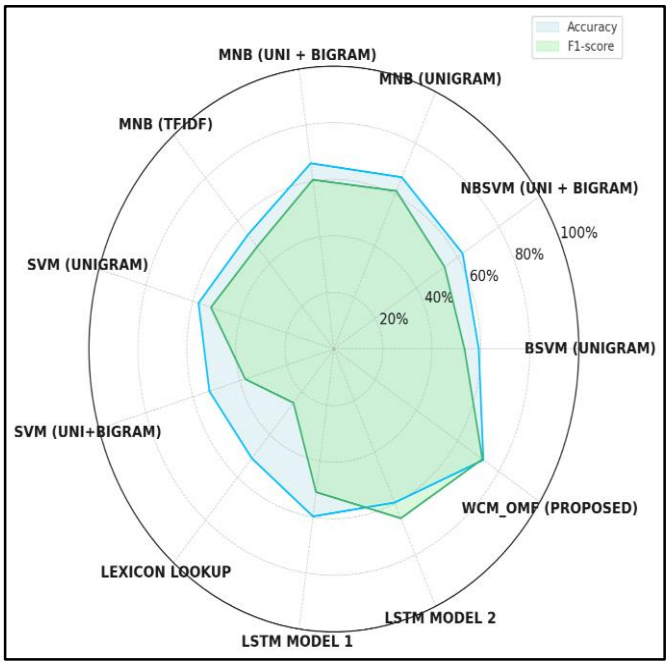

Fig. 7. Radar chart of accuracy and F1 score.

Fig. 7 visualizes the radar chart of accuracy and F1 score that demonstrates the proposed model efficiency across multiple metrics compared to the existing MNB BSVM-Unigram and BSVM- Bigram approaches.

We further validate the proposed results in Table V by implementing multiple Comparison of Means - Tukey HSD (Honestly Significant Difference) test to identify significant differences between pairs of group means with 95% confidence and p-value less than 0.05 mean difference of 9.86 for confidence interval [9.548, 10.171] and 13.21 for confidence interval [12.898, 13.521] indicating proposed method outperforms the existing approaches and differences are statistically significant.

TABLE V. TUKEYS HSD STATISTICAL SIGNIFICANCE TEST

Group 1	Group 2	Mean Diff	Lower	Upper
BSVM Unigram	MNB Unigram	7.41	7.0986	7.7214
BSVM Unigram	NBSVM Uni+Bigram	3.35	3.0386	3.6614
BSVM Unigram	Proposed	13.21	12.8986	13.5214
MNB Unigram	NBSVM Uni+Bigram	-4.06	-4.3714	-3.7486
MNB Unigram	Proposed	5.8	5.4886	6.1114
NBSVM Uni+Bigram	Proposed	9.86	9.5486	10.1714

VI. CONCLUSION

In this paper, we propose a novel WCM-OMF ensemble opinion mining framework in the context of code mixed opinions and unstructured format. We develop an end-to-end framework to handle the code-switching problem. This study also aims to bridge the gap between corpus availability and opinion mining research that would benefit researchers in analysing the proposed corpus for code mixed opinions. The results of our proposed framework are more efficient than related existing approaches in the case of code mixed opinions. The proposed method achieves an F1 score of 0.79, achieving a 6% increase in the opinion mining system. Further, we intend to extend this research to implicit opinions and word sense

disambiguation techniques concentrating on irony and other related clauses present in the opinion. This research significantly impacts creating an explainable digital environment that enhances decision-making.

Further, based on the rigorous analysis of scholarly research, we present a comprehensive framework for implementing cross-lexical opinions using cross-platform resources. Further, we suggest future developmental efforts, namely:

- Low resource corpus availability.
- Multimodal data integration capabilities.
- Open source platforms for handling big data analytics.
- Optimizing resource consumption for transformer architectures and deep learning methodologies.

The proposed solution would enable the utilization of potential applications for enterprises having an online presence for effective decision-making and business intelligence.

ACKNOWLEDGMENT

We are grateful for the insightful comments given by anonymous reviewers during the drafting of the paper.
