Software development has consistently changed the healthcare sector since the introduction of the Internet. A common instance of healthcare data digitalization is the use of electronic healthcare or health information. These documents are, nonetheless, susceptible to data loss and cyberattacks. Concerns around patient confidentiality, handling data, information credibility, and storage need all require consideration. Communication networks in the medical supply chain produce vital data and information. Healthcare providers are sharing private and sensitive information about the medical supply chain, particularly in the COVID-19 era. Because medical supply chain communication networks lack security protections, they have been the target of several cyber-attacks in recent years. Safety and personal information protection necessitate more stringent precautions in these days of cheaper and simpler cyberattacks driven by computational power and a variety of harmful algorithms. However, information-hiding techniques undermine several innovative approaches to prevent malevolent nodes from learning about critical information suggested by Kim et al. [9]. Furthermore, information hiding techniques may give stronger security and the necessary degrees of privacy with the use of blockchain technology. The purpose of this study is to improve the security and privacy of data transmission in important systems, including smart healthcare supply chain communication networks, by implementing Blockchain and smart contracts with information concealing techniques. The architecture employing Hyperledger smart contracts and the required degree of security are both feasible, according to the results. Information concealing techniques are helpful in safeguarding the confidentiality and validity of exchanged messages, informational files, and occasionally electronic contracts between businesses. Additionally, with Blockchain's backing as a decentralized distributed ledger which ensures that no blocks be altered or falsified, Blockchain technology Information Hiding Techniques can increase security and privacy standards for crucial network requirements.

Blockchain-Assisted Cybersecurity for the Internet of Medical Things (IoMT) in the Healthcare Industry proposed by Alkatheiriet al., [10]. The development of sustainable healthcare systems is significantly aided by the Internet of Medical Things. The Internet of Medical Things has a big impact on healthcare because it makes it easier to track and verify patient medical data before storing it on a cloud network for later use. Because the IoMTbecomes a massive data platform that is expanding quickly, it is imperative that all data be kept safe and secure. The report suggests using blockchain technology to help with cybersecurity for the IoMT. Blockchain is a decentralized electronic record that facilitates communication between unreliable parties and permits end-to-end functionality. Blockchain-assisted cybersecurity develops a process for gathering medical data through the Internet of Medical Things and incorporating devices by combining blockchain technology with a traditional in-depth methodology. The suggested method utilizes blockchain technology to securely keep and get backthe gathered data in a distributed way inside a secured setting that is appropriate for medical professionals, including those working in hospitals, retirement communities, and other healthcare facilities where data interchange is required. Blockchain technology combined with a traditional comprehensive methodology may significantly improve Internet of Medical Things cybersecurity. Initially, healthcare data connected to the Internet of Medical Things may be significantly protected by the inherent safeguards of blockchain, such as digital signatures and diverse encrypted communications protocols. Lastly, auto-upgrading procedures can be automatically activated by intelligent contracts built into Internet of Things sensors to improve the Internet of Things instrument.

Abdellatif et al., [11] proposed a secure, blockchain-enabled healthcare systems. New patient care models are being driven by emerging technology advancements, which are shaping the coming decades of healthcare systems. New methods that substantially enhance healthcare services may be implemented by collecting, incorporating, evaluating, and transmitting medical data at various system levels. This paper offers an innovative intelligent and secure healthcare system that enables rapid emergency response, remote monitoring, and pandemic detection by utilizing advancements in edge computing as well as blockchain technology. E-health systems may provide patients with prompt care across the closest point of care when they have an instant utilization of clinical patient information. Additionally, to improve countrywide statistics, offer a national first reaction to epidemics, and increase the efficacy of healthcare services, healthcare groups might require sharing pertinent data. Ultimately, the diagnosis and development of novel treatments for newly developing diseases depend heavily on the gathering, handling, and evaluation of medical data. To achieve the convergence of various national and international organizations and to enable the correlation of crucial medical events for the management and control of developing outbreaks, for illustration, the suggested system also permits the safe interchange of medical data among local healthcare institutions. Specifically, they create a blockchain-based architecture alongside allows for its variable configuration to maximize the exchange of medical data among various health institutions and meet the many qualities of service requirements that a Secure Healthcare System might need.

Reegu et al. [12] suggested Blockchain-Based Framework for Interoperable Electronic Health Records. Most healthcare institutions have been switching from written to electronic health records in the healthcare sector. Nonetheless, there are issues with trustworthy administration, safe data keeping, and credibility with the present frameworks for electronic health records. In the healthcare industry, accessibility and user control over sensitive information are also major challenges. While blockchain technology has become a formidable tool capable of providing permanence, safety, and user control over records that are saved, its potential utility in electronic health records systems is still unclear. The goal of this study is to fill the knowledge deficit by developing an electronic health records system based on blockchain technology that is compatible with several national and international standards, including HL7 and HIPAA, and might satisfy their criteria. The study examines several national and international standards of electronic health records, describes the interoperability challenges in the current blockchain-based frameworks for electronic health records, and then specifies the compatibility criteria based on these standards. Despite the requirement for centralized storage, the suggested framework can give the healthcare industry safer ways to exchange health information while also offering the features of inviolability, assurances, and access by users over stored records. Increasing knowledge of blockchain technology's possible adoption in electronic health record frameworks and implementing forth a compatible blockchain-based structure that might satisfy the demands outlined by numerous national and international electronic health records standards are this work's inputs. In general, this investigation may enhance the safe exchange and retention of digital medical records while protecting patient security, anonymity, and record integrity, which will have a substantial impact on the healthcare industry.

The use of wearable technology and Internet of Things devices has increased in the healthcare industry recently to collect real-time patient data and provide it to the medical staff for additional processing, analysis, and storage. Data security, mistrust among interacting parties, and isolated points of breakdown are only a few of the issues with centralized computing, interpreting, and storage. Blockchain's intrinsic properties decentralization, distributed ledger technology, immutability, consensus, security, and transparency make it a promising substitute for existing solutions to these problems. To provide a safe e-healthcare system, researchers have thus begun fusing the IoT with Blockchain system for the medical sector. In this study, they present, a blockchain-based data security framework for healthcare systems enabled by the IoT. The involvement in this study is Showing a tiered architecture for blockchain and Internet of Things-powered healthcare solutions, the entire blockchain-based data security framework for healthcare systems enabled by the Internet of Things systematic approach, including the schematic, a thorough communication flow, a Blockchain viewpoint, safety validation of the preceding proposal, an experimentation setting, and the results produced by smart contract execution. They use the most recent cryptographic choices, including public key infrastructure (RSA), integrity verification (SHA), symmetric key encryption (AES), and authenticity verification (ECDSA digital signature). Extensive empirical research is carried out to evaluate the blockchain-based data security framework for IoT-enabled medical systems, and the findings indicate that reduced latency leads to increased effectiveness [13].

The widespread integration of IoT devices into everyday health management has been facilitated by recent developments in the Internet of Health Things (IoHT). Applications using the IoHT require a feature for data provenance in addition to data precision, protection, credibility, and usability for stakeholders to accept the data. Federated learning and differential privacy were presented as ways to safeguard the security and privacy of the IoHT data. With these methods, private data may be learned on the owner's premises. Developments in hardware GPUs have made it possible for mobile devices or edge devices with the Internet of Health Things connected to their edge nodes to do federated learning. Federated learning reduces a few of the privacy issues associated with the Internet of Health Things data; however, fully decentralized federated learning remains a challenge because of the following: the history of training data; absence of learning capacity at all federated nodes; shortages of large training datasets; and authentication requirements for each federated learning node. In this work, they provide a lightweight hybrid federated learning system where the transformation of globally or locally trained models, the credibility of edge nodes as well as their transmitted datasets or models, the edge training plan, credibility administration, and verification of involving federated nodes are all managed by blockchain smart contracts suggested by Rahman et al. [14]. The predicting process, training models, and information encrypting in every aspect are also supported by the system. While the blockchain employs exponential encryption to combine the new model parameters, every federated edge node carries out additional encryption. The framework ensures that Internet of Health Things data is fully anonymous and private by supporting lightweight differential privacy. Numerous applications based on deep learning intended for COVID-19 patient clinical trials were used to evaluate this architecture. They now provide the comprehensive concept, execution, and test findings, which show great promise for more widespread and safe use of Internet of Health Things-based health administration.

Significant benefits for medical treatments come from large-scale clinical information exchange, such as improved service standards and quicker scheduling of medical services. There are several issues with the way clinical information is currently shared throughout healthcare facilities, including accessibility, confidentiality, and authenticity. Rajawat et al. [15] presents an intriguing blockchain-based electronic health record system with highly secured data exchange and synchronous backup of information. Blockchain system has the possible to streamline the use of machine learning algorithms for forecast evaluation and remediation by doing away with centralized organizations and decreasing the amount of scattered patient information. It might thus result in improved medical treatment. Through the use of an intelligent "allowed list" to customize information separation and facilitate clinician data access, the suggested paradigm enhanced patient-focused clinical information exchange. The hybrid Machine Learning-blockchain system presented in this paper combines blockchain-based access with conventional data storage. With better findings, the experimental investigation compared the suggested model's sustainability, equilibrium, safeguarding, and robustness to those of competing models in quantitative and comparative studies including massive clinical information-sharing cases. The suggested architecture protects patient data on the blockchain while enhancing safe data interchange between doctors in different institutions through the use of proxy re-encryption methods. Some of the well-known issues with medical data-sharing systems may be resolved by using the enhanced consensus method that this study suggests. Protecting medical files and confirming information access are two features of the blockchain-based system. Every medical record can keep the data's source and validate the sources of clinical information shared. Doctors can only keep an eye on the entry of information in a reliable healthcare system. Unit managers have access to data on the number of healthcare professionals who have met their goals. Additionally, intelligent agreements enhance the tracking of health information and preserve log data. Depending on where they are located, users can only use intelligent contract features to search through various log file sections.

The studied paper uses various methods utilized for the blockchain based patient information security. The integration of blockchain technology into healthcare systems holds promise for enhancing data security, privacy, and interoperability, thereby revolutionizing patient care and medical services. Several studies have explored the application of blockchain in healthcare, focusing on areas such as secure data transmission, electronic health records management, and Internet of Medical Things (IoMT) cybersecurity. These studies propose innovative solutions that leverage blockchain's decentralized nature and cryptographic features to address existing challenges in the healthcare industry, including data breaches, privacy concerns, and data integrity issues. However, while these studies demonstrate the potential benefits of blockchain in healthcare, they also highlight certain limitations and challenges. For instance, the scalability of blockchain networks, regulatory compliance, interoperability with existing systems, and the complexity of implementation remain significant hurdles to widespread adoption. Moreover, the effectiveness of blockchain-based solutions may vary depending on the specific healthcare context and infrastructure, necessitating further research and real-world validation. Therefore, while blockchain offers promising solutions for enhancing healthcare systems' security and efficiency, addressing these limitations is essential to realize its full potential in revolutionizing the healthcare industry.

## III. PROBLEM STATEMENT

To address the limitations identified in the existing literature review concerning the protection of patient information in medical informatics. Current approaches suffer from centralized storage vulnerabilities, weak access control leading to unauthorized data breaches, and inadequate encryption compromising patient privacy. To overcome these challenges, the proposed method integrates decentralized blockchain storage with PoW consensus for enhanced security and consistency. Additionally, AES-Diffie-Hellman encryption ensures secure communication, while RBAC provides granular access control, ultimately improving security and confidentiality in medical informatics. This integrated approach aims to rectify the shortcomings of existing methods and establish a more robust framework for safeguarding patient data [16].

## IV. BLOCKCHAIN-ENABLED CYBERSECURITY FRAMEWORK FOR PATIENT DATA PROTECTION

AES-Diffie-Hellman key exchange, blockchain with Proof-of-Work (PoW), and Role-Based Access Control (RBAC) are the three essential phases in the approach for building a blockchain-enabled cybersecurity framework for protecting patient information in medical informatics. Initially, the dataset includes patient data, admission information, and healthcare services rendered. After that a secure communication channel is established and shared secret keys are generated for encrypting patient data using the AES-Diffie-Hellman key exchange. To ensure confidentiality and immutability, the encrypted data is subsequently stored on a blockchain with nodes using a PoW consensus method. RBAC principles are applied to control access to patient data within the blockchain network, defining roles and permissions for healthcare providers, administrators, and patients. Using authorizations and roles for patients, administrators, and healthcare providers, RBAC principles are used to regulate the accessibility of patient data inside the blockchain network. This implies using smart arrangements to set admittance impediments and make review trails to screen information access and changes. Stakeholders are taught how to use the framework and the standards for secure data handling before it is finally integrated into the medical informatics services. To ensure patient confidentiality, integrity, and accessibility of information in the healthcare industry, regular upgrades and maintenance are carried out to meet new security threats and legal obligations. Fig. 1 depicts the suggested framework's workflow.

## *A. Data Collection*

Accessing healthcare data for research and learning can be difficult since it is frequently sensitive and governed by privacy laws. This dataset is appropriate for a variety of data analysis and modelling applications in the healthcare area since each column contains comprehensive details regarding the patient, their admittance, and the medical treatments delivered. Name and gender, year of birth, type of blood, health status, date of enrolment, physician, hospital settings, financial supplier, invoicing sum, room numbers, entrance category, departure time, therapy, and results of tests are all included in the dataset [17].

## *B. Data Encryption and Key Exchange Using Hybrid Diffie Hellmen and AES Algorithm*

*1) Diffie-Hellman Algorithm:* Diffie-Hellman Protocol, also known as Diffie-Hellman Key Exchange. This algorithm's goal is to make it possible for two users to safely exchange keys so that later messages can be encrypted and decrypted using the same key. The Diffie-Hellman protocol provided a workable solution to the problem of key distribution by allowing two individuals to establish a shared mystery through communication over an open network without ever having to physically meet or exchange keying material. After that the symmetric-key cipher will be utilized to encrypt further communications with the key. Discrete logarithm computation and the Diffie-Hellman problem's insolvability are the foundations of security. A pair of keys that are both public and private is generated by every device. Whereas the public key is available for public sharing, the private key remains confidential. The exchange of public keys is required for two devices to communicate. Every device separately determines a shared secret using its own private key and the public key that was received. Fig. 2 shows the working of Diffie-Hellman algorithm.

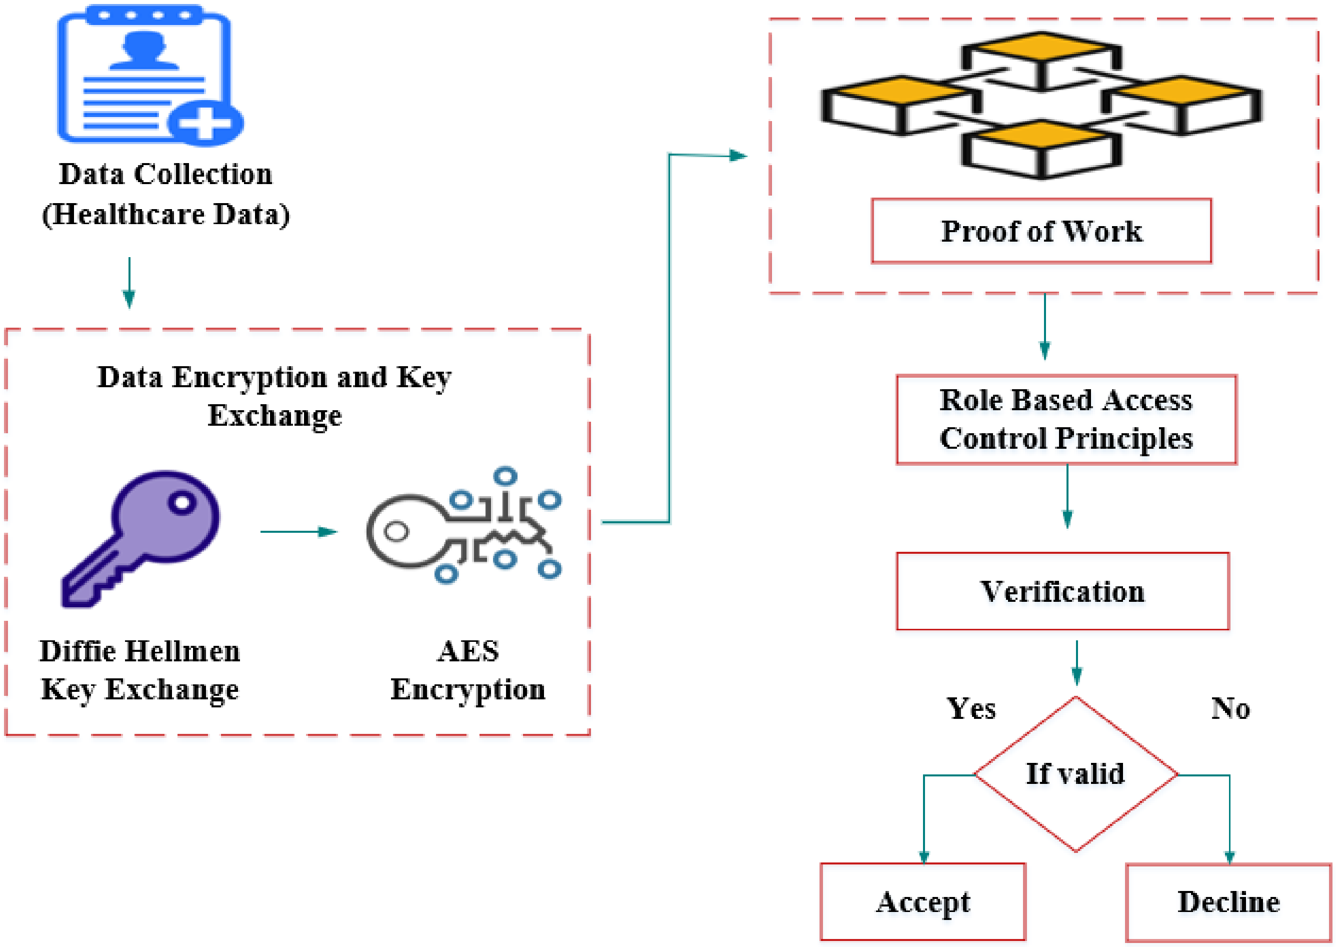

Fig. 1. Proposed blockchain-enabled cybersecurity framework for safeguarding patient data in medical informatics.

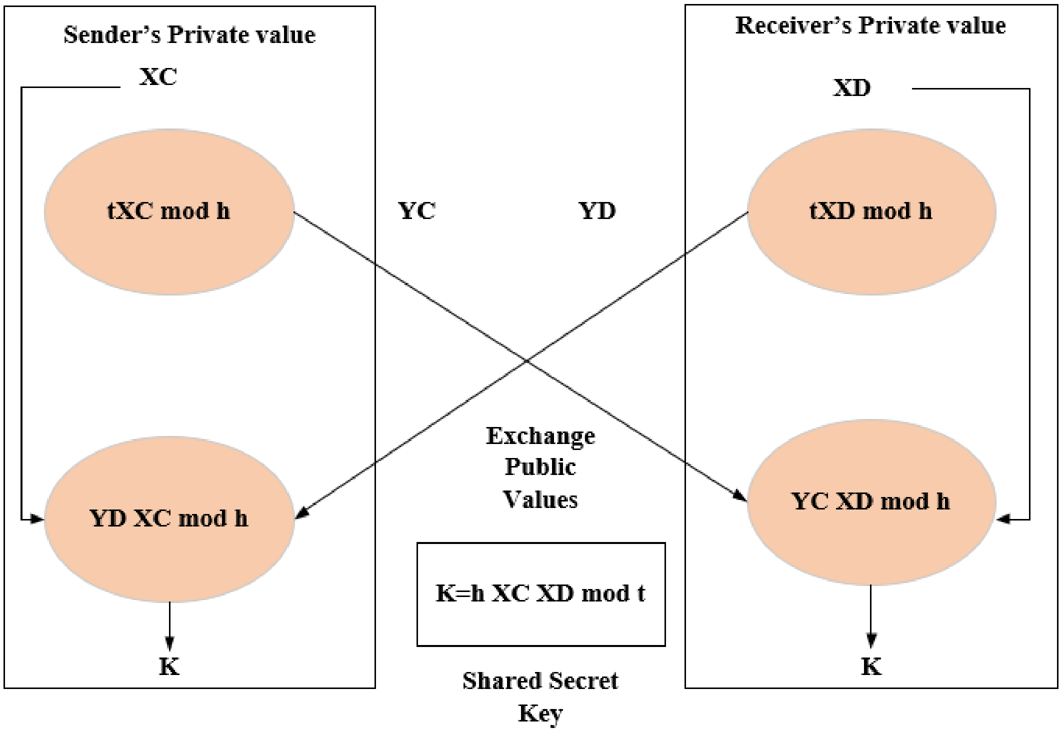

Fig. 2. Diffie Hellmen Algorithm.

The innovation of Diffie-Hellman is found in the fact that, even though both devices compute the same shared secret, it would be extremely difficult for anyone to figure it out through monitoring. The key transferring technique involves several steps:

- Parameters choosing: Both parties agreed that the basic roots exponent h (t) and a big prime integer were potential variables.
- Public Key Transfer: Each side generates a hidden key (c or d) and calculates the public key (C or D) using the predefined variables. Subsequently, the unreliable channel is used to transfer publicly available keys.
- Shared Secrets Estimation: Using their keys and the openly available keys they are given; the two parties independently compute a shared secret key. The technique functions by resolving the discrete logarithm problem, which hinders a hacker from easily deducing the transfer hidden in all cases when explicit transfers of openly available keys are made.

*2) AES Algorithm:* Public key cryptography, commonly referred to as asymmetric key cryptography, is significantly more sophisticated than symmetric key encryption when it comes to protecting sensitive data. Asymmetric keys are used in a wide range of cryptographic techniques. The AES algorithm can accommodate all possible key lengths and data combinations (128 bits). AES stands for Advanced Encryption Standard. The algorithm names are AES-128, AES-192, or AES-256, depending on how long the key is. During the encryption-decryption process, the AES technique runs a total of ten rounds over I28-bit keys, 12 rounds for I92-bit keys, and 14 rounds for 256-bit keys to deliver the final cipher text or recover the initial plain text [18]. Several encryption rounds are used by the cipher to convert simple text into cipher text. The result of one cycle becomes the input of the next. The output of the previous cycle is the encrypted simple text, often known as cipher text.

Fig. 3 illustrates how AES encryption and decoding operate. The data entered by the user is stored in a matrix known as a "state matrix." These are the four stages.

*a) Sub bytes step*: Sub Bytes, or byte substitution, are the algorithm's initial iterative step in every round. Every byte within the matrix is rearranged through the 8-bit substitution box in the Sub Bytes step. The Rijndael Sbox is the name given to this substitution box. The irregularity in the cipher is provided by this operation. The additive inverse over GF (28), which has been shown to have good non-linearity properties, is the source of the S-box that is used. In order to defend against attacks that utilized basic algebraic properties, I combined the function's inverse along with the invertible affine expansion to create the S-box. The S-box was also selected to prevent all opposite fixed points as well as any fixed points that are both fixed and abnormalities.

*b) Shift rows step:* The state matrix's rows are the focus of the Shift Rows step. The byte values in each row are shifted continuously by a predetermined offset. There are no changes to the first row. The second row's bytes are all moved to one place to the left. Similar shifts of two and three positions, respectively, are made to the third as well as the fourth rows. For both 128- and 192-bit blocks, the shifting pattern is the same.

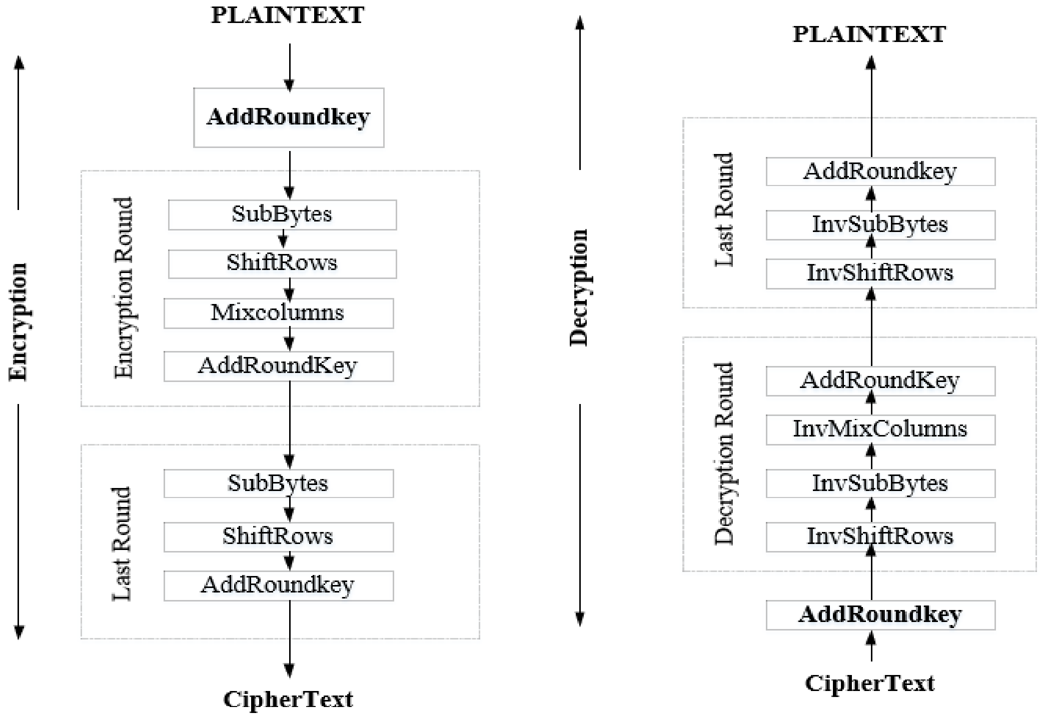

Fig. 3. AES encryption and decryption.

*c) Mix columns step:* Utilizing an inverse linear translation, each column's four bytes for a state matrix are merged in the Mix Columns step. In a 4*4 matrix, randomly selected polynomials are organized. The decryption process makes use of the same polynomial. Each of the columns within the polynomial matrix and its associated column associated with the state matrix are XOR-ed. The identical column now displays the updated result. The input for the Add Round Key function is the output matrix.

*d) Add round key:* The cipher key undergoes a number of operations to produce a round key. The round key and every byte in the state matrix are XOR-ed. By performing certain operations within the cipher key, a new round key emerges for each round.

In the data encryption and key exchange procedure, healthcare information in a Diffie-Hellman key transfer to set up a shared secret key securely. This key exchange protocol permits parties to agree upon a mystery key over an insecure communication channel without delay transmitting it. The Diffie-Hellman set of rules ensures that although an adversary intercepts the key exchange, they cannot deduce the shared mystery key. Once the shared mystery secret is installed, it is used for symmetric encryption of affected person records with the use of the Advanced Encryption Standard (AES). AES is a broadly used symmetric encryption algorithm regarded for its power and performance in defensive touchy data. It operates on fixed-length blocks of records with the usage of a shared secret key, making sure of confidentiality and integrity at some point of records transmission and garage. Patient information, together with Name, Age, Gender, Blood Type, Medical Condition, Admission Type, Medication, Test Results, and Discharge Date, is encrypted through the usage of AES with the shared mystery key obtained through the Diffie-Hellman key transfer. This method protects sensitive medical information from unwanted access by maintaining patient information consistent and secret.

## C. Block Chain

Blockchain technology, which is based on the Bitcoin cryptosystem, has become a significant technological innovation that can help manage, control, and protect the system without the need for outside intervention. Every node in the blockchain network has a copy of a block, and they are all connected in a mesh topology. A block is made up of the nonce, current hash, previous hash, and Merkle root in addition to the total amount of valid transactions. The node has the capacity for transmission to the network and establishes a transaction that integrates with a digital signature. The network then extracts and verifies the transactions. Previous hashes are the hash of the most recent block that was added. Timestamp: The block's current generation time stamps. Nonce the computation-related number. Data are the block-specific information. Merkle root is a collection of valid transactions from a block, and the hash values of each transaction are computed to create a root hash that resembles a tree. Blockchain technology presents an architectural paradigm for the arrangement of dispersed personal health data [19]. It suggests a conceptual prototype that uses the blockchain system in a peer-to-peer network to govern individual health information collected from several healthcare providers. Maintaining confidentiality and authenticity facilitates the efficient exchange of personal healthcare information between patients and healthcare providers. Immutable data records are provided by the blockchain without the involvement of a third party.

Encrypted patient records are safely stored in blocks inside a decentralized blockchain network in the blockchain implementation. The distributed ledger in this network is kept up to date by a few nodes, each of which has a duplicate copy of the whole blockchain. To settle disputes over the legitimacy of operations in a decentralized community, the Proof-of-Work (PoW) consensus process is utilized by the blockchain. The consensus method that is currently being used on most blockchains is the proof of work technique. Introduced by Bitcoin, Proof of Work (PoW) relies on the idea that each peer uses his or her "computing power" to vote by building the right blocks and resolving proof of work cases. The miner generates the block and sends it to its peers over the network layer as soon as such a nonce is discovered. By calculating the block's hash and determining if it meets the requirement to be less than the present target value, other peers throughout the network can validate the proof of work (PoW). Block interval: The delay at which material is added to the blockchain is specified by the block interval.

A transaction is verified more quickly and there is a greater chance of stale blocks with a short block interval. The block interval modification is closely related to the underlying PoW mechanism's change in difficulty. There are more blocks during the network with a lower difficulty and fewer blocks in the same amount of time with a higher difficulty. As the longest chain serves as the primary security pillar for the majority of PoW-based blockchains, it is important to examine if altering the difficulty has an impact on the adversary capabilities in attacking it. It indicates that the number of confirmations a merchant must wait for to securely accept transactions (and prevent double-spending attacks) should be adjusted. Because an entity with over 50 percent of the processing power may effectively regulate the system by maintaining the longest chain, PoW's security is based on this idea. For PoW-based blockchains, the block size and the data propagation technique are the two primary network layer characteristics that matter most. The maximum quantity of transactions that may be carried out within a block is indirectly defined by the maximum block size. Thus, the system's throughput is limited by its size. Bigger blocks have slower propagation rates, which raises the number of stale blocks and, as indicated before, compromises the blockchain's security. How data is sent to peers inside the network is determined by the block demand control system. Such a problem's basic characteristic is that, while it may be challenging to solve, it is simple to verify (the right answer). When it comes to Blockchain, the issue is distributed among the chain's stakeholders, and the first person (also known as a special member, miner, or group of miners) to solve it gets the ability to mine the block in exchange for the following mining reward. Ethereum PoW uses SHA-256. In this case, the miners must strive to calculate a number Nonce that satisfies the following Eq. (1):

$$Hash\ of\ Block\ = Hash\ (Hash\ of\ Previous\ Block\ |\ \ |Merkle\ Root\ |\ \ |Nonce)\ (1)$$

Where, all other variables are given to miners except in the PoW mechanism, miners compete to remedy complex mathematical puzzles if they want to add fresh blocks onto the blockchain and verify them. This manner includes expending computational energy and power to discover a specific hash cost that meets certain criteria, which include having a sure wide variety of main zeros. The PoW consensus mechanism ensures data integrity and immutability by using means of making it computationally infeasible to modify past blocks inside the blockchain without redoing the paintings of solving the cryptographic puzzles for next blocks. As a result, the blockchain creates a secure and obvious report of all operations, comprising encrypted patient statistics, that is, stable and immutable within the decentralized community. This method enhances the safety and confidentiality of patient information in medical informatics via using blockchain generation to enhance openness, verification, and dependability while following regulatory regulations and maintaining patient privateness. Furthermore, the decentralized shape of the blockchain community decreases the possibility of unauthorized points of failure and illegal get entry to, subsequently improving the security of patient facts maintained within the system.

### D. *Role Based Access Control*

During the access management stage, Role-Based Access Control (RBAC) standards are carried out to manipulate and adjust get entry to patient statistics in the blockchain community. RBAC is a broadly used get right of entry to manage model that assigns permissions to users based on their roles within an organisation or machine. In the context of healthcare, RBAC ensures that only legal individuals, inclusive of healthcare companies, administrators, and sufferers, have access to specific patient records primarily based on their roles and duties. Firstly, extraordinary roles are described inside the device, every representing a particular category of user with wonderful access necessities. For example, healthcare companies might also require get admission to comprehensive patient facts to offer medical treatment, even as administrators may additionally need access to control person money owed and system configurations. Patients, on the other hand, might also best need get right of entry to their non-public fitness information. Once roles are defined, specific get admission to permissions are assigned to each role based at the precept of least privilege, wherein users are granted handiest the permissions necessary to perform their activity functions. User roles are described to make certain controlled admissions to patient facts. Healthcare providers, consisting of physicians and nurses, are granted entry to patient data based totally on their area of expertise, permitting them to view and update applicable clinical statistics. Administrators have general commitments, taking care of buyer obligations, designing device settings, and administering records administration to protect security and consistency. Patients are empowered to get entry to their health facts, allowing them to view and update non-public data as wanted. IT staff are entrusted with overseeing and saving the specialized foundation helping the network safety system, guaranteeing its dependability and adequacy in shielding patient records. RBAC guarantees that get entry to patient records is controlled and constrained, lowering the danger of unauthorized access or facts breaches. By assigning permissions primarily based on predefined roles, RBAC allows hold records confidentiality, integrity, and availability inside the blockchain network. Every role is conceded explicit access consent to patient information inside the blockchain network. Furthermore, RBAC facilitates entry administration and handling by centralized management and lowers the burden of handling individual user rights. In general, RBAC improves the protection and confidentiality of patient information in medical informatics systems simultaneously allowing for effective access control and regulatory compliance.

## V. Results and Discussion

AES-Diffie-Hellman key exchange, blockchain (PoW), and RBAC are all integrated into the suggested cybersecurity architecture for protecting patient data in medical informatics, and it produces strong results in ensuring confidentiality, integrity, and controlled access to sensitive medical records. AES encryption and stable key exchange via Diffie-Hellman are used to safely encrypt and store impacted individual data within a decentralized blockchain community that uses a proof-of-work consensus process for immutability and validity. In addition, Role-Based Access Control controls access to information about impacted individuals, guaranteeing that only legitimate users may communicate with the blockchain. Safety assessments and overall performance evaluations verify the framework's efficacy by showcasing its ability to stop illegal access, maintain data integrity, and handle security issues quickly. Healthcare providers, administrators, and patients all benefit from seamless and reliable communication with the device thanks to user-friendly interfaces and quick access to settings. All things considered, the implemented framework ensures the confidentiality and safety of information about impacted individuals, fostering confidence and trust in the medical informatics setting.

The presented cybersecurity architecture, leveraging blockchain technology customized for medical informatics, offers a comprehensive solution to ensure the privacy, reliability, and legal compliance of patient information in healthcare informatics. Through the integration of AES-Diffie-Hellman key exchange for secure communication, blockchain with Proof-of-Work (PoW) consensus, and Role-Based Access Control (RBAC) for fine-grained access management, the framework addresses the challenges of secure data transport and storage effectively. Decentralized storage, access control mechanisms, and advanced encryption techniques guarantee the security and confidentiality of patient data. By employing performance evaluation, the framework demonstrates efficient AES encryption and decryption procedures, while PoW consensus ensures auditable and immutable data storage, reducing the risk of data manipulation and unauthorized access. RBAC integration enables granular access control, limiting data access to authorized personnel only. Implemented using Python, the framework significantly outperforms alternative encryption methods such as NTRU, RSA, and DES, exhibiting encryption and decryption times of 12.1 and 12.2 seconds, respectively. With a remarkable 97.9% reduction in unauthorized access incidents, the proposed Blockchain-Enabled Cybersecurity Framework offers robust protection for patient data, making it a promising solution for securing healthcare informatics systems. To further validate the efficacy of this approach, a research experiment could be designed to analyze its performance in real-world healthcare environments, assessing factors such as scalability, interoperability, and resilience to cyber threats, ultimately demonstrating its usefulness in safeguarding patient information.

### *A. Performance Evaluation*

The proposed cybersecurity framework's performance is evaluated by evaluating several important metrics, such as the time it takes to decrypt and encrypt data using AES, comparing current techniques to the suggested AES-Diffie-Hellman method, and utilizing the PoW consensus mechanism to analyse the throughput of transactions within the blockchain network. Experiments are carried out to quantify the time required to encrypt and decode patient data using AES with various key sizes to assess the encryption and decryption times. The efficacy and efficiency of the suggested AES-Diffie-Hellman technique are assessed by contrasting the findings with those of other encryption techniques.

TABLE I. AES Encryption Time

| Data Input | Time (in seconds) |
|---|---|
| 1 MB | 1 |
| 5 MB | 3.1 |
| 10 MB | 4.2 |
| 20 MB | 6.6 |
| 30 MB | 12.1 |

The Advanced Encryption Standard Encryption in Table I gives an accurate indication of how long it takes, measured in seconds, to encrypt different amounts of input data. The table provides the various data input sizes (from 1 MB through 30 MB) and the accompanying encryption time. Encrypting a single MB of data, for instance, takes around a second, but bigger data quantities, like 30 MB, take about 12 seconds. When assessing the effectiveness and adaptability of AES encryption in practical applications, this table provides information on how the algorithm performs about of processing time for various data input sizes.

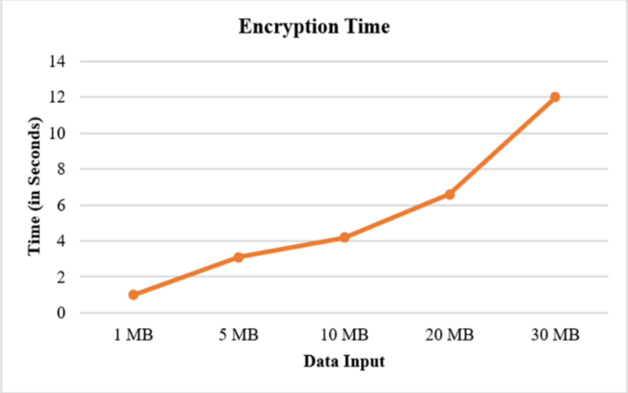

Fig. 4. Graphical depiction of AES encryption time.

The Advanced Encryption Standard encryption time in Fig. 4 shows how long it takes, in seconds, to encrypt various data quantities using the AES cryptographic method. The compatible encryption timings are indicated, and the information's input sizes span from 1 MB to 30 MB. The illustration below demonstrates the way the encryption time changes with the quantity of the input data and gives a basic explanation of how long the process takes. It provides information on how well AES encryption performs about of speed of processing and flexibility, which are critical elements to consider when assessing the efficacy and efficiency of encryption algorithms in protecting sensitive data, including patient information in medical informatics applications.

The time required to use the AES encryption technique to decode data of various sizes is shown in this Table II. There is a linear relationship between the decryption time and the amount of the data. For instance, it takes one second to decode one MB of data, but it takes 12 seconds to decrypt 30 MB. This implies that the amount of data being processed has an impact on the decryption time, with higher data volumes needing more computing time and effort.

TABLE II. AES DECRYPTION TIME

| Data Input | Time (in seconds) |
|---|---|
| 1 MB | 1 |
| 5 MB | 3.15 |
| 10 MB | 4.3 |
| 20 MB | 6.67 |
| 30 MB | 12.2 |

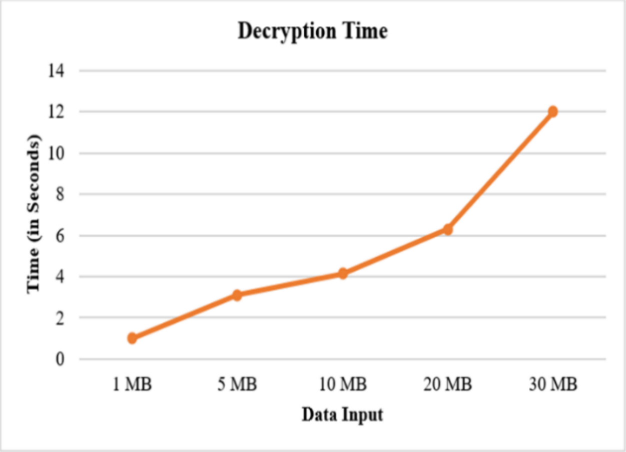

Fig. 5. AES decryption time.

Fig. 5 illustrates the AES decryption time, which is the amount of time it takes a system to decode data encrypted with the Advanced Encryption Standard method. It varies based on the amount of the encrypted data and is expressed in seconds. The presented numbers illustrate the duration required to decrypt data of varying sizes: 1 MB, 5 MB, 10 MB, 20 MB, along with 30 MB. For the data to become legible again, the decryption algorithm needs to process the data, which takes time. For evaluating the effectiveness and performance of systems processing encrypted data, the AES time for decryption is essential.

Fig. 6 shows how a Proof of Work system responds to different rates of concurrent requests in terms of transaction throughput. Throughput rises with increasing requests at first but eventually reaches a plateau at about 1500 times/sec. The system's capability doesn't change after this. Concurrent request rate is shown by the x-axis, while transaction throughput is shown by the y-axis. The pace at which transactions may be processed and verified in a blockchain network utilizing the Proof-of-Work (PoW) consensus method is known as the PoW throughput of transactions. It shows the total number of completed transactions in a given amount of time under different concurrent request rates. Increased throughput is a sign of the network's ability to process and validate transactions quickly.

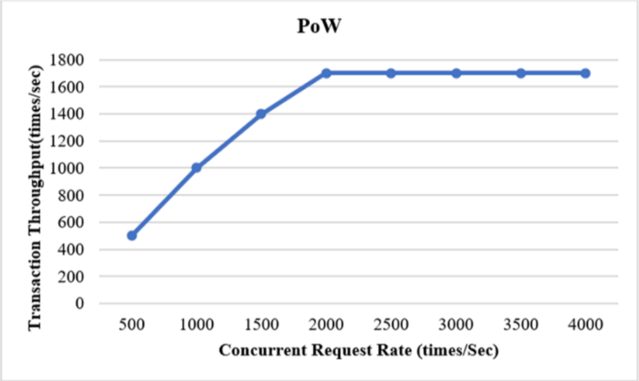

Fig. 6. Performance of PoW.

TABLE III. COMPARING EFFICIENCY WITH CURRENT METHOD ENCRYPTION TIME

| File Size | | Encryption Time (Seconds) | | |
|---|---|---|---|---|
| | *NTRU* | *RSA* | *DES* | *Proposed Hybrid Diffie Hellmen - AES* |
| 1 MB | 0.4 | 0.45 | 0.6 | 1 |
| 5 MB | 2 | 2.14 | 2.3 | 3.1 |
| 10 MB | 3.6 | 3.68 | 3.8 | 4.2 |
| 20 MB | 4.9 | 5.1 | 5.5 | 6.6 |
| 30 MB | 10 | 10.7 | 10.9 | 12.1 |

Table III lists the encryption timings, expressed in seconds, for a range of file sizes that have been encrypted using NTRU, RSA, DES, and a suggested combination of Diffie-Hellman with the AES cryptographic method. A file can have a size of 1 MB to 30 MB. The amount of time that any method takes to encrypt a given file size is referred to as the encryption time. While the suggested Hybrid Diffie-Hellman with AES proposes an integration of Diffie-Hellman key exchange for generating keys and AES for encryption, NTRU, RSA, and DES are well-known cryptographic methods. The table provides a comparative comparison of various algorithms' encryption effectiveness, making it easier to evaluate how well they secure data of different sizes.

Fig. 7 presents processing latency due to computational overhead during encryption and decryption. Propagation latency refers to the time taken for data to traverse the network medium, transmission latency arises from data transmission over the network, and processing latency occurs during data manipulation, with AES contributing to processing latency in secure communication systems. These latencies impact overall network performance and system responsiveness, with AES processing latency being a crucial consideration in designing efficient and secure data transmission systems.

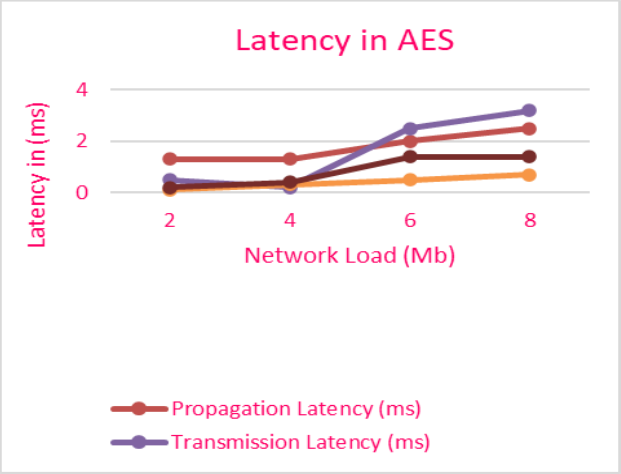

Fig. 7. Latency in AES.

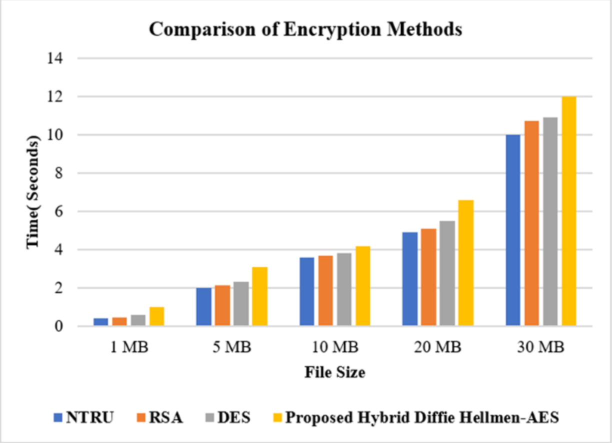

Fig. 8. Graphical illustration of various encryption methods.

Fig. 8 shows the encryption timings (in seconds) for a range of file sizes using the Proposed Hybrid Diffie Hellman -AES, RSA, NTRU, and DES encryption algorithms. It displays how long it takes to encrypt files ranging in size from 1 MB to 30 MB. For tiny files, NTRU is the quickest. The performance of DES and RSA is comparable. For bigger files, the suggested Combination Diffie Hellmen-AES is slower. The graph shows how the size of the file affects the encryption time. The encryption time needed by a given algorithm for a given file size is represented by each row.

Table IV presents the decryption effectiveness of several cryptographic algorithms in comparison to an established technique, which is likely AES. A decryption time, expressed in seconds, is given for files varying in size from 1 MB to 30 MB. Comparisons are made between NTRU, RSA, DES, and a suggested Diffie Hellmen along with the AES technique. The table below makes it easy to compare the decryption performance of different algorithms with the current AES technique. When compared to the current AES approach, lower decryption durations suggest quicker retrieval of information and higher performance, demonstrating how successful each algorithm is in safely decrypting data of different sizes.

TABLE IV. COMPARING EFFICIENCY WITH CURRENT METHOD DECRYPTION TIME

| File Size | Decryption Time (Seconds) | | | |
|---|---|---|---|---|
| | *NTRU* | *RSA* | *DES* | *Proposed Hybrid Diffie Hellmen-AES* |
| 1 MB | 0.5 | 0.52 | 0.8 | 1 |
| 5 MB | 2.1 | 2.2 | 2.4 | 3.15 |
| 10 MB | 3.5 | 3.57 | 3.72 | 4.3 |
| 20 MB | 5.1 | 5.2 | 5.8 | 6.67 |
| 30 MB | 10 | 10.3 | 11 | 12.2 |

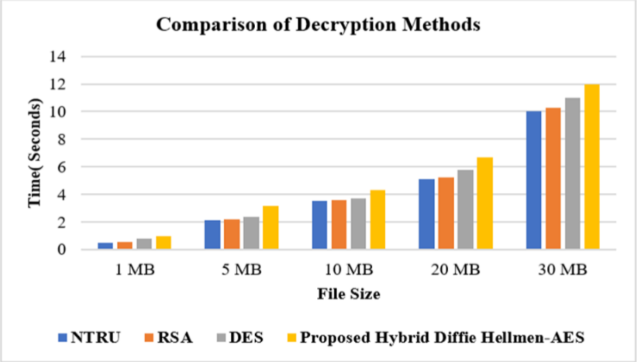

Fig. 9. Graphical illustration of various decryption methods.

Fig. 9 compares decryption speeds (in seconds) using several decryption algorithms (NTRU, RSA, DES, and Suggested Hybrid Diffie Hellmen-AES) for varying file sizes (1 MB, 5 MB, 10 MB, 20 MB, and 30 MB). The decryption time needed by a certain algorithm for a given file size is shown by each row. For instance, the proposed AES method takes 1 second to decode a file weighing one megabyte, while RSA takes 5.2 seconds, DES takes 0.8 seconds, and NTRU takes 5.1 seconds. The information helps choose the most effective decryption method for decryption jobs by comparing the performance of these algorithms for varying file sizes. Comparing Efficiency with current decryption time is given in Table V.

TABLE V. COMPARING EFFICIENCY WITH CURRENT METHOD DECRYPTION TIME

| Test | Unauthorized Access Incidents |
|---|---|
| Diffie Hellmen-AES | 1000 incidents |
| With Blockchain-Enabled Framework | 21 incidents |
| Reduction | 97.9% |

## *A. Discussion*

The integration of blockchain technology, RBAC, and the AES-Diffie-Hellman key exchange in healthcare cybersecurity architecture presents a promising solution to safeguard patient data in medical informatics. This approach offers significant advantages, including consistent encryption and decryption durations, enhanced data security through secure key setup, regulated access to confidential healthcare data, and improved data consistency and integrity. Despite these benefits, challenges such as scalability issues with proof-of-work consensus and the complexity of the architecture may impact its practical implementation, particularly in busy hospital settings with limited computational resources. However, future research endeavors, as suggested by existing literature, could explore alternative blockchain consensus mechanisms like Proof-of-Stake to enhance sustainability and energy efficiency. Additionally, integrating AI-driven anomaly detection and cutting-edge encryption methods could further bolster the safety features of the framework. While blockchain holds promise for revolutionizing healthcare data security, addressing scalability, regulatory compliance, interoperability, and implementation complexities will be crucial for its widespread adoption and realization of its full potential in improving patient care and medical services [20].

## VI. Conclusion and Future Work

The suggested cybersecurity framework, which combines blockchain, RBAC, and AES-Diffie-Hellman key exchange, shows notable benefits and accomplishments in protecting patient data in medical informatics systems. The architecture makes use of the Diffie-Hellman exchange of keys for secure key formation, blockchain with proof-of-work for decentralized and permanent data storage, RBAC for restricted access management, and AES encryption for safe information transport. It was discovered during performance assessment that the framework offers effective encryption and decryption procedures, guaranteeing patient data integrity and confidentiality. By integrating blockchain-based technologies, the framework solves important issues in handling health care data and provides improved data security, resistance against manipulation, and auditability. Furthermore, granular access control is made possible by the integration of RBAC, guaranteeing that only authorized individuals may deal with critical patient data. The innovative approach of the suggested framework offers a substantial improvement over current practices by offering a complete and safe solution designed especially for the protection of healthcare data. Future research might concentrate on several areas to improve the suggested framework even more. Examining different block chain consensus techniques, like Proof-of-Stake, is one way to make improvements to solve scalability issues and boost energy efficiency. Furthermore, including innovative cryptography methods and artificial intelligence (AI)-powered anomaly detection systems might improve the security posture of the framework and quickly identify any attacks. To assure the framework's viability in resource-constrained healthcare situations, further study might focus on lowering computing overhead and maximizing resource efficiency. Furthermore, examining data exchange methods and interoperability standards may help promote interoperability between various healthcare providers as well as seamless integration with current healthcare systems. The suggested framework may develop further and continue to be a strong and dependable solution for protecting patient information in medical informatics by tackling those fields of future research, which will eventually enhance the quality of patient care and the effectiveness of healthcare delivery.

# Reliable Hybridization Approach for Estimation of The Heating Load of Residential Buildings

Huanhuan Li
School of Civil Engineering, Xi'an Traffic Engineering Institute, Xi'an Shaanxi 710300, China

*Abstract*—**In recent times, the world's growing population, coupled with its ever-increasing energy demands, has led to a significant rise in the consumption of fossil fuels. Consequently, this surge in fossil fuel usage has exacerbated the threat of global warming. Building energy consumption represents a significant portion of global energy usage. Accurately determining the energy consumption of buildings is crucial for effective energy management and preventing excessive usage. In pursuit of this goal, this study introduces a novel and robust machine learning (ML) method based on the K-nearest Neighbor (KNN) algorithm for predicting the heating load of residential buildings. While the KNN model demonstrates satisfactory performance in predicting heating loads, for the attainment of optimal results and accuracy, two novel optimizers, the Snake Optimizer (SO) and the Black Widow Optimizer (BWO), have been incorporated into the hybridization of the KNN model. The results highlight the effectiveness of KNSO in predicting heating load, as evidenced by its impressive $R^2$ value of 0.986 and the low RMSE value of 1.231. This breakthrough contributes significantly to the ever-pressing pursuit of energy efficiency in the built environment and its pivotal role in addressing global environmental challenges.**

***Keywords—Heating load; residential buildings; k-nearest neighbor; snake optimizer; black widow optimizers***

## I. Introduction

Buildings' energy consumption has substantial consequences for both the economic and the environmental health of a country [1]. The buildings sector is responsible for roughly 40% of the total energy consumption [2]. For instance, in the United States, the building sector represents 39% of the total energy consumption, while residential buildings in the European Union account for approximately 40% of the energy consumption within the building sector [3]. This significant energy usage in the building sector has positioned carbon emissions ($CO_2$) as a primary driver of climate change, global warming, and air pollution [4], [5]. Consequently, many architects, researchers, and engineers have taken up the task of investigating models that centre on building envelopes and design features with the goal of reducing the negative effects associated with energy consumption in buildings [6], [7].

The primary elements within a building's envelope and design features that influence its energy consumption encompass the U-value of the envelope (comprising materials such as wall materials, roof materials, and glazing properties), the window-to-wall ratio, and the orientation of the façade [8], [9]. Hence, to promote sustainability and mitigate negative impacts on both the natural and built environments, it is essential to consider and comprehend these variables in terms of their thermal efficiency and energy consumption [10]. Energy prediction tools are essential for enabling well-informed decision-making aimed at reducing energy consumption in buildings [11]. These tools possess the capacity to evaluate a broad spectrum of building designs and strategies, thereby enhancing energy demand and management [12]. It is crucial to acknowledge, however, that factors other than a building's envelope and characteristics impact energy consumption, such as external weather conditions, occupant behaviour, the adoption of technologies, and equipment [13]. The task of energy prediction is a complex research challenge.

Nevertheless, progress has been achieved in the quest for sustainable buildings concerning energy demand [14]. However, energy forecasting continues to fall behind the rapid urbanization and advancements in building design and features [15]. The energy efficiency of buildings has garnered substantial research attention, with numerous studies concentrating on prediction models based on data analysis [16], [17]. AI models show substantial potential for both forecasting and enhancing building energy usage [18]. These models leverage historical data, real-time sensor information, and ML algorithms to produce precise predictions, offering valuable insights for effective energy management. Over time, the field of predicting energy consumption has witnessed notable progress. Researchers and industry experts have devised a range of methods and strategies to forecast energy utilization consistently [19]. Kim and Cho [20] introduced a neural network in their study, which combined the characteristics of Convolutional Neural Network (CNN) and Long Short-Term Memory (LSTM) architectures, tailoring them for accurate forecasting of residential energy usage. The fusion of CNN and LSTM skillfully harnessed spatial and temporal features, enabling the capture of complex energy consumption patterns with great proficiency.

Experimental results showcased the exceptional accuracy of the CNN-LSTM approach, especially in the context of electric energy usage, surpassing conventional forecasting techniques. Roy et al. [1] introduced a tailor-made Deep Neural Network (DNN) model that was specifically crafted for forecasting heating and cooling loads in residential buildings. They proceeded to perform a comparative assessment, pitting the DNN model against the gradient-boosted machine (GBM), Gaussian process regression (GPR), and minimax probability models, particularly machine regression (MPMR). The findings revealed that both the DNN and GPR models demonstrated the most substantial variance accounted for (VAF) when it came to predicting both heating and cooling loads. In a study presented by Moradzadeh et al. [15], SVR and MLP models were employed to predict Cooling and Heating

Loads. The MLP technique yielded impressive outcomes, achieving the highest R-value of 0.9993 for Heating Load prediction. In contrast, for the Cooling Load prediction, the SVR method excelled, attaining the highest R-value of 0.9878.

In this research, a fresh ML approach is presented with the objective of attaining accurate and optimal predictive outcomes. The hybridization technique employed in this study is meticulously designed to boost the effectiveness of KNN models, guaranteeing the generation of dependable results. By combining two advanced and efficient optimization methods, the creation of these novel hybrid models surpassed conventional approaches, representing a notable advancement. A thorough assessment of these models was carried out, covering both their individual and hybrid setups, in order to guarantee a fair evaluation of their capabilities. In order to ascertain the robustness of the outcomes, the evaluation of model effectiveness included well-recognized metrics like $R^2$ and RMSE. Furthermore, the purposeful choice of two separate optimizers, specifically the Snake Optimizer (SO) and the Black Widow Optimizer (BWO), for building the hybrid models was guided by the objective of harnessing the distinct advantages of each optimizer, with the ultimate aim of enhancing performance.

This study significantly contributes to the field of building energy efficiency by comparing various predictive models for heating load in residential buildings. Furthermore, the study elucidates the factors influencing predictive accuracy and provides clear visualizations of error distribution patterns, aiding researchers and practitioners in selecting appropriate modeling approaches. Overall, these contributions advance knowledge in building energy efficiency, offering pathways for future research and the adoption of more effective predictive modeling techniques in practice.

The rest of the article is organized as follows:

In section two, the explanations of the materials and the methodology which utilized in this study are provided, the methodology incudes the descriptions of the fundamental framework KNN, and the optimization algorithms SO and BWO. Then, in the third section, the performance evaluation metrics are defined, along with their formulas Furthermore in the section three, the results of the predictive models based on the results of evaluators presented. At the end of this section, a comparative analysis based on the results of the present study and the previous studies is illustrated. In section four, the potential future works are identified. Finally, the last section includes the conclusion of the study.

## II. Materials and Methodology

### A. Materials

In the realm of predicting heating load for residential buildings, the utilization of various input features plays a crucial role in model accuracy and performance. As observed in Table I, which provides a comprehensive overview of the statistical parameters associated with these inputs, these features encompass a range of factors, including Relative Compactness (RCE), Surface Area (SA), Wall Area (WA), Roof Area (RA), Overall-Height (OVH), Orientation (OR), Glazing Area (GA), and Glazing Area Distribution (GAD).

The statistical insights presented in Table I allow researchers and practitioners to assess the distribution, variability, and characteristics of these features, providing a foundation for model development and evaluation. These input features serve as the basis for data-driven approaches, where ML models, neural networks, and optimization techniques are employed to forecast and optimize heating load in residential buildings.

### B. KNN for Regression

*1) Theory:* The exact process applies to regression, attributing the entity's value as the average of its nearest neighbours. In reversal, the goal is to predict dependent variables from independent ones. The $1-$closest neighbour technique, illustrated using KNN, finds the nearest neighbour to predict outcomes [21].

*2) Distance metric:* KNN predicts based on the K nearest neighbours' outcomes, utilizing distance metrics like Euclidean, Euclidean squared, City-block, or Chebyshev:

$$D(x,p)=\begin{cases}\sqrt{(x-p)^2} & Euclidean\ squared\\ (x-p)^2 & Euclidean\ squared\\ |x-p| & Cityblock\\ Max(|x-p|) & Chebyshev\end{cases} \tag{1}$$

In which $x$ and $p$ represent the inquiry spot and an instance from the selection of the illustrations, correspondingly [22], [23].

TABLE I. Statistical properties of the variables

| Indicator | Input | | | | | | | | Output |
|---|---|---|---|---|---|---|---|---|---|
| | RCE | SA | WA | RA | OVH | OR | GA | GAD | Heating |
| Max | 0.98 | 808.5 | 416.5 | 220.5 | 7 | 5 | 0.4 | 5 | 43.1 |
| Min | 0.62 | 514.5 | 245 | 110.25 | 3.5 | 2 | 0 | 0 | 6.01 |
| Median | 0.75 | 673.75 | 318.5 | 183.75 | 5.25 | 3.5 | 0.25 | 3 | 18.95 |
| Avg | 0.764 | 671.708 | 318.500 | 176.604 | 5.250 | 3.500 | 0.234 | 2.813 | 22.307 |
| Skew | 0.496 | -0.125 | 0.533 | -0.163 | 0.000 | 0.000 | -0.060 | -0.089 | 0.360 |
| St. Dev | 0.106 | 88.086 | 43.626 | 45.166 | 1.751 | 1.119 | 0.133 | 1.551 | 10.090 |

*3) K-Nearest neighbor predictions:* Once the K value has been determined, forecasts can be generated using the KNN instances. In the context of regression, KNN forecasting is equivalent to the average of the results from the K nearest neighbours:

$$y = \frac{1}{K}\sum_{i=1}^{k} y_i \tag{2}$$

In which $y_{\ i}$ represents the $ith$ instance of the sample examples, and y is the forecast (result) of the inquiry spot. Unlike regression, regarding classification issues, KNN prognostications rely on a balloting system where the victor is employed to tag the inquiry. KNN analysis, thus far, overlooks relative proximity, giving equal influence to K neighbours. An alternative uses large K values with distance weighting for nearby instances [24].

### C. Snake Optimization (SO)

Snake reproduction is influenced by temperature and food availability. Mating in cooler regions happens in late spring and summer. Female choice, male competition, and egg-laying are part of the process [25].

*1) Inspiration source:* SO is inspired by snake mating behaviour. Mating occurs in cold conditions with food; otherwise, snakes explore for food. During exploitation, stages optimize global efficiency. High-temperature prompts feeding, while cold environments and food lead to mating, with fighting and mating modes, possibly resulting in new snakes [26].

*2) Initialization:* Like all metaheuristic algorithms, SO commences by creating a uniformly distributed random population to initiate the optimization algorithm. The original population is acquired using the following equation:

$$X_i = X_{min} + r \times (X_{max} - X_{min}) \tag{3}$$

Here, $X_i$ denotes the location of the $ith$ individual, $r$ represents a random value falling within the range of 0 to 1, while $X_{min}$ and $X_{max}$ correspond to the inferior and higher problem limits.

*3)* Diving the swarm into two equal groups, males and females Within this research, it is presumed that there is an equal distribution, with 50% males and 50% females in the population. The population is then categorized into two groups: males and females. To divide the swarm, the subsequent two Eq. (4) and (5) are employed:

$$N_m \approx N/2 \tag{4}$$

$$N_f = N - N_m \tag{5}$$

Here, $N$ stands for the total number of individuals, $N_m$ represents the count of male individuals and $N_f$ signifies the count of female individuals.

*4)* Evaluate each group defining temperature and food quantity

- Identify the top individual within each cluster and determine the best female ($f_{best,f}$), and the best male ($f_{best,m}$) along with the food position ($f_{food}$).
- The temperature, Temp, may be characterized utilizing the subsequent equation:

$$Temp = \exp(\frac{-t}{T}) \tag{6}$$

In this case, $t$ alludes to the present repetition, and $T$ represents the utmost count of repetition.

- Describing the quantity of food ($Q$) involves determining it with the subsequent equation:

$$Q = c_1 * \exp(\frac{t-T}{T}) \tag{7}$$

The constant $c_1$ is fixed at a value of 0.5.

*5) Exploration phase (no food):* When $Q$ is less than the threshold ($Threshold = 0.25$), the snakes forage for nourishment by picking a random location and adjusting their position accordingly. To simulate the exploration phase, the subsequent steps are taken:

$$X_{i,m}(t+1) = X_{rand,m}(t) \pm c_2 \times A_m \times ((X_{max} - X_{min}) \times rand + X_{min}) \tag{8}$$

Here, $X_{i,m}$ designates the position of the $ith$ male, $X_{rand,m}$ signifies the random male's position, $rand$ represents a random value ranging from 0 to 1 , and $A_m$ denotes the male's capability to locate food, which can be computed using the subsequent equation:

$$A_m = \exp(\frac{-f_{rand,m}}{f_{i,m}}) \tag{9}$$

Here, $-f_{rand,m}$ stands for the fitness of $X_{rand,m}$ , while $f_{i,m}$ represents the fitness of the ith individual within the group of males, and C2 is an unchanging continuous set at 0.05:

$$X_{i,f} = X_{rand,f}(t+1) \pm c_2 \times A_f \times ((X_{max} - X_{min}) \times rand + X_{min}) \tag{10}$$

Here, the position of the $ith$ female is denoted by $X_{i,f}$ , while the location of a random female is indicated by $X_{rand,f}$ . A random value between 0 and 1 is represented by rand, and the female's capacity to locate food is signified by $A_f$ which can be computed as follows:

$$A_f = \exp(\frac{-f_{rand,f}}{f_{i,f}}) \tag{11}$$

In this case, $-f_{rand,f}$ represents the fitness of $X_{rand,f}$ and $f_{i,f}$ denotes the fitness of the $ith$ individual within the group of females.

*6)* Exploitation phase (food exists)

If $Q\ >$ Boundary

If the Heat > Boundary (0.6)% (hot)

The snakes will exclusively relocate toward the sustenance:

$$X_{i,j}(t+1) = X_{food} \pm c_3 \times Temp \times rand \times (X_{food} X_{i,j}(t)) \tag{12}$$

If the Heat < Boundary (0.6) %cold

The snake will either engage in combat or enter the mating phase.

- Combat Mode:

$$X_{i,m}(t+1) = X_{i,m}(t) + c_3 \times FM \times rand \times (Q \times X_{best,f} - X_{i,m}(t)) \tag{13}$$

Here, $X_{i,m}$ pertains to the mode of the male in the $ith$ mode, $X_{best,f}$ signifies the location of the superior individual within the female group, and $FM$ represents the male agent's combat proficiency:

$$X_{i,f}(t+1) = X_{i,f}(t+1) + c_3 \times FF \times rand \times (Q \times X_{best,m} - X_{i,F}(t)) \tag{14}$$

In this scenario, $X_{i,f}$ designates the location of the female at the ith position, $X_{best,m}$ points to the location of the top individual within the male group, and $FF$ signifies the female agent's combat aptitude.

$FM$ and $FF$ are derivable from the subsequent equation:

$$FM = \exp\left(\frac{f_{best,f}}{f_i}\right) \tag{15}$$

$$FF = \exp\left(\frac{-f_{best,m}}{f_i}\right) \tag{16}$$

In this context, $f_{best,f}$ represents the fitness of the top agent in the female group, $-f_{best,m}$ signifies the fitness of the foremost agent in the male group, and fi denotes the fitness of an individual agent.

- Coupling Mode:

$$X_{i,m}(t+1) = X_{i,m}(t)c_3 \times M_m \times rand \times (Q \times X_{i,f}(t) - X_{i,m}(t)) \tag{17}$$

$$X_{i,f}(t+1) = X_{i,f}(t) + c_3 \times M_f \times rand \times (Q \times X_{i,m}(t) - X_{i,f}(t)) \tag{18}$$

$X_{i,f}$ represents the $ith$ agent's location in the female group and $X_{i,m}$ denotes the $ith$ agent's position in the male group. Mm and Mf indicate the reproductive capacity of males and females, respectively, which can be computed as follows:

$$M_m = \exp\left(\frac{-f_{i,f}}{f_{i,m}}\right) \tag{19}$$

$$M_f = \exp\left(\frac{-f_{i,m}}{f_{i,f}}\right) \tag{20}$$

If the eggs hatch, pick the least competent male and female and substitute them:

$$X_{worst,m} = X_{min} + rand \times (X_{max} - X_{min}) \tag{21}$$

$$X_{worst,f} = X_{min} + rand \times (X_{max} - X_{\mathrm{min)}} \tag{22}$$

The operator $\pm$, or diversity factor, influences solution positions, enhancing exploration in various directions. It is a common element in metaheuristic algorithms, as seen in Hunger Games Search and others.

### D. Black Widow Optimization Algorithm

The black widow spider in Mediterranean Europe uses Cannibalism in its lifecycle. In 2020, researchers developed the Black Widow Optimization (BWO) algorithm inspired by this behaviour, which has four key stages [27].

*1) Initialization:* $W_{N,D} = [X_1, X_2, \ldots, X_N]$ represents a group of N black widow spiders $X_1, X_2, \ldots, X_N$ . $D$ signifies the dimension relevant to an optimization problem within the given population $X_i = [x_{i,1}, x_{i,2}, \ldots, x_{i,D}] (1 \leq i \leq N)$ denotes the $i - th$ widow. Every component within an individual $X_i = [x_{i,1}, x_{i,2}, \ldots, x_{i,D}] (1 \leq i \leq N)$ each element is initialized using the formula provided in Eq. (23):

$$x_{i,j} = l_j + rand(0,1).\left(u_j - l_j\right), 1 \leq j \leq D \tag{23}$$

Here $L = [l_1, l_2, \ldots, l_D], U = [u_1, u_2, \ldots, u_D]$, which do the minimum and maximum limits of the parameters in the optimization model.

*2) Procreate:* The new generation is created through unique breeding behaviour in black spiders, randomly selecting maternal and paternal spiders to reproduce based on a specified proportion (Pp) using Eq. (24):

$$\begin{cases} Y_i = aX_i + (1-a)X_i \\ Y_j = aX_j + (1-a)X_i \end{cases} \tag{24}$$

In which $Xi$ and $Xj$ stand as maternal and paternal arachnids correspondingly. $Yi$ and $Yj$ signify the descendants resulting from mating. Additionally, $\alpha$ comprises a $D -$dimensional assortment featuring chance figures.

### E. Performance Evaluator

In this segment, a series of metrics (R$^2$, RMSE, MSE, n10-index, and MRAE) has been developed to assess the hybrid models. These metrics gauge both the degree of error and correlation, providing valuable insights into the models' performance.

*1)* R$^2$ (Coefficient of Determination):

- R$^2$ measures the proportion of the variance in the dependent variable (target) that can be explained by the independent variables (features) in the model.
- It ranges from 0 to 1, where 1 indicates a perfect fit and 0 indicates no correlation.
- A higher R$^2$ value suggests better model performance.

*2)* RMSE (Root Mean Squared Error):

- RMSE quantifies the average magnitude of errors between predicted values and actual values.
- It is calculated as the square root of the average of squared differences between predicted and actual values.

- Smaller RMSE values indicate better model accuracy.

*3)* MSE (Mean Squared Error):

- MSE is similar to RMSE but without the square root operation.
- It represents the average of squared errors.
- Like RMSE, smaller MSE values indicate better model performance.

*4)* n10-index:

- The n10-index assesses the model's ability to predict extreme values.
- It focuses on the top 10% of predictions (highest or lowest).
- A higher n10-index indicates better performance in capturing extreme events.

*5)* MRAE (Mean Relative Absolute Error):

- MRAE measures the average relative difference between predicted and actual values.
- It considers the magnitude of errors relative to the actual values.
- Smaller MRAE values imply better model accuracy.

These metrics collectively provide valuable insights into the hybrid models' performance, considering both error and correlation aspects.

The equations for these metrics, which were employed in this study, can be found in Table II [28].

TABLE II. MATHEMATIC EQUATIONS OF THE PERFORMANCE METRICS

| | | |
|---|---|---|
| Coefficient Correlation ($R^2$): | $\boldsymbol{R^2} = \left(\frac{\boldsymbol{\sum_{i=1}^{n}(b_i-\bar{b})(m_i-\bar{m})}}{\sqrt{\left[\boldsymbol{\sum_{i=1}^{n}(b_i-\bar{b})^2}\right]\left[\boldsymbol{\sum_{i=1}^{n}(m_i-\bar{m})^2}\right]}}\right)^{2}$ | (25) |
| Root Mean Square Error (RMSE): | $RMSE = \sqrt{\frac{1}{n}\sum_{i=1}^{n}(m_i-b_i)^2}$ | (26) |
| Mean Square Error (MSE): | MSE = $\frac{1}{n}\sum_{j=1}^{n}(m_i-b_i)^2$ | (27) |
| $\boldsymbol{n10-index}$: | $n10-index = \frac{n10}{n}$ | (28) |
| Mean Relative Absolute Error (MRAE) | $MRAE = \frac{1}{n}\sum_{i=1}^{n}\frac{\lvert m_i-b_i\rvert}{\lvert b_i-\bar{b}\rvert}$ | (29) |

Where:

- The measured value is indicated by $m_i$.
- Predicted values are expressed as $b_i$.
- The $n$ denotes the sample size.
- The means of the measured and predicted values are represented as $\bar{m}$ and $\bar{b}$, respectively.
- The mean of the predictor variable in the dataset is symbolized as $\bar{x}$.

## III. RESULT AND DISCUSSION

### A. *Results of the Evaluation Metrics*

The results presented in Table III illustrate the effectiveness of the developed models for predicting heating load in residential buildings. Specifically, the KNSO model, which integrates the SO, emerges as the frontrunner across various performance metrics. Its low RMSE values in the training, validation, and test phases, along with high $R^2$ values, reflect its capacity to provide accurate forecasts. The consistency of the KNSO model in maintaining low MARE values across all phases underscores its reliability in capturing the actual heating load values. Additionally, the high n10_index observed in the training phase suggests that a significant portion of the predicted values falls within a tolerance band of actual heating load values. This reflects the KNSO model's ability to match real-world heating load data closely.

Comparatively, the traditional KNN and KNBW models exhibit commendable performance, but the KNSO model stands out as the superior choice, particularly in terms of precision and accuracy in heating load prediction. The integration of the SO Optimizer effectively refines the KNN model, providing a valuable tool for optimizing energy management and enhancing sustainability in residential buildings. These findings emphasize the significance of optimization techniques in enhancing the predictive capabilities of ML models for energy consumption. The results have practical implications for energy-efficient building design and the reduction of heating load, contributing to both economic and environmental sustainability. In conclusion, the KNSO model, when applied to heating load prediction in residential buildings, demonstrates outstanding performance and offers substantial promise for improving energy efficiency in the built environment.

In order to delve deeper into the distinctions and levels of accuracy exhibited by the various models, it is crucial to turn attention to Fig. 1. This figure offers a comprehensive comparative analysis of critical evaluation metrics, namely $R^2$ values, RMSE, and MSE, which are indispensable for assessing the precision of these models in predicting heating load. As previously mentioned, the KNSO model emerges as the star performer among the models. This distinction is exceptionally evident in Fig. 1, where its results consistently demonstrate the lowest values across these metrics. The exceptionally low values of RMSE and MSE and the high $R^2$

score underscore the remarkable precision of the KNSO model in predicting heating load, making it the standout choice. In contrast, the KNN base models exhibit comparatively weaker results when scrutinized through the lens of these metrics. They demonstrate higher RMSE and MSE values and lower $R^2$ scores, signifying a lower level of accuracy in their predictions compared to the KNSO model.

TABLE III. THE RESULT OF DEVELOPED MODELS FOR KNN

| Model | Phase | Index values | | | | |
|---|---|---|---|---|---|---|
| | | RMSE | $R^2$ | MSE | n10_index | MARE |
| KNN | Train | 1.878 | 0.966 | 3.527 | 0.747 | 0.080 |
| | Validation | 2.254 | 0.952 | 5.080 | 0.635 | 0.101 |
| | Test | 2.145 | 0.956 | 4.603 | 0.696 | 0.085 |
| | All | 1.980 | 0.963 | 3.921 | 0.723 | 0.084 |
| KNSO | Train | 1.231 | 0.986 | 1.515 | 0.796 | 0.059 |
| | Validation | 1.422 | 0.979 | 2.021 | 0.896 | 0.059 |
| | Test | 1.500 | 0.977 | 2.251 | 0.922 | 0.058 |
| | All | 1.304 | 0.984 | 1.701 | 0.829 | 0.059 |
| KNBW | Train | 1.549 | 0.977 | 2.399 | 0.725 | 0.074 |
| | Validation | 1.803 | 0.967 | 3.251 | 0.661 | 0.078 |
| | Test | 1.729 | 0.970 | 2.988 | 0.774 | 0.064 |
| | All | 1.617 | 0.975 | 2.615 | 0.723 | 0.073 |

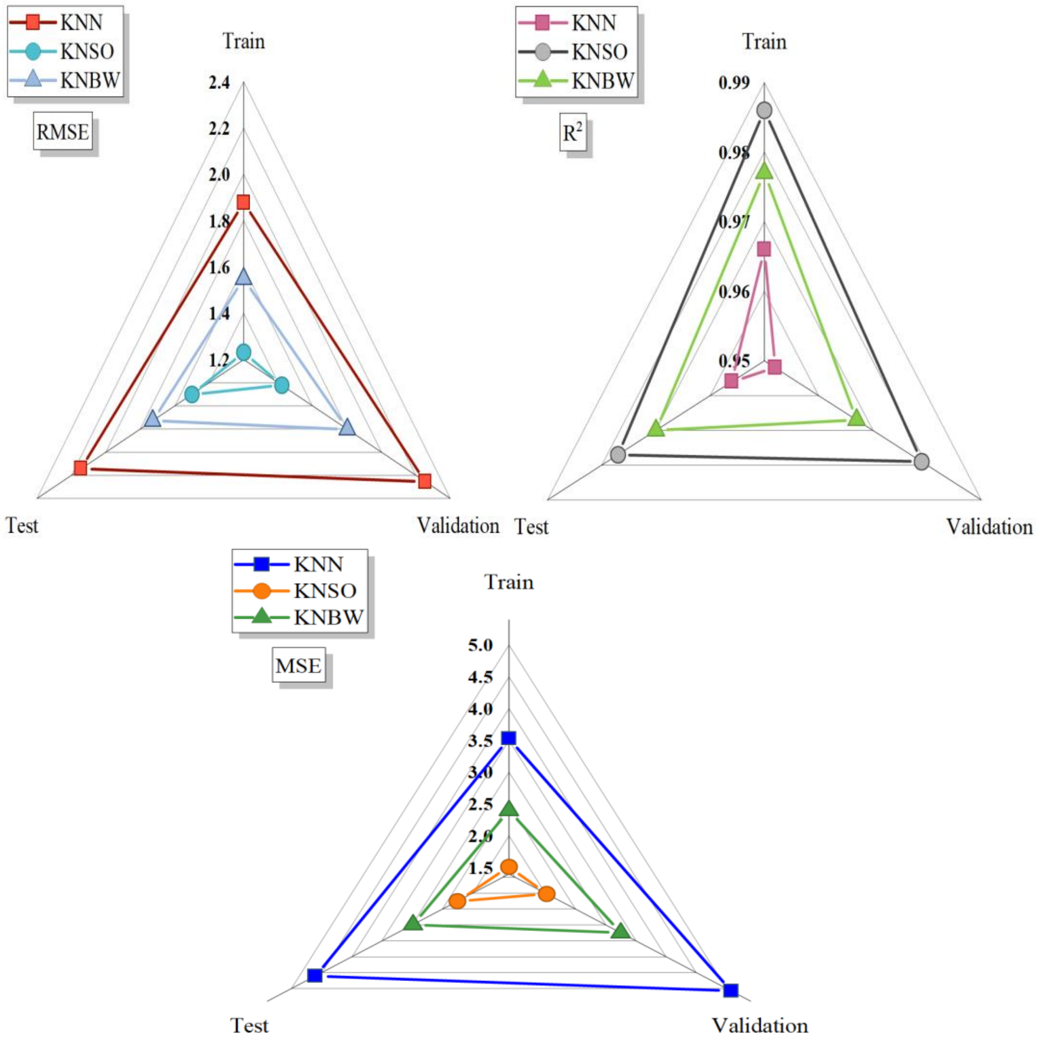

Fig. 1. Comparison between models based on RMSE, $R^2$, and MSE.

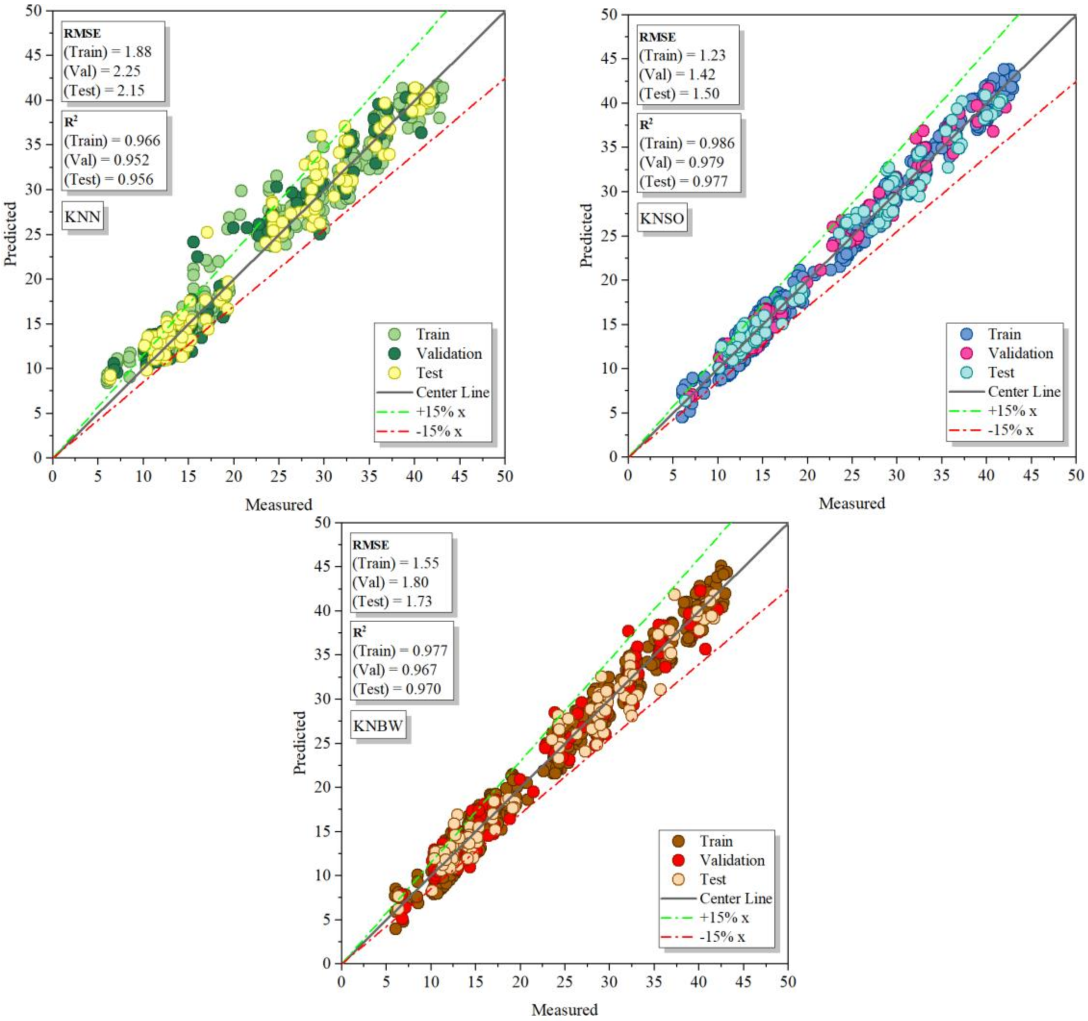

Fig. 2. Scatter plot for developed models.

In Fig. 2, a scatter plot is presented to visually illustrate the performance of the models concerning their $R^2$ and RMSE values. Each model, in both the training and validation phases, is represented by distinct circular markers distinguished by various colours. These markers converge towards a central line, symbolizing the ideal $R^2$ value of 1, signifying a perfect alignment between the predicted and actual values. A more in-depth examination of the data points associated with the KNSO model within the scatter plot reveals a closely-knit cluster positioned near the central line. The tight clustering of data points around this central line serves as compelling evidence of the KNSO model's precision in prediction, consistently remaining in proximity to the ideal $R^2$ value. In contrast, the KNBW and KNN models exhibit scattered data points, indicative of a broader spread of values. This dispersion within the scatter plot implies that these models show less consistency and accuracy in predicting heating load, as their data points deviate more widely from the ideal $R^2$ value of 1.

Carrying out a comprehensive error analysis is essential to gain a more profound understanding of the distinctive attributes and accuracy of the models under scrutiny. Such an analysis allows us to delve into the complexities of their performance. In this endeavour, Fig. 3 plays a pivotal role, offering valuable insights into the models' performance in terms of errors. Of particular note, the graph underscores the noteworthy error rate associated with the KNN model, which was particularly prominent during the testing phase. This observation serves as a crucial reference point for evaluating the model's performance in real-world scenarios, shedding light on areas where improvements may be necessary. The maximum error rate reached as high as 30%, highlighting the challenges faced by the KNN model, particularly when it comes to accurately predicting heating load (HL) values within this specific range of samples. In contrast, a more detailed examination of the KNSO model reveals an exceptional level of precision in the training phase, where the majority of data points exhibit nearly negligible errors, staying close to 0%.

This demonstrates the KNSO model's proficiency in accurately forecasting HL values during the training phase. However, the testing phase presents a slightly different scenario, with some errors emerging, although they remain relatively lower than those observed in the KNN model. Conversely, the performance of the KNBW model displays distinct characteristics. During the training phase, it registered a peak error of 50%, signifying a certain degree of inconsistency in its predictive accuracy. Remarkably, these errors persist across all three phases: training, testing, and validation, further emphasizing its unique behaviour.

In Fig. 4, the distribution characteristics of the proposed models are visually represented through a scatter interval plot, encompassing the three distinct phases: training, validation, and testing. Particularly noteworthy is the scattering of data points that correspond to the KNN model, which spans a broad range of error percentages, extending from 60 to -20. This dispersion is most conspicuous during the training phase. To effectively identify outlier data points for comparative analysis among the models, a range equivalent to 1.5 times the Interquartile Range (IQR) is employed. In contrast, the data points associated with the KNSO model are notably concentrated within a relatively narrow range of error percentages, which extends from 20 to -20. This concentration signifies a higher degree of consistency in the predictions generated by the KNGO model. On the other hand, the data points for KNBW have contained a range of -40 to 40 per cent errors, indicating a distinct distribution pattern when compared to both the KNN and KNSO models.

### B. *Comparison between the Outcomes of Present Study and the Existing Studies*

Heating Load prediction has been the subject of numerous studies, including those conducted by Afzal et al. [29], utilizing the MLP model, and Gong et al. [30], employing the GBM technique. Notably, among the various studies referenced in Table IV, superior performance was demonstrated by the GPR model, achieving an $R^2$ value of 0.99 and an RMSE value of 0.059 in research conducted by Roy et al. [31]. In the current study, the foundational framework adopted was the KNN model, which was enhanced through hybridization with BWO and SO algorithms. Upon evaluating the results obtained, it was found that the integration of SO into the KNN model demonstrated exceptional applicability, yielding an $R^2$ value of 0.986 and an RMSE of 1.231, surpassing the performance of the other two models in this study.

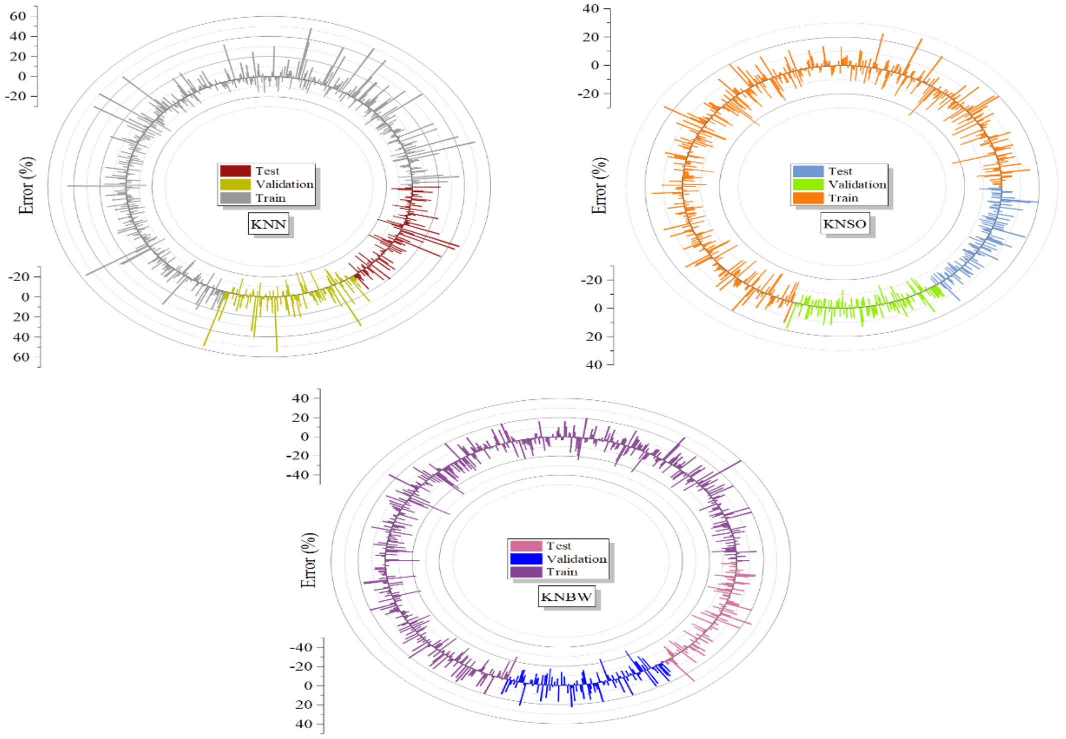

Fig. 3. The models' error percentage based on the Radial Staked Bar plot.

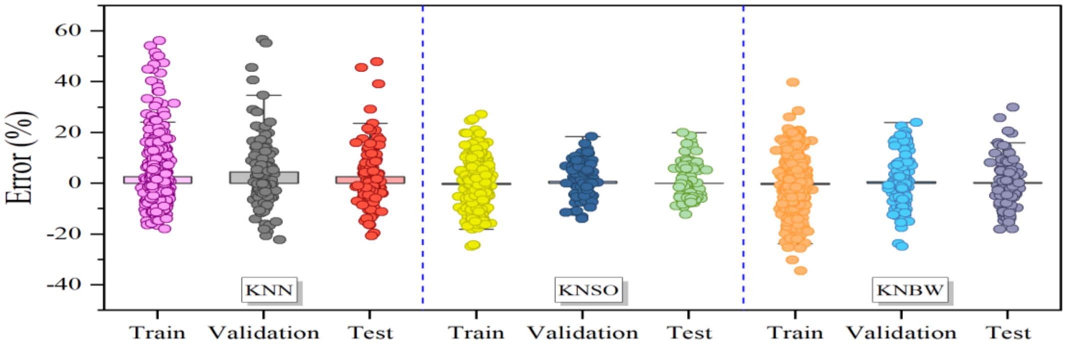

Fig. 4. The Bar Overlap of errors among the developed models.

TABLE IV. THE COMPARATIVE ANALYSIS BETWEEN EXISTING PUBLICATIONS AND CURRENT STUDY

| Name | Model | Results | |
|---|---|---|---|
| | | RMSE | $R^2$ |
| Roy et al. [31] | GPR | 0.059 | 0.99 |
| Gong et al. [30] | GBM | 0.1929 | 0.9882 |
| Afzal et al. [29] | MLP | 1.4122 | 0.9806 |
| Present study | KNSO | 1.231 | 0.986 |

## IV. CONCLUSION

The article discussed herein delves into the realm of predictive modelling for heating load in residential buildings, focusing on the performance of various models. This exploration of the models' precision and characteristics has revealed several key insights. One of the most prominent findings is the substantial variation in accuracy across the models. The KNSO model, enhanced by the Snake Optimizer, emerges as the star performer. This model consistently exhibited the lowest RMSE and MARE values and the highest $R^2$ scores. These results indicate the remarkable precision of the KNSO model in predicting heating load, which holds significant promise for improving energy efficiency and sustainability in building design and management. Conversely, the KNN model, serving as the baseline, demonstrated weaker performance, with notably higher RMSE and MARE values and lower $R^2$ scores. This performance divergence emphasizes the significance of optimization techniques, such as the Snake Optimizer, in enhancing predictive capabilities. The KNBW model, while not reaching the same level of accuracy as the KNSO model, displayed moderate performance. Its performance characteristics, including errors and consistency, were distinct from both the KNN and KNSO models. This suggests that the optimization techniques applied in each model have a significant impact on their predictive accuracy. Furthermore, the distribution patterns of error percentages among the models, visualized in the scatter interval plot, underline the consistency and accuracy disparities. The KNSO model exhibited a notably concentrated distribution within a narrow range of error percentages, reflecting its consistent and precise predictions. In contrast, the KNN model showed a wide scattering of data points with a broader range of errors, particularly during the training phase. KNBW had its distinct distribution pattern, encompassing a specific range of errors. In conclusion, this study underscores the pivotal role of optimization techniques in refining predictive models for heating load. The KNSO model, with the Snake Optimizer, stands out as a powerful tool for accurate heating load prediction, offering valuable insights for sustainable building design. These findings hold significant implications for energy efficiency and environmental sustainability in the construction and management of residential buildings. By harnessing the capabilities of advanced optimization techniques, substantial strides could be made toward more energy-efficient and environmentally friendly building practices, contributing to a greener and more sustainable future.

## V. FUTURE WORK

To enhance the effectiveness of predictive modeling for heating load in residential buildings, a multifaceted approach is warranted. Firstly, an in-depth exploration into the integration of additional variables, such as occupancy patterns, weather forecasts, and building materials, holds promise for refining prediction accuracy and capturing the intricacies of real-world scenarios more comprehensively. Moreover, delving into the application of a broader spectrum of ML algorithms, beyond those examined in this study, could yield fresh perspectives and potentially unveil more efficient models. Concurrently, conducting rigorous field studies to validate predictive model performance in authentic settings would furnish invaluable practical insights, substantiating the conclusions drawn from this research. Furthermore, a longitudinal analysis of optimized models, assessing their adaptability to evolving environmental conditions and shifting building usage patterns, stands to offer crucial data for informing sustainable building management strategies. Lastly, integrating cutting-edge advancements in optimization techniques and data analytics methodologies holds the potential to usher in a new era of even more robust and precise predictive models, thereby advancing the overarching objective of fostering energy-efficient and environmentally sustainable residential constructions.

# Enhancing Security in IoT Networks: Advancements in Key Exchange, User Authentication, and Data Integrity Mechanisms

Alumuru Mahesh Reddy[1], Dr. M. Kameswara Rao[2]
Research Scholar, Department of ECM, Koneru Lakshmaiah Education Foundation, Green Fields, Vaddeswaram, Guntur, India[1]
Professor, Department of ECM, Koneru Lakshmaiah Education Foundation, Green Fields, Vaddeswaram, Guntur, India[2]

***Abstract*—Future Internet (FI) will be shaped by the Internet of Things (IoT), however because of their limited resources and varied communication capabilities, IoT devices present substantial challenges when it comes to securing connectivity. The adoption of robust security measures is hindered by limited compute power, memory, and energy resources, hence diminishing the promise for improved IoT capabilities. Confidentiality, integrity, and authenticity are ensured via authentication mechanisms are influenced by privacy needs, which are driven by sorts of customers that IoT networks service. Authentication is crucial in vital industries like linked cars and smart cities where hackers might use holes to access sensor data. Verification of the Gate Way Node (GWN), which is responsible for mutual authentication, user and sensor registration, and session key creation, is essential. The efficiency of key creation has been enhanced to tackle temporal intricacies linked to different key lengths. With notable advantages, the novel method shortens the time required to generate cryptographic keys: only 60 milliseconds for 100-bit keys and 120 milliseconds for 256-bit keys. This improvement fortifies resistance against new cyber threats by strengthening security basis of IoT networks and enhancing responsiveness and dependability. Through open transmission channels, users send login requests, and after successfully authenticating, they create session keys to establish secure connections with cloud servers. Python simulation results show how resilient the system is to security threats while preserving affordable interaction, processing, and storage. This development not only strengthens IoT networks but also guarantees their sustainability in the face of changing security threats.**

***Keywords*—IoT; Public key; key authentication; gate way node; data integrity mechanisms***

## I. Introduction

Improvements in wireless communication, embedded systems, and energy-efficient radio technologies over the past decade were crucial in enabling tiny devices to react and monitor their surroundings and shape a new networking paradigm able to act upon physical objects, ushering in the era of the Internet of Things (IoT) [1]. Connecting "Anything" to "Anyplace" and "Anytime" enables the third dimension of the Internet of Things vision, which will lead to the development of new applications and services that will affect the ecological, medical, financial, and social well-being. The potential for IoT to revolutionize human interaction with the physical environment is enormous. Smart cities, health monitoring, home automation, smart transportation, smart agriculture, and smart grids are just a few of the many possible uses for the Internet of Things. By 2020, there will be almost 50 billion "things" connected to the internet, or IoT devices, according to a recent study by CISCO [2], [3]. IoT's enormous potential has led some to call it the "next wave" of the Internet. The widespread use of IoT technology and applications relies heavily on their security. Without guarantees in terms of system-level confidentiality, authenticity, and privacy, IoT solutions are unlikely to be adopted on a large scale. It is difficult to establish end-to-end secured communications between IoT entities because of the heterogeneity of IoT and because the majority of IoT devices are resource constrained. Organizational and academic researchers continue to focus on the problem of IoT security. Fig. 1 shows the Future Vision of IoT.

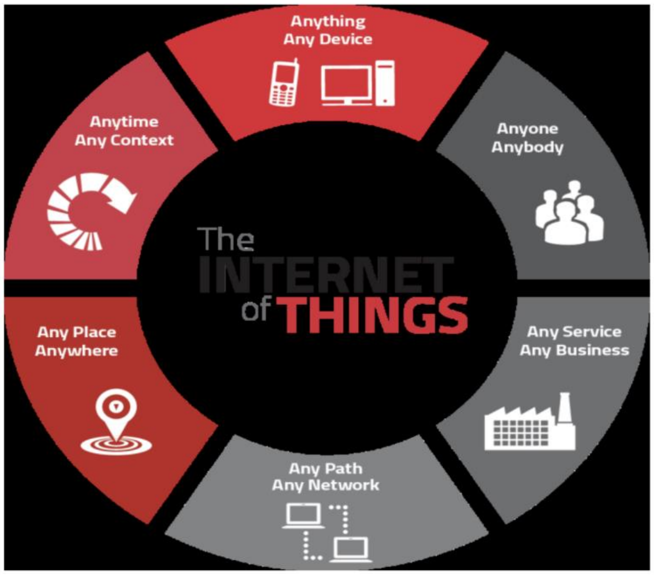

Fig. 1. Future vision of IoT.

The number of devices connected to the Internet of Things (IoT) is rising. The Internet of Things (IoT) encompasses not just traditional computing and communication equipment but also a wide variety of other devices utilized in various spheres of everyday lives. As a result, hundreds of billions of gadgets could end up linked together [4]. In the IoT ecosystem, inanimate things automatically share data and communicate with one another over the Internet. With IoT, information may be shared between living and nonliving things to accomplish tasks. The data they collect, evaluate, and act upon can all be done automatically by those devices [5]. Authentication can be thought of as the first line of defense because it guarantees that security procedures will be followed. A handshake is an optional authentication procedure that must be completed before permission may be given. Authenticating a device entails checking its claimed characteristics [6]. Sensitive information can be stolen and malicious acts carried out if authentication is weak. One of the first stages in ensuring the security of the entire system is to deploy strong authentication procedures [7]. Before any information can be transferred between IoT devices, authentication must take place. Traditional authentication methods often need one of the well-known authentication elements, such as a secret the user knows or a token the user possesses, to verify the identity of a user.

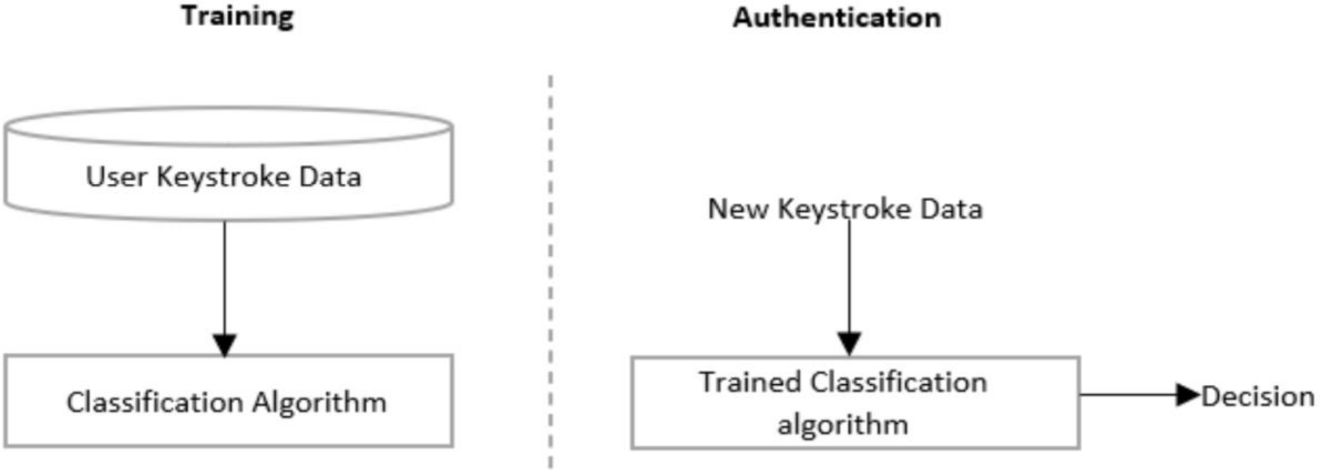

Fig. 2. Process of continuous authentication.

Two-factor authentication and multi-factor authentication are two examples of current authentication methods that use multiple authentication factors to verify the identity of a person or device [8]. To make it extremely difficult, if not impossible, for an unauthorized party to obtain access to a protected resource, security experts have developed two- or multi-factor authentication systems [9]. Two-factor authentication methods have gained popularity in recent years as a means to guarantee safe system logins by adding an extra layer of security and inspiring user confidence. There are two main types of authentication procedures: machine-to-machine and human-to-machine [10]. Classification is the challenge of determining to which group an observation belongs in a statistical classification scheme. Assigning a spam or non-spam classification to an email or a patient's diagnosis based on observable characteristics (Sex, blood pressure, the presence or absence of particular symptoms, etc.) are two examples. Continuous authentication makes use of keyboard data for user classification using classification algorithms. The continuous authentication process is depicted in Fig. 2. The user's new keystroke data is fed into the trained algorithm, which was itself trained using keystroke data [11]. Authentication is considered to have been successful if the categorized user is the same as the input user. Users are denied access if the algorithm's classification of them does not match the supplied user. The system architecture of the proposed work incorporates components from the Cloud, Industry, Sensing Devices, Gateway Node (GWN), Trusted Third Party, and Sensing Devices to provide a safe framework for industrial monitoring. Users with smart cards may monitor factories remotely over the internet, protecting comprehensively address the multifaceted aspects of advancing security protocols in IoT networks. Section I introduces the overarching challenges in IoT security and highlights the privacy of any data that is sent. To effectively transmit sensor data, steps for key agreement and authentication are started by the consumer, the GWN, and the sensors. The GWN creates and distributes session keys, registers sensors, and preloads them with credentials to enable secure connection. In industrial contexts, this method improves user oversight and data transfer security. Energy consumption must be taken into account while implementing efficient key generation techniques in the Internet of Things. In addition to increasing computing performance, optimizing key generation lowers energy consumption, which is essential for IoT devices with constrained power sources.

The following is the proposed work's primary contribution,

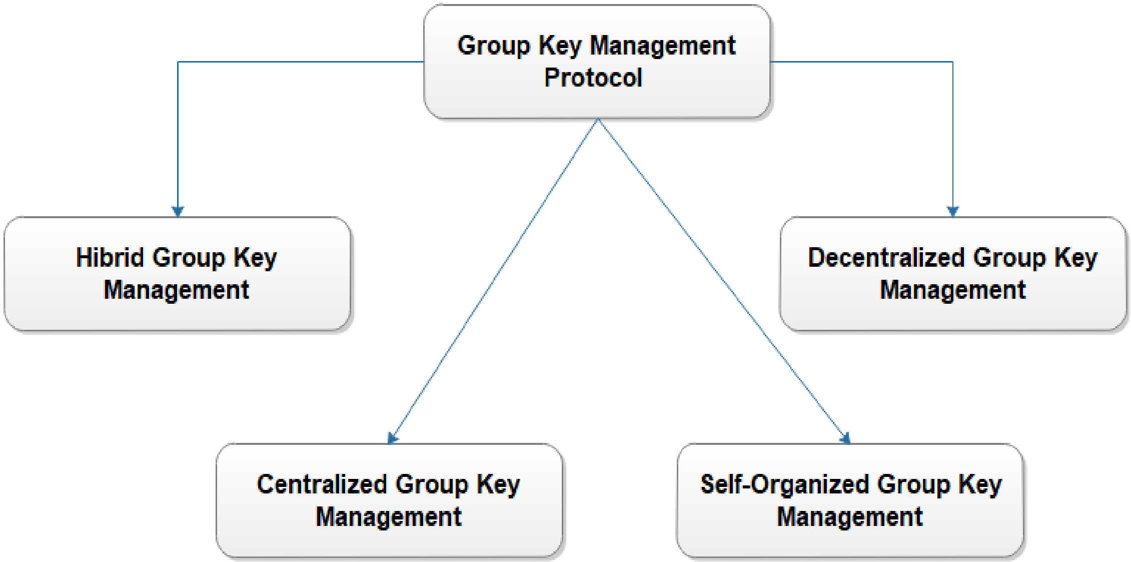
- Enhanced security without compromising performance is made possible by optimized algorithms, which are essential for Internet of Things devices with limited resources.
- Secure access to sensing devices is ensured via smart card-enabled user authentication through GWN, enhancing system integrity overall.
- The timely monitoring of production processes made possible by the prompt transfer of sensor information to users improves productivity and decision-making skills.
- Enabling safe connections between users and sensing devices, the authenticated key agreement mechanism assures the production of shared session keys.

- The suggested system design provides a secure and reliable data transmission framework, enabling users to efficiently monitor industrial operations.

The study is divided into five parts that concentrate on improvements in data integrity, user authentication, and key exchange. Section I provides the Authentication Methods in IoT Security. Group key management mechanisms in IoT networks are examined in Section II. The limitations of traditional approaches are covered in Section III. The process for enhancing key generation algorithms is described in Section IV. Section V presents the results and discussion, while Section VI provides a final summary.

## II. Classification of Group Key Management Protocols based on IoT Network Nodes

With the development of so many joint programs, the importance of group key management has grown substantially. There are two main types of group communication: static and dynamic. Members of a static group do not rotate or shuffle about. Keys do not need to be updated after they have been disseminated. Members of a dynamic group, on the other hand, come and go regularly. The Group Controller (GC) is responsible for handling the frequent key updates necessary to keep forward and backward secrecy[12]. Fig. 3 displays the variety of GKM methods now in use. Centralized key management refers to the method by which all key management functions are performed by a single organization. In the distributed GKM method, a member of the group is chosen on the fly and given responsibility for running the GKM. It is possible to categorize IoT network group key management protocols according to the types of network nodes used in the protocol. Each participant in the contributory key management method does its part in generating the group key. Both tree-based and non-tree-based models can be used to accomplish these important management strategies [13]. The literature on GKM is rife with examples of tree-based models. In tree-based models, each leaf stands for a user, and each node in the tree's path to the root represents that person's auxiliary keys. The inherent hierarchy of a tree-based organization is implicitly encouraged. The rekeying process is simplified by the group controller's logical organization of the keys within the structure. Some popular types are as follows:



Group Key Management Protocol
Hibrid Group Key Management
Decentralized Group Key Management
Centralized Group Key Management
Self-Organized Group Key Management

Fig. 3. Group key management protocol.

### A. Centralized Group Key Management

The group keys in an IoT network are managed by a centralized authority in this sort of protocol. The group keys are generated, disseminated, and kept up-to-date by a centralized authority. Logical Key Hierarchy (LKH) and Group Key Management Protocol (GKMP) are two exemplars of centralized group key management protocols[14]. One way to handle group keys in a network is using centralized group key management, in which a single server or other coordinating body is in charge of key generation, distribution, and upkeep for all users. Secure communication between a set of network nodes is the primary function of group keys. The central authority in a centralized group key management system is responsible for managing the production and distribution of keys. The group keys are generated by a trusted source and safely disseminated to all participating nodes via cryptographic protocols. Network nodes make contact with a centralized authority to request and receive the group keys required for secure group communication. The coordinating body carries out a number of crucial managerial tasks, including:

*1) Key generation:* The central authority uses cryptographic procedures to produce random, robust group keys.

*2) Key distribution:* Once the group keys have been generated, they will be sent out to all of the connected devices. To protect the privacy and safety of the keys, they might be dispersed through encrypted channels or protocols.

*3) Key updates:* The group keys may be updated at regular intervals by the central authority to account for network changes and new security standards. This keeps the group's communication secure by ensuring that compromised or obsolete keys are changed.

*4) Key revocation:* The central authority can revoke the associated key in the event that a node is compromised or departs the group. In this way, unrecognized nodes are denied access to the group's communication.

Smaller networks with a controllable number of nodes and generally stable network topologies are often good candidates for centralized Group Key Management. Scalability, security, and privacy issues in bigger or more dynamic IoT systems should be carefully considered, despite the fact that it provides a clear and regulated solution to group key management.

### *B. Decentralized Group Key Management*

Multiple entities or nodes in the IoT network share the duty of key management thanks to decentralized protocols[15]. These methods do not require a governing body to control keys. Using methods like key trees or shared key derivation, nodes coordinate to set up and maintain group keys. Both the Tree-based Key Management Protocol (TKMP) and the Distributed Group Key Management Protocol (DGKMP) are examples of protocols for decentralized group key management. When it comes to handling group keys in a network, decentralized group key management is the way to go because it allows for key production, distribution, and maintenance to be handled by a number of different entities or nodes. Decentralized group key management is based on cooperation amongst nodes, as opposed to centralized group key management, which is controlled by a single body[16]. Decentralized Group Key Management has the following salient features and qualities:

*5) Key generation:* In a decentralized system, many different nodes work together to generate keys. The group keys are generated by these nodes working together using cryptographic procedures. Methods like key derivation and tree-based key establishment can be used in the key generation process.

*6) Key distribution:* Decentralized protocols use procedures for key distribution among the participating nodes rather than depending on a centralized entity. In order to disperse the group keys, the nodes in the network either disclose their keying material or engage in key exchange protocols. To protect the privacy and authenticity of the key distribution procedure, secure channels or protocols can be used.

*7) Key updates:* Without requiring a central authority, decentralized Group Key Management techniques allow for instantaneous key upgrades. When changes are required to the group keys, such as when new nodes join or depart the group, the nodes work together to make such changes. Because of this adaptability, the network can better accommodate shifts in its constituent nodes.

*8) Key revocation:* Decentralized protocols deal with the issue of key revocation in the event that a node is compromised or unauthorized in the same way that centralized methods do. In order to keep group communication safe in the face of compromised keys, nodes coordinate a process of revocation.

For larger IoT networks, especially ones with fluid memberships or dispersed designs, decentralized Group Key Management methods are a good option. Decentralized techniques offer scalability, resilience, and adaptability but require special consideration of complexity, communication overhead, and trust issues.

### *C. Hybrid Group Key Management*

When it comes to managing group keys, hybrid protocols incorporate the best features of both centralized and decentralized systems. They use the strengths of the two models to create a workable, scalable plan[17]. The initial group keys, for instance, may be generated and distributed by a centralized body, while subsequent key modifications may be handled independently by each participant. The goal of hybrid protocols is to strike a compromise between centralized management and decentralized robustness. HKMP and CDKMP are two examples of hybrid group key management protocols. A hybrid way to managing group keys in a network, Hybrid Group Key Management takes the best features of both centralized and decentralized systems. Its goal is to provide an effective and scalable solution for group key management in IoT networks by combining the best features of the two models[18]. The key management process in Hybrid Group Key Management is split between centralized and decentralized elements. Some critical administration tasks are under the purview of the coordinating body, while others are delegated to the various nodes. Depending on the protocol and the demands of the network, the precise allocation of tasks may change. The essential features and qualities of Hybrid Group Key Management are as follows:

*1) Centralized functions:* The coordinating body carries out essential management tasks, such as

*a) Key generation:* The first group keys are generated using cryptographic procedures by a centralized body.

*b) Key distribution:* The initial group keys are dispersed to the nodes by the coordinating body.

*c) Policy enforcement:* The governing body regulates who is allowed to access the group keys and what they may do with them.

*2) Decentralized functions*: The participating nodes work together and supply input for a variety of critical management tasks, including:

*a) Key updates:* When necessary, nodes work together to update keys by creating new ones or modifying existing ones.

*b) Key revocation:* When a node is compromised or leaves the group, the other nodes work together to revoke its access to the shared keys.

*c) Key distribution and storage:* Group keys can be distributed to newly joined nodes by existing nodes, or keys can be securely stored and shared across nodes.

*3) Coordination and communication:* Hybrid Group Key Management techniques call for a centralized organization and all participating nodes to coordinate and communicate with one another[19]. Distributing initial group keys, enforcing policies, and receiving updates all need communication between the central entity and the nodes. The updating, revoking, and distribution of group keys are all processes that require cooperation between nodes.

Hybrid Group Key Management techniques combine the benefits of centralized and decentralized approaches to group key management. They may function for IoT networks with various needs for scalability, compositional flexibility, and security policy variety. However, care must be taken during design and implementation to handle the complexity and trust issues raised by the hybrid nature of these protocols.

### D. Self-Organizing Group Key Management

Nodes can create groups and generate group keys independently of any central authority or predetermined network architecture thanks to self-organizing protocols. The establishment, distribution, and maintenance of keys are all key management processes that need cooperation across nodes[20]. These protocols work well in ever-changing, low-resource Internet of Things settings. Protocols like Peer Group Key Management (PGKM) and SOGM are examples of self-organizing group key management. In self-organizing group key management, nodes in a network work together to set up and manage group keys without any central authority. In this method, keys are not managed by a centralized authority or within a strict framework. Instead, the participating nodes work together to carry out essential management functions. Self-Organizing Group Key Management has the following salient features and qualities:

*1) Autonomous group formation:* The network's nodes will naturally cluster together based on shared characteristics or geographic closeness, for example. These clusters could evolve over time as nodes enter and exit the network.

*2) Key establishment:* Each group's keys are determined by a consensus of the members. To generate a group key securely, they may use a key establishment technique like Diffie-Hellman key exchange or elliptic curve cryptography. In most cases, a combination of safe pairwise communication and cryptographic activities makes up the key establishment procedure.

*3) Key distribution:* After a group key has been formed, it will be shared across the participating nodes. The key can be efficiently disseminated to all group members by either direct communication between nodes or through the use of multicast communication mechanisms. The delivery of the key is encrypted or conducted through a secure channel to prevent unauthorized parties from gaining access to it.

*4) Key updates:* Nodes in a self-organizing system coordinate the distribution of critical updates in response to shifts in the group's make-up or the level of protection it needs. The group key is updated by consensus whenever there is a change in membership due to either new or departing nodes. This replaces revoked or compromised keys to keep group communication safe.

Protocols for self-organizing key groups provide a decentralized and autonomous solution for IoT network key management. They work well in situations where a centralized authority would be impossible due to a lack of stability or sufficient resources[21]. However, self-organizing systems necessitate careful study and robust processes to assure the entire system's integrity and resilience, particularly in the areas of security, scalability, and management. It should be noted that the aforementioned categorization is not comprehensive, and that different group key management protocols used in IoT networks may utilize a variety of modifications or combinations of these classifications.

## III. Problem Statement

The constant change of their surroundings combined with the complexity and diversity of IoT networks may lead to limitations. Furthermore, the classification offered could not cover all conceivable iterations or pairings of group management of key protocols utilized in Internet of Things networks, which could restrict its usefulness in specific situations[18].The proposed work entails creating a thorough framework that takes into consideration the complicated and changing characteristics of settings for group management of keys in Internet of Things networks. By providing flexible and adaptive protocols, this framework will solve the shortcomings of existing classifications and efficiently handle a variety of network conditions.

## IV. Methodology

The system architecture utilized in this study is elucidated in Fig. 4, comprising six integral components: Trusted Third Party, Gateway Node (GWN), Sensing Devices, User, Cloud, and Industry. Positioned as a top-level industry official, the user possesses the capability to remotely monitor individual factories via the web at regular intervals. Crucially, maintaining the privacy of data transmitted among the user, GWN, and sensors is imperative [19]. Smart card-equipped users leverage the GWN to solicit access to the sensors. The information collected by sensors is promptly relayed to the user in near-real time. An authenticated key agreement process is initiated with a login request transmitted from the user to the GWN. Subsequently, the GWN verifies the user's identity and forwards the request to the sensors. In response to GWN's request, sensing devices provide their secret shares, allowing GWN to reconstruct the secret value. Utilizing this reconstructed secret value, sensing devices generate a shared session key and transmit messages to the user securely. Ultimately, the user gains access to sensor-collected data, empowering them to efficiently oversee and manage the manufacturing process. This intricate system architecture establishes a secure and efficient framework for data transmission and user interaction within the context of industrial monitoring.

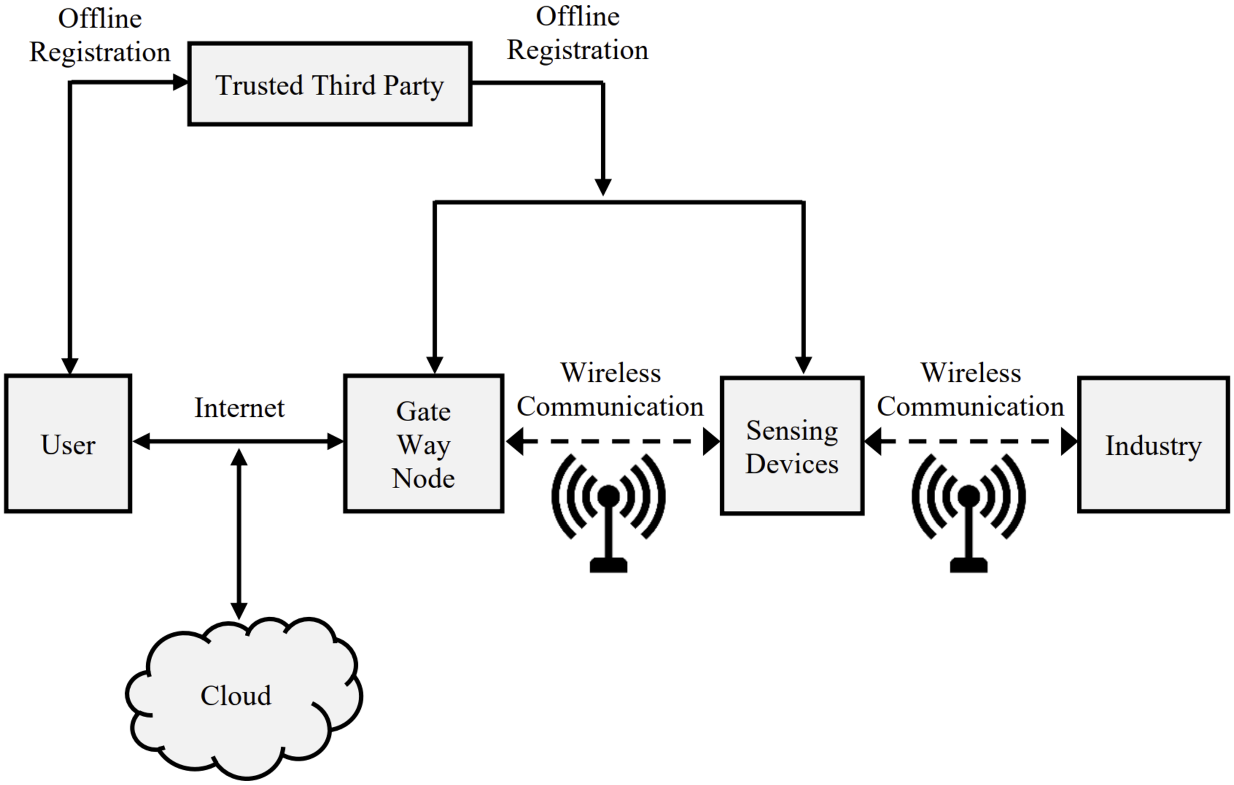


Fig. 4. Proposed system architecture.

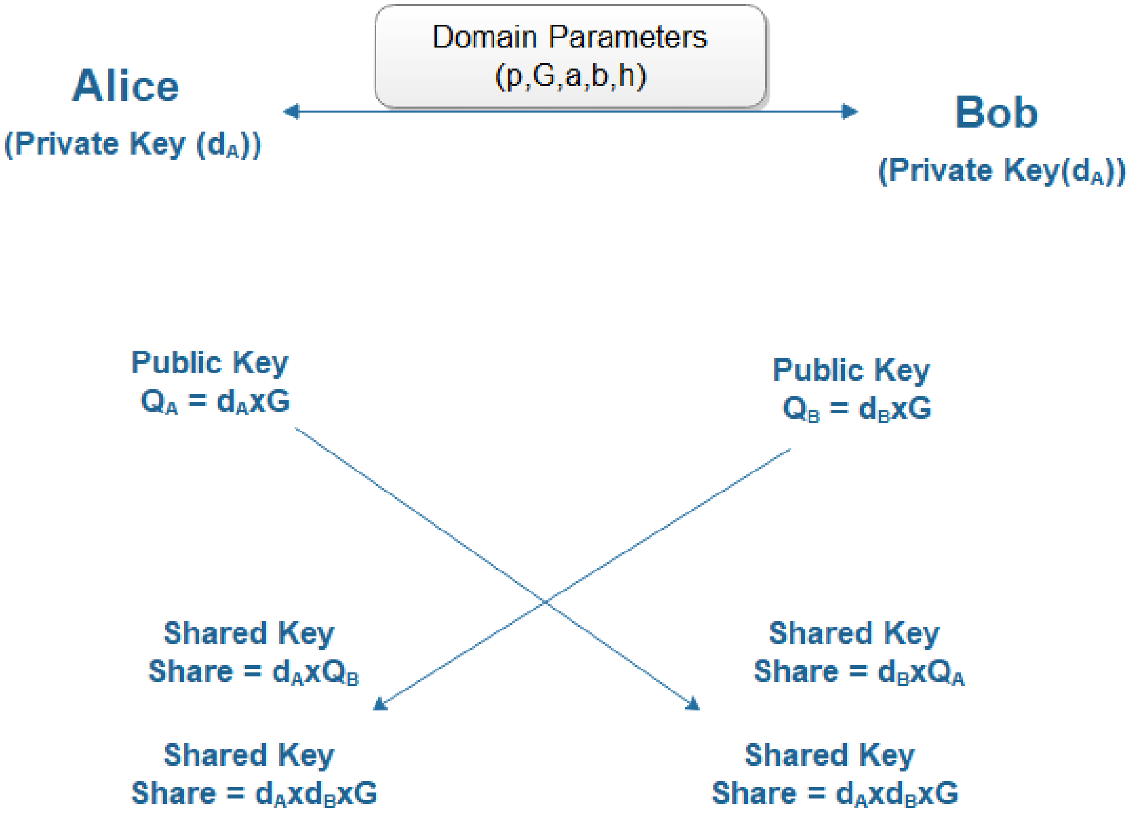

Fig. 5. Generalized key management scheme.

The suggested approach relies on a trustworthy third party, the Gate Way Nodes (GWN), which not only registers the sensors but also pre-loads them with credentials. At first, the user and GWN utilize the TTP private key to generate a shared secret key. The idea of existing cryptography algorithms is used to calculate this shared secret key[22]. The user then sends the GWN node the key agreement protocol using the shared secret key. The user transmits a set of confidential parameters to the GWN, which in turn causes the GWN to generate a group key. This group key is passed around in a safe manner. At this point, the sensors use the group key to generate a new session key for use in GWN communications between the user and sensors. The user will also be given the group key from GWN to use in generating the session key. The session key computed by the user and the sensors must be same for the protocol to function properly. The user and the sensors will communicate over GWN by exchanging the industrial data using this session key.

In Fig. 5, is an example of a centralized GKM scheme, in which all group key management functions are handled by a single location. It's crucial that the key is kept secret and only the authorized individuals have access to it. New group members join and old group members leave frequently in most group focused applications.[4] It is crucial to keep both forward secrecy (wherein new members are not revealed with the old key) and backward secrecy (wherein former members are not revealed with the new key) in place. The ability to easily share data in the cloud is essential for businesses and organizations that have made the decision to move their operations to the cloud. The businesses have benefited from working with their contemporaries because it has increased output. As a result, healthcare expenditures decrease and doctors have a more complete picture of their patients' health. Students have little trouble cooperating on group assignments.

Sharing data in the cloud always involves more than one person having access to that data, making data privacy and security paramount. Protecting data privacy while enabling data sharing is of paramount importance. Generation, distribution, and updating of group keys for use in encryption and decryption are all critical functions of group key management in cloud data sharing.

The best encryption is useless without secure key management. Therefore, a new Compressed Trie based Group Key Distribution (CTGKD) method is proposed in this chapter to ensure the construction of trustworthy groups and the safe distribution of keys. The primary focus of this effort is on decreasing rekeying-related communication and computation costs. In this case, a secure group is formed using a compressed trie structure, and keys are dispersed among the members. The steps of the proposed Compressed Trie based Group Key Distribution (CTGKD) protocol are shown in Fig. 6.

*1) Key generation:* The key freshness attribute, in which the session key is never reused, is an important part of the security architecture of group key establishment.

The gateway and the group members then safely exchanged a session key after this. The gateway then encrypts the session key with the shared long-term secret S. Given that the proxy has a share (ci,di), he needs to acquire (m-1) shares from the other members of the group in order to rebuild the secret S and extract the session key. Fig. 7 and its explanation follow to provide more detail about this stage.

*2) Key distribution and verification:* Message authentication and message integrity of key shares between the gateway and each member of the group are required because the communication medium between the gateway and the group members is an unprotected public wireless channel. The gateway uses a lightweight and safe approach based on cryptographic hash functions and the xor operation to disperse the shares. To ensure the safe transfer of the secret shares (ci, di), mutual authentication between the GWN, Nj, and P is kept active at this stage. If an attacker tried to reconstruct the secret S, at least (m=5) out of n shares are necessary to recover the secret S, and even if the attacker acquired (m-1shares), he still cannot recover S. At the completion of this phase, each node in the group will have a share. The values (ci, di) are used by the proxy node to reconstruct the secret S, which is then used to encrypt the session key SK, which is used for encryption/decryption of communication between the GWN and the multicast group members n, after an authenticated shares distribution has taken place. Fig. 8 shows the Development of Key Exchange, User Authentication and Data Integrity mechanisms for IoT based network.

## V. Discussion and Result

Memory use, response time, MAC generation time, and security overhead are all evaluated to gauge how well the proposed framework performs. The suggested framework has a high security cost. Consumption of memory is the amount of computer memory actually being put to use storing information. Memory usage for the proposed system is depicted in Fig. 9 in relation to the encrypted data partitions. Table I numbers show that the amount of data storage needed for each component is roughly the same size.

TABLE I. Memory Consumed by Various Partitions of the Split Encrypted Data

| Partition | Memory Used (in Bytes) |
|---|---|
| Partition 4 | 442 |
| Partition 3 | 453 |
| Partition 2 | 438 |
| Partition 1 | 442 |

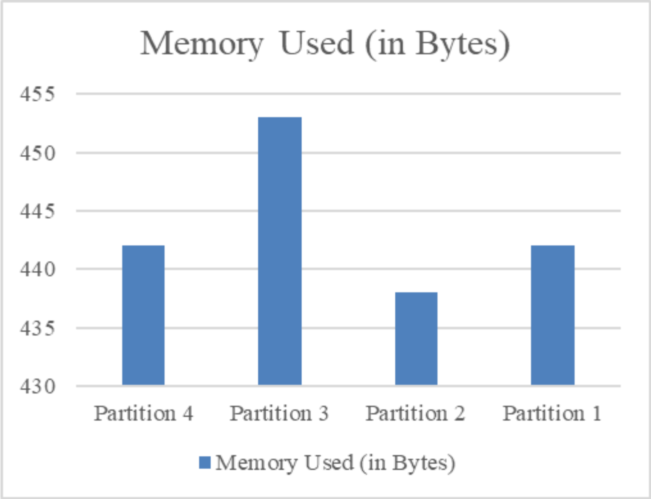

Fig. 9. Plot for memory consumed by various partitions of the split encrypted data.

The time it takes to generate a key at different key lengths is shown in Fig. 10 and Table II. The time required to generate a key grows proportionally with its length. Key generation for 100-bit keys takes 60 milliseconds, for 256-bit keys it takes 120 milliseconds, and so on.

TABLE II. THE TIME REQUIRED TO GENERATE A KEY GROWS PROPORTIONALLY WITH ITS LENGTH

| Key Length (bits) | Key generation (ms) |
|---|---|
| 1024 | 800 |
| 512 | 320 |
| 256 | 120 |
| 128 | 80 |
| 100 | 60 |

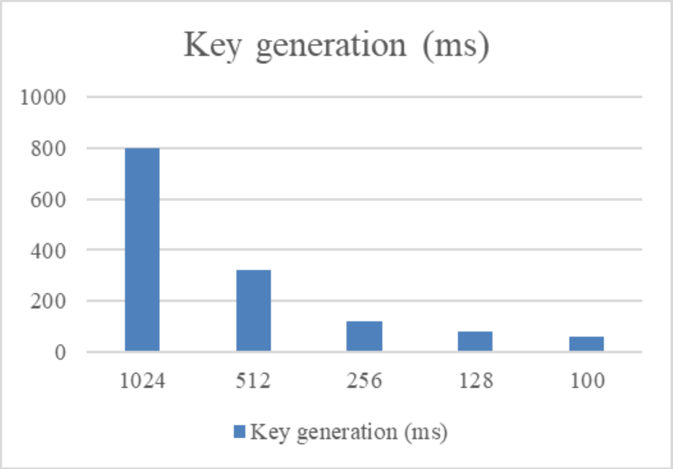

Fig. 10. Plot for the time required to generate a key grows proportionally with its length.

System delay on either the end-user or the service provider's end might contribute to the security burden. The security overhead causes a system delay because of the time it takes to verify and decrypt data on the user's side and to generate and encrypt data on the owner's side. By dividing the total duration of transmission by the total time of security operations (MAC Generation/Verification and Encryption/Decryption), get the security overhead percentage. The burden of data transfer must be minimized.

Fig. 11 depicts the Plot for Security overhead at Data Owner. PUF, a one-way hash function, a bitwise XOR operation, and symmetric encryption will be used in this stage to build two-factor mutual authentication. Throughout this stage, messages are encrypted using the AES method and a 128-bit key length to ensure their safety throughout transmission. Data integrity between N and the IG is also validated and guaranteed by employing a 256-bit cryptographic hash function that operates in one direction only. The parties exchange proposals for how to generate session keys during this stage. The parties might choose to use the Elliptic Curve Diffie Hellman Key Exchange Protocol (ECDH) or a one-way hash function to produce the session key. To generate a common secret key, you can utilize a key-agreement technique like ECDH Key Exchange. Key exchange is depicted in Fig. 12.

To guarantee the highest level of source location anonymity, combined two steps in the proposed method: random multipath and tunnels with spoofed communications. To determine how well the proposed method conceals the location of the source, we must calculate the safety period, which is defined as the estimated number of hops an adversary must take to retrace their steps from the sink to the source. With the suggested method, the hop count can range from 10 to 35, and each relaying node has a probability of P = 0.8 of generating a tunnel with a length L, i=0.5, and D=3. In Fig. 13, show how the suggested method greatly lengthens the safety time compared to RPL, and how it may be used to protect the anonymity of the source location. We found that the source location privacy is better protected and the safety duration is longer with a longer tunnel. However, the suggested method still outperforms RPL in safeguarding the confidentiality of the source location, despite the fact that the safety time noticeably increases when tunnels length L= 10 and reduces when tunnels L = 3.

TABLE III. SECURITY OVERHEAD AT DATA OWNER

| File Size (MB) | Security Overhead at Data Owner | |
|---|---|---|
| | *Symmetric Encryption with AES-256* | *Proposed Method* |
| 800 | 12.9 | 12.2 |
| 700 | 12.7 | 12.1 |
| 600 | 12.5 | 11.8 |
| 500 | 13.4 | 12.9 |
| 400 | 12.8 | 12.5 |
| 300 | 13.7 | 13.4 |
| 200 | 15.1 | 14.8 |
| 100 | 16.5 | 16 |

### A. Discussion

Because of the limited resources and various communication capabilities of IoT devices, the discussion of the offered remark emphasises how crucial it is to solve security issues in IoT networks. Although key generation process optimisation presents promise increases in efficiency, more study is necessary to investigate complete security measures that can adapt to emerging cyber threats. Future research may concentrate on creating cryptographic algorithms that are lightweight and sensitive to the constraints of Internet of Things devices, improving their security without appreciably raising computing cost. Additionally, studies should look at fault tolerance and anomaly detection techniques as ways to lessen the impact that hacked sensors might have on network communication protocols. Notwithstanding the noteworthy progress, it is imperative to recognize its limits, such as the possible trade-offs among security and resource restrictions and the continuous upgrades and maintenance required to handle new vulnerabilities. Given the constantly changing cyber dangers, this emphasizes the need for ongoing multidisciplinary interaction among researchers, industry stakeholders, and policymakers to guarantee the sustainability and resilience of IoT ecosystems.

*1) Key generation optimization:* Central to contributions is the optimization of key generation algorithms, acknowledging the proportional relationship between key length and generation time. The substantial reduction in key generation times, exemplified by 60 milliseconds for 100-bit keys and 120 milliseconds for 256-bit keys, marks a significant stride in bolstering the efficiency of security processes. This enhancement not only addresses a pressing issue in existing protocols but also positively impacts the responsiveness of IoT systems, mitigating potential vulnerabilities during key establishment phases [16].

*2) User authentication and data integrity*: The optimized key generation process plays a pivotal role in strengthening user authentication procedures. The authenticated key agreement, initiated through a login request from the user to the Gateway Node (GWN), ensures secure access to sensors. The exchange of secret shares between sensing devices and the GWN, leading to the reconstruction of the secret value, forms a robust foundation for secure communication and authentication. Moreover, the heightened efficiency in key generation positively influences data integrity. The secure and prompt transmission of sensor-collected data to the user in near-real time is instrumental in ensuring the reliability of the information. This, in turn, empowers users to make informed decisions and manage manufacturing processes with confidence.

*3) System architecture and user empowerment:* The elucidation of the system architecture, encompassing components such as the Trusted Third Party, GWN, Sensing Devices, User, Cloud, and Industry, provides a comprehensive understanding of the ecosystem. The user, positioned as a top-level industry official, gains the ability to remotely monitor factories, emphasizing the practical implications of our advancements in real-world scenarios.

Research not only addresses existing vulnerabilities in IoT security but propels the field forward by optimizing key generation, enhancing user authentication, and ensuring data integrity. Establishing an equilibrium between customization and standardization, guaranteeing interoperability with various IoT network topologies, and successfully managing dynamic security risks might present difficulties of proposed work. Subsequent efforts will focus on improving the suggested framework via empirical assessment, assessing its resilience and scalability in actual Internet of Things implementations, and investigating innovative methods for improved security and effectiveness.

## VI. Conclusion

While low-power, low-performance devices are the foundation of IoT networks, the field of IoT safety and privacy has generated a lot of interest from academics recently. This work developed CTGKD, a unique strategy that uses a compacted trie-based structure to address the scalability difficulties of cloud key distribution. This approach differs from the traditional tree-like architectures seen in previous literature. This work is unique because it closes a gap in existing solutions by using compressed attempts to the key management problem. The findings of the performance analysis show that CTGKD is more effective at communicating than standard LKH tree-based key management. In the future, the emphasis will be on creating new methods and altering current security guidelines to achieve a balance between the strict protocol requirements and the resource-constrained characteristics of Internet of Things devices. In these methods for lightweight authentication, key creation, and origin location privacy have been developed to tackle some of the security issues in Internet of Things networks. To improve these techniques and guarantee that they are appropriate for IoT situations with limited resources, more study is necessary. Furthermore, while identification, confidentiality, and key management are addressed in the suggested security architecture for cloud data storage, access control methods are absent, making it impossible to guarantee correct data access by authorized users. To ensure allowed access to cloud data, further work will require incorporating access control procedures and regulations into the security architecture. Additionally, simplifying access for clients to all cloud services through the integration of Single Sign-On (SSO) within the security architecture would improve efficiency and user experience. These improvements will ensure that authorized users may obtain and use data safely and effectively while also improving the total safety and accessibility of IoT networks.

***Abstract*—In the current era of intense educational competition, institutions must effectively classify individuals based on their abilities, proactively forecast student performance, and work towards enhancing their forthcoming examination outcomes. Providing early guidance to students is crucial in helping them focus their efforts on specific areas to boost their academic achievements. This analytical approach supports educational institutions in mitigating failure rates by utilizing students' previous performance in relevant courses to predict their outcomes in a specific program. Data mining encompasses a variety of techniques used to reveal hidden patterns within vast datasets. In the context of educational data mining, these methods are applied within the educational sphere, with a specific emphasis on analyzing data from both students and educators. These patterns can offer significant value for predictive and analytical objectives. In this study, Gaussian Process Classification (GPC) was employed for the prediction of student performance. To improve the model's accuracy, two cutting-edge optimizers, namely the Golden Eagle Optimizer (GEO) and the Pelican Optimization Algorithm (POA), were incorporated. When assessing the model's performance, four widely used metrics were utilized: Accuracy, Precision, Recall, and F1-score. The results of this study underscore the effectiveness of both the POA and GEO optimizers in enhancing GPC performance. Specifically, GPC+GEO demonstrated remarkable effectiveness in the Poor grade, while GPC+POA excelled in the Acceptable and Excellent category. This highlights the positive impact of these optimization techniques on the model's predictive capabilities.**

Graphical Abstract

# I. Introduction

One of the fundamental difficulties with every nation's instructive organization lies in the exact evaluation of students' academic achievements [1]. This precise assessment is instrumental for educational administrators in pinpointing and addressing issues within the educational system. Academic performance encompasses the array of actions undertaken by students throughout their academic journey [2]. The critical post-implementation phase of educational programs is the assessment of students. Assessment is the procedure via which the accomplishment of instructive goals for both the teacher & the student is ascertained. Student assessment takes place through various methods [3]. The evaluation approaches can include techniques such as examination, conduct scrutiny, evaluation of schemes, assessment of documents and summaries, and the use of theoretical development tests for measurement [4].

Predicting students' performance early on is beneficial for enhancing learning results [5]. The capacity to anticipate a pupil's theoretical achievements clasps significance by way of driving modifications in college theoretical policies notifies teaching techniques, assesses the proficiency and efficiency of education, offers respected input to educators and learners, and modifies knowledge environments [6]. At the commencement of the educational journey, accurately identifying underperforming students is valuable. Educational institutions utilize data mining methods to analyze available data, a practice commonly referred to as Educational Data Mining (EDM) [7]. While data mining supports knowledge discovery, it is important to note that MLA delivers the indispensable tackles for this procedure. Correct prediction of pupil presentation is valuable as it enables the early detection of underperforming students [8], [9]. Educational Data Mining (EDM) aids educational institutions in enhancing and innovating learning approaches through the analysis of pertinent educational data [10]. In practice, forecasting a pupil's theoretical success is crucial for every one of their educational progress, yet it can be challenging due to the influence of numerous factors on student performance [11]. The constant evolution of technology has opened up novel avenues for the expansion and enhancement of educational systems. Recent research indicates that the machine learning (ML)-based methods employed in this study have proven to be highly efficient [12].

In the realm of educational institutions, a multitude of researchers have utilized statistical approaches and ML algorithms to forecast student performance [13]. Ogunde et al. [14] initiated the development of a system that utilizes the Iterative Dichotomiser (ID3) decision tree methodology and input data to anticipate grades. The authors suggest that their approach shows substantial potential for precise forecasting of students' ultimate graduation results. Bharadwaj et al. [15] utilized data sourced from a prior student database, integrating elements such as student attendance, class participation, participation in seminars, and assignment scores to make projections regarding semester-end outcomes. Their results revealed that decision tree analysis produced the highest accuracy, followed by K-nearest neighbor (KNN) classification [16]; on the other hand, Bayesian classification systems demonstrated the least accuracy. Duzhin and Gustafsson [17] introduced an ML technique to account for students' prior knowledge. Their approach relies on symbolic regression and incorporates historical university scores as non-experimental input data. This classification method has the potential to aid the Ministry of Education in enhancing student performance through early predictions. Naïve Bayes [18] displays traits of conditional independence, which makes it proficient at estimating class conditional probabilities. Watkins et al. [1] introduced a technique called SENSE (Student Performance Quantifier using Sentiment Analysis) to enrich the content of secondary school reports by leveraging natural language processing. Sentiment analysis [19] can play a significant role in impacting student performance.

Several studies have demonstrated the practical application of data mining in education. In order to forecast student performance and arrange the students appropriately, Sunita and LOBO L.M.R.J. [20] used classification and clustering methods. Thammasiri et al. [21] created a model to predict poor academic performance in first-year students, and by integrating support vector machines with SMOTE, they were able to achieve an astounding accuracy of 90.24%. Using classification algorithms, Bichkar and R. R. Kabra [22] concentrated on identifying first-year engineering students who were at risk. Surjeet and Pal [23] employed decision tree algorithms to forecast the performance of first-year engineering students, with a specific emphasis on identifying those at risk of failure. The C4.5 decision tree outperformed other classifiers and offered insights into factors influencing student performance, according to Mustafa et al. [24], who evaluated student data in C++ courses using the CRISP framework. Using academic markers as a basis, Bharadwaj and Pal [25] predicted student divisions using the ID3 decision tree method. Nguyen and Peter [26] compared decision trees and Bayesian networks in predicting undergraduate and postgraduate academic performance, with decision trees demonstrating superior performance.

Table I offers an overview of many relevant investigations.

TABLE I. Literature Review

| No. | Author (s) | Models | Accuracy | Reference |
|---|---|---|---|---|
| 1 | Carlos et al. | $ADTree$ | 97.3% | [27] |
| 4 | Edin Osmanbegovic et al. | $NBC$ | 76.65% | [28] |
| 3 | Al-Radaideh et al. | $DTC$ | 87.9% | [29] |
| 2 | Nguyen and Peter | $DTC$ | 82% | [26] |
| 5 | Bichkar and R. R. Kabra | $DTC$ | 69.94% | [22] |

The literature review revealed the high effectiveness of ML methods for assessing and appraising students' performance [30]. Although various studies [31], [32], [33], [34], [35] have employed diverse models, each with distinct conditions and characteristics tailored to the specific problem context, also, there are gaps in the literature in the field of utilizing GPC model in integration with several optimization algorithms. Therefore, the main purpose of this study is to succeed in a framework to forecast students' academic performance by amalgamating ML models with meta-heuristic algorithms, considering the unique educational circumstances throughout their academic journey. In this research, substantial variations of Gaussian Process Classification (GPC) algorithms have been included to assist educators and parents in predicting the performance of new students and improving next year's outcomes. Additionally, to ensure the utmost reliability in the results, both POA and GEO techniques were integrated, leading to the attainment of promising outcomes. The proposed framework not only enhances prediction accuracy but also provides practical applications for educators and parents, empowering them with valuable insights into students' performance and potential areas for improvement. Anticipating promising outcomes, this research offers a systematic approach to leveraging advanced techniques for educational prediction, thereby facilitating more effective decision-making and ultimately improving student outcomes.

The structure of the remaining sections in this article is as follows:

- Section II outlines the research methodology, encompassing an explanation of evaluation metrics, ML-based classifiers, meta-heuristic algorithms, and an overview of the dataset used in the study.
- In Section III, the outcomes of the case study were investigated and analyzed using actual data. This section is subdivided into three parts: results pertaining to the initial dataset, results related to the balanced (edited) data, and findings associated with the application of hybrid models on the balanced dataset.
- Finally, Section IV presents the concluding remarks.

## II. Datasets and Methodology

### A. Data Gathering

In this research, a dataset pertaining to the Portuguese educational system was employed. This dataset comprises 33 distinct attributes thoughtfully selected to provide a precise representation of students' academic advancement, considering their unique characteristics and situations [36]. The dataset was generated by merging data obtained through two survey techniques with the academic records of the students. These attributes encompass a broad spectrum of student-related factors, including demographics such as gender, age, school attended, and residential type (address). Additionally, these attributes encompass parental characteristics such as parents' cohabitation status ( Pstatus ), educational background, and occupation (Medu, Mjob, Fedu, Fjob). Other factors considered include the student's parent, family attributes like the size of the family ( famsize ), the caliber of familial connections ( famrel ), & various attributes for example, the cause of selecting an educational institution (rationale), commuting duration to an educational institution (journey duration), weekly schoolwork hours (studytime), past academic setbacks (disappointments), contribution in supplementary academic programs ( schoolsup ), (famsup), engagement in extracurricular actions (activities), attendance in paid classes ( paidclass ), internet accessibility (internet), attendance at nursery school (school), aspirations for higher education (higher), romantic relationship status (romantic), availability of leisure time after school (freetime), socializing preferences (goout), weekday alcohol consumption ( Dalc ), weekend alcohol consumption ( Walc ), and the present physical condition of the individual (well-being).

Furthermore, besides these characteristics, there are 3 extra attributes, namely G1, G2, & final, which signify the grades of students across 3 assessment stages throughout their learning journey, ranging from 0 (the minimum grade) to twenty (the maximum grade). G3 signifies the students' ultimate score. These 3 attributes, al chose as pattern results along with the count of college nonappearances (nonappearances), were selected as model outputs, serving as reliant on parameters. For grading purposes, they were categorized into 4 groups: zero–twelve: Deprived, twelve –fourteen: Acceptable, fourteen – sixteen: Respectable, and sixteen –twenty: Outstanding. In Fig. 1, as anticipated, cells along the central axis are displayed in red, indicating a correlation value of 1. From the visual representation above, it is evident that the three attributes, G2, G1 & last, all of which are considered reliant on parameters and represent students' grades, exhibit the highest correlation values among themselves.

### B. Gaussian Process Classification (GPC)

Gaussian process priors offer expressive nonparametric function models. To conduct classification using this prior, the process is compressed through a sigmoidal inverse-link function, and a Bernoulli likelihood is applied to the data based on the transformed function values [37]. The binary class observations are denoted as y = $\{y_1, y_2, \dots, y_N\}$, and the input data is organized into a design matrix X = $\{x_1, x_2, \dots, x_N\}$. The covariance function is computed for all pairs of input vectors to create the covariance matrix $K_{nn}$ following the standard process. This results in a prior distribution for the values of the Gaussian Process function at the input points: $p(f) = N(f \mid 0, K_{nn})$.

The $probit$ inverse link function is represented as $\emptyset(x) = \int_{-\infty}^{x} N(f|0, K_{nn})$, and the Bernoulli distribution $, B(y_n \mid \emptyset(f_n)) = \emptyset(f_n)^{y_n}.(1-\emptyset(f_n))^{\{1-y_n\}}$. This leads to the joint distribution of data and latent variables [38].

$$p(y, f) = \prod_{n=1}^{N} B(y_n \mid \emptyset(f_n)) N(f|0, K_{nn}) \qquad (1)$$

The primary emphasis lies in the approximation of the posterior distribution of function values, labeled as $p(f \mid y)$. Furthermore, there is a requirement for an approximation of the marginal likelihood, p(y), to enable the optimization or marginalization of covariance function parameters. Various methods for approximation have been suggested, but all of them necessitate computation on the order of $O(N^3)$. Fig. 2 illustrates the structure of the GPC model.

### C. Pelican Optimization Algorithm (POA)

In the year 2022, the POA, a novel nature-inspired approach, was introduced by Dehghani and Trojovský. This algorithm is influenced by the social behavior and hunting strategies of pelicans [39]. Pelicans, characterized by their large size and elongated beaks, have a sizeable throat pouch that they use for capturing and consuming prey. They typically live in significant colonies, making up the population of concern. The individuals within this population are randomly initialized using the following equation:

$$x_{i,j} = l_j + rand.\left(u_j - l_j\right), \quad i = 1,2,3,\dots,N\ , j = 1,2,3,\dots,m \tag{2}$$

Within this equation, $x_{i,j}$ denotes the value of the $j - th$ variable as indicated by the ith candidate solution. The parameters N and m correspond to the count of individuals in the population and the total number of problem variables, respectively. Furthermore, $l_j$ and $u_j$ signify the lower and upper boundaries of the problem variables. The term "rand" represents a random number within the [0,1] range. The population matrix, representing the individuals within the candidate solutions, is formed using Eq. (3):

$$X = \begin{bmatrix} X_1 \\ \vdots \\ X_i \\ \vdots \\ X_N \end{bmatrix}_{N\times m} = \begin{bmatrix} X_{1,1} & \dots & X_{1,j} & \dots & X_{1,m} \\ \vdots & & \vdots & & \vdots \\ X_{i,1} & \dots & X_{i,j} & \dots & X_{i,m} \\ \vdots & & \vdots & & \vdots \\ X_{N,1} & \dots & X_{N,j} & \dots & X_{N,m} \end{bmatrix}_{N\times m} \tag{3}$$

The objective function is computed based on the expression given in Eq. (4).

$$F = \begin{bmatrix} F_1 \\ \vdots \\ F_i \\ \vdots \\ F_N \end{bmatrix}_{N\times m} = \begin{bmatrix} F(X_1) \\ \vdots \\ F(X_i) \\ \vdots \\ F(X_N) \end{bmatrix}_{N\times 1} \qquad (4)$$

The objective function vector, labeled as F, comprises individual objective function values denoted as $F_i$ for each candidate's solution. The hunting process of pelicans is bifurcated into two phases: exploration and exploitation. In the exploration phase, pelicans approach their prey, whereas, during the exploitation phase, they gracefully glide along the water's surface. During the initial stage of the exploration phase, pelicans close in on the prey by identifying its position, which is randomly generated. The stochastic nature of the prey's location enhances the exploration capacity of the POA [40]. The mathematical expression of the initial phase is depicted in Eq. (5):

$$x_{i,j}^{p_1} = \begin{cases} x_{i,j} + rand.\left(p_j - I.x_{i,j}\right), & F_p < F_i; \\ x_{i,j} + rand.\left(x_{i,j} - p_j\right), & else, \end{cases} \qquad (5)$$

Let $x_{i,j}^{p_1}$ signify the revised state of the ith pelican in the jth dimension following the first phase. This update is contingent on a random variable $I$, which can assume values of 1 or 2, $p_j$ indicating the prey's location in the $j-th$ dimension and $F_p$ denoting the prey's objective function value. In the POA algorithm, a pelican's new position is deemed acceptable if it enhances the objective function value at that particular position. This procedure, termed effective updating, safeguards the algorithm against converging to suboptimal regions. Mathematically, this concept can be expressed as follows:

$$x_i = \begin{cases} X_i^{p_1}, F_i^{p_1} < F_i \\ X_i \qquad else \end{cases} \qquad (6)$$

The mathematical depiction of the hunting process is as follows: $X_i^{p_1}$ signifies the updated state of the $i-th$ pelican after the second phase, and $F_i^{p_1}$ represents the objective function value of the pelican derived from this phase. During the second phase, pelicans enhance their prospects of capturing more fish by lifting them upward through wing expansion while on the water's surface [41]. Following this, they ensnare the prey within their throat pouches. Consequently, this phase substantially enhances the effectiveness of the POA algorithm, facilitating the convergence of enhanced solutions within the hunting region.

$$x_{i,j}^{p_1} = x_{i,j} + R.\left(1 - \frac{t}{T}\right).(2.rand - 1).x_{i,j} \qquad (7)$$

During the second phase, the updated state of the $ith$ pelican in the $j-th$ dimension indicated as $X_{i,j}^{p_2}$, is determined considering several factors. One of these factors is the constant R, which is set to 0.2. The neighborhood radius of $x_{i,j}$ is influenced by the term $\left(1 - \frac{t}{T}\right)$, where t represents the iteration count, and T is the maximum number of iterations. Moreover, an effective updating procedure is implemented in this phase, where the new pelican position, as per Eq. (8), may be either accepted or rejected.

$$x_i = \begin{cases} X_i^{p_2}, F_i^{p_2} < F_i \\ X_i \qquad else \end{cases} \qquad (8)$$

$X_i^{p_2}$ signifies the revised condition of the $i-th$ pelican and $F_i^{p_2}$ indicates the respective objective function value for that pelican. Once all individuals in the population have been updated, the subsequent iteration commences, and the series of steps outlined by Eq. (5) to (8) are reiterated until the entire execution process is completed [42]. The POA flowchart, which is displayed in Fig. 3, illustrates the iterative process.

## D. Golden Eagle Optimizer (GEO)

GEO is inspired by the spiral flight pattern of golden eagles. Each golden eagle remembers its most rewarding locations visited thus far. It combines both gliding in search of food and hunting prey simultaneously. The ROD image is subjected to segmentation, which involves breaking it down into distinct regions using a geometrically active multilevel contour. This segmentation process enables precise scrutiny and disease diagnosis. Initially, the chosen experimental image is processed with multiple threshold levels (Th) using the geometrically active multi-contour method. Data preprocessing is carried out using the GEO and Shannon entropy method (GEO + SE). GEO + SE enhances ROD by combining similar pixel values determined by Th allocation. Entropic techniques are commonly utilized for the evaluation of medical images. A hypothetical RGB image is considered with dimensions M*N. In this case, the pixel at (x, y) is defined as:

$$F(x,y) while\ x \in \{1,2,3,\dots,M\}\ and\ y \in \{1,2,3,\dots,N\}$$

Given that T represents the gray level of the experimental image, with the entire range of gray values spanning from 0 to T-1, denoted as R, as follows:

$$F(x,y) \in R^{\forall}(x,y) \in picture \quad (9)$$

Here is the description of the standardized histogram (bar chart) for the image:

$$J = \{j0.j1,\dots jR1\} \quad (10)$$

The previously mentioned equation can be formulated as follows using the geometrically active multi-contours method:

$$J(Th) = j0(th_1) + j1(th_2),\dots,jR-1(th_{k-1}) \quad (11)$$

$$Th *= \max\{J(Th)\} \quad (12)$$

$Th *$ represents the selected threshold. Eq. (11) employs Shannon entropy. The GEO typically demands fewer initial parameters for allocation compared to other established methods. The required data is usually extracted from the preprocessed image using the segmentation approach. In this paper, this task is achieved using the widely recognized DRLS technique. A dynamic bounding box is integrated into DRLS, adapting its dimensions based on the region to be extracted. The adjustments in the dimensions of this box align with the boundaries of the ROD, depending on the extent of the repetitive process. Once the predefined repetition level is complete, the adjustments cease, and the extracted ROD is presented. There is no doubt that this approach outperforms the methods employed in the articles, namely the turning point and Chan-Vese methods. Initially, normalization is conducted in this phase, and subsequent results are extracted. A subset of the data is utilized as training data for the vector machine model, which is then constructed using this dataset. Weight tests for this algorithm are calculated to assess its performance in this context further. Each image contains a multitude of reference data points gathered from diverse sensors. In a comparative analysis, segmented discs were scrutinized alongside expert observational data images. The initial phase entails the computation of image similarity metrics such as GEOccard, Dice, FPR, and FNR, following the methods detailed in the articles. The mathematical formula is displayed below. Furthermore, Fig. 4 shows the flowchart of the GEO.

$$Jaccard\ (I_g, I_m) = I_g \cap I_m / I_g \cup I_m \quad (13)$$

$$Dice\ (I_g, I_m) = 2(I_g \cap I_m)/|I_g| \cup |I_m| \quad (14)$$

$$FPR\ (I_g, I_m) = \ (I_g/I_m)/\,(I_g \cup I_m) \quad (15)$$

$$FNR\ (I_g, I_m) = \ (I_m/I_g)/\,(I_g \cup I_m) \quad (16)$$

### E. Performance Evaluators

In the evaluation of classifier performance, various assessment criteria are at one's disposal. Accuracy, a commonly used metric, evaluates the classifier's effectiveness by measuring the percentage of samples correctly predicted. In addition to Precision, Accuracy, and Recall are widely employed metrics. Recall measures the proportion of correctly predicted positive instances among all actual positive instances, while Precision assesses the likelihood that positive predictions are correct. The combination of Precision and Recall produces a composite measure known as the f1-score.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{17}$$

$$Precision = \frac{TP}{TP + FP} \tag{18}$$

$$Recall = TPR = \frac{TP}{P} = \frac{TP}{TP + FN} \tag{19}$$

$$F1\ score\ = \frac{2 \times Recall\ \times\ Precision}{Recall + Precision} \tag{20}$$

In these formulas, TP denotes a positive prediction that accurately matches the true positive outcome. FP represents a positive prediction when the actual outcome is negative. TN indicates a negative prediction that correctly corresponds to the true negative outcome. FN is used to indicate a negative prediction when the actual outcome is positive.

## III. Result and Discussion

### A. Prediction and Classification Results

Fig. 5 offers a comprehensive illustration of the convergence curve for the proposed models, providing a visual representation of the algorithm's progression towards its predefined objective. This curve meticulously traces the accuracy performance metric across a sequence of iterations. The shape and trends within this curve offer valuable insights into the optimization process. A steep descent in the curve indicates rapid convergence, signifying swift progress towards the objective. Conversely, a flattened or erratic curve suggests potential challenges in attaining the optimal solution. These hurdles may encompass tasks like parameter refinement, managing computational intricacies, and enhancing the algorithm's efficiency. Convergence curves play a pivotal role in the field of algorithm assessment. They act as a guiding tool for researchers and professionals, helping them gauge the algorithm's performance and aiding in the intricate process of parameter fine-tuning. These curves also reveal the subtle balance between the requirement for speed and the quest for Precision in diverse computational tasks.

Focusing on the convergence curves of the two models, GPC+POA and GPC+GEO, as depicted in Fig. 5, a in the convergence curves becomes evident. Notably, the curve representing GPC+POA starts with a more favorable initial accuracy point compared to GPC+GEO. Moreover, it reaches its optimal outcome swiftly within a smaller number of iterations in contrast to GPC+GEO. This observation suggests that, as iterations progress, GPC+POA demonstrates greater efficiency for the specified task.

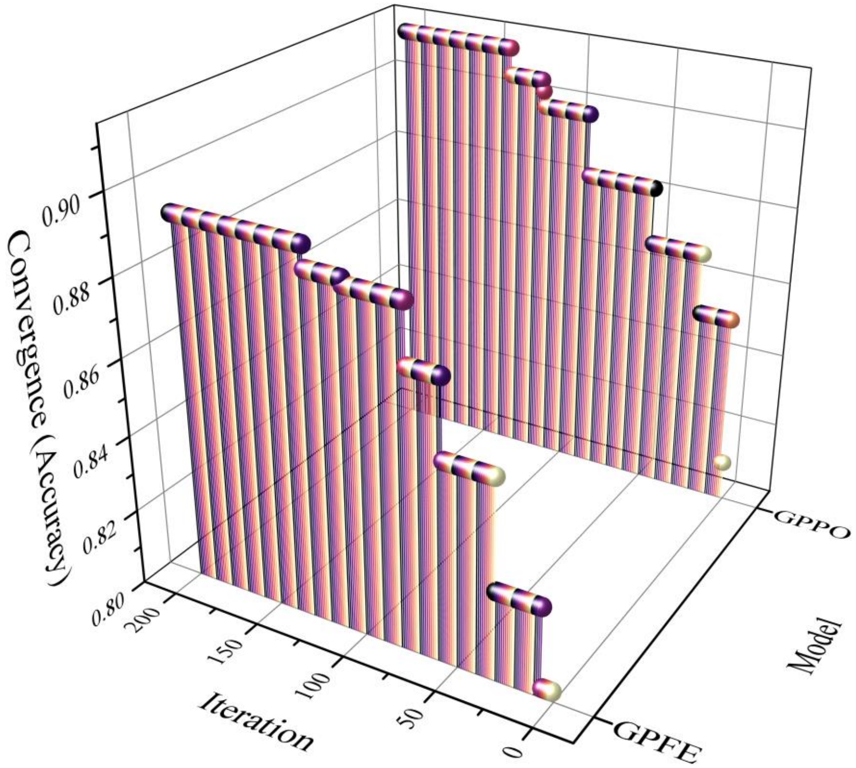

Fig. 5. Convergence curve of hybrid models.

TABLE II. RESULT OF PRESENTED MODELS

| Model | Index values | | |
|---|---|---|---|
| | GPC | GPC+GEO | GPC+POA |
| Accuracy | 0.884 | 0.894 | 0.911 |
| Precision | 0.879 | 0.90 | 0.912 |
| Recall | 0.882 | 0.892 | 0.905 |
| F1 _core | 0.884 | 0.889 | 0.914 |

Table II provides a comprehensive overview of the models evaluated in this study, namely GPC+POA, GPC+GEO, and GPC. Their visual representation can be found in Fig. 6. The key performance metrics, including accuracy, Precision, recall, and F1-score, are examined for each model. Starting with GPC+POA, this model impresses with an exceptional accuracy of 0.91, indicating its ability to classify a substantial portion of the dataset accurately. Moreover, its Precision and recall both stand at 0.91, emphasizing its proficiency in correctly identifying positive instances. The F1-score of 0.91 highlights a remarkable balance between Precision and recall, further confirming GPC+POA's effectiveness. Moving to GPC+GEO, this model showcases strong overall performance with an accuracy of 0.8937. Its precision value of 0.9 suggests a low rate of false positives, and a recall of 0.89 indicates its capability to detect actual positive instances correctly. The F1-score of 0.89 signifies a well-balanced trade-off between Precision and recall in GPC+GEO.

Lastly, the base GPC model demonstrates respectable results with an accuracy of 0.8835. Its Precision and recall, both at 0.88, indicate a good balance between correctly identifying positive instances and minimizing false positives. The F1 score of 0.88 underscores its well-rounded performance in terms of Precision and recall. In the discussion, it becomes evident that GPC+POA leads the pack, excelling in scenarios where Precision and recall are of utmost importance, such as medical diagnoses or critical decision-making contexts. GPC+GEO closely follows, offering a balanced approach that suits applications requiring a trade-off between Precision and recall. The base GPC model, while still delivering a strong performance, is a reliable choice for more general applications where a well-rounded performance is required. Ultimately, the choice of the model should align with the specific needs and priorities of the task at hand, with GPC+POA, GPC+GEO, and GPC offering valuable options catering to different scenarios.

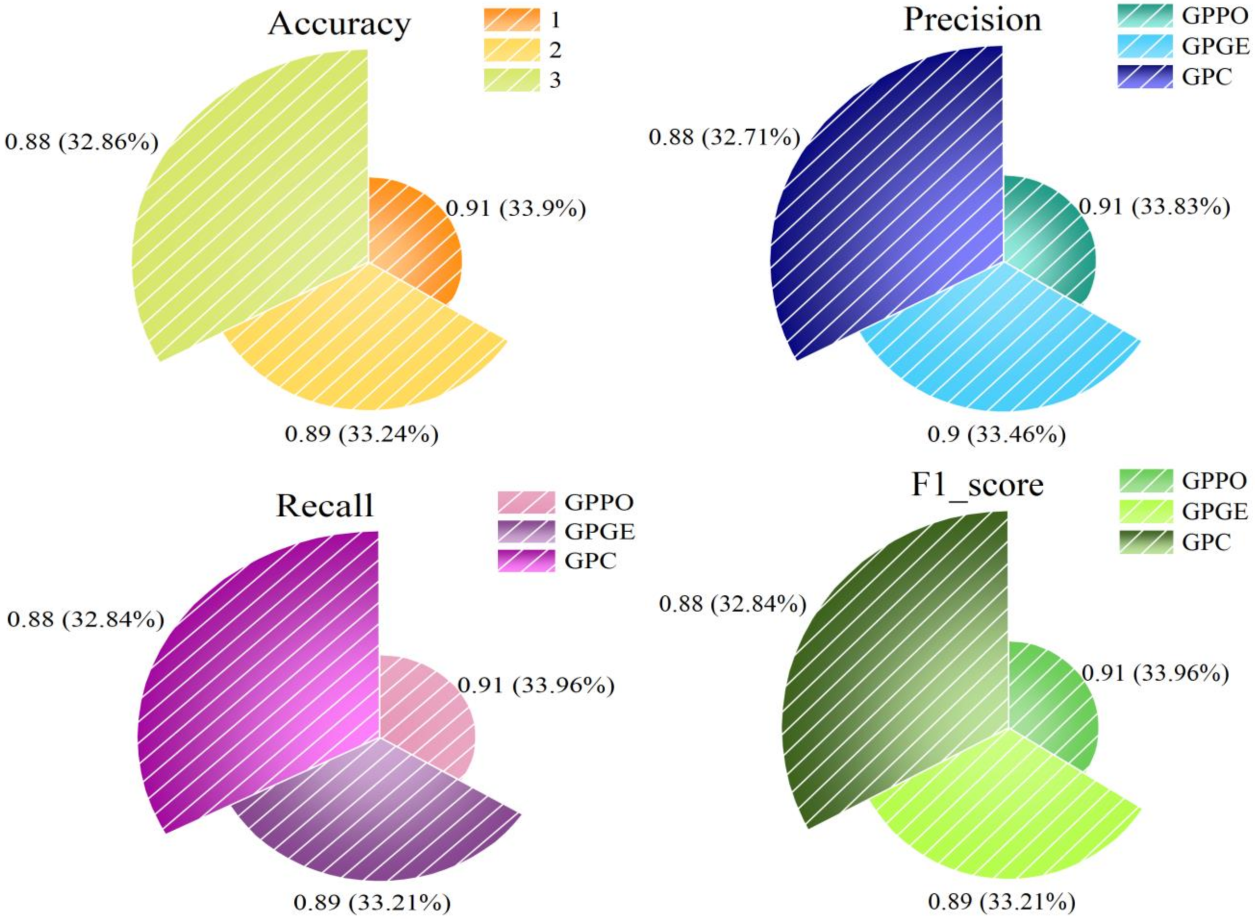

Fig. 6. Radial comparison of developed models based on metrics.

The created models' performance evaluation indicators on the basis of grades are displayed in Table III. These models, GPC+POA, GPC+GEO, and GPC, are assessed across various grade categories, including Excellent, Good, Acceptable, and Poor. The evaluation metrics considered are Precision, recall, and F1-score in each grade category. When examining the performance of GPC+POA, it is evident that this model excels in the Excellent grade category with a precision of 0.93, a recall of 0.93, and an F1-score of 0.93. In the Good category, GPC+POA maintains a high precision of 0.91 but experiences a slight decrease in recall to 0.8, resulting in an F1-score of 0.85. The Acceptable and Poor categories also display strong performance, with particularly impressive results in the Poor category, where the model achieves a precision, recall, and F1-score of 0.96.

Shifting focus to GPC+GEO, this model demonstrates outstanding Precision in the Excellent grade category, reaching a perfect score of 1. However, its recall in the Excellent category is 0.6, leading to an F1-score of 0.75. In the Good and Acceptable categories, GPC+GEO performs well, with balanced Precision and recall, resulting in F1-scores of 0.81. The Poor category maintains a high precision and recall, with an F1-score of 0.96. Finally, the base GPC model's performance is assessed. In the Excellent category, GPC achieves a precision of 0.88, but the recall is relatively lower at 0.7, resulting in an F1-score of 0.78. The Good category exhibits a balanced precision and recall, with an F1-score of 0.82. The Acceptable category presents a similar pattern, with an F1-score of 0.79. In the Poor category, GPC maintains strong Precision and recall, leading to an F1 score of 0.94. It is important to relate these results to the previous table (Table I), which evaluated the models based on general performance metrics. The results in Table III provide a more nuanced view of the models' performance across different grade categories. GPC+POA consistently achieves high Precision, recall, and F1 scores across all grade categories, highlighting its effectiveness in various scenarios. GPC+GEO shows strengths in Precision but faces challenges in the recall, particularly in the Excellent category. The base GPC model also exhibits solid performance, with well-balanced Precision and recall in most grade categories.

Overall, these findings emphasize that the choice of the model should align with the specific needs of the task, considering both general and grade-based performance metrics. GPC+POA excels in Precision and recall across all grade categories, while GPC+GEO and GPC offer balanced performance suitable for various applications.

For a comprehensive evaluation of the model's predictive capabilities and for facilitating model comparisons, Fig. 7 illustrates a bar chart displaying the four distinct grades. This visual representation effectively conveys the models' proficiency in predicting the observed values for each grade, offering insights into their relative performance. When examining the Poor grades, it is noteworthy that the GPC+GEO hybrid model accurately predicted 227 out of 233 measured values, surpassing both the GPC+POA and GPC models in terms of correct predictions. Shifting the attention to the Acceptable grade, the performance of the hybrid models closely aligns, with only a 1 percent difference between them. GPC+POA correctly predicted 51 out of 62 measured values, which is quite similar to GPC+GEO, with 50 correctly predicted values.

In contrast, the GPC model falls behind the hybrid models with only 47 correctly predicted values. When evaluating the good grade, it is evident that the GPC+GEO model outperforms the others by correctly predicting 52 out of 60 measured values, with the GPC model coming close to 51 predicted values. However, in the highest grade, Excellent, the GPC+POA model excels by correctly predicting 37 out of 40 measured values. Notably, in the Excellent grade, the GPC+GEO model lags behind the GPC model's performance. Overall, it is challenging to determine the clear superiority of the models due to their varying performances in different grade categories.

TABLE III. PERFORMANCE EVALUATION INDICES FOR THE DEVELOPED MODELS BASED ON GRADES

| **Model** | **Grade** | **Index values** | | |
|---|---|---|---|---|
| | | Precision | Recall | F1-score |
| GPC+POA | Excellent | 0.93 | 0.93 | 0.93 |
| | Good | 0.91 | 0.8 | 0.85 |
| | Acceptable | 0.75 | 0.82 | 0.78 |
| | Poor | 0.96 | 0.96 | 0.96 |
| GPC+GEO | Excellent | 1 | 0.6 | 0.75 |
| | Good | 0.76 | 0.87 | 0.81 |
| | Acceptable | 0.82 | 0.81 | 0.81 |
| | Poor | 0.96 | 0.97 | 0.96 |
| GPC | Excellent | 0.88 | 0.7 | 0.78 |
| | Good | 0.78 | 0.85 | 0.82 |
| | Acceptable | 0.82 | 0.76 | 0.79 |
| | Poor | 0.93 | 0.96 | 0.94 |

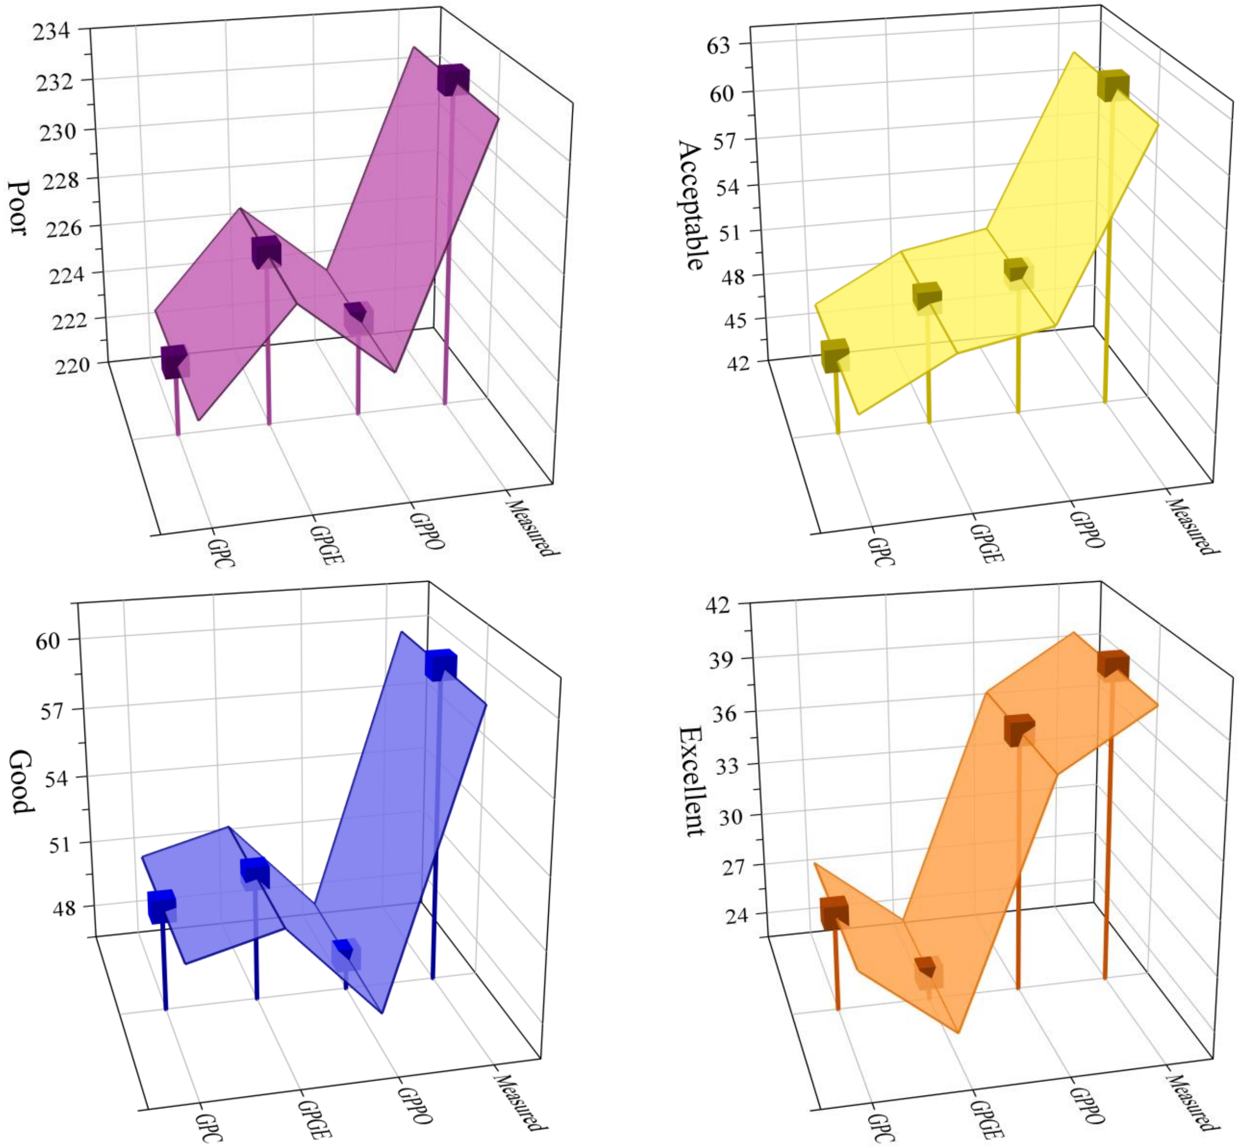

Fig. 7. Column plot for the measured and predicted values.

In Fig. 8, the confusion matrix visually depicts the correspondence between observed and predicted classes by the models. The vertical axis shows the expected classes, and the horizontal axis shows the observed classes. It is evident from this visual representation that the cells along the matrix's main diagonal contain a more significant number of values compared to the remaining cells.

For example, GPC+GEO considers a model that demonstrates a strong ability to make accurate predictions, particularly in the Poor grade. To illustrate this, when dealing with 233 students categorized as Poor, GPC+GEO successfully predicted 227 of them within this category, with only six students being misclassified. This results in the model accurately predicting 97.40% of the observed data within the Poor category. In the case of the Acceptable, Good, and Excellent classes, GPC+GEO achieves prediction accuracies of 80.64%, 86.46%, and 60%, respectively. On the other hand, GPC+POA also displays a high accuracy rate in correctly predicting the Poor, Acceptable, Good, and Excellent classes, with accuracy percentages standing at 96.13%, 82.25%, 80%, and 92.5%, respectively. Similarly, GPC delivers accuracies of 95.70%, 75.80%, 85%, and 70% for the corresponding classes. These examples highlight the models' prediction capabilities in various grade categories, emphasizing their accuracy in predicting student performance across a wide spectrum of Poor, Acceptable, Good, and Excellent classifications.

## *B. Discussion*

*1) Sensitivity analysis:* The impact of input parameters on output values is assessed through the SHAP (Shapley Additive Explanations) sensitivity analysis. Based on the results of this analysis, the significance of the variables has been identified. Fig. 9 illustrates the outcomes of the SHAP-based sensitivity analysis for student performance prediction. According to this figure, it is observed that Freetime, Failures, Medu, Schoolsup, and Fedu experience the highest impact on the G3 values across all categories. Within the Excellent category, these features are found to exert the most substantial influence on the target values. However, for the Good and Acceptable categories, these inputs are not identified as the most influential. In summary, all the inputs are observed to have effects on the G3 values, and through parameter optimization, it is feasible to achieve the highest values.

*2) Comparing previous studies vs present research study:* A thorough synopsis of the conclusions from four groundbreaking research in the field of student performance is given in Table IV. Among these investigations, Nguyan and Peter's inquiry [26] achieved the best accuracy rate of 82% by using the DTC model. This is noteworthy. However, in the current study, a novel approach integrating the GPC model and POA algorithm yielded exceptional results, achieving a noteworthy accuracy score of 0.911 for G3 prediction. This stands out as the highest accuracy achieved among all referenced works, underscoring the effectiveness and superiority of the proposed methodology.

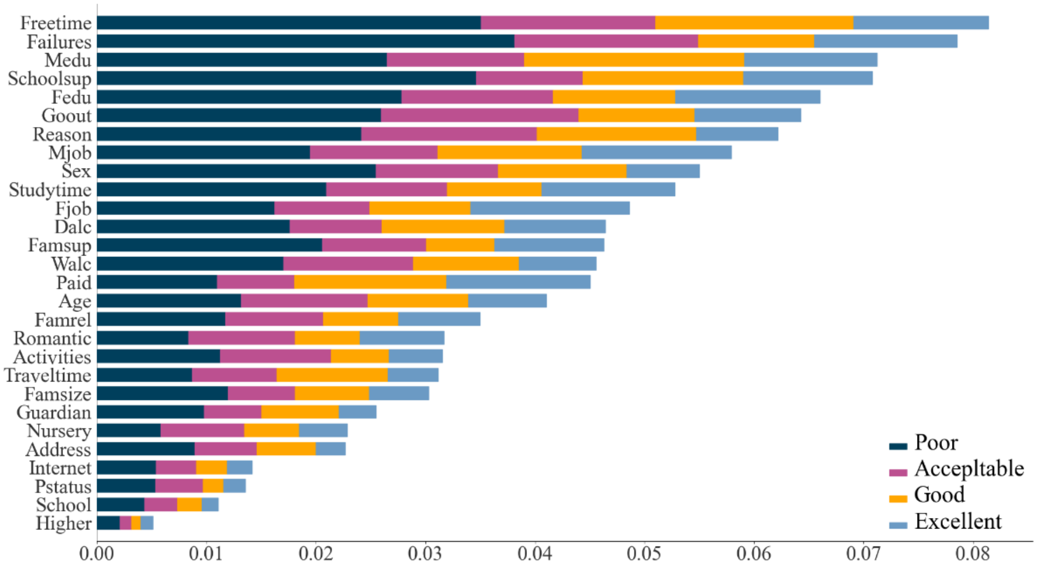

Fig. 9. The results of the SHAP-based sensitivity analysis for assessing the features' impact on output parameters

TABLE IV. EXTENSIVE STUDY RESULTS COMPARED TO THE CURRENT WORK

| Author (s) | Models | Accuracy |
|---|---|---|
| Bichkar and R. R. Kabra [22] | DTC | 69.94% |
| Kabakchieva [43] | DTC | 72.74% |
| Edin Osmanbegovic et al. [28] | NBC | 76.65% |
| Nguyen and Peter [26] | DTC | 82% |
| Present study for G3 | GPC+POA | 91.1% |

## IV. CONCLUSION

In the realm of education, predicting student performance is a critical task, as it holds the potential to revolutionize the way educational institutions operate and provide valuable insights for educators, administrators, and policymakers. This study delved into the world of student performance estimation by harnessing innovative classification techniques, offering an array of promising models such as GPC, GPC+POA, and GPC+GEO. The results of this research have shed light on the capabilities and performance of these models across different educational contexts. GPC, a fundamental model, displayed commendable performance in accurately predicting student grades across various categories, showcasing its reliability in providing a well-rounded assessment of student performance. However, it was the hybrid models, GPC+POA and GPC+GEO, that truly stood out. These models demonstrated their prowess in achieving high Precision, recall, and F1 scores, which are crucial for applications demanding a fine balance between correctly identifying positive instances and minimizing false positives. GPC+POA excelled in predicting Excellent grades, while GPC+GEO showcased its strength in Poor and Good grades, emphasizing the flexibility of these models across different educational scenarios. One of the key takeaways from this study is the importance of model selection based on the specific requirements of the educational task at hand. GPC+POA and GPC+GEO offer tailored solutions for scenarios where Precision, recall, and F1 scores play a pivotal role. In contrast, GPC remains a reliable choice for more general applications. The performance evaluation, as reflected in the results, further demonstrated the versatility of these models in addressing the unique challenges posed by different student performance grades. GPC+POA, for example, showcased superior accuracy in the Excellent grade, while GPC+GEO excelled in the Poor grade. This versatility in handling various performance categories is a testament to the potential of these models to cater to diverse educational settings. As a parting thought, it is essential to recognize the evolving landscape of education and the role that innovative classification techniques can play in shaping its future. These techniques not only provide accurate predictions but also contribute to informed decision-making processes, thus enabling institutions to allocate resources efficiently and support struggling students proactively. In conclusion, this study has provided a glimpse into the exciting possibilities of using innovative classification techniques to estimate student performance. The hybrid models, in particular, have exhibited their potential to enhance the educational landscape by delivering accurate and context-specific predictions. As the field of education continues to evolve, the integration of these innovative techniques may very well hold the key to unlocking a brighter and more data-driven future for both students and educators alike.

# Penetration Testing Framework using the Q Learning Ensemble Deep CNN Discriminator Framework

Dipali Nilesh Railkar, Dr. Shubhalaxmi Joshi
Department of Master of Computer Application, MIT-WP University, Pune, Maharashtra, India

***Abstract*—Penetration testing (PT) serves as an effective tool for examining networks and identifying vulnerabilities by simulating a hacker's attack to uncover valuable information, such as details about the host's operating and database systems. Strong penetration testing is crucial for assessing system vulnerabilities in the constantly changing world of cyber security. Existing methods often struggle with adapting to dynamic threats, providing limited automation, and lacking the ability to discern subtle security weaknesses. In comparison to manual PT, intelligent PT has gained widespread popularity due to its efficiency, resulting in reduced time consumption and lower labor costs. Considering this, the effective penetration testing framework is developed using prairie natural swarm (PNS) optimized Q-learning ensemble deep CNN. Initially, the penetration testing environment (Shodan search engine) is simulated, and along with that expert knowledge base is also generated. Subsequently, the Nmap script engine and Metasploit are deployed, providing robust tools for network investigation and vulnerability assessment. The system state is then relayed to the Q-learning ensemble deep convolutional neural network (Q-learning ensemble deep CNN) classifier. This unique ensemble combines the strengths of Q-learning and deep CNNs, enabling optimal policy learning for decision-making. The prairie natural swarm optimization algorithm is developed through the hybridization of coyote and particle swarm characteristics to fine-tune classifier parameters, enhancing performance. Additionally, the discriminator is trained to maximize standard action rewards while minimizing discounted action rewards, distinguishing valuable from less valuable information. By evaluating the advantage function, successful penetration likelihood is determined, informing situational decision-making through the Q-learning ensemble deep CNN classifier. Accuracy, sensitivity, and specificity as well as the proposed PNS-optimized Q-learning ensemble deep model are used to evaluate the output. In comparison to other approaches currently in use, CNN achieves values of 94.54%, 94.40%, 94.90% for TP, 94.64%, 94.69%, and 94.52% for k-fold.**

***Keywords*—Penetration testing; Q-learning; ensemble deep CNN; prairie natural swarm optimization; Nmap script engine**

## I. INTRODUCTION

In today's interconnected world, the significance of robust cybersecurity measures cannot be overstated. With the relentless advancement of technology, the frequency and sophistication of cyber threats have risen to unprecedented levels. This digital age has ushered in a landscape where individuals, businesses, and governments are all interconnected through complex networks, presenting both unparalleled opportunities and considerable risks [1]. The escalating frequency of cyber threats underscores the gravity of the situation. Malicious actors are exploiting vulnerabilities in software, networks, and infrastructure at an alarming rate, leading to data breaches, financial losses, and significant disruptions. These threats are not confined to specific sectors; they affect organizations of all sizes across industries, as well as individuals who rely on technology for daily tasks. The sophistication of modern cyber threats adds another layer of complexity. Hackers are using advanced tactics, techniques, and procedures that can bypass traditional security measures [2]. From advanced malware to social engineering and zero-day vulnerabilities, cyber threats have become multifaceted and difficult to predict. This calls for cyber security measures that can adapt and respond to evolving attack vectors [3]. As our lives become increasingly digitized, from critical infrastructure to personal devices, the potential consequences of a successful cyber attack become more severe. Breaches can compromise sensitive data, disrupt essential services, and even pose risks to public safety. This underscores the urgent need for robust cyber security measures that can effectively counter these threats.

The threat landscape in the realm of cyber security is dynamic and ever-evolving. It is a landscape characterized by constant change, as cybercriminals consistently innovate and develop new techniques to exploit vulnerabilities and breach systems [4]. This dynamic nature of the threat landscape presents a significant challenge to individuals, organizations, and institutions responsible for safeguarding digital assets and sensitive information. Cybercriminals exhibit remarkable adaptability, constantly refining their tactics, techniques, and procedures (TTPs) to stay one step ahead of security measures [5]. Just as security professionals identify and mitigate one vulnerability cybercriminals quickly shift their focus to discover new avenues of attack [6][7]. This agility allows them to circumvent traditional security mechanisms and exploit unforeseen weaknesses [8]. ML and AI have transformed cyber security by automating complex tasks, analyzing vast data to detect anomalies, and adapting to evolving threats. In penetration testing, ML and AI automate threat detection, identifying vulnerabilities, and simulating attacks. They enhance response by swiftly isolating threats, and minimizing damage. This automation accelerates testing, enabling security professionals to focus on strategic analysis [9]. By enhancing threat detection accuracy, optimizing resource allocation, and reducing false positives, ML and AI elevate penetration testing's efficiency and effectiveness, fortifying cyber security in an increasingly intricate threat landscape.

The fusion of Q Learning, a reinforcement learning technique, with Deep CNNs forms a powerful strategy to tackle intricate, ever-changing decision-making tasks across diverse domains, spanning from robotics to gaming [10]. This combination leverages the strengths of both techniques to maximize decision-making accuracy in high-dimensional state spaces [11]. Q Learning, as a model-free reinforcement learning method, operates through trial-and-error, learning optimal actions by maximizing long-term rewards. It's particularly well-suited for sequential decision-making tasks in dynamic environments. However, it often faces challenges when dealing with high-dimensional or intricate state representations, which are common in applications such as image-based gaming or robotic perception [12]. This is where CNNs come into play. By using convolutional layers to recognize hierarchical patterns, these neural networks excel in processing complicated data, such as videos or images. They can extract meaningful features from raw sensory input, reducing the dimensionality of the state space and enabling more effective decision-making. CNNs also enable end-to-end learning, allowing the agent to autonomously discover relevant features for its task [13]. CNNs can analyze complex data and close the gap between perception and action when used in conjunction with Q Learning. The combination empowers reinforcement learning agents to operate efficiently in scenarios with high-dimensional state spaces [14]. For instance, in gaming, an agent can learn to play complex video games directly from pixel inputs, making it more versatile and adaptive. In robotics, it enables intelligent machines to navigate and interact with their environment, making them suitable for real-world applications [15]. The integration of Q Learning with CNNs represents a promising approach for enhancing decision-making accuracy in dynamic, high-dimensional environments. This combination of deep learning and reinforcement learning methods has the potential to completely transform a variety of applications by enhancing their intelligence, adaptability, and capacity for processing complex data, bringing in a new era of machine learning-driven solutions.

The main aim of the research is to develop a prairie natural swarm-optimized Q-learning ensemble deep CNN for penetration testing. The initial step involves simulating a penetration testing environment using the Shodan search engine, alongside the generation of an expert knowledge base. Subsequently, the deployment of powerful tools, namely the Nmap script engine and Metasploit, facilitates the comprehensive investigation and assessment of network vulnerabilities. The state of the system is then conveyed to the Q-learning ensemble deep CNN classifier, which uniquely amalgamates the capabilities of Q-learning and deep CNNs to enable the acquisition of optimal decision-making policies. The optimization process involves the development of a prairie natural swarm optimization algorithm, achieved through the fusion of coyote and particle swarm characteristics, resulting in the refinement of classifier parameters for enhanced performance. Additionally, the discriminator is trained to maximize standard action rewards while minimizing discounted action rewards, discerning between valuable and less valuable data. The evaluation of the advantage function aids in determining the likelihood of successful penetrations, subsequently guiding situation-based decisions through the Q-learning ensemble deep CNN classifier. The contributions of the research are as follows.

Prairie natural swarm optimization: The prairie natural swarm optimization (PNS) is developed through the hybridization of coyote and particle swarm algorithms. In the coyote algorithm, the velocity and position are not interpreted so it faces limited capability to explore the search space effectively and slower convergence to optimal solutions. Considering this, the particle swarm algorithm velocity is merged with a coyote for faster convergence and balanced exploration and exploitation.

PNS-optimized Q-learning ensemble deep CNN: The PNS-optimized Q-learning ensemble deep CNN classifier is a combination of two powerful techniques in artificial intelligence such as Q-learning and deep CNNs. The advantage of an ensemble Q-learning and deep CNN classifier in penetration testing is its capacity to enhance the accuracy of identifying vulnerabilities and security weaknesses. The PNS algorithm helps in the fine-tuning of the parameters inside the classifier, which helps in enhancing the performance of the classifier.

The manuscript follows a structured organization, commencing with Section II, which delves into the comprehensive reviews of penetration testing. Moving on to Section III, this section elaborates on the proposed methodology for conducting penetration testing and introduces the mathematical equation underpinning the PNS algorithm. Section IV is dedicated to a detailed examination of the empirical results and overarching conclusions drawn from the research findings. Finally, in Section V, the manuscript wraps up by presenting the ultimate thoughts and conclusions that emerge from the research work.

## II. Literature Review

The vulnerability scanning and penetration testing with respect to network security reviews are as follows: A black-box Reinforcement Learning-based framework was presented by Wei Song et al. [13] to provide Adversarial Examples (AEs) for PE threat classifiers and AV engines. Although this approach achieved notably higher evasion rates and a more effective search for successful adversarial patterns, it may necessitate substantial computational resources and time to optimize the generation process. Soheil Malekshah et al. [4] introduced a deep reinforcement learning approach for identifying optimal strategies to adjust power flow when network reliability diminishes. While this method considered uncertainties and variability associated with distributed generation, providing a more precise representation of network performance, it introduced some complex challenges. A digital twin-powered IIoT architecture was introduced by Wei Yang et al. [15], in which the characteristics of industrial devices are captured for real-time processing and intelligent choice-making. This method facilitated smoother and more effective collaborative learning, contributing to enhanced overall training accuracy. However, it may require specialized expertise in both industrial processes and advanced machine learning techniques. Mohsen Ahmadi et al. [1] presented DQRE-SCnet, a Deep-Q-Reinforcement Learning Ensemble integrated with Spectral Clustering, aimed at selectively sharing data among nodes in Federated Learning. This approach improved privacy protection and efficiency, yet it grappled with overfitting challenges. LSTM-EVI, a deep learning-based penetration testing system specially created for scanning assaults within a smart airport-based test bed, was introduced by Nickolaos Koroniotis et al. [12]. It outperformed its peer techniques and effectively-identified vulnerabilities in systems. Nonetheless, it exhibited computational complexity. A smart penetration testing framework that included expert demonstration data was introduced by Yongjie Wang et al. [8]. This approach successfully mitigated overfitting concerns and improved the efficiency of penetration testing. However, it demanded significant computational resources and expertise in machine learning. Yang Li et al. [9] introduced an enhanced network graph model for penetration testing, which seamlessly integrated pertinent security attributes into the process. This intelligent penetration testing method leveraged reinforcement learning and social engineering factors. Yet, it entailed complexity and resource-intensiveness, necessitating expertise in both penetration testing and machine learning. An automated penetration testing methodology designed to find the most common weaknesses in IoT devices used in smart homes was presented by Rohit Akhilesh et al. [2]. This method reduced the time and effort required for penetration testing compared to manual approaches, enhancing efficiency. However, it confronted overfitting issues.

The review on penetration testing in network security highlights various approaches, each with strengths and limitations. Common challenges include the need for significant computational resources and time, complexity in dealing with uncertainties and overfitting, resource intensiveness demanding specialized expertise, and struggling with overfitting issues. To address these limitations, a novel PSN-optimized Q-learning ensemble deep CNN framework is developed in this research that integrates multiple techniques like reinforcement learning, deep learning, and expert demonstration data while optimizing efficiency, enhancing robustness, and improving usability. This approach aims to advance the field of vulnerability scanning and penetration testing by mitigating drawbacks, improving the effectiveness of cyber security measures in network environments, and facilitating practical implementation in real-world scenarios.

### A. *Challenges*

- Combining Q-learning, deep CNNs, and a discriminator framework presents integration challenges, requiring the harmonization of these diverse components for effective operation.
- Handling intricate data sources in penetration testing, like network traffic, may lead to data preprocessing and feature extraction challenges for deep CNNs.
- The discriminator requires a robust dataset of real-world attacks, which may be limited and pose challenges in creating a representative knowledge base.
- Optimizing parameters for Q-learning, deep CNNs, and the discriminator, including learning rates and network architectures, presents challenges to achieving optimal performance.
- Ensuring the framework's scalability to accommodate various network sizes and complexities while maintaining efficient decision-making can be challenging.

## III. Proposed Methodology for Penetration Testing

Penetration testing also referred to as pen testing, is a cyber security procedure that involves simulating actual assaults on computer networks, applications, or systems in order to find security flaws and vulnerabilities. The objective of penetration testing is to proactively assess the security measures of an organization's IT infrastructure and applications, with the goal of uncovering potential weaknesses before malicious attackers can exploit them. Initially, the penetration testing environment (Shodan search engine) is simulated and along with that expert knowledge base is generated. A CVE dataset is utilized in this research for penetration testing. After simulating the penetration testing environment, the Nmap script engine and Metasploit are employed. The Nmap script engine serves as a penetration scanning framework within Nmap, a robust tool for investigating and evaluating networks. NSE empowers users to develop and deploy scripts that automate a range of *tasks* pivotal to penetration testing. Similarly, Metasploit is a widely-used penetration testing framework that helps cyber security professionals and ethical hackers identify vulnerabilities in computer systems, networks, and applications. It provides a range of tools and resources for assessing and exploiting security weaknesses, as well as testing the effectiveness of defense mechanisms and security controls. A deep CNN known as the Q learning ensemble is formed by combining the power of deep learning with reinforcement learning. Deep CNNs receive the state (current circumstance) as input and provide predictions for each possible action. To enable an agent to acquire the best policy for making decisions, Q-learning must be enabled. A model-free reinforcement learning algorithm called Q-learning is used by the agent to learn the optimal policy for making decisions in a given state. It helps the agent to determine the best course of action by maximizing cumulative rewards over time. aids the agent in determining the optimal course of action to pursue in a particular state in order to optimize cumulative rewards over time. Here, Q learning is used to guide the agent in choosing actions that lead to successful penetration by mapping the states to action and optimizing the Q values which represent the predicted cumulative rewards. The Deep CNNs are efficient in handling complex data and extracting relevant features, making them suitable for analyzing the diverse aspects of penetration testing environments and decisions. The optimized Q-learning ensemble deep CNN classifier is a combination of two powerful techniques in artificial intelligence, Q-learning and deep CNNs. In reinforcement learning problems, this hybrid technique is applied when the agent has to learn an optimal policy for making decisions. An agent engages with its surroundings in reinforcement learning, and it is rewarded for its behaviors. The agent aims to learn a policy that maximizes the predicted cumulative reward, or Q-value, by mapping states to actions. The predicted cumulative reward if the agent begins in a state, performs a certain action, and then proceeds with further decisions in accordance with its policy is represented by the Q-value of a state-action pair. Here, the standard hybridization of the coyote and particle swarm characteristics leads to the development of the prairie natural swarm optimization. These hybridized characteristics help in the fine-tuning of the parameters inside the classifier, which helps in enhancing the performance of the classifier. Simultaneously, the discriminator receives the expert knowledge base and the data from the penetration testing environment. The discriminator plays a crucial role in training the agent by providing feedback on the quality of actions taken. A discounted reward is obtained by maximizing the typical action reward and reducing the action reward output, hence providing training for the discriminator. This feedback loop enables the agent to refine its decision-making process and improve its performance over time. The discounted reward provides the less valuable information and the q value provides the efficient information. Here the discounted reward is subtracted from the q value. In comparison to alternative possible actions, the advantage function calculates the benefit or advantage of performing a specific action in a given situation. Using this advantage function the possibility of successful penetration is determined and the decision according to the situation is made using the Q learning ensemble deep CNN classifier. The collaborative approach enhances operational efficiency by leveraging advanced machine learning techniques to navigate and adapt to the dynamic and complex nature of penetration testing environments. Overall, the model can facilitate adaptive and intelligent decision-making, leading to more effective penetration testing outcomes. The systematic representation of the proposed penetration testing framework is depicted in Fig. 1.

## A. *Penetration Testing Environment*

A penetration testing environment, often referred to as a pen-testing lab, is a controlled and isolated system or network setup specifically designed for simulating real-world cyber attacks safely. It duplicates the company's actual IT architecture, including its systems, networks, and apps, enabling cybersecurity experts to find security flaws without endangering sensitive data or operational systems. This environment is equipped with various security tools and resources to assist in the testing process. Data sanitization is crucial to protect privacy and comply with regulations. Comprehensive documentation is essential for tracking and reporting findings. Penetration testing environments facilitate proactive security assessments and help organizations strengthen their cyber security defenses. Creating a penetration testing environment that simulates the Shodan search engine and incorporates an expert knowledge base is a valuable approach for cyber security testing. Shodan is a specialized search engine for finding and analyzing internet-connected devices. It is used by cybersecurity professionals to identify and assess potential security vulnerabilities and misconfigurations in these devices. Its advantage lies in helping experts proactively secure networks by providing insights into exposed assets and potential risks, enhancing cyber security posture. Segmenting the penetration testing environment into two distinct components, one for the Nmap Script Engine (NSE) and the other for the Metasploit framework, can provide an organized and efficient approach to penetration testing.

*1) Nmap Script Engine (NSE):* The Penetration Scanning Framework for the Nmap Script Engine (NSE) is a critical component of a penetration testing environment. It serves as the initial reconnaissance and vulnerability scanning phase, aiming to identify weaknesses and potential entry points in target systems and networks. NSE leverages the Nmap tool, a versatile and widely used network scanner. Within this framework, NSE scripts are employed to automate specific scanning tasks. These scripts are highly customizable, allowing penetration testers to tailor them to the testing objectives. NSE is used to discover live hosts and open ports within the target environment. It helps testers map out the network's topology and identify reachable systems. By utilizing NSE scripts, the framework gathers information about services running on open ports. This includes identifying service versions, banners, and configurations. NSE scripts capable of detecting vulnerabilities are executed against target systems. These scripts may check for known vulnerabilities in services, applications, or system configurations. Information obtained during scanning, such as service banners and version details, is collected and analyzed to identify potential weaknesses or misconfigurations. Comprehensive reports are generated based on the findings of NSE-based scans. These reports provide organizations with insights into their network's security posture, highlighting vulnerabilities that require remediation.

*2) Metasploit:* The Penetration Testing Framework for Metasploit, often simply referred to as Metasploit, is a powerful and widely used penetration testing and exploitation framework. It provides security professionals, ethical hackers, and penetration testers with a comprehensive set of tools and resources for identifying vulnerabilities, exploiting them, and assessing the security of computer systems, networks, and applications. Metasploit includes a vast collection of exploit modules that allow testers to exploit known vulnerabilities in target systems. These modules are organized by the target's operating system, service, and application, making it easier to find and execute the right exploit. Metasploit supports various payloads, which are pieces of code that are delivered to the target system after a successful exploit. Payloads can be used for tasks like gaining remote access, executing commands, or performing post-exploitation activities. The framework provides post-exploitation modules and functionalities to maintain control over compromised systems. This includes activities like privilege escalation, data exfiltration, and lateral movement within a network. Metasploit includes auxiliary modules for various tasks, such as scanning, reconnaissance, and vulnerability detection. These modules can be used to gather information about target systems or to perform non-exploitative actions. Metasploit maintains a database of known vulnerabilities, exploits, payloads, and compromised hosts. This database helps testers keep track of their findings and simplifies the exploitation process. Metasploit can be integrated with other security tools and frameworks, making it a versatile tool for comprehensive security assessments. Integration with tools like Nmap, Wireshark, and Burp Suite enhances its capabilities. Metasploit is available in both open-source community and commercial versions. The community version is free and open-source, while the commercial version offers additional features, support, and updates. Users can create custom scripts and automate tasks within Metasploit, allowing for more efficient and tailored penetration testing processes. Exploit Development: Metasploit provides a platform for developing custom exploits and modules for zero-day vulnerabilities. The framework offers reporting capabilities to document findings, vulnerabilities, and the overall security assessment process.

### B. *Optimized Q learning Ensemble Deep CNN*

The optimized Q-learning ensemble deep CNN classifier is a combination of two powerful techniques in artificial intelligence such as Q-learning and deep CNNs. The advantage of an ensemble Q-learning and deep CNN classifier in penetration testing is its capacity to enhance the accuracy of identifying vulnerabilities and security weaknesses. The PNS algorithm helps in the fine-tuning of the parameters inside the classifier, which helps in enhancing the performance of the classifier.

A popular model-free reinforcement learning algorithm is Q-learning. Assessing the effectiveness of taking particular actions in distinct states, aids an agent in decision-making. By making updates to a Q-table or function that gives each state-action pair a Q-value, the agent gradually learns to optimize its cumulative rewards. The predicted cumulative benefit of performing a certain action in a particular condition is represented by the Q-value. The Q-learning ensemble deep CNN combines the strengths of both Q-learning and deep CNNs. In this approach, the deep CNN is used as a function approximation to estimate Q-values. The agent uses the neural network to anticipate Q-values for state-action pairs rather than keeping a Q-table. This neural network is trained using Q-learning principles, such as temporal difference updates, to learn an optimal policy. With the help of the optimized Q-learning ensemble deep CNN classifier, the agent is able to decide depending on the Q-values that have been learned. The agent can utilize the neural network to evaluate the Q-values of potential actions given a current state and choose the action with the greatest estimated Q-value. This decision-making process is guided by the goal of maximizing cumulative rewards over time.

*1) Deep CNN classifier:* A deep CNN is a specialized neural network created for processing organized grid-like data, with images being a common application. It has gained significant popularity in the realm of malware detection, where the primary objective is to categorize input data as either benign (safe) or potentially harmful (malicious). The input data typically takes the form of an image or a structured grid-like representation. In the context of malware detection, this representation could be a visual rendering of binary code, a heat map detailing system behavior, or some other organized format. The CNN's architecture typically begins with one or more convolutional layers. These layers employ a set of learnable filters, also known as kernels, which are applied to the input data. Each filter traverses the input data, extracting features by performing convolutions. These convolution operations are meticulously designed to identify distinct patterns or characteristics within the input data. In the context of malware detection, these patterns might correspond to specific code structures or behaviors typically associated with malicious software. An element-wise application of a non-linear activation function, such as ReLU, follows each convolution operation. This introduces essential non-linearity into the model, enabling the network to grasp intricate relationships within the data. In order to reduce the spatial dimensions of the feature maps produced by the convolutional layers, pooling layers, which can be either MaxPooling or AveragePooling, are extremely important. This downsampling serves to simplify computational complexity while capturing the most significant features. The generated feature maps flatten into a 1D vector following many convolutional and pooling layers. This vector encapsulates the high-level features extracted from the input data. This flattened vector then passes through one or more completely connected layers. These layers are akin to conventional neural network layers, with each neuron establishing connections to every neuron in the preceding and following layers. The fully connected layers master intricate combinations of features and ultimately map these features to the output classes, namely benign or malicious. The final fully connected layer commonly employs a softmax activation function to yield probability scores for each class. The output layer, generally featuring two neurons representing benign and malicious classes, produces the ultimate classification results. The softmax function is instrumental in converting the network’s outputs into class probabilities, with the class exhibiting the highest probability serving as the ultimate prediction. For training, the network relies on labeled data where the ground truth (benign or malicious) is known. During this training process, the network adjusts its internal parameters, encompassing weights and biases, employing optimization algorithms. The goal is to reduce the size of a loss function that measures the discrepancy between expected and real labels. The network is assisted in learning to differentiate between benign and malicious data by this repeated training procedure. Fig. 2 illustrates the architecture of the deep CNN classifier.

*2) Q-learning algorithm:* A method for reinforcement learning called Q-learning is essential in assisting agents in understanding the best course of action to adopt in contexts where their goal is to maximize their cumulative rewards. This algorithm proves to be particularly valuable when the agent starts with limited knowledge of the environment and needs to gather insights and refine its strategy through interactions over time. Its fundamental concept is rooted in Markov decision processes. The core process involves the agent perceiving the current state of the environment, deciding on the action to take through a specific strategy, and then receiving immediate feedback in the form of a reward. The information regarding the future state of the environment is also included in this comment. Essentially, Q-learning functions by creating a map that connects the present environmental condition to the most beneficial course of action. The primary steps of the algorithm can be summarized as follows.

Step 1: To begin, define the state set as $Se=\{se_1, se_2, ....se_n\}$ and the actions set as $Ae=\{ae_1, ae_2, ....ae_n\}$ and also initiate the state-action function, denoted as $Q(se, ae)$, and create the reward matrix, represented as Re . Additionally, set crucial parameters, including the maximum number of iterations, denoted as $M$ .

Step 2: The process commences by randomly selecting an initial state from the state set S. The iteration ends and a new initial state is selected if, by chance, the initial state is already the goal state. On the other hand, the algorithm moves on to step 3 if the starting state is not the desired state. This mechanism ensures that the algorithm begins with a suitable starting point and repeats until it reaches the target state.

Step 3: The algorithm chooses an action from the pool of all feasible actions available in the current state, adhering to the ε-greedy strategy. This chosen action then guides the agent to transition to the next state within the environment. This approach effectively balances exploration and exploitation, allowing the agent to make decisions that prioritize known, rewarding actions while occasionally exploring new possibilities.

Step 4: Eq. (1) serves as the means to update the Q-matrix.

$$Q(se_t, ae_t)=Q(se_t, ae_t)+\beta*\left[R(se_t, ae_t)+\gamma\max_{ae'\in A}Q\left(\left(se_{t+1}, ae'\right)-Q(se_t, ae_t)\right)\right] \quad (1)$$

Where $se_t$ is the environment's state at the time $t$ , at is the agent's action at time $t$ , $Q(se_t, ae_t)$ is the state-action operates at time $t$ , $se_{t+1}$ is the environment's state at time t + 1, $R(se_t, ae_t)$ is the immediate reward of the environment's feedback from time t to time t + 1, and $ae^{'}$ is the action that maximizes value. Q When the agent arrives $se_{t+1}$ , the learning rate is $\beta$ varies from $\beta\in(0,1)$ the discount factor is $\gamma\in[0,1]$, and γ is the discount factor.

Step 5: Proceed by updating the state for the next moment, setting it as the current state, which is expressed as $se_t = se_{t+1}$ . If the current state ( $se_t$ ) is not the target state, the algorithm loops back to step 3. This iterative process continues until the target state is reached, ensuring that the agent refines its decision-making strategy over multiple cycles.

Step 6: The method ends when the maximum number of iterations is reached, indicating that the training phase is complete. At this point, the converged Q-matrix is acquired, and the optimal action strategy is determined using Eq. (2). However, if the maximum iterations have not been reached, the process returns to step 2, initiating the next iteration. This iterative approach continues until the training process reaches its defined limit, thereby ensuring the refinement of the optimal action strategy.

$$\pi^*(se)=\arg\max_{a\in A}\left(Q*(se, ae)\right) \quad (2)$$

*3) Prairie natural swarm optimization (PNS):* The prairie natural swarm optimization (PNS) is developed through the hybridization of coyote and particle swarm algorithms. In the coyote algorithm, the velocity and position is not interpreted so it faces limited capability to explore the search space effectively and slower convergence to optimal solutions. Considering this, the particle swarm algorithm velocity is merged with coyote for faster convergence and balanced the exploration and exploitation.

Motivation  Coyote (prairie) Optimization is a novel meta-heuristic algorithm that draws inspiration from the remarkable problem-solving and adaptability exhibited by coyotes, an exceptionally resourceful species. The development of this optimization technique is driven by several factors. Firstly, coyotes showcase remarkable problem-solving skills and adaptability in diverse environments, making them an intriguing source of inspiration for optimizing complex and dynamic scenarios. Their intelligence, social behavior, and efficient foraging strategies offer valuable insights for algorithm design. Secondly, in addressing complex and dynamic problems, existing optimization algorithms may not always be well-suited. Prairie Optimization aims to bridge this gap by providing a nature-inspired approach capable of effectively handling real-world complexities. Additionally, as researchers continue to explore nature-inspired optimization techniques, drawing inspiration from a wide array of species, the creation of new algorithms like Prairie Optimization adds to the expanding toolbox of computational intelligence methods for solving intricate problems in various domains, including engineering, logistics, and finance.

Particle Swarm Optimization (Natural swarm) is an algorithm driven by the emulation of the collective behavior of birds and fish, drawing inspiration from the flocking patterns of birds and schooling behaviors of fish in the natural world. Natural Swarm aims to enhance the optimization of solutions within complex search spaces. Its motivation lies in harnessing the potential of swarm intelligence for problem-solving, with each particle in the swarm representing a potential solution. These particles interact with one another based on the principles of exploration and exploitation. They adjust their positions by learning from both their individual experiences and those of their neighbors, all with the aim of converging toward optimal solutions. Natural swarm is particularly well-suited for tackling optimization problems that challenge traditional methods, such as those in high-dimensional spaces, non-convex landscapes, and scenarios with numerous local optima. Its foundation in nature highlights the strength of collective decision-making, adaptability, and the synergy among individual agents. In essence, the motivation behind natural swarms is to develop a versatile optimization technique that leverages the collective intelligence of swarms to discover high-quality solutions across a broad spectrum of applications in fields like engineering, economics, science, and more.

### C. *Mathematical Equation of Prairie Natural Swarm Optimization*

This section delves into the mathematical equation that underpins Prairie Natural Swarm Optimization, which is presented in the following passage.

In the COA algorithm, the coyote population is partitioned into $M_q \in M^*$ packs, with each pack comprising $M_a \in M^*$ coyotes. This initial suggestion assumes that there are the same number of coyotes in each pack, everywhere. Thus, the algorithm's total population is determined by multiplying $M_q \in M^*$ and $M_a \in M^*$. To simplify matters, this initial version of the algorithm does not take into account solitary coyotes. In this formulation, each coyote symbolizes a potential solution to the optimization issue, and its social condition is expressed in the cost associated with the objective function. This is crucial to note for the convenience of the reader.

Inspired by the social dynamics of coyotes, which are equivalent to the choice variables $\vec{y}$ in a global optimization problem, the COA mechanism was devised. Therefore, the social condition, denoted as V (comprising the set of decision variables), for the $a^{th}$ coyote in the $q^{th}$ pack during the $s^{th}$ time instance is expressed as follows,

$$V_a^{q,s} = \vec{y} = (y_1, y_2, ......y_E) \tag{3}$$

The first step in the COA is to establish the coyote population worldwide. Due to the stochastic nature of the COA, randomization is used to set the initial social conditions for every single coyote. To do this, random values are assigned for the $a^{th}$ coyote in the $q^{th}$ pack and along the $i^{th}$ dimension within the defined search space, as follows.

$$V_{a,i}^{q,s} = L_i + k_i \cdot (U_i - L_i) \tag{4}$$

Where $E$ denotes the search space's dimension and $L_i$ and $U_i$ represent the $i^{th}$ decision variable's lower and upper bounds, respectively. Furthermore, inside the range [0,1], $k_i$ represents a true random number that is produced from a uniform probability distribution. Following this randomization process, the adaptation of the coyotes within their current social conditions is assessed.

$$f_a^{q,s} = f\left(V_{a,i}^{q,s}\right) \tag{5}$$

Coyotes are randomly assigned to packs at the beginning. However, there are times when coyotes decide to leave their existing packs and live alone or decide to join a new pack. A coyote's eviction from a pack is contingent upon the size of the pack at that moment and occurs with a probability represented by the symbol qr. The following is a description of this process,

$$Q_r = 0.005 \cdot M_a^2 \tag{6}$$

Considering the parameter $Q_r$ can take values exceeding 1 for $M_a \le \sqrt{200}$, causing a maximum quantity of coyotes per pack to be limited to 14. The goal of this mechanism is to promote contact and diversity among all of the coyotes in the population. In essence, it encourages cross-cultural communication among people everywhere, leading to a more extensive and dynamic process of information sharing.

In the natural behavior of this species, packs typically consist of two alpha individuals. However, in the COA, only one alpha is considered, specifically the one that demonstrates the highest level of adaptation to the environment. When dealing with a minimization problem, the following definition applies to the alpha of the $q^{th}$ pack at the $s^{th}$ time instance,

$$\alpha^{q,s} = \left\{ V_{a,i}^{q,s} \mid h_{a=\{1,2,\ldots M_a\}} \min f\left( V_{a,i}^{q,s} \right) \right\} \tag{7}$$

The COA operates under the assumption that coyotes possess a level of organization that allows them to share their social conditions and aid in the upkeep of their packs, given the observable signs of swarm intelligence within this species. As a result, the COA compiles all of the data that came from the coyotes and treats it as the pack's cultural inclination.

$$T_i^{q,s} = \begin{cases} G^{q,s}_{\frac{(M_a+1)}{2}}, & M_a \text{ is odd} \\ \dfrac{G^{q,s}_{\frac{M_a}{2},i} + G^{q,s}_{\left(\frac{M_a}{2}+1\right),i}}{2}, & \text{otherwise} \end{cases} \tag{8}$$

For each $i$ in the range, $G^{q,s}$ represents the social conditions that are ranked for all coyotes in the $q^{th}$ pack during the $s^{th}$ time occurrence [1, E]. To put it simply, the median social conditions of all the coyotes in that specific pack are computed to identify the pack's cultural inclination.

With birth and death as basic biological events in mind, the COA determines the coyote's age $b_d^{q,s} \in \mathrm{N}$ in years. A new coyote's social circumstances are said to be a combination of its two randomly chosen parents' social circumstances as well as external factors. This can be stated in the manner shown below:

$$g_i^{q,s} = \begin{cases} V_{k1,i}^{q,s}, & kn_i < Q_t \text{ or } i = i_1 \\ V_{k2,i}^{q,s}, & kn_i \geq Q_t + Q_d \text{ or } i = i_2 \\ B_i, & \text{Otherwise} \end{cases} \tag{9}$$

In this case, $i_1$ and $i_2$ stand for two randomly selected problem dimensions, and $k1$ and $k2$ stand for two randomly chosen coyotes from the $q^{th}$ pack. Furthermore, $B_i$ is a random number inside the boundaries of the $i^{th}$ dimension's decision variable, $kn_i$ is a uniformly produced random number within the range [0,1], and $Q_t$ , $Q_d$ , and $kn_i$ represent the scatter and association probabilities, respectively. The scatter and association probability, $Q_t$ and $Q_d$ , are important factors that influence how diverse the coyotes' cultures are within the pack. Here are the definitions of $Q_t$ and $Q_d$ in this first edition of the COA.

$$Q_t = 1/E \tag{10}$$

$$Q_d = (1 - Q_t)/2 \tag{11}$$

Where, $Q_d$ exerts an equivalent influence and impact on both parents. To capture the cultural dynamics within the packs, the COA introduces the concepts of the alpha influence $(\gamma_1)$ and the pack influence $(\gamma_2)$. The alpha influence is the difference in culture between a randomly picked coyote in the pack $(ak_1)$ and the alpha coyote, while the pack influence is the difference in culture between another randomly selected coyote $(ak_2)$ and the group's cultural tendency. The uniform probability distribution is used to select these random coyotes, and $\gamma_1$ and $\gamma_2$ are expressed as follows,

$$\gamma_1 = \alpha^{q,s} - V_{ak_1}^{q,s} \tag{12}$$

$$\gamma_2 = T^{q,s} - V_{ak_2}^{q,s} \tag{13}$$

In the coyote algorithm, the velocity and position is not interpreted so it faces limited capability to explore the search space effectively and slower convergence to optimal solutions. Considering this, the particle swarm algorithm velocity is merged with a coyote for faster convergence and balanced exploration and exploitation. Then the new mathematical equation becomes,

$$X^{t+1} = X^t + k_1\gamma_1 + k_2\gamma_2 + v^{t+1} \tag{14}$$

$$X^{t+1} = X^t + k_1\gamma_1 + k_2\gamma_2 + \left[ v(t) + g_1u_1\left(D_{best}(t) - y(t)\right) + g_2u_2\left(H_{best}(t) - y(t)\right) \right] \tag{15}$$

Where, the weighing factors for the pack influence and the alpha influence are represented by the variables $k_1$ and $k_2$ , respectively. First, a uniform probability distribution is used to produce random numbers within the range [0,1] for both $k_1$ and $k_2$. Furthermore, the particle swarm optimization's social and cognitive acceleration coefficients are represented by the parameters $g_1$ and $g_2$ . In the meantime, two uniformly distributed random numbers produced within the interval [0, 1] are $u_1$ and $u_2$.

In the optimization process, the strategies employed draw from the adaptability and strategic decision-making observed in coyote behavior. This entails dynamically adjusting parameters in response to changes in the penetration testing environment. Just as coyotes adapt their hunting strategies based on factors like prey behavior and environmental conditions, the PNS optimization enables the system to flexibly modify parameters to optimize the performance as new threats emerge. Moreover, the PNS optimization leverages the collaborative optimization capabilities inspired by particle swarm behavior. Similar to how swarms of particles collectively explore and converge toward optimal solutions. This collaborative aspect ensures that the optimization process explores a diverse range of parameter configurations, allowing for the discovery of superior settings that enhance the system's overall performance.

The PNS optimization is used to fine-tune the hyperparameters in Q learning ensemble deep CNN. This fine-tuning process ensures that the models are configured optimally for the specific task of penetration testing. By tuning the parameters such as weight and bias, the optimization contributes to improved convergence rates, higher accuracy, and enhanced generalization capability of the models involved in penetration testing. This leads to more effective identification of security flaws and vulnerabilities within the IT applications. Additionally, the dynamic adjustment of parameters enables the system to adapt rapidly to new threats or changes in the environment, thereby enhancing operational efficiency and ensuring robust cyber security measures. Overall, by combining adaptability, strategic decision-making, and collaborative optimization, PNS optimization enables the system to achieve superior performance, effectively mitigating security risks and safeguarding the organization against cyber threats.

## IV. Result

The subsequent section provides a comprehensive account of the outcomes achieved through the application of Q-learning ensemble deep CNN with Prairie Natural Swarm Optimization for the purposes of penetration testing.

### A. Experimental Setup

The experiment, which centers on penetration testing and employs the optimization of Q-learning ensemble deep CNN, is conducted using Python. The experiment is conducted on a Windows 10 computer that has 8GB of internal memory.

### B. Dataset

CVE dataset [22]: The research utilizes a dataset sourced from the National Institute of Standards and Technology (NIST) called Common Vulnerabilities and Exposures (CVE). The CVE dataset contains information about cyber security threats, vulnerabilities, and exposures making it a valuable source for penetration testing. It includes various software systems, networks, and applications, ensuring the dataset's diversity. Furthermore, since CVE entries are meticulously documented and categorized, the dataset's representativeness is enhanced, allowing for a wide range of cyber security threats to be captured and analyzed.

### C. Parameter Metrics

*1) Accuracy:* Accuracy in penetration testing refers to the overall correctness of the testing results. It is a measure of how well the test findings and identified vulnerabilities align with the actual security weaknesses present in the target system. High accuracy means that the test results are reliable and reflect the true security status of the system, while low accuracy indicates a higher likelihood of false positives or false negatives.

$$acc = \frac{R_{tn} + R_{tp}}{R_{tn} + R_{tp} + R_{fn} + R_{fp}} \tag{16}$$

*2) Sensitivity:* Sensitivity, also known as the true positive rate or recall, represents the ability of the penetration test to correctly identify and report actual vulnerabilities or security issues present in the system. A high sensitivity means that the test is effective at finding true vulnerabilities and minimizing the risk of overlooking them.

$$sen = \frac{R_{tp}}{R_{tp} + R_{fn}} \tag{17}$$

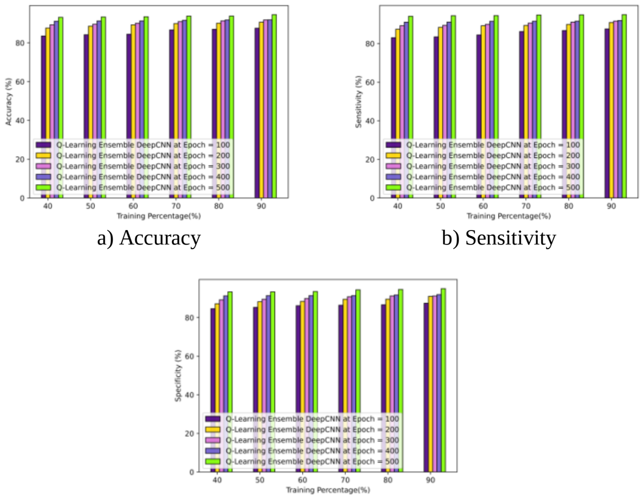
*3) Specificity:* Specificity, on the other hand, measures the ability of the penetration test to avoid false alarms or false positives. A high specificity indicates that the test is less likely to report security issues that do not exist. This is important for minimizing the time and resources required for investigating and remediating issues, as well as preventing unnecessary disruption to the target system.

$$spec = \frac{R_{tn}}{R_{tn} + R_{fp}} \tag{18}$$

### D. Performance Analysis

Two important performance indicators are used to demonstrate the efficacy of Q-learning ensemble deep CNN optimization via Prairie Natural Swarm such as training percentage (TP) and k-fold. To fully evaluate its performance, this evaluation is carried out throughout several epochs, namely at intervals of 100, 200, 300, 400, and 500.

*1) Performance analysis with TP:* Fig. 3 vividly illustrates the effectiveness of Prairie Natural Swarm (PSN) optimized Q-learning ensemble deep CNN when applied to penetration testing within the context of the TP. Fig. 3(a) shows that the PSN-optimized Q-learning ensemble deep CNN performs admirably when it comes to evaluating accuracy at TP 90, with results of 87.55%, 90.65%, 91.84%, 91.86%, and 94.54. Similarly, when evaluating sensitivity at TP 90 through the PSN-optimized Q-learning ensemble deep CNN, the results are notably robust, registering figures of 87.57%, 90.90%, 91.63%, 91.96%, and 94.98 [as illustrated in Fig. 3(b)]. The PSN-optimized Q-learning ensemble deep CNN consistently yields high results in the evaluation of specificity for the 90% training, with values of 87.44%, 90.98%, 91.19%, 91.93%, and 94.99% [as shown in Fig. 3(c)]. These outcomes highlight the method's effectiveness over many epochs and show how proficient it is becoming in penetration testing situations.



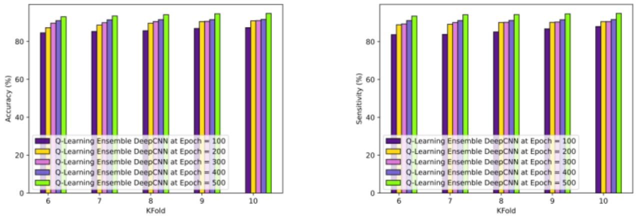
a) Accuracy

b) Sensitivity

c) Specificity

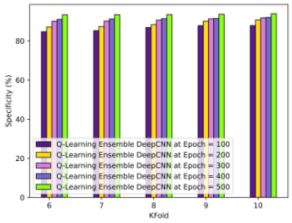
Fig. 3. Performance with TP.

*2) Performance analysis with k-fold:* Fig. 4 shows the effectiveness of the Q-learning ensemble deep CNN optimized for Prairie Natural Swarm (PSN) in penetration testing, specifically using the k-fold evaluation framework. In the context of assessing accuracy at TP 90, the PSN-optimized Q-learning ensemble deep CNN demonstrates performance results of 87.29%, 90.86%, 91.00%, 91.67%, and 94.82% ([as presented in Fig. 4(a)]. Similarly, when considering sensitivity at TP 90 through the PSN-optimized Q-learning ensemble deep CNN, the results remain robust, recording figures of 87.97%, 90.58%, 90.60%, 91.68%, and 94.90% [as depicted in Fig. 4(b)]. The PSN-optimized Q-learning ensemble deep CNN regularly produces good results in the evaluation of specificity for the 90% training, with values of 87.83%, 90.70%, 91.76%, 91.99%, and 93.89% [as shown in Fig. 4(c)]. These results illustrate the approach's efficacy in the k-fold evaluation and point to its possible applications in penetration testing scenarios.



a) Accuracy

b) Sensitivity



c) Specificity

Fig. 4. Performance with k-fold.

### E. Analysis based on Q-learning

Fig. 5 provides a visual representation of the effectiveness of PSN-optimized Q-learning ensemble deep CNN in the context of penetration testing, specifically within the framework of loss and rewards evaluation. In the context of assessing loss at 90% data demonstrates results of 0.007982595, 0.007981617, 0.007982108, 0.007980786, and 0.00798194 for 995, 996, 997, 998, 999 episodes [as presented in Fig. 5(a)]. Similarly, when considering rewards at 90% data demonstrates results of 978, 979, 980, 980, and 981 for 995, 996,997, 998, 999 episodes [in Fig. 5(b)].

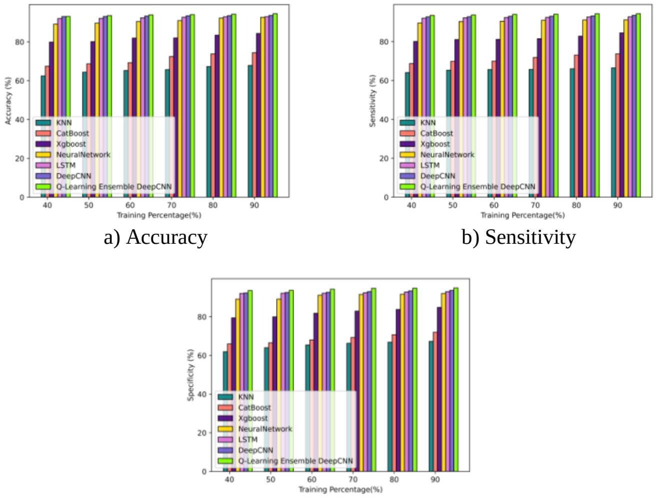
### F. Comparative Methods

KNN [H1] [16], CatBoost [H2] [17], Xgboost [H3] [18], Neural Network [H4] [19], LSTM [H5] [20], Deep CNN [H6] [21] is compared with PSN optimized Q-learning ensemble deep CNN [H7].

*1) Comparative analysis with TP:* Fig. 6 provides a visual representation of the penetration testing methodology evaluation. Surprisingly, Fig. 6(a) depicts that the H7 outperforms the H6, outperforming by a gradually increasing margin of 0.93 when it comes to accuracy evaluation inside the 90% training. This significant improvement is also seen when sensitivity is assessed in the same training setting which is presented in Fig. 6(b), where H7 once more demonstrates a notable increase of 0.89 relative to H6. In addition, when looking at specificity for the 90% training, the H7 shows a 1.34 gain over the H6, continuing its remarkable performance trend, and the analysis of specificity is illustrated in Fig. 6(c). These results highlight the H7's obvious benefits in the field of penetration testing.

*2) Comparative analysis with k-fold:* Fig. 7 provides a visual representation of the penetration testing methodology assessment. Surprisingly, Fig. 7(a) depicts that the H7 outperforms the H6 by a steadily increasing margin of 1.00 when it comes to accuracy assessment inside the nine-fold framework. This significant improvement is also shown in the sensitivity analysis in the same training situation which is presented in Fig. 7(b), where the H7 again demonstrates a noteworthy rise of 1.01 in comparison to the H6. In addition, the H7 exhibits a 1.01 improvement over the H6 in terms of specificity inside the 9-fold, thereby sustaining its remarkable performance trend, and the analysis of specificity is illustrated in Fig. 7(c). These outcomes highlight the H7's noteworthy benefits when it comes to penetration testing.



a) Accuracy

b) Sensitivity

c) Specificity

## G. *Comparative Discussion*

Comparisons with other current methods are used to determine the efficacy of the proposed PSN-optimized Q-learning ensemble deep CNN method. The PSN-optimized Q-learning ensemble deep CNN outcomes are 94.54%, 94.40%, and 94.90% respectively for TP. For the k-fold, the PSN-optimized Q-learning ensemble deep CNN obtained values are 94.64%, 94.69%, and 94.52% respectively. Table I depicts the obtained values of the PSN-optimized Q-learning ensemble deep CNN method with existing methods.

TABLE I. COMPARATIVE DISCUSSION OF PROPOSED METHOD WITH EXISTING METHODS

| **Methods** | **TP(90)** | | | **k-fold (9)** | | |
|---|---|---|---|---|---|---|
| | **Accuracy (%)** | **Sensitivity (%)** | **Specificity (%)** | **Accuracy (%)** | **Sensitivity (%)** | **Specificity (%)** |
| KNN | 67.87 | 66.53 | 67.29 | 66.62 | 67.13 | 67.14 |
| Cat Boost | 74.45 | 73.74 | 72.00 | 73.80 | 73.92 | 73.26 |
| Xgboost | 84.36 | 84.53 | 84.86 | 83.52 | 83.83 | 84.73 |
| Neural Network | 92.64 | 91.22 | 92.05 | 91.47 | 92.20 | 92.30 |
| LSTM | 92.96 | 92.77 | 92.99 | 92.81 | 92.54 | 92.86 |
| Deep CNN | 93.66 | 93.56 | 93.63 | 93.69 | 93.74 | 93.56 |
| Proposed | 94.54 | 94.40 | 94.90 | 94.64 | 94.69 | 94.52 |

# V. CONCLUSION

In this research the effective penetration testing framework is developed using prairie natural swarm (PNS) optimized Q-learning ensemble deep CNN. Initially, the penetration testing environment (Shodan search engine) is simulated and along with that expert knowledge base is also be generated. Subsequently, the Nmap script engine and Metasploit are deployed, providing robust tools for network investigation and vulnerability assessment. The system state is then relayed to the Q-learning ensemble deep CNN classifier. This unique ensemble combines the strengths of Q-learning and deep CNNs, enabling optimal policy learning for decision-making. The prairie natural swarm optimization algorithm is developed through the hybridization of coyote and particle swarm characteristics to fine-tune classifier parameters, enhancing performance. Additionally, the discriminator is trained to maximize standard action rewards while minimizing discounted action rewards, distinguishing valuable from less valuable information. By evaluating the advantage function, successful penetration likelihood is determined, informing situational decision-making through the Q-learning ensemble deep CNN classifier. PNS-optimized Q-learning ensemble deep learning is used to measure the output along with accuracy, sensitivity, and specificity. In comparison to other current approaches, it achieves higher efficiency, achieving 94.54%, 94.40%, 94.90% for TP and 94.64%, 94.69%, 94.52% for k-fold. In the future, advanced deep learning techniques, dynamic environment adaption, integration with security operations, privacy–preserving techniques will be involved to address the robustness and resilience challenges.

# Educational Data Mining in European Union – Achievements and Challenges: A Systematic Literature Review

Corina Simionescu, Mirela Danubianu, Bogdănel Constantin Grădinaru, Marius Silviu Măciucă
Faculty of Electrical Engineering and Computer Science, Stefan cel Mare University of Suceava, Romania

***Abstract*—The quality of education is one of the pillars of sustainable development, as set out in "The 2030 Agenda for Sustainable Development", adopted by all United Nations Member States in 2015. Recent social and technological developments, as well as events such as the COVID-19 pandemic or conflicts in many parts of the world, have led to essential changes in the way education processes are carried out. In addition, they have made it possible to generate, collect and store large amounts of data related to these processes, data that can hide useful information for decisions that, in the medium or long term, can lead to a significant increase in the quality of education. Uncovering this information is the subject of Educational Data Mining. To understand the state-of-the-art reflected by recent developments, trends, theories, methodologies, and applications in this field, in the European Union, we considered it appropriate to conduct a systematic and critical literature review. Our paper aims to identify, analyze, and synthesize relevant information from these articles, both to build a foundation for further studies and to identify gaps or unexplored issues that can be addressed in future research. The analysis is based on research identified in three international databases recognized for content quality: Scopus, Science direct, and IEEEXplore.**

***Keywords*—Educational data mining; systematic literature review; European Union; Kitchenham methodology; data mining techniques**

## I. Introduction

Nowadays, educational institutions generate, collect and store huge volumes of data from a variety of sources and processes. The use of computers, of internet or learning management systems (LMS) has triggered an exponential growth in the amount of data. Much of this is generated through online technologies, such as e-learning platforms, search engines, social networks, electronic communication, or through watching videos, etc., but also through direct collection from assessment processes or from monitoring students' behavior. Different types of data about users' online interactions, such as clicks, browsing preferences and behaviors, or about learning outcomes and student preferences are collected and stored. This avalanche of educational data provides opportunities for deeper understanding of learning processes, increasing the quality of education and improving teaching strategies.

To harness this wealth of data, researchers have used data mining techniques to extract "unexpected and valuable" patterns and knowledge [1]. Thus emerged the interdisciplinary field of Educational Data Mining (EDM), which focuses on obtaining hidden but potentially valuable information in the context of education and learning through specific data mining methods applied to data collected from these processes. It establishes a connection between two distinct fields: education, on the one hand, and computer science, specifically data mining, on the other [2] combining elements from artificial intelligence, machine learning, statistics, expert systems, databases, and visualization to investigate and optimize educational processes.

The International Educational Data Mining Society, which hosts and publishes the Journal of Educational Data Mining, offers the following definition of EDM: "Educational Data Mining is an emerging discipline concerned with developing methods for exploring the unique types of data that come from educational environments and using these methods to better understand students and the environments in which they learn" [3].

To identify the newest trends in the field, we conducted a Systematic Literature Review (SLR) in the EDM field. To reflect a state as close as possible to the present moment, we have chosen as our target publications from 2013 to 2023. It is well known that EU member countries have educational systems with specific local characteristics and there is no uniform standard. However, the application of EDM techniques on the data collected from these systems can lead to valuable information for decision making, and why not, to their optimization at EU level. This is why we have turned our attention to those papers that have authors affiliated to educational institutions in EU member countries or that use datasets collected from these institutions.

This analysis allows us to identify the challenges and opportunities associated with the use of data mining techniques in education, leading to the discovery of information that supports decisions that target more effective, personalized, and results-oriented learning. The research aims to provide a documented response regarding the data mining methods used in EDM, the level to which they have been used, their benefits and shortcomings.

In a preliminary survey of SLRs on EDM to which we had access, we found that although there are still such papers in the field, they address issues other than those proposed by us and do not reflect the current state of research. For example, the first such study was conducted by Romero and Ventura [4] and was updated in 2010 [5] and 2013 [6]. In these, 11 categories of tasks in EDM were identified including: data analysis and visualization, feedback to support instructors, recommendations for students, predicting student performance, modeling student behavior, grouping students, social network analysis, concept map development, and curriculum construction. Specific methods and techniques were presented for each of these.

In [7], a study that identified a set of educational functionalities, an approach to EDM, and two patterns describing EDM based on descriptive and predictive models was proposed. The computational techniques and not the applications were mainly analyzed. Other research is focused on the current state of application of different approaches in EDM. In [8] a systematic review of the literature addressing the use of clustering in EDM is given, and in [9] performance prediction based on machine learning techniques is addressed.

As a result, the novelty of our work lies in the fact that it provides an up-to-date overview of research and trends in EDM use across the European Union assesses the level of interest in the field and uncovers those aspects that may constitute new directions for research.

To carry out this analysis we considered the Kitchenham methodology [10]. This has become a well-known and respected approach in the academic community and has been applied in various research fields, from software engineering to public health.

Further, our paper is structured as follows: Section II introduces the concept of EDM, Section III discusses the methodology with all three stages of the Kitchenham methodology for conducting an SLR, Section IV provides a discussion on the reported results, Section V addresses some limitation and Section VI draws conclusions of the research.

## II. Educational Data Mining

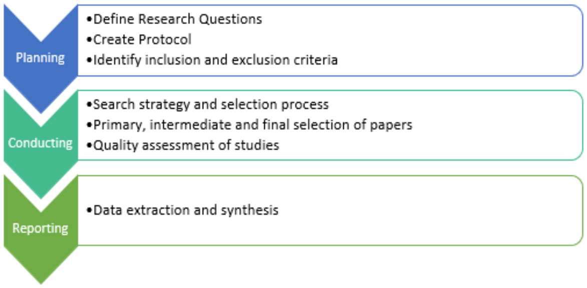
EDM process “converts raw data from educational systems into useful information with a potential positive impact on educational research and practice" [5].

It uses some of the core technologies in data mining to improve the quality of learning by modeling and discovering the correlation between learner's academic performance and learning behavior, teaching purpose and teaching strategy [8]. To achieve this goal, the following are mainly used: classification, association rules, clustering, regression, text mining, and web mining.

## III. Working Methodology

Systematic literature review is an approach that, to be effective, must provide meaningful information as a foundation for decision-making. In this paper we have used the Kitchenham method [10] which states that the purpose of conducting a SLR is a broad review of the studies included in a particular field to recognize gaps in existing research for further investigation and to provide a thorough understanding of the field.

In accordance with the outlined guidelines, a systematic literature review consists in three distinct phases necessary for a formal research process, each of which containing specific steps and activities [10], as is presented in Fig. 1.



Planning
•Define Research Questions
•Create Protocol
•Identify inclusion and exclusion criteria
Conducting
•Search strategy and selection process
•Primary, intermediate and final selection of papers
•Quality assessment of studies
Reporting
•Data extraction and synthesis

Fig. 1. Kitchenham methodology.

### *A. Planning the Review*

We start by identifying the research questions followed by a description of the predefined used protocol. This includes information on the steps to be carried out in the review processes, such as:

*1)* Search strategy;
*2)* the paper selection strategy;
*3)* quality assessment;
*4)* data extraction and synthesis [11]
*5)* Additionally, a predefined review protocol reduces researchers bias [11]. In order to not duplicate the information, the protocol elements are described during the steps in which they are applied.

### *B. Purpose and Objectives of the Analysis, and Identification of Research Questions*

The aim of our review is to assess the current state of research on EDM methods and techniques and their extent of use in the European Union.

The research has been focused on published works in the field of EDM, in the years 2013-2023, targeting countries belonging to the European Union. By identifying, then analyzing and synthesizing existing research we aim to gain an understanding of the trends of evolution, the methods and techniques used, and the results obtained from their application, thus facilitating an understanding of the current progress, opportunities and challenges in the field.

The objectives we propose are:

O1: To identify methods, techniques and algorithms used in EDM practice;

O2: To build a picture of EDM by analyzing and synthesizing published research from 2013-2023 on education systems in EU countries;

O3: To gain insight into the benefits of using data mining methods and techniques in education;

O4: To identify challenges, possible gaps and future research directions in EDM.

In line with the proposed goal, we formulated the following research questions:

RQ1: What is the extent to which EDM is implemented at the different levels of education systems in the EU?

RQ2: What is the trend of evolution of EDM research at EU level?

RQ3: To what extent are data mining techniques used in education?

All these lead to a documented answer to the following summary question: What is the current state of EDM research for education systems in EU countries?

### *C. Inclusion and Exclusion Criteria*

To ensure that the literature under review fits the research aim, objectives and questions, we have established a set of rules in the form of inclusion and exclusion criteria. These allowed us to select relevant, quality and suitable papers to be considered for literature review in educational data mining.

*1)* Inclusion criteria
I1: Studies based on authors/data sets from the education system of European Union countries;

I2: Studies describing the use of data mining methods and techniques in the educational field of European Union countries;

I3: Papers that consistently address topics related to the purpose, objectives of the analysis and research questions.

*2)* Exclusion criteria
E1: Books and book chapters, book reviews, tutorials, errata, encyclopedias, editorials;

E2: Studies whose content could not be accessed (not Open access);

E3: Studies presenting a literature review covering aspects of Educational Data Mining.

E4: Papers written in other languages than English.

### *D. Metadata Used in the Analysis Process*

An important aspect in achieving the proposed objectives is related to the design of the dataset to be collected. Beyond reading the articles, their analysis also requires the extraction of associated metadata values, which can be subject to different processing. We considered the following: authors, title of the paper, year of publication, abstract, paper length (in pages), DOI, document type, and keywords.

### *E. Conducting the Review*

*1) Search strategy and selection process:* The first step in this process was to choose the appropriate international databases from which to select papers. For this purpose, we took into account three factors: the quality and international recognition of the database, the relevance for EDM, and the existence of advanced search tools. Accordingly, we chose three international databases: Scopus, Science direct, and IEEEXplore.

Our choice is motivated by the following considerations:

- Quality and international recognition: Scopus, ScienceDirect, and IEEEXplore are the benchmarks for the quality and international recognition of their content. They host peer-reviewed papers published by authors with expertise in the field, which makes the available information credible and reliable.
- Relevance for EDM: These databases host a significant number of scholarly articles and research papers in computer science, technology and education that are essential to EDM. This makes it possible to carry out a broad analysis and to identify trends in the field [12].
- Advanced search tools: all three platforms offer filters and advanced search tools, making it easy to identify and select relevant articles for deeper analysis [13].

Therefore, the choice of Scopus [14], ScienceDirect and IEEEXplore databases is justified to perform a comprehensive literature review, ensuring the selection of reliable and relevant sources. Access to the databases in this paper was provided through an institutional account provided by "Stefan cel Mare" University of Suceava, Romania.

*2) The study selection process goes through three stages:*

- Initial identification of published papers that could plausibly satisfy the search queries;
- Selection of candidate papers;
- Selection of final studies to analyze;
- Identification of potentially useful studies;
- This first step involved going through a systematic process of identifying and selecting papers that meet the purpose of our research. To find the best results for the research questions we used and tested various search strings.

In the beginning we used the string educational AND data AND mining as search expression in all metadata. As a result of the search, we obtained a very large number of articles in all three databases. For Scopus we obtained 99.731papers, for Science Direct, Elsevier 24.544 papers and for IEEExplore 8.937 works. We have found that many articles that comply with the search string do not actually relate to educational systems. As a result, we have restricted the search space to those papers with this string in the title. We have refined the search by adding a filter that only searches for papers published in the target interval, i.e., 2013-2023. Finally, we also considered the term school as a generic address targeting both university and pre-university environments. Table I shows the search strings in the four databases, constructed according to their specific rules.

TABLE I. SEARCH STRINGS TO IDENTIFY POTENTIALLY USEFUL STUDIES

| Digital Library | Search string |
|---|---|
| Scopus | (ALL (educational AND data AND mining) AND TITLE (educational AND data AND mining) AND ALL (school)) AND PUBYEAR > 2012 AND PUBYEAR < 2024 |
| Science direct, Elsevier | Educational AND data AND mining AND school Year:2013-2023 Title:educational AND data AND mining |
| IEEEXplore | ("All Metadata":educational AND "All Metadata":data AND"All Metadata":mining) AND ("Document Title":educational AND ("Document Title":data AND "Document Title" :mining) AND ("All Metadata":school) Filters Applied: 2013 - 2023 |

A summary of the search results illustrating the evolution of the number of articles found initially and after the three refinements is presented in Table II.

TABLE II. POTENTIALLY USEFUL STUDIES

| | Scopus | Science Direct | IEEE |
|---|---|---|---|
| Articles containing in all metadata the string ***educational AND data AND mining*** | 99.731 | 24.544 | 8.937 |
| Articles published between 2013-2023 | 91.013 | 15.356 | 4.276 |
| Articles having in title the string ***educational AND data AND mining*** | 636 | 28 | 183 |
| Articles with the word ***school*** in all metadata | 326 | 16 | 52 |

To ensure that the selected papers were useful for our research we scanned the titles, removed duplicates, considered the size of the paper in number of pages as a measure of consistency, reviewed papers under five pages and concluded that a paper of less than four pages did not provide sufficient information, and researched the affiliations of the authors and the language in which the paper was written. We applied additional filters in the search strings, where it was possible.

The structure of Scopus database allowed us to apply (extra) filters, unlike the other databases we searched. As a result, we easily applied filters that helped to reduce the number of items matching our criteria, such as:

- Language selection: we removed Portuguese, Chinese, Turkish, and we obtained 241 results.
- Country selection (we selected EU member countries).

(ALL (educational AND data AND mining ) AND TITLE ( educational AND data AND mining ) AND ALL ( school ) ) AND PUBYEAR > 2012 AND PUBYEAR < 2024 AND ( LIMIT-TO ( DOCTYPE , "ar" ) OR LIMIT-TO ( DOCTYPE , "cp" ) ) AND ( LIMIT-TO ( SRCTYPE , "j" ) OR LIMIT-TO ( SRCTYPE , "p" ) ) AND ( LIMIT-TO ( LANGUAGE , "English" )) AND ( LIMIT-TO ( AFFILCOUNTRY , "Bulgaria" ) OR LIMIT-TO ( AFFILCOUNTRY , "Cyprus" ) OR LIMIT-TO ( AFFILCOUNTRY , "France" ) OR LIMIT-TO ( AFFILCOUNTRY , "Finland" ) OR LIMIT-TO ( AFFILCOUNTRY , "Germany" ) OR LIMIT-TO ( AFFILCOUNTRY , "Greece" ) OR LIMIT-TO ( AFFILCOUNTRY , "Ireland" ) OR LIMIT-TO ( AFFILCOUNTRY , "Italy" ) OR LIMIT-TO ( AFFILCOUNTRY , "Latvia" ) OR LIMIT-TO ( AFFILCOUNTRY , "Lithuania" ) OR LIMIT-TO ( AFFILCOUNTRY , "Netherlands" ) OR LIMIT-TO ( AFFILCOUNTRY , "Poland" ) OR LIMIT-TO ( AFFILCOUNTRY , "Romania" ) OR LIMIT-TO ( AFFILCOUNTRY , "Slovakia" ) OR LIMIT-TO ( AFFILCOUNTRY , "Spain" ) OR LIMIT-TO ( AFFILCOUNTRY , "Sweden" ) OR LIMIT-TO ( AFFILCOUNTRY , "Czech Republic" ) OR LIMIT-TO ( AFFILCOUNTRY , "Croatia" ) OR LIMIT-TO ( AFFILCOUNTRY , "Portugal" ) )

We obtained 43 results, three of which refer to the description of conference volumes. Consequently 40 papers remained for further analysis.

A scan of the titles revealed that some of them [15] [16] [17] [18] [19] [20] are themselves literature reviews that focus on different aspects of EDM. As a result, according to E3, they have been removed. Papers that do not meet criterion I3 and those papers that have been duplicated from other databases have also been removed. Table III summarize the studies removed, indicating the eligibility criteria and the reason for removal.

TABLE III. STUDIES REMOVED FROM SCOPUS

| Reference | Removal reason | Comments |
|---|---|---|
| [15][16][17][18][19] [20] | E3 | A Systematic Literature Review |
| [21] | I3 | The study contains only 2 pages. |
| [22][23][24][25][26] [27][28] | - | Duplicates. Articles found in IEEExplore |
| [29][30][31] | - | Duplicates Articles found in Science Direct, Elsevier |

For Science Direct, Elsevier we have removed four articles whose titles showed them to be reviews or surveys and one article referring to Brazil. Analyzing the affiliation of the authors, we also removed seven articles whose authors are all affiliated with institutions in countries outside the EU. Their details are shown in Table IV.

TABLE IV. STUDIES REMOVED FROM SCIENCE DIRECT AND ELSEVIER

| Reference | Removal reason | Comments |
|---|---|---|
| [7][32][33] [34] | E3 | Survey /A Systematic Literature Review |
| [35] | I2 | The research concerns Brazil |
| [36][37] [38][39] [40][41] [42] | I1 | The study does not meet criterion I1. Authors are affiliated to institutions in non-EU countries |

Metadata analysis of the 52 results obtained in the IEEEXplore database led to the elimination of 45 papers, based on the failure to comply with the inclusion criteria or to comply with the exclusion criteria, as shown in Table V.

At this stage we obtained the following results: Scopus- 22 studies, Science Direct – 4 studies and IEEExplore 7 studies.

Final studies selection:

For the final selection of articles to be analyzed, we carried out a complete reading of the papers obtained in the previous stage, assessed their quality, and kept only those that fully met the inclusion/exclusion criteria.

TABLE V. STUDIES REMOVED FROM IEEEXPLORE

| Reference | Removal reason | Comments |
|---|---|---|
| [43] | I2 | The research concerns a school in South Africa |
| [44][45][46] | E3 | A Systematic Literature Review |
| [11][47] | I2 | The research concerns India |
| [48][49][50] [51][52][53][54][55][56] | I1 | All authors are affiliated to institutions in China |
| [57] [58][59] [60][61] [62] [63][64][65] [66] [67] [68][79][80][81] | I1 | All authors are affiliated to institutions in Ecuador, Thailand, India and Brazil |
| [69][70][71] [72] [73] [74] [75] | I1 | All authors are affiliated to institutions in Japan, Israel, Serbia, Turkey and United Arab Emirates |
| [76] | I1 | All authors are affiliated to institutions in Great Britain, and the paper was published in 2023, when it is out of EU |
| [77][78] [82] [83][84] [85] | I1 | The study does not meet criterion I1. All authors are affiliated to institutions in Mexico, Argentina, South Africa and USA |
| [86] | I2 | The research concerns Pakistan |

According to criterion I1 we considered relevant for our research studies based on authors/data sets from the education system in the European Union countries. We motivate this choice by the fact that Romania - as a member of the European Union - shares many of the educational directives and regulations with other member states. This means that studies from these countries can better reflect the potential challenges, requirements, and opportunities that Romania might face or already faces. Education systems in EU countries tend to pursue a certain alignment with skills and knowledge standards, which can influence approaches to educational data mining, as they target comparable educational outcomes. Although cultural differences are present, education in the EU reflects also a certain cultural uniformity given by European values and principles. Therefore, research based on data from this region may be more relevant for Romania than research analyzing completely different educational systems, such as those in Asia or North America, for example.

At the time of the study, the UK was no longer a member of the European Union, imposing a different legislative and regulatory framework from the EU. Therefore, practices and policy on data mining in education may differ significantly. EU member countries are governed by common regulations and directives, including in the area of data protection (GDPR), which influence how information can be collected and analyzed in the education sector. This gives a more consistent basis of comparability between them, unlike the UK which may now have its own rules.

A full examination of the 22 articles previously obtained in Scopus database revealed that some of them do not meet the inclusion criteria or align with the exclusion criteria. Table VI presents the status of the articles removed in the current stage and the reasons for their removal.

TABLE VI. STATUS OF THE ARTICLES REMOVED FROM SCOPUS

| Reference | Removal reason | Comments |
|---|---|---|
| [87][88] [89] | E3 | A Systematic Literature Review |
| [90] | I1 | The research is based on a dataset from a school in Iraq. The study has seven authors: five are affiliated with educational institutions in Iraq, one author from Hungary, and another from Germany. |
| [91] | E2 | The study is not full accessible |
| [92] | I3 | The paper provides a review of EDM and compares existing techniques, defines the concept of explainability and reviews recent advances in explainable artificial intelligence, assesses the current state of explainability in modern EDM approaches, discusses the multidimensional requirement for educational data mining, highlighting limitations of prediction accuracy metrics, and proposes integrating explainability into future EDM techniques to fill accuracy gaps. |
| [93] | I1 | UK is no longer in the EU |
| [94][95] | E2 | The study is not full accessible |
| [96] | I2 | The authors use the mystery method to explore educational data. This method does not belong to the field of EDM. |
| [97] | I2 | The study has 5 authors, 4 authors from Ecuador, one author from Spain. Although we have gone through the study very carefully, the authors do not specify the country of the educational institution from which the dataset was collected. At the end of the paper thanks are given to the institution Escuela Politécnica Nacional, from which we infer that the research is based on a dataset from a non-EU country. |

At the end of the candidate studies search stage in Science Direct, Elsevier 4 research articles remained.

Considering author affiliation, we found some studies that have team authors affiliated to institutions in both EU and non-EU countries. In these cases, we read the whole paper to identify the origin of the underlying dataset. For example, in [98], the author group consists of 3 researchers affiliated with a university in Pakistan and one researcher affiliated with a university in Germany. Near the end of the paper, the authors note that the research was based on a dataset collected from a university in Pakistan, which does not meet inclusion criterion I1.

The article [31] has two authors, one affiliated with a university in Africa, the other with a university in France. Although it passed the four filters initially applied to all studies, we consider it not relevant to our research, because it assesses the affective states and behavior of people who use serious collaborative crisis management games to improve their quality of life.

A surprising situation we encountered in [29]. The paper has four authors: Three authors affiliated with universities in EU member countries (Cyprus, The Netherlands, Finland) and one author affiliated with a university in Australia. In their study the authors research two datasets: a dataset collected from EU member countries and a dataset collected from Australia. We considered that the paper fits the specified criteria. Table VII summarizes the articles removed and the reason for their removal.

TABLE VII. STATUS OF THE ARTICLES REMOVED FROM SCIENCE DIRECT, ELSEVIER

| Reference | Removal reason | Comments |
|---|---|---|
| [98] | I1 | Data collected from Pakistan |
| [31] | I3 | The topic is outside the scope of our research |

Finally, we studied the seven articles obtained in the previous step in IEEExplore.

The aim stated in [23] is to identify the influence of thermal conditions in classrooms on learning, to facilitate specific measures to improve these conditions. The research is motivated by the fact that the expense of ensuring energy efficiency in schools represents a very large amount of money allocated from the budget of educational institutions. The authors carried out an analysis of data collected from the GAIA platform to investigate the condition of school buildings in Europe. The GAIA platform deployed a pilot IoT infrastructure in three countries (Greece, Italy, Sweden), monitoring 18 school buildings in real time for electricity consumption and indoor and outdoor environmental conditions. Data collected over 2 years is examined to assess the indoor conditions of classrooms and provide insight into the functioning of these educational buildings. This is the first initiative to establish a quantitative comparison between different buildings and classrooms. The analysis presented here can serve as a tool for school managers and building administrators, helping them to quickly identify classrooms that do not meet standards for indoor environmental conditions and take specific actions to improve them. Data was collected in the cloud using IoT devices. Cloud delivery was not always done correctly due to the instability of the wi-fi connection. Although in the title the authors refer to the use of data mining techniques in the research, they did not describe any of the techniques used, which led to the study being eliminated, according to I2.

We also found an article that is a variant of an analyzed one, and a work that is in line with the exclusion criterion E3. Finally, we removed three more items as shown in Table VIII.

TABLE VIII. PAPERS REMOVED FROM CANDIDATE STUDIES IN IEEEXPLORE

| Reference | Removal reason (inclusion/exclusion criterion) | Comments |
|---|---|---|
| [23] | I2 | The article does not meet the objectives of the review |
| [24] | E2 | The article is a variant of the study [22]. It cannot be accessed because it is not open access. |
| [25] | E3 | The study explores the challenges and opportunities related to the analytical processing of big data generated and stored in higher education institutions. One of its chapters contains a brief overview of the most commonly used EDM techniques in educational research, with the authors stating that the most commonly used are classification techniques. |

At the end of each of the three selection rounds the results were as follows:

TABLE IX. NUMBER OF STUDIES SELECTED FOR FINAL REVIEW

| Digital Repository | Initial identification | Candidate selection | Final selection |
|---|---|---|---|
| Scopus | 326 | 22 | 11 |
| Science direct, Elsevier | 16 | 4 | 2 |
| IEEExplore | 52 | 7 | 4 |

## F. *Reporting*

As it is presented in Table IX the final review covers 17 articles. Table X presents a summary of these papers and highlights for each of them, the research objectives, the country whose educational system is targeted, data mining techniques and tools (applications) used, year of publication and the education level addressed in the research.

TABLE X. OVERVIEW OF SELECTED STUDY ANALYSES

| *Reference* | *Objectives* | *Country* | *Methods/techniques* | *Year* | *Educational level* |
|---|---|---|---|---|---|
| [22] | Development of a game portal to help first graders to solve their homework, with the aim of analyzing the learning process. | Slovakia | **Classification** (Fuzzy Decision Trees), **Association Rules** | 2013 | Preuniversity |
| [26] | Strategies and algorithms for handling and managing missing data, in the context that if each student has control over their data and decides what data to make available for analysis, there is a possibility that this phenomenon will alter the quality of the models. Some classification algorithms were evaluated, simulating missing values on data sets collected from students. | Portugal | **Classification** (Support Vector Machine, Neural Network, Decision Trees, Random Forrest) | 2018 | Preuniversity |

## IV. Discussions

Based on data summarized above, some interesting aspects about the current level of involvement of EDM in increasing the quality of the educational process in European Union can be revealed.

- Data mining techniques have been used mainly at the academic level. 53% of the papers refer to universities while only 47% address problems in the preuniversity environment (Fig. 2).
- Educational Data Mining not only facilitates the efficient discovery of useful patterns and knowledge but supports strategic decision-making in this vital area. Based on the data presented in Table II, we can state that worldwide interest in EDM research is high and justified by the increasing availability of educational data, but also by the development of technologies. In the second selection stage of studies, we noted the interest and upward trend for EDM research in countries such as China, India, Japan.

The number of studies selected in the final phase reflects a medium interest of researchers affiliated to educational institutions in EU member countries (Fig. 3).

This proves the need to continue our research on educational datasets. The aim is to transform data into useful knowledge to contribute to the improvement of educational processes.

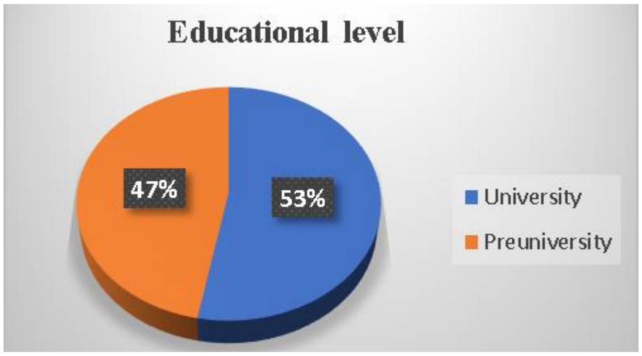

Fig. 2. Education level at which EDM was used.

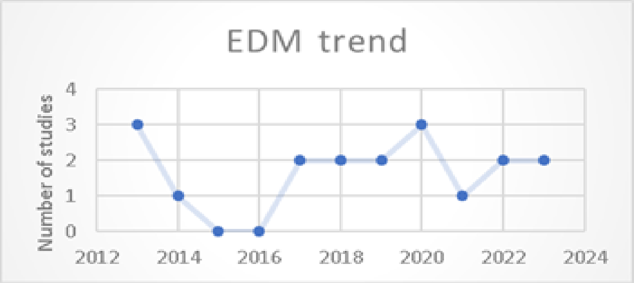

Fig. 3. Trends in EDM research in EU member countries, 2013-2023.

It is necessary to mention that our research includes papers published until September 2023, so it is possible that the number of papers will increase until December 2023.

- EDM uses different methods to extract information. In the reviewed papers we found that classification is most used (Fig. 4), especially decision trees which allowed the development of predictive models, followed by regression as a predictive technique (Fig. 5). To discover relationships between different variables or events in the data, researchers used association rules. Clustering techniques were applied to identify groups with similar needs to develop personalized teaching strategies.

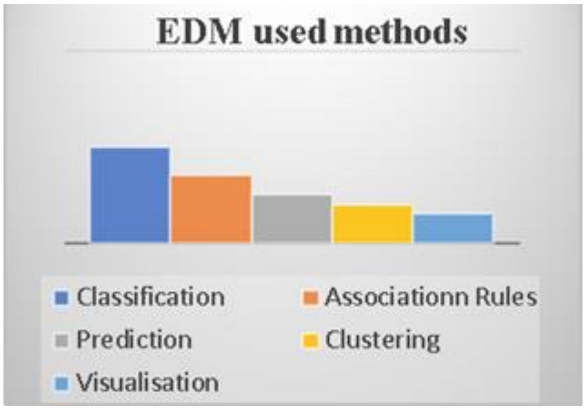

Fig. 4. Data mining methods used in the final selection of studies to be reviewed.

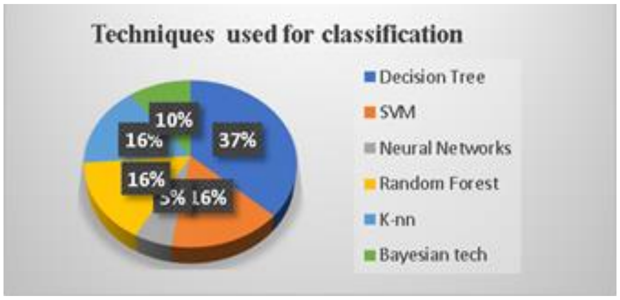

Fig. 5. Data mining methods used for the final selection of studies to be reviewed.

- The current relatively low level of EDM research interest in EU is highlighted by the fact that the 17 articles analyzed come from only 10 of the 28 Member States, as shown in Fig. 6.

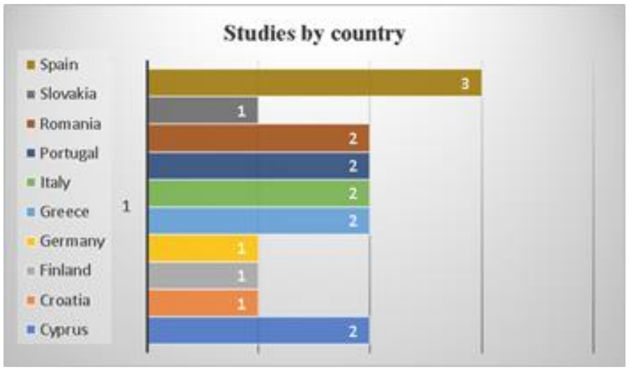

Fig. 6. EU member countries contributing with studies to our research.

Datasets and tools:

In most cases, source datasets were used. These were collected from students and teachers as responses to questionnaires, or by directly retrieving the necessary data from the LMSs used. Some of the sources of these datasets are listed below (Table XI).

TABLE XI. SUMMARY OF ORIGINAL DATASETS SOURCES

| Reference | Country | Source of dataset |
|---|---|---|
| [26] | Portugal | 649 students from secondary schools |
| [27] | Italy | 197 students from secondary schools |
| [30] | Spain | 31236 students from 896 secondary schools |
| [99] | Cyprus | 101 students |
| [100] | Finland | 116 students at Medical School of Tampere<br>Moodle log |
| [101] | Romania | original dataset collected in Babeș-Bolyai University for three years, for a Computer Science discipline |
| [102] | Italy | data collected through an online questionnaire completed by 561 undergraduate students of an Italian university |
| [103] | Croatia | 185 students – 59.605 records -from a university in Croatia |
| [104] | Greece | data collected from learning platforms in Aristotle University of Salonic |

| | | |
|---|---|---|
| [105] | Germany | Study 1: 47 students<br>Study 2: 64 students from a secondary school |
| [106] | Greece | Hellenic Open University |
| [108] | Spain | archives of multiple-choice test answers for 12 exams between 2004-2006 |
| [109] | Romania | 105 teachers from schools in Cluj Napoca |

From the provided data concerning the used tools, data presented in Table XII, and in Fig. 7 it is evident that the most used environments for designing and executing data mining processes were Weka and RapidMiner.

Finally, we propose a brief discussion of the insights gained from this research which aims to highlight the current state of research, achievements, and challenges that induce the need for further directions of work.

TABLE XII. SUMMARY OF RESULTS FROM THE SELECTED STUDIES ANALYSIS

| Reference | Tools /applications |
|---|---|
| [29] | Statistica, Data Miner |
| [30] | HLM 7 |
| [99] | Model-It ® |
| [100] | SPY US |
| [101] | IntelliDaM |
| [102] | Freel R package, PReMiuM |
| [103] | RapidMiner |
| [104] | Weka |
| [106] | KNIME |
| [107] | Weka |
| [108] | Python, R, GNU Octave |
| [109] | Rapid Miner, Weka |

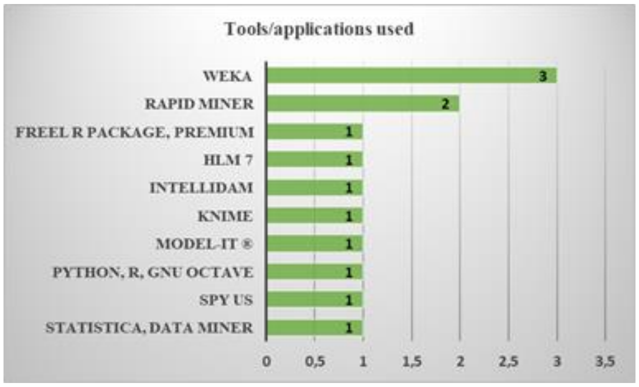

Fig. 7. Most used tools in studies of our research.

The methods used most frequently in extracting patterns from the data in the studies reviewed are classification followed by association rule discovery.

- Classification was used to understand the learning process of primary school children aiming to identify individual and group patterns and to design appropriate educational resources to maintain their motivation and attention [22]. In [27], classification was used to predict student performance in solving problems raised by real scenarios and in [30] to identify factors associated with the effectiveness of secondary schools. Other topics related to the educational process were also covered. In [109] a study of the quality of life of teachers in the pre-university environment and their perception on the education system was carried out, exploring a dataset containing the opinions of 105 teachers in Cluj-Napoca (Romania). Beyond finding patterns directly related to educational activity, research has also been targeted on the usefulness of exploring data from the logs of the LMSs used (mainly Moodle) [100] [103] or the effect of introducing of Augmented Intelligence method in EDM [107].
- Association rules as rule-based statements, that aim to find interesting relationships between data items in large datasets, were used in [108] to discover the relationships between answers to different test questions in order to be able to infer from them the relationships between competences in an educational area. In [28] a subtype of these, called Causal Data Mining, was used to find causal relationships between different events. In [29] association rules were a useful method for finding relationships between learners' use of simulation and their performance in this context. Another variant of association rules, namely Sequence Association, has been used for the purpose of referencing an immediately following action as a function of a previous one [99].

At the same time, the reviewed studies revealed a variety of challenges, including:

- Data quality: the quality of educational data can vary and can be influenced by human error, incorrect input or different data sources that are not standardized. Ensuring data quality is essential for accurate results.
- Confidentiality and ethics: Educational data may contain sensitive information about students and teachers. It is crucial to protect the confidentiality of this data and to respect ethical standards regarding its collection, storage, and use. In [26] the issue of confidentiality and transparency is addressed, and the idea that each student should have control over the data they make available in the dataset is stated. It is found, however, that this approach results in datasets with a lot of missing data, which can seriously distort the quality of the acquired information.
- Generalizing results: Some patterns or findings may be specific to one context or group of learners and may be difficult to generalize to wider or other educational situations.
- Evaluation and validation: Rigorous evaluation of models and methods is essential to ensure that the results obtained are valid and reliable. However, there are cases where model validation is still subjective, with no metrics being used to assess the results obtained [108].

- Prediction vs. interpretation: Another issue is the balance between creating accurate predictive models and understanding the reasons behind these predictions. To have a meaningful impact on education, it is important to be able to explain why and how certain conclusions are reached.

## V. Limitations

The limitations that may affect the relevance and applicability of the results in the diverse educational context of EU member countries are multiple.

One of the main barriers is the costs associated with obtaining access to the literature. We consider this to be a significant barrier to in-depth analysis of the field of Educational Data Mining (EDM). In our approach, our ability to consult published materials was limited by the resources available through the University "Ştefan cel Mare" of Suceava.

On the other hand, the accessibility and quality of data can differ substantially between EU countries. While some countries may have extensive and well-organized digital resources, others may still be in the early stages of developing the infrastructure necessary for effective research. Thus, the literature may disproportionately focus on research from countries with more advanced infrastructure, providing an incomplete picture.

The applicability of survey findings across the EU can also be difficult due to socio-economic and educational differences. It is important to put the results in context to ensure correct interpretations and to avoid inappropriate extrapolations.

We believe that a careful and reflexive approach is essential in any effort to reduce limitations and maximize the potential of EDM in a unified, yet diverse, European educational area.

## VI. Conclusions

The originality of our research lies in providing an updated perspective on the state of research and current dynamics in the field of Educational Data Mining (EDM) within the European Union. Our work aims to assess the level of integration of EDM in the educational systems of EU Member States, exploring the extent of use of these innovative technologies at different levels of education. We believe that the level of interest shown in EDM by the academic and educational communities in EU member countries can be improved. On the other hand, we believe that to contribute to quality improvement in education through the use of EDM techniques, open access to EDM research is imperative.

Regarding the impact, the research emphasizes the transformative potential of EDM in tailoring educational experiences to meet the individual needs of students, thus enhancing the personalization of learning. It also highlights the essential role of EDM in predicting students' academic performances, which allows educators to provide timely support to students at risk of poor performance. Moreover, the study showcases the broader applications of EDM in refining educational strategies and addressing systemic issues, such as reducing school dropout rates and addressing the root causes of poor performance among students and teachers.

This approach advances the understanding of the role of EDM in education and also sets the "scene" for future innovations and improvements in the educational landscape.

Within the analytical approach, the paper is structured around some essential research questions. The first question investigates the extent to which EDM practices are embedded in the educational mechanisms of the European Union, revealing the level of penetration and acceptance of these methods among educational institutions.

The fact that for the period under review, i.e. 2013-2023, only two of the articles are from Romania, draws our attention to a modest presence in the literature in the field at national level. This highlights an untapped potential and the opportunity to further explore the contributions that EDM can bring to Romanian pre-university education, where the adoption of such analytical technologies could catalyze significant advances in the adaptation and personalization of the educational process. We thus justify our approach to use EDM techniques with the aim of improving the quality of pre-university education in Romania.

Research on the use of EDM in the European Union over the last decade has focused mainly on higher education. One of the reasons could be that at this level LMSs are more widely used, allowing relatively easy data collection.

Interest in applying EDM methods in EU member countries is low. This is reflected on the one hand, by the small number of papers that met our selection criteria, to which authors from less than half of these countries contributed, and on the other hand, by the trend of published research in the considered interval (Fig. 3).

The analysis shows that understanding learning and the educational process through data mining techniques can provide deep and detailed insight into how students learn, behave, interact, and progress. Summarizing our research, it can be stated that EDM techniques contribute to:

- Personalizing learning by identifying individual learning patterns for each student or for groups of students with similar characteristics. By data mining one can discover the learning preferences and rhythms of everyone or group. This makes it easier to personalize content and teaching methods, ensuring that each student/group gets the support they need;
- Predicting performance by developing predictive models to predict student academic performance. This can help teaching staff to early identify students who may be struggling and to intervene with additional measures;
- Improving educational processes by using patterns uncovered in data about the effectiveness of teaching methods, learning materials or educational resources. In this way, educational institutions can optimize their strategies to improve students' growth and learning experience;
- Structural problems identification by detecting and combating high dropout rates, and factors contributing

to low student or teacher performance. The insights hidden in data can help the development of educational policies and the efficient allocation of resources.

In 2020 the European Parliament conducted a study on “rethinking education in the digital age” in which it stressed the need for learning content personalization, and for the monitoring and control of learners' behavior, which overlaps very well with the objectives of EDM. As until now efforts in this area have been modest, it opens up wide perspectives for research to address issues related to:

- the widespread use of EDM methods and techniques applied to real data, from all sources of educational data, generated by individuals or groups of individuals in institutional frameworks, the results of which form the basis for quality decisions;
- confidentiality and ethics of data collection and analysis, protocols for developing appropriate procedures to preserve data and protect student privacy;
- the use of multimodal data mining methods, knowing that the data collected can be of different types (images, text, structured data), and a multimodal approach can better capture the subtleties.

Future research directions discussed in the material include:

- Integration of EDM Tools into E-Learning: Advancing the incorporation of Educational Data Mining (EDM) components into e-learning systems and tools for designing e-learning courses.
- Cross-Domain Application: Exploring the application of the semi-automatic generation of competency maps across various educational domains beyond the initially tested field.
- Methodology Refinement: Further developing and refining the presented methodology based on additional experiments and feedback, aiming to establish a more robust EDM process and software platform.
- Automation and Teacher Support: Enhancing the level of automation in the generation of competency maps and educational recommendations, thereby providing more significant support to teachers and learners.
- These directions aim to expand the scope and efficacy of EDM in improving educational outcomes and tailoring learning experiences.

Thus, it highlights the need for a continuous effort in the use and improvement of educational tools and strategies through data-driven perspectives, with the goal of supporting educators and enhancing learning outcomes.

***Abstract*—Cybercriminals now find cryptocurrency mining to be a lucrative endeavour. This is frequently seen in the form of cryptojacking, which is the illegal use of computer resources for cryptocurrency mining. Protecting user resources and preserving the integrity of digital ecosystems depend heavily on the detection and mitigation of such threats. This research presents a unique method that combines Black Widow Optimisation (HBWO) with Generative Adversarial Networks (GANs) to improve the detection of cryptojacking. Due to its covert nature and tendency to elude conventional detection methods, cryptojacking is still a widespread concern. In order to overcome this difficulty, our work makes use of the complementary abilities of deep learning and metaheuristic optimisation. To maximise feature selection for efficient identification of cryptojacking activity, BWO—which draws inspiration from the foraging behaviour of spiders—is utilised. Simultaneously, GANs are employed to produce artificial intelligence (AI) augmentations, which strengthen the detection model's resilience and enrich the training dataset. Utilising HBWO to identify the most discriminative features is the first step in our technique, which also includes preprocessing the dataset to extract pertinent features. The training dataset is then supplemented with artificial data samples created using GANs, which enhances the detection model's capacity for generalisation. Experiments conducted on real-world datasets show the effectiveness of our solution, outperforming baseline techniques. The hybrid technique that has been suggested offers a viable way to improve the detection of cryptojacking. Through the combination of HBWO for feature optimisation and GANs for data augmentation, our approach demonstrates improved 98.02% accuracy and resilience in detecting cryptojacking activity. With its novel framework for fending against new dangers in the digital sphere, this research adds to the continuing efforts in cybersecurity.**

***Keywords*—Cryptojacking; attack detection; Generative Adversarial Networks; Black Widow Optimization; cybercriminals***

## I. Introduction

Technology is always progressing and becoming more advanced. With the Internet and cloud computing, we are able to accomplish many tasks through digital means. Novel approaches have been developed to be adaptable and on-demand [1]. Their assistance has facilitated connections among people in fields such as education, healthcare, privacy and security, culture, personal development, and online commerce [2]. Cybercriminals can generate bitcoin employing the processing power of another entity by utilizing a technique known as crypto jacking, which is a type of illicit cryptomining. As a result of the roughly threefold increase in cryptojacking attempts in 2022, targets experienced exorbitant expenses for cloud computing and power. It is more crucial than ever to comprehend how cryptojacking operates and how to attempt to prevent it from occurring to you, since the number of incidents of cryptojacking cases keeps rising. Cybercriminals could gain cryptocurrency such as Bitcoin through lawful crypto mining, but a harmful kind of mining called cryptojacking gives hackers access to free mining. Crypto mining incurs hefty power and cloud service expenses, which are left on the shoulders of entities harmed by cryptojacking. According to recent statistics from SonicWall, worldwide ransomware volumes decreased by 23 percent year over year (YoY) in the first half of 2022 [3], while total malware increased by eleven percent during same time. Based on monitoring of one million security sensors across 200 nations and third-party sources, the company's mid-year update to its 2022 SonicWall Cyber Threat Report was released. According to SonicWall, the first documented increase in worldwide malware volumes in three years was seen in the 2.8 billion malware assaults that were discovered in the first six months of 2022. A twenty-nine percent YoY rise in total malware assaults was also observed in Europe, where ransomware volumes increased by sixty-three percent despite dropping to two hundred and thirty- million. Bill Conner, CEO and president of SonicWall, stated, "As bad actors diversify their tactics and look to expand their attack vectors, expect global ransomware volume to climb - not only in the next six months, but in the years to come [4]." "With the geopolitical environment so unstable, cybercrime is become more sophisticated and diversified in terms of threats, tools, targets, and locations." Additionally, there was a significant rise in encrypted attacks that target Internet of Things (IoT) devices and are intended to avoid detection (132%) by employing HTTPS tunnelling. The actual quantities that were reported were 4.9 million units and 57 million, respectively. However, since these are attack statistics rather than compromise statistics, it is unknown how many organisations were actually negatively harmed by them. Cybersecurity leaders must ensure they have all the tools as well as technology necessary to proactively identify and combat more sophisticated and targeted threats to their business, according to Conner, given the significant rise in encrypted threats, IoT malware, crypto jacking, and new unknown variants [5].

An illicit kind of cryptomining is called cryptojacking. The process of creating new cryptocurrency, or digital money produced and encrypted on the blockchain technology for record-keeping, is known as cryptomining [6]. In order to validate and finalise a blockchain transaction, it is necessary to solve intricate mathematical problems that are generated. The individuals that decipher encrypted riddles, verify transactions, and get bitcoin in exchange for their work are known as cryptocurrency miners. On the blockchain, new currencies can only be created and encrypted through the cryptomining process [7]. Cryptojacking is the practice of mining cryptocurrencies using a victim's computer resources to carry out difficult mathematical calculations and transmit the results to the hacker's server [8]. It is intended to take use of its victims' resources for as long as possible without being noticed, in contrast to other forms of malware that harm victims' equipment or data [9]. Cryptojackers target a huge number of victims while using very little of the victim's computing power. While operating in the background, the virus covertly reroutes the victims' computer resources to unapproved cryptocurrency mining endeavours [10]. The two primary attack methods used by cryptojackers are host-based and web browser-based. When a victim visits a website that has cryptomining software embedded in it, the programme runs on their browser [11]. Malware that is downloaded into the device of the victim is employed in host-based assaults [12].

In order to defend against these dangers and preserve the integrity of computer networks and systems, it is critical to identify and mitigate cryptojacking attempts. Conventional approaches to detection, including heuristic analysis or signature-based algorithms, could find it difficult to keep up with the ever-evolving strategies employed by cybercriminals to hide their activity. More sophisticated and adaptable detection systems that can precisely identify cryptojacking instances across a variety of data sources are thus desperately needed. With the goal of maximising the benefits of both approaches to improve detection skills, a hybrid strategy combining Generative Adversarial Networks (GANs) and Black Widow Optimisation (HBWO) has been developed and proposed. With its strong optimisation framework derived from nature, HBWO can quickly and effectively explore large search areas and find the best solutions. By using Black Widow Optimisation (BWO) to choose characteristics for cryptojacking detection, one may effectively locate discriminative features by emulating the hunting activities of black widow spiders. Using concepts inspired by nature, BWO can efficiently explore feature space and minimize computational expenses, setting it apart from other metaheuristic algorithms possibly resulting in more useful feature subsets for improved detection performance. However, GANs offer a potent instrument for creating artificial data samples, enhancing the training set and enhancing the model's capacity to generalise to new data. Using GANs for data augmentation and BWO for feature selection together is a novel way to improve detection accuracy when it comes to cryptojacking. Black widow spiders' hunting habits are utilized by BWO to effectively discover the most discriminative elements pertinent to detecting cryptojacking activities. Through feature selection optimization, BWO improves the efficacy of later detection algorithms. However, GANs offer a potent means of producing artificial data samples that enhance the training dataset, enhancing the model's capacity to generalize and identify instances of cryptojacking in practical contexts. The suggested strategy maximises the benefits of both approaches by combining them: GANs' ability to add realistic and diverse samples to the dataset and BWO's ability to detect important traits. This novel combination has the potential to greatly increase resilience against developing cryptojacking approaches and detection accuracy. The objective is to create a hybrid framework that combines BWO and GANs to identify cryptojacking in a way that is more adaptable and resilient. The shortcomings of conventional techniques may be addressed by this hybrid strategy, which also promises improved detection resilience and accuracy against complex cryptojacking attempts. The details of the suggested methodology, which includes the creation of synthetic data using GANs, feature extraction and selection using BWO, and the integration of both methods into an all-inclusive detection framework, will be covered in length in the upcoming parts.

- The study proposes a unique hybrid strategy that combines Generative Adversarial Networks (GANs) and Black Widow Optimisation (HBWO) to close the gap in current crypto jacking detection approaches. More sophisticated and adaptable detection systems are required since traditional approaches frequently fail to correctly identify cryptojacking because of attackers' constantly changing strategies.

- The system offers proactive defence against cryptojacking attacks and improves detection capabilities by utilising the strengths of GANs and HBWO.

- This has consequences for preserving the integrity of the system, minimising performance deterioration, and averting possible data breaches brought on by illicit bitcoin mining operations.

- When compared to current techniques, the hybrid strategy that has been suggested provides considerable gains in resilience and detection accuracy.

A summary of pertinent research on the subject of cryptojacking detection is given in Section II, along with an analysis of current approaches and their drawbacks. The research need is highlighted in Section III along with the need for more sophisticated and flexible detection techniques to deal with the attackers' changing strategies for cryptojacking. The suggested method, which combines Generative Adversarial Networks (GANs) and Black Widow Optimisation (HBWO) for improved cryptojacking detection, is described in Section IV. This section describes the HBWO feature extraction and selection process and how to integrate GANs to create synthetic data. In Section V, the hybrid approach's performance analysis and conclusions are presented, showcasing its advantages over conventional approaches with respect to robustness and accuracy of detection. Section VI concludes the study by summarising the findings and highlighting the importance of the hybrid strategy that has been suggested in order to protect system integrity and mitigate the threat of cryptojacking.

## II. Literature Review

There is a rise in a different kind of cybersecurity attack. A malicious actor covertly deploys crypto-mining software on individuals' devices without their awareness. This is becoming a problem in real life and in what is being written about cybersecurity. This type of attack is called cryptojacking. It operates successfully as a result of the ability to install a crypto program on a device without the owner's knowledge. Many different ways to protect against something have been suggested. They all use a system that is based on the device itself. This method of protection does not effectively safeguard a company's network from insider threats. According to this paper, a network can be utilized to detect and classify crypto-client activities by examining the network traffic, even if it is encrypted. The initial focus is on studying the genuine data collected from the networks of three leading cryptocurrencies: Bitcoin, Monero, and Byte coin. It examines both the typical traffic and the traffic altered by a VPN. Crypto-Aegis, a novel framework, utilizes Machine Learning to determine whether individuals are engaged in activities such as pool mining, solo mining, and active full nodes with cryptocurrencies. Furthermore, it comes with other benefits, such as not depending on specific devices or infrastructure. Due to the magnitude and novelty of the threat, we believe that our method and its positive outcomes could prompt further investigation in this field. Building Decision Trees is a lengthier process and they are more susceptible to errors in the absence of sufficient training data or accurate data [13].

With the rise in popularity of cryptocurrency, utilizing a mining script in a web browser with JavaScript has become a more effective method of mining cryptocurrency. A recently emerged form of threat known as cryptojacking has gained traction online. When a website falls victim to cryptojacking, it exploits its visitors' computers to mine cryptocurrency without their consent. The focus of this article is the development of a new web extension named CMBlock. It can find mining scripts running on websites. This app will use two methods to stop cryptojacking. - User actions will be monitored and a blacklist will be utilized to identify and halt the attack. Through using mining behavior detection, the app can find unknown domains that are not on the blacklist. This app offers superior protection against cryptojacking attacks compared to the current options available. However, he No Coin application is limited to blocking certain items [14].

A new harmful software utilizes your computer's resources without your awareness. The majority of individuals with this malware on their computer remain oblivious to the fact that their computer power is being exploited without their knowledge, as the creators of the malware employ deceptive tactics to conceal it. Multiple approaches can be utilized to detect and prevent these dynamic analysis-based detection techniques. However, because these methods use moving parts, collecting those parts and finding the malware takes time. The malware needs to operate for an extended period, conducting mining operations and generating additional tasks. This article presents MINOS, a straightforward new system designed to identify covert cryptocurrency mining on your computer.Quickly finding this out is made possible through the use of deep learning. MINOS relies on visuals to distinguish between safe webpages and those that engage in unsanctioned mining using Wasm. A specific type of computer program is employed by the classifier to differentiate between harmful and harmless Wasm files. It acquires information from an extensive collection of instances. MINOS maintains high precision even with its low true negative and false positive rates. Moreover, thorough analysis of MINOS indicates that the new detection method can swiftly detect crypto mining activity in the latest malware. It could do this with an average accuracy of 25.9 milliseconds without using a lot of the computer's resources. MINOS demonstrates its effectiveness, speed, and efficiency without requiring substantial computing power. There may be technical hurdles in implementing the MINOS framework into the intended Chrome extension, potentially diminishing its effectiveness in identifying and halting unauthorized cryptocurrency mining [15].

The act of cryptojacking entails the surreptitious utilization of your computer for cryptocurrency mining, generating profit without your knowledge. Network security has been at risk since 2017, with it becoming increasingly prevalent. In order to illustrate the dangers of cryptojacking, this research introduces a new technique known as Delay-CJ for mining cryptocurrency in web browsers. The effectiveness of this method was assessed through a simulation to see how well it worked. Delay-CJ utilizes sophisticated techniques to avoid detection while stealing computer power for cryptocurrency and abstains from engaging in any activity on video websites in the trial version. The findings suggest that the existing tests may be ineffective in identifying issues with this new design. Due to this circumstance, a new system called CJDetector was developed to detect cryptojacking. It looks for signs of cryptojacking in systems. It identifies detrimental mining activities by monitoring the computer's workload and examining its command usage. The attack in our example can be identified by this system, which is also useful for a wide range of situations. CJ Detector has a 99% accuracy rate in accurately identifying objects.33% of the time. Our testing involved 50,000 popular websites to verify if they were involved in cryptojacking activities. Despite the decline in cryptojacking, it remains a significant threat to network security that cannot be overlooked. However, CJ Detector still possesses certain shortcomings [16].

Malware has become a significant issue for numerous individuals in recent times. Numerous computer attacks exploit people's devices, with one popular method involving using a large amount of computer processing power to generate digital currency. Cybercriminals exploit individuals' computer processing power to generate cryptocurrency. The focus of this research is on detecting and halting malicious cryptomining behavior through the use of network monitoring techniques. Discovering new essential network flow features is essential for effectively detecting cryptomining flow in real-time using machine and deep-learning models. The purpose of our experiment was to develop a tough and accurate cryptocurrency mining scenario in order to practice and evaluate machine and deep learning models. Users access genuine servers on the internet with encrypted connections. Extensive experimentation revealed that the utilization of particular features and advanced computer programs enables us to detect and thwart cryptomining attacks on the internet with a high level of accuracy, even when the data is obscured. Although current data analysis methods can detect crypto mining attacks, they may not be sufficient in the future when such attacks become more covert [17].

The expansion of electronic currency has sparked numerous concerns. A recently emerged threat known as cryptojacking involves cyber criminals infiltrating computers and unlawfully transferring money using stolen information. Specialized software is being implemented on the computers to facilitate cryptocurrency mining. This is a growing problem for the future. Experts predict that there will be approximately 30 billion IoT devices worldwide by 2020. The susceptibility of most devices to attack is due to their weak passwords, unpatched problems, and inadequate monitoring. So it's likely that IoT devices will be targeted by cryptojacking malwares. Cryptojacking malware has not been adequately examined in terms of its classification in numerous studies. A straightforward method is necessary for IoT devices to detect cryptojacking malware in order to operate efficiently without impacting other tasks. A new method is proposed for identifying and putting a stop to cryptojacking. To spot cryptojacking code, we employ a simple model and machine learning in our method. This investigation aims to analyze the components of the existing cryptojacking classification system, enhance it, and then evaluate its effectiveness. The outcome of this research will be instrumental in uncovering and halting cryptojacking malware assaults. This will have a positive impact on various sectors, including cyber security, oil and gas, water, power, and energy. It also abides by the National Cyber Security Policy, which is geared towards safeguarding critical information systems [18].

The assessment of the literature includes a range of research on the growing danger of crypto jacking, a hack in which attackers stealthily use their targets' computer power to mine cryptocurrency. Conventional defences mostly depend on host-based designs, which could not be effective against insider attacks on corporate networks. In order to address this, network-based techniques that are suggested analyse network traffic in order to identify crypto-client activity, even while communication is encrypted. Furthermore, the threat posed by browser-based cryptojacking is noteworthy, which is why programmes like CMBlock that identify mining scripts operating on webpages were created. Moreover, the development of WebAssembly (Wasm)-based cryptojacking poses difficulties for identification because of its obfuscated and lightweight nature. This has prompted the creation of MINOS, a lightweight detection system that uses deep learning algorithms for real-time detection. Furthermore, investigations investigate hidden browser-based mining attacks such as Delay-CJ and suggest countermeasures like CJDetector, which keeps track of CPU utilisation and function calls in order to accurately identify illicit mining activity. A viable method for real-time crypto mining flow identification is the combination of passive network monitoring with deep learning and machine learning models. With the growing risk to Internet of Things devices, lightweight classification models play an increasingly important role in identifying crypto jacking malware without sacrificing system efficiency. The literature emphasises how urgent it is to handle cryptojacking risks in a variety of digital scenarios and stresses the necessity of developing novel, effective, and portable detection techniques in order to protect against this ubiquitous threat.

## III. RESEARCH GAP

There are several challenges to overcome in order to effectively identify cryptojacking operations. Initially, these assaults function covertly, frequently employing minimum system resources to evade identification. Long-term compromise is more likely because to the covert nature of cryptojacking, which makes it challenging for typical detection techniques to quickly identify and stop the activity. Even with advancements in conventional detection techniques, a more creative and flexible approach to detection is required due to the dynamic nature of cryptojacking threats. The majority of the research that is now available concentrates on single detection methods, including heuristic or signature-based analysis, which might not be sufficient to handle the complex issues that cryptojacking assaults present. The literature is conspicuously lacking in information on how to combine various detection techniques to improve the precision, effectiveness, and scalability of cryptojacking detection. To efficiently detect and counteract cryptojacking actions in real-time, a creative solution that integrates several detection approaches, makes use of sophisticated optimisation algorithms, and leverages machine learning is required. Furthermore, the necessity of creating reliable and adaptable detection systems is highlighted by the rising frequency of cryptojacking assaults across a variety of platforms and situations. Protecting digital assets and maintaining the integrity of computing infrastructure requires an inventive solution that can minimise false positives and resource overhead while responding to the ever-changing nature of cryptojacking threats.

## IV. Proposed Mechanism

The suggested methodology integrates Generative Adversarial Networks (GANs) with Black Widow Optimisation (HBWO) to identify cryptojacking in a comprehensive manner. The approach starts with data preparation, which involves normalising and standardising raw data to maintain consistency and speed up model convergence from a variety of sources, including cybersecurity repositories and network traffic logs. After that, feature selection techniques are employed to find pertinent qualities for detection. The feature subset is then optimised using the HBWO method, which makes use of its spider-inspired behaviour to quickly scan the search space and find the most discriminative characteristics for detection. Simultaneously, GANs are employed to produce artificial data samples, which improve the detection model's resilience by expanding the training dataset and resolving class imbalance problems. Through synergistic optimisation made possible by the hybridization of HBWO and GANs, the detection model's accuracy and generalisation capacity are improved by utilising the complementing advantages of both approaches. In order to determine how well the suggested framework performs in comparison to baseline techniques for identifying cryptojacking activities, known measures like accuracy, precision, recall, and F1-score are employed to assess its efficacy. The suggested framework seeks to enhance the current state of the art in crypto jacking identification and support continuing initiatives to reduce cybersecurity risks in contemporary computing settings with its all-encompassing approach. Fig. 1 depicts the Suggested Approach's Workflow.

### A. *Data Collection*

An Intel Core i5-7500 computer running Ubuntu 18.04 was used to collect data for this investigation. The browser employed in this study was Google Chrome. Data was gathered for two unique cases: the "ideal" situation, in which the cryptojacking browser was the only one operating, and the "real-world" scenario, in which cryptojacking was happening alongside other high-performance functions. A YouTube movie was loaded in a different browser tab to replicate more system load in the real-world scenario. Prioritised gathering important metrics during data collection, such as CPU power usage, network traffic traces, and cache hits and misses. The psutil library was used to track CPU power consumption and provide insights into the CPU utilisation of the system in the background [19]. The pyshark library was utilised to record network traffic traces, which allowed us to examine the ways in which the browser communicates with outside entities like command-and-control servers or mining pools. Moreover, information on cache hits and misses was gathered using the perf programme, which revealed patterns of memory access and possible performance bottlenecks. The goal was to evaluate the effect of simultaneous high-performance activities on crypto jacking detection by collecting data independently for the ideal and real-world scenarios. This all-encompassing strategy enabled us to assess the resilience of the detection methods in practical contexts and examine the system's behaviour under various scenarios.

### B. *Data Pre-processing*

Min-max normalisation is employed in the data preparation step to guarantee that the numerical characteristics in the dataset are scaled consistently. Based on the lowest and greatest values found in the dataset, the min-max normalisation procedure adjusts every characteristic to a given range, usually between 0 and 1. The following is the Eq. (1) for min-max normalisation:

$$v_{norm} = \frac{v - v_{min}}{v_{max} - v_{min}} \tag{1}$$

Where,

$v$ *is the original value of the feature*

$\boldsymbol{v_{min}}$ *is the minimum value of the feature in the dataset*

$\boldsymbol{v_{max}}$
*is the maximum value of the feature in the dataset*

$\boldsymbol{v_{norm}}$ *is the normalized value of the feature*

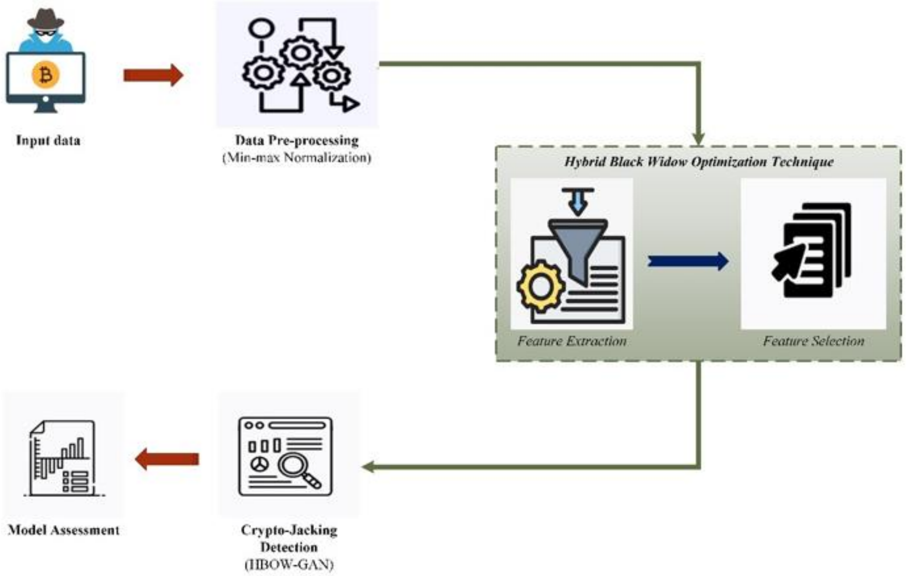

Fig. 1. Workflow of the suggested approach.

Through the utilisation of min-max normalisation, all of the dataset's numerical characteristics are scaled to a similar range, aiding in convergence during optimization and preventing certain characteristics from predominating during training. This pretreatment stage makes sure that the data is prepared to undergo further analysis and training of models, which improves the detection framework's ability to recognize crypto jacking activity.

### C. Feature Extraction and Selection using Black Widow Optimization (BWO)

A novel metaheuristic optimisation method based on black widow spider mating behaviour was initially developed by V. Hayyolalam and A. Pourhaji Kazem in 2020, and because of its adaptability and simplicity of usage, it has been utilised for a variety of engineering and scientific issues solutions [20]. The peculiar mating habits of black widow spiders served as the model for the Black Widow Optimization Algorithm (BWO). Cannibalism is a stage that is unique to this methodology. This stage of the process causes rapid convergence by removing species from the circle that have an unsuitable fitness level. The effectiveness of the BWO algorithm in finding the best solutions to the challenges is assessed using three real-world engineering optimization problems and 52 different baseline variables. When compared to alternative techniques, the BWO algorithm differs in several significant ways. The BWO algorithm eliminates local optimisation problems and provides quick convergence speed while performing well in the exploitation and exploration phases. It's also important to emphasise that BWO is able to keep exploration and exploitation under check. Starting with an initial population of spiders, every spider in the BWO algorithm symbolises a potential solution. These first spiders attempt to procreate in pairs with their subsequent generation. During or after mating, the female black widow consumes the male. She then releases the sperm that have been deposited in her sperm thecae into egg sacs. Spider lings emerge from the egg sacs as early as 11 days after they are placed. For many days to a week, they live together on the mother web, and during that period, sibling cannibalism is seen. After that they take off by riding the wind.

*1) Initial population:* An optimisation problem could only be solved when the outcomes of its problem variables constitute a suitable structure for resolving the present difficulty. This structure is referred to as "chromosome" and "particle position" in the Genetic Algorithm and PSO terminology, accordingly, however it is named "widow" in the black widow optimization method (BWO). The potential answer to any difficulty has been seen as a Black widow spider in the Black widow Optimisation Algorithm (BWO). The issue variables are displayed for every Black widow spider. In this work, it is necessary to treat the framework as an array in order to execute benchmark functions. An array of size $1 \times N_{var}$ that represents the answer to an $N_{var}$ dimensional optimisation problems is called a widow. The assessment of a widow's fitness function (f) yields the widow's fitness was expressed in Eq. (2):

$$Fitness = f(window) \tag{2}$$

The optimisation process begins by creating an ideal widow matrix with a baseline spider population of size $N_{Pop} \times N_{var}$. The following stage in the reproductive process is the mating of randomly assigned parent-child pairings, during which the female black widow eats the male.

*2) Procreate:* In nature, partners mate independently of one another inside their web to create the next generation. This is because the pairs are independent of one another and begin mating in simultaneously. Every mating in the actual world results in about 1000 eggs being laid, although some of the stronger offspring do make it through. In order for this process to replicate, an array named alpha must also be constructed, and as long as the widow array contains arbitrary integers, children are formed by utilizing $\alpha$ with the resulting Eq. (3), where parents are $m_1$ and $m_2$ and offspring are $v_1$ and $v_2$.

$$\begin{cases} v_1 = \alpha \times m_1 + (1-\alpha) \times m_2 \\ v_2 = \alpha \times m_2 + (1-\alpha) \times m_1 \end{cases} \tag{3}$$

$\frac{N_{var}}{2}$ iterations of this method are performed, however the randomly chosen numbers shouldn't be replicated. Ultimately, the mother and kids are put to an array and sorted based on their fitness value—now determined by their cannibalism rating—with a few of the most fit people being added to the newly formed community. These procedures are applicable to every pair.

*3) Cannibalism:* There are three categories of cannibalism present here. After mating, the female black widow spider may consume her male partner. The algorithm has the ability to determine an individual's gender based on their level of fitness. A different form of this behavior is exhibited when powerful baby spiders devour their weaker siblings. The number of survivors in this plan is determined by a rating known as cannibalism rating (CR). Every now and then, baby spiders feed on their mother. Spiderlings' strength or weakness is determined based on their fitness value.

*4) Mutation:* The number of Mutepop people from the population is chosen at random in this step. Every one of the selected solutions switches two members in the array at random. The mutation rate determines mutepop.

*5) Convergence:* Three stop criteria are comparable to those of other evolutionary algorithms:

*a)* A set quantity of repetitions.

*b)* Maintaining the best widow's fitness value for several iterations without seeing any change.

*c)* Attaining the specified degree of precision.

BWO could be utilised to address a few benchmark optimization issues in the upcoming part. A certain degree of precision is thought to be the determining factor for the accuracy level of the experimental algorithms, as optimal solutions for benchmark functions are known in advance.

*6) Parameter setting:* Certain factors are crucial to achieving optimal outcomes in the suggested BWO algorithm. These variables include the rate of mutation (PM), cannibalism (CR), and reproduction (PP). For the algorithm to be more effective in producing better answers, the parameters need to be changed accordingly. In addition to increasing the likelihood of breaking out of any local optimum, fine-tuning more parameters will also increase the search space's global exploration potential. Therefore, the appropriate number of factors can guarantee the management of the equilibrium between the stages of exploration and exploitation. Three essential regulating parameters—PP, CR, and PM—are included in the BWO algorithm:

*a)* The procreation proportion, or PP, establishes the appropriate number of participants for any procreative endeavour. Further variety and increased opportunities to more thoroughly investigate the search space are provided by this parameter, which regulates the creation of different offspring.

*b)* One of the cannibalism operator's regulating parameters, CR, removes unsuitable people from the population. Through moving the search agents from the local to the global stage and vice versa, the appropriate value adjustment for this variable could ensure great performance for the exploitation phase.

*c)* The proportion of people who participate in mutation is known as PM. Maintaining a balance among the exploration and exploitation stages could be ensured by setting this variable appropriately. The search agents' transition from the global to the local stage and their direction towards the optimal solution could both be managed by this variable.

The first phase in BWO is to randomly initialize the group of agents known as the widows. These agents then undergo an assessment based on their suitability for the given task utilising a custom-created score. The programme then couples the strongest agents and goes through cannibalism and mating process to remove the weakest. The ideal solution could then be found more easily by building a web around these agents' positions in the solution space. The population, or set of agents, is modified continually as the algorithm develops to increase its overall fitness. Until an acceptable resolution is found or a prearranged stopping point occurs, the procedure keeps on. Accordingly, the solutions progressively improve in order to identify a single global optimum solution—that is, the best answer when compared to all of the alternatives in the population—based on the fitness score provided from the objective/fitness ratio. The architecture of the BWO algorithm is demonstrated in Fig. 2.

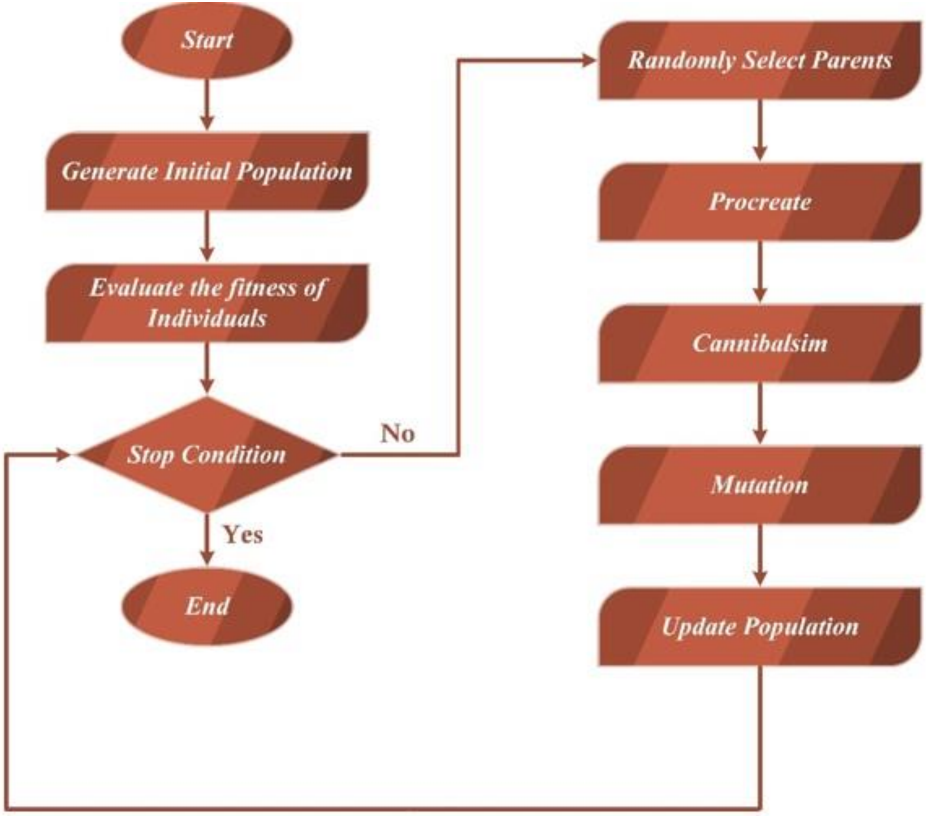

Fig. 2. Architecture of BWO algorithm.

Black Widow Optimisation (BWO) is a potent metaheuristic optimisation algorithm that could be employed for feature extraction and selection in the framework of cryptojacking recognition, as demonstrated by the research. It is inspired by the predatory strategies employed by black widow spiders. Initially like the strands of a spider web, BWO initializes a population of possible feature subsets. These feature subsets include different combinations of metrics, such as CPU power consumption, network traffic traces, cache hits and misses, and so on, that are essential to comprehending system behaviour during possible cryptojacking events. To begin exploring the feature space, one must first examine this population. As the optimisation progresses, BWO methodically assesses each feature subset's fitness in relation to a predetermined objective function, presumably gauging how well the system detects cryptojacking activities. In order to demonstrate the thoroughness of the study, this function combines the many metrics that were acquired during data collecting. During the optimisation process, BWO constantly strikes a balance between exploitation—finding new feature combinations—and exploration—tuning in on promising subsets to raise their quality. This adaptive method allows BWO to continuously modify its search parameters and techniques in response to the changing optimisation problem environment, resembling the adaptable hunting strategies of black widow spiders. Through efficient feature space navigation and discriminative feature identification that significantly assists in the detection of crypto jacking, BWO enhances the detection techniques' ability to accurately identify and lessen possible threats in real-world situations. BWO is positioned to be a useful tool for improving the robustness and efficacy of cryptojacking detection systems, supporting ongoing efforts in cybersecurity research and practice through its synergistic synthesis of concepts inspired by nature and optimization methodologies.

Utilizing BWO for feature selection, the most discriminative characters relevant to the detection of cryptojacking are found by imitating the hunting habits of black widow spiders. BWO optimizes the efficiency of the detection model by carefully choosing indicators that are most suggestive of cryptojacking activity, a strategy inspired by the effective hunting techniques of spiders. Its capacity to effectively explore feature space and discover important qualities that minimize computational overhead and contribute to successful identification is the basis for its application. BWO's distinct approach, which is specifically tailored to feature selection tasks, draws on nature-inspired principles, unlike some other metaheuristic optimization algorithms like genetic algorithms or particle swarm optimization. This could result in more effective and comprehensible feature subsets for improved detection performance.

### D. *Generative Adversarial Networks*

With its use of convolutional neural network topologies, Generative Adversarial Networks, or GANs [21], constitute a state-of-the-art method for generative modelling in deep learning. The objective of generative modelling is to allow the model to generate new instances that could reasonably mimic the original dataset by independently spotting patterns in the input data. An effective class of neural networks for unsupervised learning is called generative adversarial networks, or GANs. Two neural networks, a discriminator and a generator, make up a GAN. They create synthetic data that is exact replicas of real data by using adversarial training process. Producing random noise samples, the Generator tries to trick the Discriminator—which has to correctly discriminate between generated and real data. It is this competitive interaction that propels both networks towards progress and yields realistic, high-quality samples. Due to their widespread application in text-to-image synthesis, style transfer, and image synthesis, GANs are demonstrating their great versatility as artificial intelligence tools. Generative modelling has also been transformed by them. The Architecture of GAN is shown in Fig. 3. There are three components that make up Generative Adversarial Networks (GANs):

- Generative: To become familiar with generative frameworks, that explain how data is generated in terms of probabilistic approaches.
- Adversarial: The term antagonistic describes the act of positioning one object against another. This indicates that the generating result in the context of GANs is compared with the real images in the data set. A model that aims to differentiate between actual and fraudulent images is applied via a technique called a discriminator.
- Networks: Apply artificial intelligence (AI) methods for training employing deep neural networks as the basis.

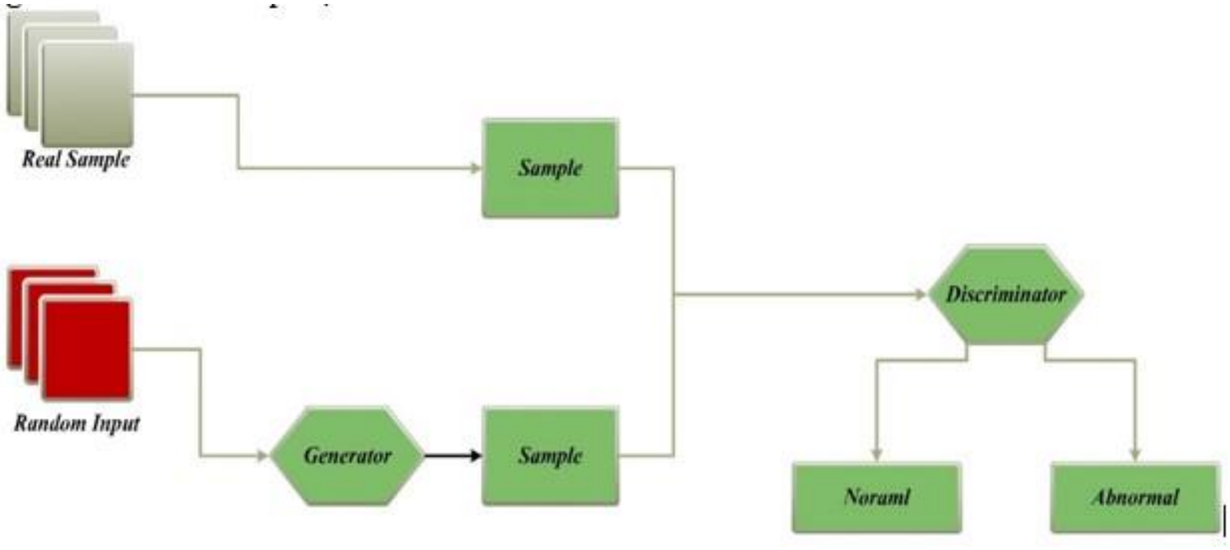

Fig. 3. Workflow of GAN.

*1) Architecture of GAN:* A Generative Adversarial Network (GAN) is composed of two primary parts, which are the Generator and the Discriminator. The generator generates synthetic samples from random noise, while the discriminator distinguishes between real and synthetic samples. During training, the generator aims to produce samples that are indistinguishable from real data, while the discriminator learns to distinguish between real and synthetic samples. This adversarial training process leads to the refinement of both networks. The loss function for the discriminator involves minimizing the binary cross-entropy between its predictions and the ground truth labels, while the generator aims to maximize this loss to fool the discriminator. Additionally, the generator's loss function includes a feature matching term, encouraging the generator to generate samples that match the statistics of real data. To ensure the quality and relevance of the generated synthetic samples, techniques such as mini-batch discrimination, spectral normalization, and feature matching are employed. These methods aim to stabilize training, prevent mode collapse, and ensure diversity and realism in the generated samples. Additionally, extensive experimentation and validation are conducted to verify the synthetic samples' fidelity to real data distributions and their relevance to the cryptojacking detection task.

*a) Generator model:* The generator model is a crucial component that generates new, correct data in a Generative Adversarial Network (GAN). The generator transforms random noise into sophisticated data samples, such text or graphics, based on its input. Often, it is shown as a deep neural network. Through training, layers of learnable parameters in its architecture capture the underlying distribution of the training data. As it is being trained, the generator employs backpropagation to fine-tune its parameters and modifies its output to create samples that closely resemble actual data. What differentiates a good generator is its capacity to produce diverse, high-quality samples that deceive the discriminator.

*2) Generator Loss ($V g$)*: The generator reduces the log chance of the discriminator being correct for samples that are created. This loss motivates the generator to provide samples that the discriminator is likely to identify as genuine $\log D(g(p_j))$ near to 1) was expressed in Eq. (4):

$$V_g = -\frac{1}{k}\sum_{j=1}^{k} \log D(g(p_j)) \tag{4}$$

Where,

- $V_g$ evaluate the degree to which the generator might deceive the discriminator.
- $\log D(g(p_j))$ symbolises the log likelihood that the discriminator could be accurate for samples that are created.
- In a strategy to reduce this loss of data, the generator promotes the creation of samples that the discriminator values as real $\log D(g(p_j))$ around 1.

*b) Discriminator model:* In order to distinguish between generated and actual input, Generative Adversarial Networks (GANs) employ an artificial neural network known as a discriminator model. The discriminator performs the role of a binary classifier by assessing incoming samples and assigning a probability of authenticity. Eventually, the discriminator has the ability to distinguish between real data from the dataset and synthetic samples produced by the generator. It can gradually refine its settings and raise its degree of expertise as an outcome. When handling image data, its design often makes utilisation of convolutional layers or relevant structures for other modalities. The goal of the adversarial training process is to maximise the discriminator's ability to correctly identify produced samples as legitimate and genuine samples as fraudulent. The combination of the discriminator and generator makes the discriminator more and more discriminating, which contributes to the GAN's overall ability to generate synthetic data that seems incredibly realistic.

*c) Discriminator loss ($V_D$):* In order to accurately categorise both manufactured and actual samples, the discriminator lowers the negative log probability. The discriminator is motivated by this loss to correctly classify produced samples as real samples ( $D(p_j)$ near to 1) and fraudulent samples $\log(1 - D(g(q_j))$ close to 1) was expressed in Eq. (5):

$$V_D = -\frac{1}{k}\sum_{j=1}^{k} \log D(p_j) - \frac{1}{k}\sum_{j=1}^{k} \log(1 - D(g(q_j)) \tag{5}$$

- $V_D$ evaluates the discriminator's capacity to distinguish between manufactured and real samples.
- Logistic probability of the discriminator correctly classifying actual data is given by $\log D(p_j)$.
- $\log(1 - D(g(q_j))$ represents the average likelihood that the discriminator could properly classify produced samples as fake.
- The discriminator seeks to minimise this loss by precisely distinguishing between synthetic and authentic samples.

*3) Integration of BWO and GANs into a hybrid framework for cryptojacking detection:* The incorporation of Generative Adversarial Networks (GANs) and Black Widow Optimisation (BWO) into a hybrid framework for cryptojacking detection is an innovative approach meant to capitalize on the distinct advantages of both methods to improve the robustness and efficacy of detection mechanisms. Initially the algorithm does a BWO, which involves methodically analyzing and choosing pertinent characteristics from the dataset. These features include measurements like CPU power utilization, network traffic traces, and cache hits and misses. Through identifying discriminative features through iterative exploration and exploitation, BWO successfully reduces the dimensionality of the feature space while maintaining important information. These features greatly aid in the identification of cryptojacking activities. Simultaneously, GANs are employed to create artificial data samples that complement the actual dataset, improving its representativeness and variety. GANs' adversarial training process makes it possible to create synthetic data samples that accurately reflect the original dataset's complexity and unpredictability, enriching the training set and enhancing the model's capacity to generalise to new data. In order to create an enhanced dataset, the chosen features from BWO are combined with the synthetic data produced by GANs in a process known as BWO and GAN hybridization. This hybrid dataset increases the variety of the training data and offers a thorough representation of the feature space by combining real and synthetic data samples. The chosen characteristics are then further refined and the identification framework is optimised by applying BWO to the expanded dataset. Iteratively exploring the enhanced feature space and identifying high-quality feature subsets that maximise detection performance are made possible by BWO's flexibility. Finally, the efficacy of the hybrid framework in identifying crypto jacking activity is demonstrated by evaluating the detection model's performance using common assessment metrics including accuracy, precision, recall, and F1-score. The amalgamation of BWO and GANs inside a hybrid framework presents a potent and all-encompassing method for detecting cryptojacking, permitting the recognition of intricate threats in practical situations while augmenting the robustness and dependability of detection procedures.

## V. Results and Discussion

The experimental assessment that was carried out to gauge the effectiveness of the suggested hybrid framework for crypto jacking identification is shown in the findings section. The efficacy and resilience of the detection model in correctly detecting cryptojacking activity under many circumstances are discussed in this section. To assess the performance of the detection model and compare it with baseline techniques, key performance indicators such as accuracy, precision, recall, and F1-score are examined. Furthermore, the outcomes illustrate the usefulness of combining Generative Adversarial Networks (GANs) and Black Widow Optimisation (BWO) in augmenting detection capabilities, indicating the hybrid framework's potential in tackling cryptojacking detection problems in practical situations. The results of applying the suggested hybrid architecture with simulation tools based on Python for crypto jacking identification.

### A. *Experimental Outcome*

1) *CPU power utilization:* The monitoring of CPU power utilisation is an essential measure in the detection of cryptojacking, since it helps identify aberrant activity that may be suggestive of cryptojacking. An abnormally high CPU power usage might indicate the existence of unapproved cryptocurrency mining activities operating in the background, which could jeopardise system security and performance. Detection procedures protect computer systems' integrity and performance by efficiently identifying and mitigating cryptojacking threats through the monitoring of CPU activity and the analysis of power consumption trends.

TABLE I. Cryptojacking Detection Based on CPU Power

| Approach | Precision (%) | Recall (%) | F1-score (%) | Accuracy (%) |
|---|---|---|---|---|
| KNN | 91.34 | 92.01 | 91.56 | 95.33 |
| SVM | 90.11 | 90.02 | 89.44 | 91.22 |
| RF | 87.12 | 86.33 | 86.11 | 88.80 |
| Proposed (HBOW-GAN) | 98.02 | 97.22 | 97.44 | 98.45 |

Table I compares several cryptojacking detection techniques and displays performance metrics under optimal CPU power circumstances. The metrics—precision, recall, accuracy, and F1-score—are crucial measures of the detection model's efficacy. The suggested Hybrid Black Widow Optimisation and Generative Adversarial Networks (BOW-GAN) architecture performs noticeably better than the baseline techniques among the methodologies examined. The greatest outcomes are obtained by BOW-GAN, which has the following metrics: accuracy, F1-score, precision, recall, and 97.44%, respectively.

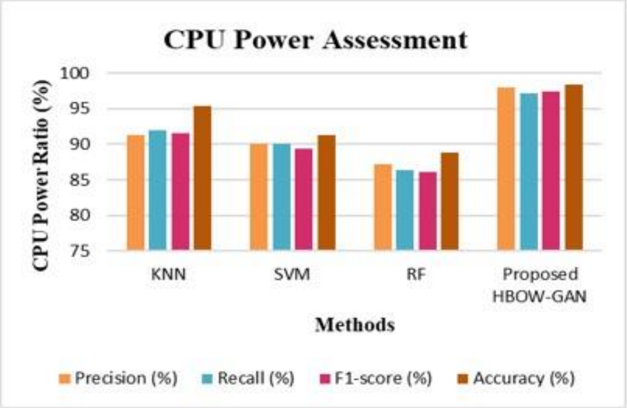

Fig. 4. Metrics for real world-CPU Power case.

This suggests that at optimal CPU power levels, the hybrid framework perform exceptionally well in detecting cryptojacking activities, proving its superiority over conventional approaches in this regard. Furthermore, the outcomes demonstrate that the Support Vector Machine (SVM) method outperforms the K-Nearest Neighbours (KNN) and Random Forest (RF) approaches in terms of performance. Nevertheless, these are not as effective as the suggested HBOW-GAN structure. The hybrid approach's ability to improve the accuracy of cryptojacking detection is demonstrated in Fig. 4, which also illustrates how, under the right circumstances, it could reduce cybersecurity concerns.

2) *Network trace analysis:* A computer or network device's network traces are comprehensive logs of the communications it has with other devices or servers on the internet. Network traces offer important information about the customs and communication patterns connected to bitcoin mining operations when it comes to the discovery of cryptojacking. Detection systems are able to spot unusual patterns that point to cryptojacking, including links to command-and-control servers or mining pools, by examining

network traffic, which includes packet transfers, requests, and answers. In order to protect network integrity and avert any performance degradation or security breaches, monitoring network traces enables the prompt detection and mitigation of unauthorised cryptocurrency mining activity.

TABLE II. CRYPTOJACKING DETECTION BASED ON NETWORK TRACE ANALYSIS

| Approach | Precision (%) | Recall (%) | F1-score (%) | Accuracy (%) |
|---|---|---|---|---|
| KNN | 41.15 | 41.87 | 41.87 | 42.61 |
| SVM | 43.43 | 43.73 | 43.73 | 44.03 |
| RF | 50.47 | 51.38 | 51.38 | 52.32 |
| Proposed (HBOW-GAN) | 58.20 | 57.05 | 57.62 | 56.70 |

Table II presents a thorough analysis of several cryptojacking detection methods based on how well they perform in analysing network traffic traces. The metrics that are assessed comprise precision, recall, F1-score, and accuracy. These measures together assess how well each technique performs in identifying cryptojacking activity based on network behaviour. With the best precision, recall, F1-score, and accuracy of any of the evaluated approaches—58.20%, 57.05%, 57.62%, and 56.70%, respectively—the suggested Hybrid Black Widow Optimisation and Generative Adversarial Networks (HBOW-GAN) framework outperforms the others. Fig. 5 shows the comparison of detection approaches based on network traffic analysis.

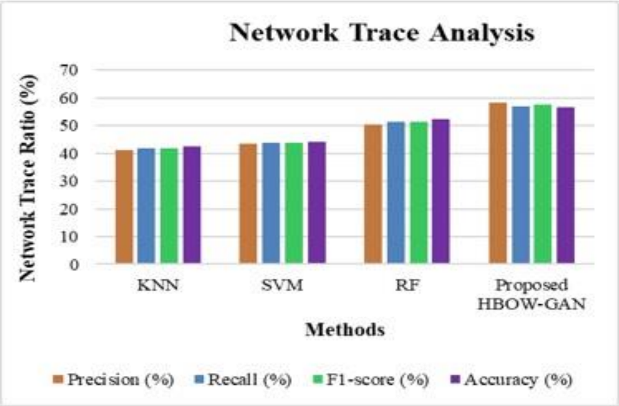

Fig. 5. Comparison of detection approaches based on network traffic analysis.

Based on network traces, this suggests that the hybrid framework performs better than more conventional techniques like Random Forest (RF), Support Vector Machine (SVM), and K-Nearest Neighbours (KNN) in terms of reliably recognising cryptojacking operations. Despite demonstrating comparatively better performance than KNN and SVM, the HBOW-GAN architecture continues to outperform the RF method in terms of effectiveness. The findings highlight how important it is to employ generative adversarial networks and hybrid optimization approaches to improve the identification of cryptojacking, especially when examining network traffic traces. Furthermore, the HBOW-GAN framework that has been suggested shows promise in reducing cybersecurity risks related to cryptojacking, protecting network integrity and efficiency.

*3) Cache data analysis:* A computer's cache memory, a high-speed memory intended to temporarily store frequently accessed data for speedy retrieval by the CPU, is where the term "cache data" refers to information found there. Analysing cache data for the purpose of detecting cryptojacking entails keeping an eye on how frequently users access and use cache memory in order to spot unusual patterns that point to illicit cryptocurrency mining activity. Cache data anomalies, including repeated reads or writes to particular memory regions, may indicate the existence of malware known as cryptojacking or programmes that try to exploit system resources for cryptocurrency mining without the user's permission. Detection techniques protect system integrity and performance by identifying and mitigating cryptojacking risks by closely examining cache data.

TABLE III. CRYPTOJACKING DETECTION BASED ON CACHE ANALYSIS

| Approach | Precision (%) | Recall (%) | F1-score (%) | Accuracy (%) |
|---|---|---|---|---|
| KNN | 90.78 | 89.23 | 90.01 | 88.08 |
| SVM | 94.25 | 95.67 | 96.44 | 95.33 |
| RF | 93.29 | 93.13 | 93.21 | 92.78 |
| Proposed (HBOW-GAN) | 96.11 | 96.22 | 96.44 | 97.80 |

A comprehensive analysis of several cryptojacking detection techniques based on their analytical parameters for cache data analysis is shown in Table III. Considered together, these measurements assess how well each method detects cryptojacking activity based on cache behavior. The results of the assessment indicate that the Hybrid Black Widow Optimisation and Generative Adversarial Networks (HBOW-GAN) framework is the most effective among the evaluated techniques. It achieves the best accuracy, F1-score, precision, recall, and accuracy at 96.11%, 96.22%, 96.44%, and 97.80%, respectively.

Fig. 6 depicts the comparison of detection approaches based on cache data analysis. This suggests that the hybrid framework outperforms more conventional techniques like K-Nearest Neighbours (KNN), Support Vector Machine (SVM), and Random Forest (RF) in precisely detecting cryptojacking operations based on cache data. In comparison to KNN, SVM and RF techniques also perform pretty well, however they are not as effective as the HBOW-GAN system. The findings highlight how important it is to employ generative adversarial networks and hybrid optimisation approaches to improve the detection of cryptojacking, especially when it comes to examining cache behaviour. Furthermore, the HBOW-GAN framework that has been suggested shows promise in reducing cybersecurity risks related to cryptojacking, protecting system functionality and integrity.

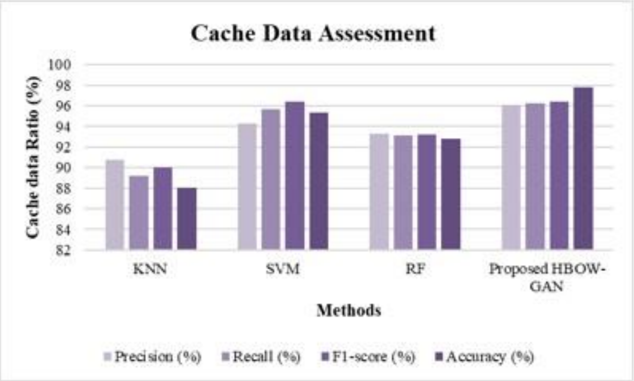

Fig. 6. Comparison of detection approaches based on cache data analysis.

### B. *Performance Evaluation*

The suggested hybrid approach's effectiveness is assessed in comparison to baseline strategies—such as conventional machine learning algorithms or single optimisation techniques—that are frequently used for cryptojacking detection. Key performance indicators are compared between the hybrid methodology and the baseline techniques, including accuracy, precision, recall, and F1-score. This comparison makes it possible to evaluate the hybrid approach's excellence and relative efficacy in identifying instances of cryptojacking. Through the examination of these measures, researchers may ascertain whether the hybrid technique is superior to more conventional approaches and gain important understanding of how it might be improved for detection in practical situations.

1) *Accuracy:* The percentage of cases that were accurately categorised out of all the occurrences. The accuracy was stated as follows in Eq. (6):

$$Accuracy = \frac{T_{pos}+T_{Neg}}{T_{pos}+T_{neg}+F_{pos}+F_{neg}} \tag{6}$$

2) *Precision:* The percentage of real positive predictions among all positive predictions, signifying the capacity of the model to prevent false positives. The precision was stated as follows in Eq. (7):

$$Precision = \frac{T_{pos}}{T_{pos}+F_{pos}} \tag{7}$$

3) *Recall:* The percentage of real positive instances that were true positive forecasts, demonstrating the model's capacity to include all pertinent cases. The recall was stated as follows in Eq. (8):

$$Recall = \frac{T_{pos}}{T_{pos}+F_{neg}} \tag{8}$$

4) *F1-measure:* An equitable way to assess a model's performance is to take the harmonic mean of accuracy and recall. Eq. (9) was employed to express the F1-measure.

$$F1 - measure = 2 * \frac{p*r}{p+r} \tag{9}$$

The Table IV presents a thorough analysis, based on precision, recall, F1-score, and accuracy metrics, of many detection techniques, including KNN, SVM, Random Forest (RF), and the suggested Hybrid Black Widow Optimization and Generative Adversarial Networks (HBOW-GAN) framework. With an F1-score of 92%, accuracy of 83%, recall of 80%, and precision of 87%, KNN performs well. SVM shows comparable accuracy of 84%, slightly lower precision of 82%, recall of 75%, and F1-score of 85%. With an accuracy of 93%, F1-score of 90%, recall of 82%, and precision of 89%, Random Forest performs better than both KNN and SVM.

TABLE IV. PERFORMANCE COMPARISON OF DETECTION APPROACHES

| Approach | Precision (%) | Recall (%) | F1-score (%) | Accuracy (%) |
|---|---|---|---|---|
| KNN | 87 | 80 | 92 | 83 |
| SVM | 82 | 75 | 85 | 84 |
| RF | 89 | 82 | 90 | 93 |
| Proposed (HBOW-GAN) | 98.02 | 97.22 | 97.44 | 98.45 |

However, all measures demonstrate that the HBOW-GAN framework that has been suggested performs better. It attains an impressive 98.02% precision, 97.22% recall, 97.44% F1-score, and 98.45% accuracy. This indicates that the HBOW-GAN strategy outperforms conventional approaches by a large margin in terms of improving the identification of the target anomaly. The HBOW-GAN architecture has been shown to be successful in enhancing detection accuracy and reliability (Fig. 7), which makes it a viable solution to the detection issues presented by the anomaly under investigation.

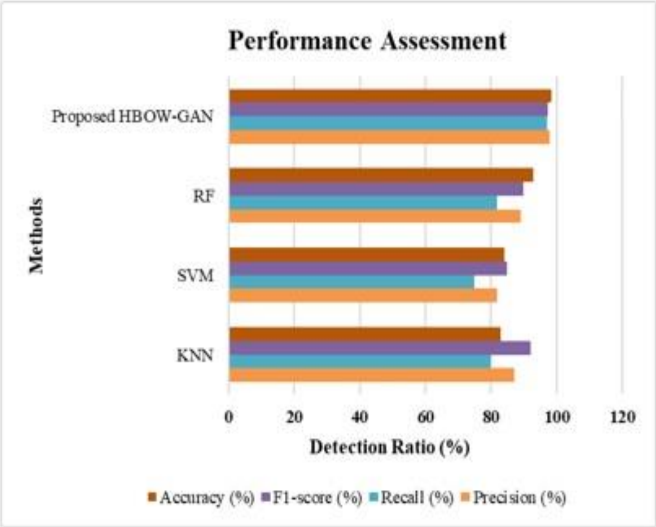

Fig. 7. Comparing the effectiveness of different cryptojacking detection techniques.

TABLE V. COMPARISON OF DIFFERENT DATASETS [22]

| Datasets | F1-score (%) |
|---|---|
| In the wild Dataset | 95.04 |
| Youtube Video | 96.7 |
| Youtube Movie | 98.45 |

Table V presents a comparison of several datasets according to their F1-Scores: Attains an F1-Score of 95.04% in the Wild Dataset. The YouTube Video Dataset has a 96.7%

F1-Score. YouTube Movie Dataset: 98.45% is an outstanding F1-Score, indicating an outperformance. These ratings show how well each dataset performed when it came to determining whether or not it was appropriate for a certain job or project. Fig. 8 gives the comparison of the F1-Score of different datasets.

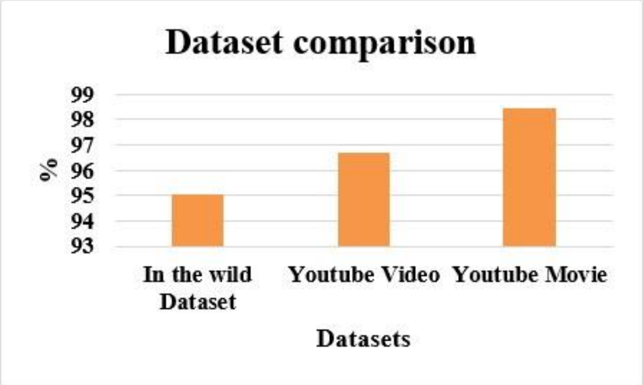

Fig. 8. Comparison of F1-Score of different datasets.

### C. Discussion

Enhancing cryptojacking detection by HBWO with GANs is a potential approach. Cybercriminals are using cryptojacking to profit illegally from cryptocurrency mining, which highlights the necessity for efficient detection techniques. Conventional detection tools are significantly challenged by the clandestine nature of cryptojacking and its evasive strategies. The technique takes these problems into account by utilizing the complementary strengths of metaheuristic optimization and deep learning [23]. By optimizing feature selection and taking cues from spiders' hunting habits, HBWO makes it possible to identify cryptojacking activities with ease. Concurrently, GANs provide artificial intelligence enhancements to improve the robustness of the detection model and enhance the training data [24]. This combination strategy provides a fresh framework for enhancing the resilience and accuracy of detection. Experimental assessments show encouraging outcomes with the integration of GANs for data augmentation and HBWO for feature optimization. The conversation emphasizes how successful the suggested hybrid strategy is in thwarting dangers posed by cryptojacking. Because the suggested technique depends on deep learning and metaheuristic optimization, its implementation could need a large amount of computing power and specialized knowledge. Furthermore, the sophistication and constantly changing strategies employed by hackers to avoid detection may place limitations on the approach's efficacy. This study advances detection capabilities and advances cybersecurity efforts by addressing the dynamic nature of digital threats and preventing malicious exploitation of user resources and digital ecosystems.

## VI. Conclusion

The objective of this study was to create and assess a hybrid method that combines Generative Adversarial Networks (GANs) with Hybrid Black Widow Optimisation (HBWO) for the detection of cryptojacking operations. The study approach comprised gathering information from many sources, including CPU power consumption, network traffic traces, and cache behaviour, and then using the hybrid framework for identification. Key findings from a rigorous examination show that the suggested hybrid strategy outperforms conventional approaches in precisely detecting instances of cryptojacking across many data sources. The creation of a strong and flexible detection mechanism that can mitigate the changing threat environment of cryptojacking is the main contribution of this research. The suggested method improves detection accuracy and resilience against complex threats by utilising generative adversarial networks and hybrid optimisation approaches. A notable advance over current approaches is seen from the suggested hybrid approach's outstanding 98.02% detection accuracy. Furthermore, this study emphasises how important it is to include cutting-edge AI techniques in cybersecurity plans in order to successfully counter new threats. The suggested hybrid strategy offers a proactive defence mechanism against cryptojacking assaults, which represent serious threats to both persons and organisations. This has important implications for cybersecurity. The hybrid architecture helps avoid possible performance degradation, financial losses, and data breaches connected with unauthorised cryptocurrency mining operations by recognising and managing cryptojacking situations in real-time. The study's conclusions also emphasise the wider significance of improving detection skills for other cyberthreats that employ comparable tactics in addition to cryptojacking. The suggested hybrid approach establishes a standard for proactive and adaptable cybersecurity tactics that put detection and prevention first as cyber threats intensify and change. To sum up, this study highlights the significance of ongoing innovation and cooperation in cybersecurity to remain ahead of changing risks. We can strengthen defences against cryptojacking and other harmful acts by creating and assessing sophisticated detection frameworks, such as the hybrid method put out here. This will eventually protect digital assets and guarantee the integrity of digital ecosystems. The study's findings and insights support ongoing efforts to create a more robust and safer cyber environment, as cybersecurity continues to be a top priority in a world growing more linked by the day.

Future directions for this study might entail investigating different optimization methods and data augmentation strategies to further improve detection accuracy, hence enhancing the hybrid approach. The method's usefulness might be further expanded by looking at real-time implementation methodologies and scalability to large-scale networks. Additionally, investigating the combination of blockchain-based solutions and anomaly detection methods may provide an all-encompassing defence against new crypto-jacking attacks.

# DeepEmoVision: Unveiling Emotion Dynamics in Video Through Deep Learning Algorithms

Prathwini[1], Prathyakshini[2]*

Department of Master of Computer Applications, NMAM Institute of Technology, NITTE (Deemed to be University), India[1]
Department of Information Science and Engineering, NMAM Institute of Technology, NITTE (Deemed to be University), India[2]

*Abstract*—**Emotion detection from videos plays a pivotal role in understanding human behavior and interaction. This study delves into a cutting-edge method that leverages Recurrent Neural Networks (RNN), Support Vector Machines (SVM), K-Nearest Neighbours (KNN), Convolutional Neural Networks (CNN) and to precisely detect emotions exhibited in video content, holding significant importance in comprehending human behavior and interactions. The devised approach entails a multi-phase procedure: initially, employing CNN-based feature extraction to isolate facial expressions and pertinent visual cues by extracting and pre-processing video frames. These extracted features capture intricate patterns and spatial information crucial for discerning emotions. The results of the trials show that CNN, SVM, KNN, and RNN have promising performance, highlighting their potential. Among the other machine learning models, RNN has attained a 95% accuracy rate in recognizing and classifying emotions in video information. This combination of approaches provides a thorough plan for identifying emotions in dynamic visual material in real time.**

***Keywords—Emotion detection; video analysis; Recurrent Neural Networks (RNN); Support Vector Machines (SVM); K-Nearest Neighbours (KNN); Convolutional Neural Networks (CNN); facial expression recognition; machine learning***

## I. Introduction

The foundation of social dynamics and interpersonal communication is an understanding of human emotions. Human-computer interaction, affective computing, and psychology all heavily rely on the detection and interpretation of emotions [6], especially from appearances like facial expressions. With the increased popularity of video content in digital media, there is a growing interest in investigating techniques for identifying emotions in videos. Numerous emotional clues can be inferred from facial expressions, which range from delight and surprise to despair and rage. Combining computer vision and machine learning has greatly enhanced automated facial expression analysis, particularly in the field of video-based emotion identification [13]. However, there are difficulties in this endeavor. Accurate and reliable emotion recognition is hampered by the complexity of facial expressions, individual differences, occlusions, illumination variances, and the dynamic nature of emotions [11]. Moreover, temporal dependencies, nuanced facial dynamics, and the need for real-time analysis introduce additional complications to video content. With a focus on facial expression concepts, the difficulties in recognizing emotions in videos to improve interpretability and contextual understanding in emotion analysis [7], this research aims to investigate emotion detection in videos. The expressions on our faces, which are produced by a variety of facial muscles, are an essential means of conveying human emotions. Gaining an understanding of the principles underlying facial expressions is essential to correctly deciphering and classifying the emotions shown in video clips. Identifying emotions from video data poses a multitude of intricate difficulties. Significant challenges are created by the diversity of facial expressions people display, the coexistence of several emotions, and the fact that emotions change over time. Accurately identifying emotions in video content [9] is further complicated by environmental conditions, data noise, and occlusions. When opposed to still photos, videos present unique difficulties mostly because of timing dependencies. Emotion analysis over consecutive frames necessitates methods able to capture the dynamic nature of facial expressions. Resilient methods for feature extraction and classification across video frames are also necessary due to fluctuations in facial positions, motions, and occlusions. It may be possible to improve the analysis of emotions in films by incorporating natural language processing (NLP) tools [14]. NLP techniques provide additional cues for a more complex understanding of emotions and improve the overall precision of emotion detection systems by integrating contextual data, dialogues, or subtitles that accompany video content. In order to strengthen the interpretive power and robustness of emotion recognition models, this study will explore approaches and developments that address these issues in video-based emotion detection [10]. It will place particular emphasis on the combination of NLP techniques and the application of face expression concepts. Convolutional neural networks (CNNs) are one type of Deep Learning neural network design that is widely used in computer vision. "Computer vision" is the area of artificial intelligence that allows computers to interpret and process images and other visual data. In Machine Learning, Artificial Neural Networks exhibit remarkable performance. Neural networks are used in a number of datasets, including text, audio, and image datasets. Various neural network types are applied to various applications [12]. For example, convolution neural networks are utilized to classify images, whereas RNNs—more particularly, LSTMs—are used to predict word sequences.

A regular neural network has three main types of layers: Layers of Input: It is the layer where the data is fed. The total number of features in our data, or pixels in the case of an image, is same as the total number of neurons in this layer. Secret Layer: The input that was previously sent to the input layer is received by the concealed layer. Several hidden layers could exist, depending on our model and the volume of data.

Each hidden layer has a dissimilar number of neurons, but generally speaking, greater than the number of features. The output of each layer is determined by multiplying its predecessor's output by the learnable weights of that layer is a kind of neural network architecture made to manage sequential data by preserving a hidden state that records details about the sequence's earlier inputs. RNNs are very helpful in Natural Language Processing (NLP) applications involving language production and understanding, where word or character order is important [15] Here is an overview of the main ideas behind recurrent neural networks in natural language processing: Processing Sequential Data: RNNs work well when processing data in sets, such time series or sentences. They work on a single sequence element at a time, keeping a concealed state that contains data from earlier components. Hidden State: An RNN's hidden state acts as a memory for earlier inputs. Natural language processing (NLP)-based emotion identification in video is a significant and developing field of study with great potential across many areas. This innovative combination of computer vision, machine learning, and natural language processing aims to interpret the rich lexicon of human emotions as they are depicted in visual data. Within the framework of our work, we concentrate on the subtle interpretation of recorded facial expressions in order to understand the underlying affective states. There are several possible uses for emotion recognition in videos, including market research, psychology, human-computer interface, and healthcare. Comprehending human emotions is essential for developing more responsive and empathic technology systems, improving user experience, and allowing machines to interact with humans more deeply [8]. Research work goes beyond the conventional limitations of text-based analysis by expanding on the foundations of natural language processing (NLP) approaches to extract significant insights from visual data. We want to push the limits of accuracy and applicability in emotion identification from video information by using sophisticated machine learning models, such as Support Vector Machines (SVM), Convolutional Neural Networks (CNN), k-Nearest Neighbors (KNN) and Recurrent Neural Networks (RNN). This work explores the methods used, the outcomes of the experiments, and the possible ramifications of our conclusions. Our goal is to further the field of emotion detection technology by investigating the combination of natural language processing and video analysis. This will enable the development of more advanced applications that will help close the gap between artificial intelligence and human emotions. The following sections include a review of the literature that identifies research gaps in the study, a methodology section that provides an overview of the proposed model and results, a discussion section that analyzes the results using figures and graphs, a conclusion, and future work that details the proposed work's conclusion and its future endeavor.

In the proposed work, the top 10 frames are taken into consideration every other second to analyze a person's emotion and forecast it using machine learning algorithms. To facilitate pre-processing and recognition, the top ten image frames are considered. The image frame is preprocessed to remove noise and enhance the quality of the image. In the end, the enhanced image frames are used to train and evaluate RNN, CNN, SVM, and KNN models in order to determine the image's emotion. Following are the contribution.

- The dataset consists of 32,298 different facial expression which includes seven categories (0=angry, 1=contempt, 2=disgust, 3=fear, 4=happy, 5=sadness, and 6=surprise).
- To identify the emotion of the person in the stored video using RNN and other machine learning algorithms.

## II. Literature Survey

Wang, S. et al. [1] proposed a work that uses adversarial learning to systematically understand emotion distributions for classifying emotions in multimedia content is being done to solve this discrepancy. We use a discriminator and an emotion classifier in our technique. The discriminator distinguishes between expected and actual emotion labels, whereas the classifier predicts emotion labels by examining the multimedia content. The two components receive training at the same time, competing to improve their own performances. Sindhu, N. et al. [2] proposed research on a multimedia recommendation system powered by user emotions is presented in this research. The system chooses audio/video content automatically based on user emotions, eliminating the need for human browsing. The database is made up of ECG signals that were gathered from DECAF, with an emphasis on emotions that negatively affect mood, such as melancholy and rage. Raheel, A. et al. [3] aimed at enhancing the audience's emotional experience by utilizing rich multimedia content that stimulates their touch senses in addition to their visual and audio senses. The resulting p-values demonstrate substantial differences in valence and arousal levels between standard multimedia and TEM content, underscoring the greater emotional impact of TEM clips. Twelve temporal domain variables are taken out from the preprocessed EEG input for emotion recognition, and four human emotions—happy, furious, sad, and disgusted—are classified using a support vector machine. Zhang, X. et al. [4] proposed research on augment visual and aural perceptions with tactile multimedia content in order to increase the audience's emotional engagement. Using a t-test on valence and arousal levels highlights important differences between TEM and traditional multimedia, highlighting the higher emotional resonance of TEM content. In the field of emotion recognition, the preprocessed Four human emotions—happy, angry, sad, and calm—are classified by a support vector machine using the twelve temporal domain variables that an EEG signal produces. The remarkable results of 43.90% and 63.41% accuracy against TEM clips and standard multimedia, respectively, demonstrate the improved efficacy of EEG-based emotion recognition, particularly in stimulating the touch sense. Bhattacharya, S. et al. [5] focused on the research emotion detection in online social networks (OSNs) has the potential to enhance several applications, including targeted advertisement services and recommendation systems. Emotion analysis has historically focused mostly on identifying single emotion labels or predicting sentence-level polarity, ignoring the potential of many coexisting emotions from the viewpoint of users. In this work, we refer to the topic as a multilabel learning challenge and tackle multi-emotion recognition in

OSNs from a user-level perspective. First, we use an annotated Twitter dataset to investigate relationships between emotion labels, social ties, and temporal patterns. Chen, L. et al. [15] gives a summary of current work in the rapidly developing topic of automatic group emotion identification is given in this article. Research has used a variety of datasets, modalities (video, pictures, social media posts, audio), and approaches to investigate emotion analysis in crowds or groups. When possible, we want to provide code access and implementation details. Subsequent research endeavors will focus on developing real-world-applicable systems, accommodating varying group sizes, affective subsets, and affective evolution, enhancing resilience, and employing less biased datasets. Abdu, S. A. et al. [16] centered on a novel approach that uses Bag-of-Audio-Words (BoAW) to extract features from conversational audio data. It offers an advanced Recurrent Neural Network (RNN)-based emotion recognition model that is great at forecasting the present emotions while also capturing the emotional states of the participants and the context of the conversation. The effectiveness of the strategy is demonstrated by experiments on two benchmark datasets and realistic real-time assessments. This strategy outperforms the current state-of-the-art models with weighted accuracy of 60.87% and unweighted accuracy of 60.97% for six basic emotions on the IEMOCAP dataset. Chen, L. et al. [17] reports on our preliminary investigation of sophisticated multimodal emotion detection techniques used to evaluate interviewee performance in emotionally charged situations. Although the results point to the potential of FACET in emotion recognition, there don't seem to be many advantages to using SER. Fernandes, R et. al. [18] focused on video captures the human face in action and provides further insights into human emotions, we have utilized emotion recognition to analyze human emotions in this work. Deep learning algorithms are applied in this article to identify human emotions from archived video footage. In an effort to predict the many emotions shown in a stored video—namely, anger, surprise, happiness, and neutrality—we have looked at Convolutional Neural Networks (CNNs). Wei, J. et al. [19] proposed an affective saliency estimation-based key frames extraction approach. Key frames are extracted from videos by calculating their emotive saliency value in order to prevent emotion-neutral frames from affecting the recognition outcome. To extract useful deep visual information, pretrained models and conventional models are employed. Random Forests (RF), Support vector machines (SVM), and deep model Convolutional Neural Networks (CNN) are used to recognize emotions. Washington, P. et al. [20] suggested a secure web-based platform that transforms manual labeling work into an activity. We gathered and tagged 2,155 films. However, 79.1% balanced accuracy and 78.0% F1-score were obtained for the CAFE Subset A, which had at least 60% human agreement on emotion labels. Siam, A. I. et. al. [21] Based on the real-time deep learning-based MediaPipe face mesh technology, the main concept is to produce key locations. To further encode the generated key points, a number of well-designed mesh generator and angular encoding modules are employed. Moreover, feature decomposition employs Principal Component Analysis (PCA). Gunawan, T. S. et al. [22] focused on the process of identifying emotions from films using deep learning algorithms. This paper presents the methodology and explanation of the recognition process. We also look at some of the video-based datasets that are utilized in numerous academic publications. The performance metrics of the various emotion recognition models are shown with the results. Results from an experiment on depression detection using Google 97% accuracy on the training set and 57.4% accuracy on the testing set were demonstrated by Colab's fer2013 dataset. Jaiswal, A. et al. [23] The development of a system that recognizes emotions in facial expressions using artificial intelligence (AI) is underway. The three primary processes in the emotion detection process face identification, feature extraction, and emotion classification are covered. To identify emotions from photos, this study presented a deep learning architecture based on convolutional neural networks (CNNs). Two datasets are utilized to examine the performance of the advised method: the Japanese Female Facial Emotion (JAFFE) and the Facial Emotion Recognition Challenge (FERC-2013). For the FERC-2013 and JAFFE datasets, the accuracy percentages yielded by the suggested model were 70.14 and 98.65, respectively. Mukhopadhyay, M. et al. [24] four intricate feelings were chosen from an actual poll. Basic human emotions are grouped together to form complex emotions, which are frequently felt by a group of students throughout a lesson. Rather of using discrete images, we thought of using a predetermined collection of continuous image frames to accurately convey these related feelings. In order to categorize the fundamental emotions and determine the learners' mental states, we constructed a CNN model. Both a mathematical verification and a learner survey are used to confirm the results. The findings indicate that the accuracy rates for classifying emotions and identifying states of mind are 65% and 62%, respectively. Mehendale, N. et al. [25] The FERC is based on research on two-part convolutional neural networks (CNNs). In the first section, the image's backdrop is removed, and in the second, the focus is on facial feature vector extraction. The FERC model uses the expressional vector (EV) to distinguish between five different types of regular facial expression. From the 10,000 images (154 individuals) that were stored in the database, supervisory data was obtained. It is possible to illuminate the emotion with 96% accuracy when the EV of length 24 values is used. While the two-level CNN functions in series, the last layer of the perceptron alters the weights and exponent values for each iteration. FERC improves accuracy by deviating from commonly used single-level CNN techniques. Additionally, a unique background cleaning process used prior to EV creation prevents. Yadav et al. in study [26], talks about the survey article attempts to provide reviews of the most recent machine learning architectures, the applications of the system, the use of algorithms, and speech and vision processes. The technology of today presents enormous research opportunities.

Algorithms and architectures in machine learning can also be intelligently applied to generate new ideas and intelligently replicate speech and vision systems. The degree of commercialization and personal computing is at an all-time high. Huge amounts of sensor data and cloud computing can be used for machine learning and training. Even more advanced technologies can be found in mobile and embedded systems. Abdullah et al. [27] A vital component of human communication is facial expression. Thus, accurate facial expression classification in picture and video data has become a major research goal for the software development community. In this work, we offer a method for classifying videos by capturing both the temporal and spatial aspects of a video sequence using Recurrent Neural Networks (RNN) in addition to Convolution Neural Networks (CNN). The Ryerson Audio-Visual Database of Emotional Speech and Song (RAVDESS) is used to test the method. Assuming that visual analysis was the sole technique available to gather data on this dataset, the proposed approach yields the initial benchmark of 61% test accuracy. Awais et al. [28], the suggested system provides emotional recognition and real-time communication, allowing for remote learning support and health monitoring during pandemics. The study's obtained results show great promise. The proposed IoT protocols, TS-MAC and R-MAC, achieve an ultralow latency of 1 ms. Furthermore, reliability is improved by R-MAC in comparison to state-of-the-art. Moreover, the proposed deep learning method achieves remarkable performance, with an f-score of 95%. The outcomes in the domains of AI and communications are consistent with the interdependency requirements of deep learning and Internet of Things frameworks. This ensures that the suggested task is suitable for usage in healthcare, student engagement, emotion support, remote learning, and general wellness. Zahara et al. [29] This study recommends developing a system that extracts characteristics from facial expressions and utilizes the Convolution Neural Network (CNN) technique to classify them in real-time. It does this by utilizing the OpenCV library's TensorFlow and Keras. The study design used with the Raspberry Pi consists of three main processes: face detection, face feature extraction, and facial emotion classification. 65.97% (sixty-five point ninety-seven percent) of the facial expressions in the study utilizing the Facial Emotion Recognition (FER-2013) Convolutional Neural Network (CNN) technique were predicted. Mohan et. al. [30] proposed FER-net, a convolution neural network that efficiently differentiates FEs by using the softmax classifier. We implement our method, FER-net, and assess it on five benchmarking datasets: FER2013, Extended Cohn-Kanade, Karolinska Directed Emotional Faces, Real-world Affective Faces, and Japanese Female Facial Expressions. We also use twenty-one other state-of-the-art methodologies. The seven FEs—neutral, anger, disgust, fear, pleasure, sorrow, and surprise—are examined in this essay. The average accuracy ratings for these datasets are 81.68%, 96.7%, 97.8%, 82.5%, and 78.9%, in that order. The obtained findings demonstrate the superiority of FER-net over twenty-one state-of-the-art methods. Unlike prior studies that concentrated primarily on real-time streaming videos with audio, the current work aims to discern people's moods from recorded videos. The proposed work aims to recognize people's emotions from recorded films, which distinguishes us from other studies that just focused on videos streamed in real time with a limited range of emotion classifications. Unlike previous work that employed webcams and a convolutional neural network, our method explores a wide range of machine learning techniques to improve the accuracy of emotion identification.

## III. Methodology

Fig. 1 depicts the block diagram of proposed model. This section covers the methodology used for the emotion detection such as Data collection, Image Preprocessing, Feature Extraction, Classification using machine learning algorithms and result analysis.

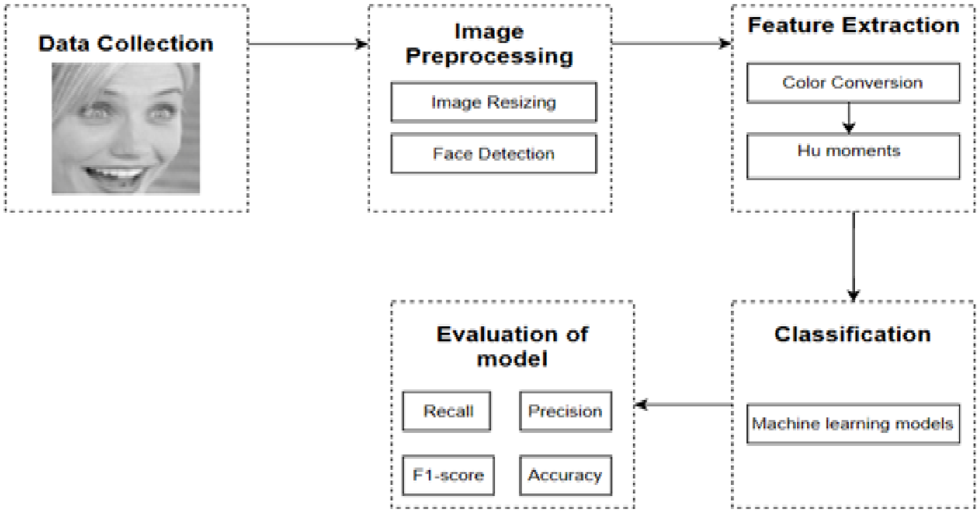

Fig. 1. Block diagram of proposed model.

### A. Data Collections

The data set was gathered from https://www.kaggle.com/datasets/msambare/fer2013 on Kaggle. The videos are in the mp4 format and have been resized to 320*240 pixels. Each video has a duration of twenty seconds. The top ten frames will be taken into consideration after the model has received video input per second.

### B. Image Preprocessing

Using face detection techniques, such Haar cascades, to locate and extract face regions from an image is a basic first step. These techniques are essential for precisely identifying faces in a range of positions and angles. Aligning the identified faces to a consistent orientation is a crucial preprocessing step once faces are discovered. Because it minimizes variation in face positions and increases the general dependability of ensuing analysis, this alignment procedure is essential for guaranteeing data consistency. Aligning the faces enables more reliable and precise results by allowing the later phases of facial recognition and feature extraction to function on uniform facial structures.

### C. Feature Extraction

From the previously processed images, extract pertinent features that effectively capture facial expressions. Facial landmarks, texture features, or other features can be used as these, or deep learning-based feature representations using convolutional neural networks (CNNs) or other machine learning techniques used in this study. The main process in the feature extraction is color conversion where the colored image is being converted into the gray image and then feature is extracted by using Hu moments feature. Hu moments feature are used where the shape of the face is being identified.

Algorithm 1: Feature Extraction algorithm

```
Read the input image from the specified image_path
Resize the image to 320x240 pixels.
Load the pre-trained Haar cascade classifier for face detection.
Convert the resized image to grayscale.
Detect faces in the grayscale image using the Haar cascade classifier.
Initialize an empty list to store extracted features
For each detected face:
a. Crop the face region from the grayscale image.
b. Calculate moments for the cropped face region.
c. Calculate Hu moments from the moments.
d. Add the extracted features to the list.
Output the extracted features for each detected face
```

### D. Classification Using Machine Learning Algorithms

To train the model, 16861 facial expression photos were used in the dataset. The labels that corresponded to the images were used to obtain them. Testing and training sets were created from the dataset. To reduce the possibility of overfitting, the model, which was built using the Keras sequential technique, uses dropout to randomly deactivate specific neurons. The dataset, which was divided into seven classes: anger, contempt, disgust, fear, happiness, sadness, and surprise was used to train the model. The provided dataset was employed to train a convolutional neural network. To better understand multi-class categorization, we looked at seven different classes: Happiness, anger, surprise, sadness, contempt, disgust, and fear.

### E. Recurrent Neural Network

Among the Neural Network types that tackle the problem of predicting the next word in a sequence, the Recurrent Neural Network (RNN) stands out. In contrast to conventional neural networks, which function independently of inputs and outputs, Because of their architecture, RNNs can remember words that have come before them, which is a vital feature for tasks that require sequential prediction. The most important component that makes this memory function possible is the Hidden Layer in RNNs. In some applications, this layer resolves the need on previous context by maintaining crucial information about a sequence and differentiating RNNs. The state, sometimes known as the Memory State, keeps data from the prior input in the network. It reduces parameter complexity compared to other neural networks by using the same parameters for every input or hidden layer, which allows it to do the same task for every input. Fig. 2 depicts the block diagram of recurrent neural network. Table I and II provides the details of hyperparameter values of CNN and RNN algorithms.

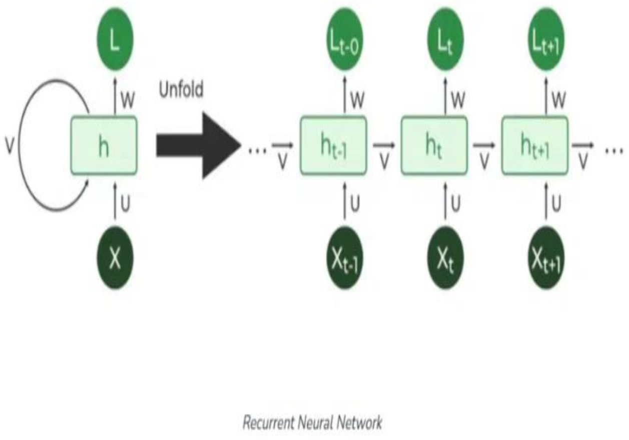

Fig. 2. Block diagram of recurrent neural network.

TABLE I. HYPERPARAMETERS OF RECURRENT NEURAL NETWORK

| Hyperparameters | Values |
|---|---|
| hidden_size | 128 |
| num_layers | 2 |
| learning_rate | 0.001 |
| dropout | 0.5 |
| batch_size | 64 |
| seq_length | 20 |
| optimizer | ‘Adam’ |
| activation | 'tanh' |

TABLE II. HYPER PARAMETERS OF CONVOLUTION NEURAL NETWORK

| Hyper parameters | Values |
|---|---|
| Learning Rate | 0.1 |
| Number of Epochs | 100 |
| Batch Size | 64 |
| Filter Size | 3x3 |
| Pooling Type | Max |
| optimizer | 'Adam |
| activation | 'tanh’ |

## IV. RESULT AND DISCUSSION

Fig. 3 illustrates the Loss analysis model plotted against epochs, demonstrating favorable outcomes on validation data. Epochs of 100 is considered for the analysis of loss model. Fig. 4 illustrates the Accuracy analysis model plotted against epochs, demonstrating favorable outcomes on validation data.

Epochs of 100 is considered for the analysis of the Accuracy model. ROC graph is plotted by considering the 7 classes. A graph illustrating precision versus recall is generated for the seven classes. The four classes are represented, with class 0 corresponding to anger, class 1 to contempt, class 2 to disgust, class 3 to fear, class 4 to happy, class 5 to sadness, and class 6 to surprise. Curves that deviate from the baseline indicate higher potential levels, as shown in Fig. 5.

Fig. 7 Performance Evaluation Matrix The confusion matrix is graphed to assess the effectiveness of N classes, forming an NxN matrix. In this analysis, we consider 7 classes, denoted as 0=angry, Sure, here is a rearrangement of the words: 1=happy, 2=disgust, 3=fear, 4=contempt, 5=surprise, 6=sadness. The matrix serves to contrast predicted values with actual values, as illustrated in Fig. 6. Fig. 6 compares several models, including the 95% accurate Recurrent Neural Network (RNN), the 92% accurate onvolution Neural Network (CNN), the 90% accurate Support Vector Machine, and the 87% accurate K Nearest Neighbor. Fig. 8 compares the performances of several models using characteristics like F1-score, accuracy, precision, and recall. Table III shows the performance metrics of different algorithms.

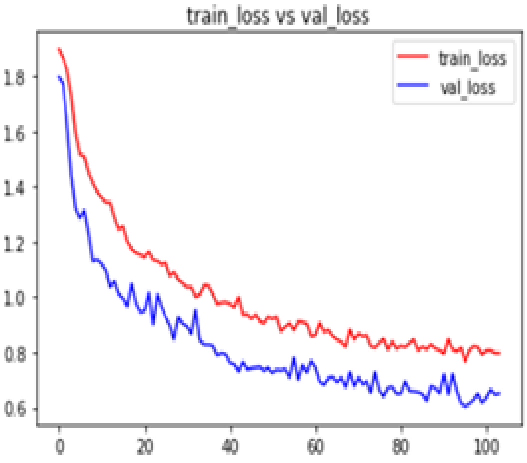

Fig. 4. Accuracy analysis model.

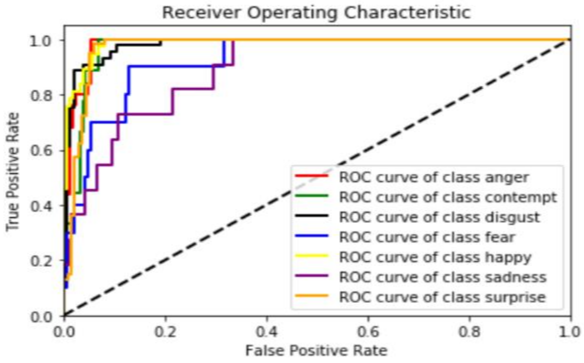

Fig. 5. ROC curve graph.

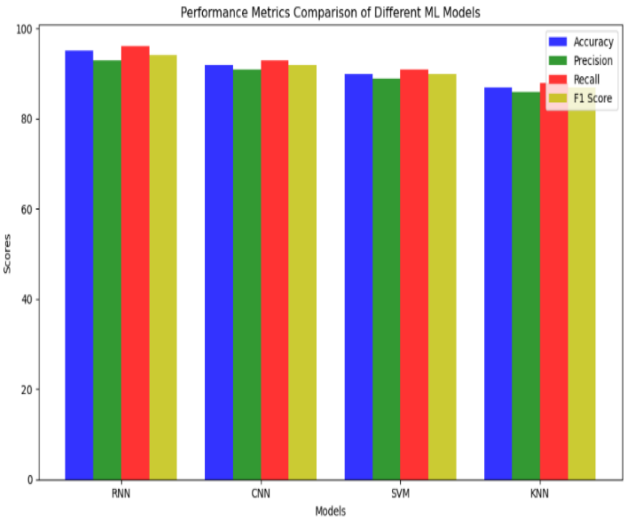

Fig. 6. Performance metrics of different models.

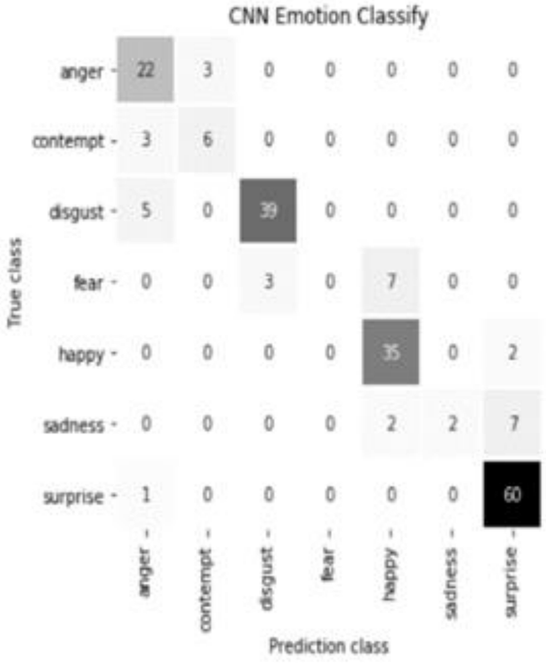

Fig. 7. Confusion matrix.

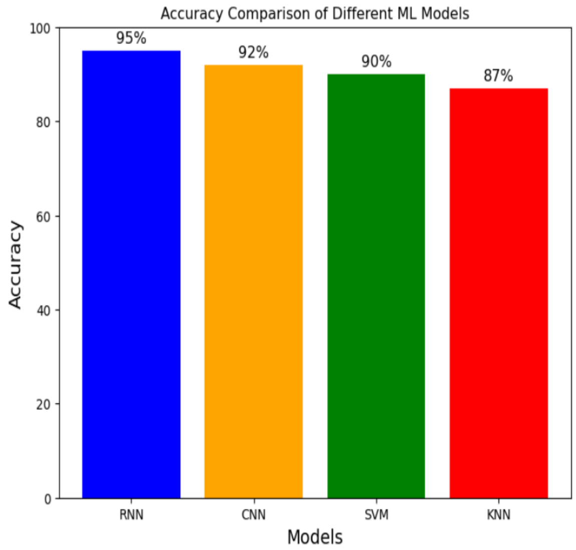

Fig. 8. Model accuracy comparisons.

TABLE III. PERFORMANCE METRICS OF DIFFERENT ALGORITHMS

| Algorithm | Precision (%) | Accuracy (%) | Recall (%) | F1-Score (%) |
|---|---|---|---|---|
| RNN | 93 | 95 | 96 | 94 |
| CNN | 91 | 92 | 93 | 92 |
| SVM | 89 | 90 | 91 | 90 |
| KNN | 86 | 87 | 88 | 87 |

## V. CONCLUSION AND FUTURE WORK

The results of the studies emphasize the significant potential that Convolutional Neural Networks (CNN), Recurrent Neural Networks (RNN), k-Nearest Neighbors (KNN), Support Vector Machines (SVM), and RNN possess. These models show impressive skills that show how well they can decode and interpret the complex web of facial expressions. The decision to employ the RNN model is guided by its intrinsic sequential nature, aligning seamlessly with the temporal dynamics present in video data. Impressively, the RNN model attains a commendable 95% accuracy rate, attesting to its proficiency in discerning and categorizing emotional nuances portrayed through facial expressions. This high accuracy rate lays the groundwork for potential expansions of the project, such as predicting varying levels of emotions like playfulness and delight. Looking ahead, the project could evolve towards predicting emotional states, offering a more nuanced understanding of human affect.

A strategic step towards refining the model involves its application across diverse datasets, ensuring that it can adapt and perform optimally across a spectrum of scenarios. This iterative process not only enhances the model's accuracy but also positions it as a robust tool for real-world applications in emotion recognition technology.

# Botnet Detection and Incident Response in Security Operation Center (SOC): A Proposed Framework

Roslaily Muhammad, Saiful Adli Ismail, Noor Hafizah Hassan
Advanced Informatics Department-Razak Faculty of Technology and Informatics, Universiti Teknologi Malaysia

***Abstract*—In the dynamic landscape of evolving cyber threats, Security Operations Centers (SOCs) play an important role in protecting digital assets. Among these threats, botnets are particularly challenging due to their ability to take over many devices and launch coordinated attacks. Through comparative analysis, the research gaps in existing frameworks have been identified. Based on these insights, a botnet detection and incident response framework aligned with SOC practices has been proposed. This proposed framework emphasizes proactive measures by integrating threat intelligence, detection and monitoring tools to detect botnet attack and facilitate rapid response. Future research will focus on conducting evaluation and validation studies to assess the effectiveness and performance of the framework in controlled environments. This effort will contribute to develop the framework and ensuring it aligns with practical cybersecurity needs.**

***Keywords—Botnet detection; threat incident response; security operation center***

## I. Introduction

Botnet is one of the most dangerous threats that occur in cyberattacks today which can compromise the computer systems or smartphones. Detecting it is becoming more sophisticated and challenging to detect due to the growth of Internet of Things (IoT), smart devices, cloud platforms and social media. Wainwright & Kettani [1] defined as botnets consisting of hundreds or thousands of connected devices that run bots or scripts, controlled by a single machine referred to as botmaster via Command and Control (C&C) channel. Botnets generally could propagate themselves throughout a network and infect vulnerable machines. They operate by maintaining contact with the botmaster for command and control or by using specific modules in their architecture for the same purpose [2]. A compromised host also will be infected when they open a malicious email attachment, visit an affected website, and accidentally download the bot onto their computer. Once infected, the botmaster will gain access to the victim's computer without victim acknowledgment [3]. In [4], botnet can perform DDoS attacks, spamming, malware and compromise a large computer. These activities pose a significant risk to national security, public or private organizations, and individual.

Botnets are capable of being remotely controlled by botmasters from any geographical location through Command and Control (C&C) channels. Botmasters generate revenue by renting and leasing botnets on the darknet market. Attackers frequently modify and update the structures and methodologies of botnets to evade detection [5]. This makes botnets difficult to detect. Furthermore, the complicated topological structure of botnets, particularly peer-to-peer (P2P) topology, adds to the difficulty of detection. P2P topologies are more dangerous and resilient compared to centralized topologies. The merging of malicious and legitimate traffic within P2P botnets presents one of the most significant challenges in botnet detection [6].

According to the International Data Corporation, Malaysia's cybersecurity expenditure surged to RM2.6 billion (US$627 million) in 2019 and is anticipated to exceed RM4 billion (US$1 billion) by 2024. This data is highlighted in a report from the Ministry of Communications and Digital website [7]. Companies face challenges when the time needed to detect and mitigate threats increases, along with rising costs. This indicates the inefficiencies within companies in managing incident reports related to these threats. Vielberth et al. [8] indicated that these inefficiencies are not only from within the company but also from inadequate devices, systems, applications, and networks. Additionally, there is a lack of awareness regarding which assets require protection and how to integrate tools with the existing infrastructure. Moreover, the rapid evolution of the threat landscape makes it harder for companies to keep up with new technologies.

As the threat landscape continues to evolve, organizations must deploy defensive mechanisms to safeguard their operations. In study [9], among the relevant strategies is the establishment of a Security Operations Center (SOC), which serves to monitor and protect against potential danger. Within SOC operations, threat intelligence enables the detection of botnets through analysis from diverse sources. Additionally, it facilitates the identification of patterns and behaviors based on potential indicators of their presence [10]. Furthermore, threat information can be disseminated to other organizations via threat intelligence sharing platforms and standards such as the Malware Information Sharing Platform (MISP), OpenCTI, STIX/TAXII, and OTX ([11], [12], [13].

The purpose of this study is to identify the components involved in botnet detection and incident response, with the aim of designing a comprehensive framework aligned with Security Operations Center (SOC) practices.  The main contributions in this study are:

- Conducting study on botnet detection framework to discover the main components and features in framework.
- Conducting study on threat detection and incident response framework to identify the framework components, security tools and cybersecurity standard practiced by SOC.

- Provides a comprehensive analysis of framework components to identify research gaps for designing botnet detection and response framework align with the SOC practices.

This paper is organized as follows. Section II studies related work on the botnet detection framework and threat detection and incident response related to SOC. Section III discuss the methodology and framework implementation. Section IV identifies the research gaps and discussion on a proposed framework. Section V concludes the paper and discusses the potential future research.

## II. Related Work

Various detection methods have been proposed by researchers in literature to detect botnets. Based on literature [14], there are three major methods of botnet detection such as host-based detection, honeynet detection and network-based detection. Recently, machine learning based detection has become the most widely used for detecting botnets methods as proven by previous literature [15], [16], [4], [5]. In addition, the number and complexity of IoT devices is also growing, it has become important to develop effective botnet detection methods.

To enhance botnet detection methods, collaboration with Security Operations Centers (SOCs) is crucial for strengthening the capability to monitor and respond the emerging botnet effectively. It is also responsible to monitor network activity, analyzing, investigate and response to the security threat by using a range of tools and technologies [17], [18], [8]. Incorporating advanced technologies, such as machine learning-based detection, within the SOC framework enables real-time analysis of network traffic and anomalies. Iqbal & Anwar [19] and Islam et al [20] utilized the machine learning approach that enable rapid detection and automates alert for immediate response to identify threat. The SOC is supported by the advanced technology tools such as the Security Information and Event Management (SIEM) system, intrusion detection/prevention system (IDS/IPS), advanced threat intelligence and forensic analysis tools as defense mechanism, protect organizations from the potential damage caused by threats [21], [9], [22], [23], [8].

Security Operations Centers (SOCs) also utilize the MITRE ATT&CK framework for its standardized approach to describing adversarial behaviors throughout the cyber-attack lifecycle. The MITRE ATT&CK maps adversarial behaviours into a structured matrix representation of tactics and techniques followed by procedures [24]. By incorporating botnet-related techniques into the MITRE ATT&CK matrix, organizations can map specific tactics, techniques, and procedures (TTPs) associated with botnets, enhancing their overall threat detection capabilities. MITRE ATT&CK integrates well with Threat Intelligence (TI), helping SOC analysts in correlating real-world threat intelligence with specific tactics used by attackers. This enhances their ability to detect threats. Bajpai & Enbody [25] incorporated MITRE ATT&CK mapping into their ransomware response framework to prompt technical responses, thereby enhancing their overall capabilities in dealing with ransomware.

### A. Botnet Detection Framework

Many researchers have focused on finding the solutions to detect botnets by sharing their experimental experiences and suggested various solutions to mitigate this issue. Most of the solutions that authors proposed are based on machine learning approach. The purpose of the botnet detection framework is to identify botnet activity and distinguish it from legitimate network traffic.

In study [14] the authors introduced a botnet detection framework based on comparative analyses from previous research, focusing primarily on effective measures for detection. However, this framework lacks emphasis on early-stage prevention. In contrast, the collaborative framework presented by [16] provides a comprehensive approach to botnet detection, incorporating a two-phase decision-making process involving the Host Agent Detector (HAD) and Network Agent Detector (NAD). HAD captures suspicious behavior using machine learning models, extracting features from network logs. NAD was activated by HAD alerts, identifies infected machines by analyzing network flow logs. The two-phase decision-making process ensures a more accurate performance, as NAD's actions depend on HAD's alerts. Furthermore, this framework was evaluated using real-world benchmark datasets, enhancing its practical applicability. The classifier utilized in this collaborative framework aids in generating infection reports when detecting RAT-bots. However, this framework is only able to detect RAT-bots and requires time complexity to evaluate.

BotDet is a framework developed by Ghafir et al. [26] tovidentify botnet C&C traffic and consists of two main phases. Multiple modules are executed during the initial phase to find various potential botnet C&C communication methods. This framework allowing network traffic to be analyzed in real time without storing it. In addition, it uses information from the different intelligence feeds to update all blacklist. The module allows to block all alerts with same infected host and malicious item in one alert per day. This can reduce the number of email alerts received by security teams. However, external IDS alerts have been integrated to reduce the false positive rate.

In study [27], the authors utilized Correlation Attribute Eval and Principal Component filters to identify botnet features, reducing dataset dimensions and improving botnet detection efficiency. This framework consists of five components such as botnet dataset, Data pre-processing, Data normalization, machine learning and evaluation. The six classifiers (Random Forest, IBK, JRip, Multilayer Perceptron, Naive Bayes, OneR) are compared for an optimized detection model. The results highlight the significant improvement in botnet detection when combining Correlation Attribute Eval with JRip, particularly on the CICIDS2017 dataset. However, it only focuses at one dataset, might be simplifying how features are chosen, and lack of exploration of pros and cons of the chosen method.

Ismail et al. [4] proposed a Botnet Analysis and Detection System (BADS) which could detect Botnet in encrypted channel and includes the autonomous feature. The BADS framework comprises of three main components which are Network Analysis System (NAS), IDS and Alarm System

(AS). Due to conflict with some tools used to detect the botnet, this framework unable to determine the severity of botnet attack. If this method can be employed, it can assist network manager to monitor the system and provide the automation solution.

The study conducted by Ibrahim et al. [28] focuses on utilizing flow-based behavior analysis to identify newly emerging botnets, addressing the difficulties in recognizing consistent patterns within a botnet that consistently alters its signature. The framework initiates by selecting a network traffic dataset and then proceeds with the pre-processing of the chosen dataset. This study emphasizes the importance of the pre-processing phase, ensuring that the data is handled effectively to produce high performance during classification.

Peertrap is a botnet detection framework developed by Xing et al. [6] based on Self- avoiding random walks (SAW) algorithm to detect the unstructured P2P botnet under C&C channel encryption. The dataset was used for an evaluation experiment, and the experimental results were compared to those of the current method on an unstructured data set. This framework has achieved high accuracy detection of P2P bots with existence of legitimate P2P traffic. Nevertheless, this framework only focuses on P2P botnet detection process without provides response should be taken by security team. The report will be generated once the P2P botnet has been detected.

Table I provides a comprehensive overview of various studies conducted on the detection methods and framework components employed in botnet detection.

### *B. Threat Detection and Incident Response Framework related to SOC*

Threat detection and Incident response framework refers to a structured approach used by security operations teams to detect and respond to security incidents within an organization's information systems. A Security Operations Center (SOC) is a centralized unit that monitors and manages security-related issues on an ongoing basis. The framework provides guidelines and processes for identifying, analysing, responding, and mitigating security incidents. To achieve the SOC goal of providing and responding to incident threat, the framework such as Incident Response Lifecycle, ISO/IEC 27035:2016 and NIST Computer Security Incident Handling Guide have been used as guides to respond the incident threat [23]. SOC incident management is the process of identifying, detecting, analyzing, and responding to the information security in a systematic way.

Ti Dun et al. [31] investigated how Next Generation Security Operation Centers (NGSOCs) respond to malicious activities in their research. A specific use case was developed to detect the Hermes Ransomware v2.1 malware, utilizing complex correlation rules within the SIEM anomalies engine. This study aimed to analyze and identify the presence of Hermes Ransomware v2.1. However, this framework has a limitation because many of these use cases are created for specific companies, which may pose challenges when trying to apply them to different environments with varying needs.

In research [20], a novel Artificial Intelligence (AI)-based framework called SmartValidator was developed to automate the validation of alerts using Cyber Threat Information (CTI) in Security Operation Centres (SOCs). This framework was developed to overcome the manual updating process that caused delays in responding to attacks. SmartValidator, leveraging Machine Learning (ML) techniques, consists of three layers for data collection, model building, and alert validation.

Wang et al. [32] introduced a comprehensive Security Operation Center (SOC) to address and mitigate the identified issues. This framework focuses on establishing essential components within the SOC to enhance defense against specific types of attacks, acquire high-quality threat intelligence, and achieve faster automated response capabilities. In this framework, a multi-perspective behavior analysis component is implemented to analyze various types of attacks. Furthermore, additional components were developed to construct an integrated SOC platform, including those for data collection and big data storage.

A framework [25] has been developed for combating ransomware attacks that provides a detailed approach that balances between adaptability and practicality, making it useful for both technical team and stakeholders. The framework components were adapted from general IR procedure. However, technical response actions in the framework were derived using MITRE ATT&CK mappings and the identification of process-related actions depended solely on the authors' industry experiences.

Lai et al. [33] introduced a framework for the Security Operations Center (SOC) known as RansomSOC, designed to enhance detection and response capabilities against ransomware attacks. It incorporates a unique real-time emergency local data backup scheme that exploits ransomware design flaws, ensuring immediate backup of critical files even post-attack initiation to minimize the impact on encrypted files. Additionally, RansomSOC employs easily detectable ransomware honey files, created based on entropy value changes, facilitating rapid detection of ransomware attacks. The framework primarily consists of eight components: Ransomware Sandbox, Logs Analyzer, Logs Collector, File Content Entropy and Extension Comparison, File Protector Definition Generator, Administrator Notification Center, Data Backup Orchestra Center, and Defense Command Orchestra Center. However, this framework requires a broader investigation into various ransomware families and practical integration scenarios of RansomSOC with a typical SOC.

Table II summarizes various studies focusing on different types of cyber threats and the corresponding frameworks, components, cybersecurity tools, and standards or frameworks utilized.

TABLE I. SUMMARY STUDIES OF BOTNET DETECTION FRAMEWORKS

| Author | Type of threat | Framework Components | Cybersecurity tool | Cybersecurity standard & framework |
|---|---|---|---|---|
| [34] | Cyber threat | • Data source layer<br>• System management<br>• Services management layer | Network Management System (NMS) | Not mentioned |
| [20] | Cyber threat | • Threat collection data layer<br>• Threat data prediction model building layer.<br>• Threat data validation layer | OSINT, MISP | Not mentioned |
| [31] | Ransomware | • Correlation rules for Hermes Ransomware<br>• Enriching<br>• Combining rules<br>• Detection performance | SIEM | Not mentioned |
| [32] | Cyber threat | • Data Collection<br>• Data Pre-processing<br>• Big Data Storage<br>• Multi perspective Behavior Analysis<br>• Threat Intelligence<br>• Application services | ElasticSearch | Not mentioned |
| [25] | Ransomware | • Preparation<br>• Identification<br>• Containment<br>• Eradication<br>• Recovery<br>• Post-incident | EDR | NIST, MITRE ATT&CK |
| [35] | Cyber threat | • Data sources and threat intelligence<br>• Data pipelines<br>• Storage and visualization<br>• Alerting | MISP, ZEEK, ELASTIC Search, KIBANA, ElastAlert, PocketSOC | Not mentioned |
| [33] | Ransonware (Black Matter, Conti, Dark Side, and Revil) | Ransomware Sandbox, Logs Analyzer, Logs Collector, File Content Entropy and Extension Comparison, File Protector Definition Generator, Administrator Notification Center, Data Backup Orchestra Center, and Defense Command Orchestra Center | Not mentioned | Not mentioned |

TABLE II. SUMMARY OF THREAT DETECTION AND INCIDENT RSSPONSE FRAMEWORK RELATED TO SOC

| Author | Detection methods | Framework Components | Features |
|---|---|---|---|
| [6] | Machine Learning | • data pre-processing<br>• features extraction<br>• shared neighbour graph construction.<br>• community detection<br>• Classification | • real network traffic, P2P botnet traffic, P2P<br>• legitimate application<br>• P2P Feature Extraction<br>• Community Detection using Self- avoiding random walks (SAW) algorithm.<br>• Filter out the botnet community |
| [4] | Signature based | • Network Analysis System (NAS) - data collection and conversion - Feature Extraction and selection -Botnet Prediction and Classification<br>• IDS - Intrusion Detection System<br>• Alarm system (AS) | • Data set of encrypted, Botnet traffic, public data set<br>• Tranalyzer is used to extract the Botnet features.<br>• IDS -Snort based detection mechanism.<br>• Notify the severity of attacks, suggest the protection strategy and generate report. |

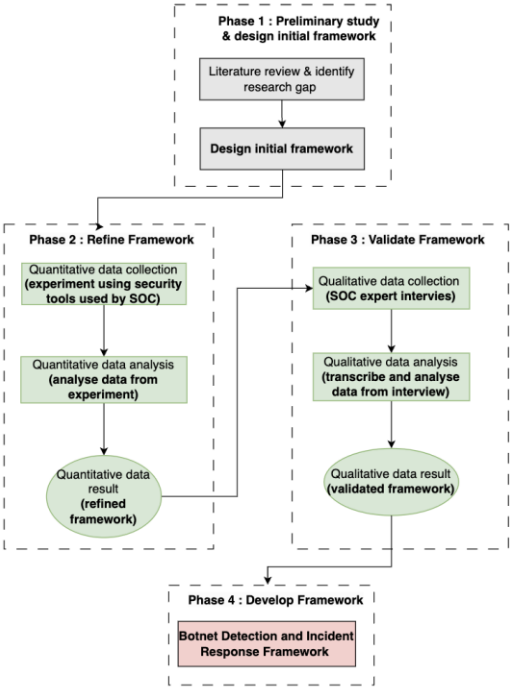
## III. METHODOLOGY

This research began with Phase 1 which involved a comprehensive review of existing literature conducted across various academic databases, including Scopus, IEEE, ScienceDirect, and Google Scholar. Keywords and phrases related to the research question were used to construct an effective search strategy. The search terms included "botnet" OR "threat" AND "detection framework" AND "incident response framework" AND "security operation center". Boolean operators have been used to refine and broaden the search needed. In this paper, the researcher utilizes a literature review to identify existing frameworks related to botnet and SOC, analyze them, and extract the information presented in Table I and Table II. The findings of the review are presented in Table III, which outlines the research gaps necessary for designing a proposed framework.

Based on the research gaps gained from the literature review, an initial framework was developed. This framework was designed to address the specific components of detecting and responding to botnet activities within a SOC environment. The phase 2 will involve conducting experiments to refine and improve the initial framework. This phase may include testing detection and response strategies, evaluating the effectiveness of various tools and technologies, and simulating botnet attacks in a controlled environment.

Once the framework is refined through the experimental phase, expert interviews will be conducted. In Phase 3 which validates the framework, experts in the field of cybersecurity and SOC management will be selected based on their knowledge and experience with botnet detection and incident response. The open-ended questions will be used to validate the framework through these interviews. Expert feedback on the framework will help validate its relevance, practicality, and effectiveness in real-world SOC environments. This validation process will help ensure that the framework is aligned with industry best practices for botnet detection and incident response in SOC. A comprehensive framework and a well-validated approach to botnet detection and incident response in SOCs will be developed in Phase 4. This framework will also incorporate threat intelligence and best practices in the field. The overall research methodology is presented in Fig. 1.



Phase 1 : Preliminary study & design initial framework
Literature review & identify research gap
Design initial framework
Phase 2 : Refine Framework
Quantitative data collection (experiment using security tools used by SOC)
Quantitative data analysis (analyse data from experiment)
Quantitative data result (refined framework)
Phase 3 : Validate Framework
Qualitative data collection (SOC expert intervies)
Qualitative data analysis (transcribe and analyse data from interview)
Qualitative data result (validated framework)
Phase 4 : Develop Framework
Botnet Detection and Incident Response Framework

Fig. 1. Research methodology.

## IV. Results and Discussion

This research has identified nine relevant papers on botnet detection frameworks and seven related papers focusing on threat detection and response frameworks associated with Security Operations Centers (SOCs). This paper should focus on the development of a framework for detecting botnets that aligns with Security Operations Center (SOC) practices. Table III provides a comparison of the framework components derived from Table I and Table II, facilitating the development of frameworks for botnet detection and incident response.

This section provides several observations on how botnet detection frameworks can be aligned with Security Operations Center (SOC) practices by identifying gaps in the existing literature. There are several research gaps in the current literature dealing with botnet detection that can be identified from the current review. These gaps can be summarized as follows:

- There is a lack of botnet-focused frameworks. While various frameworks have been developed and studied, none seem to focus on the detection of botnet activity. This gap in the literature suggests future research to design and implement a botnet detection framework aligned with SOC practices.
- There is limited on alert notification and response mechanisms, it facilitates quick actions upon the identification of botnet activities, contributing to accurate detection and immediate response efforts.
- The limited utilization of security tools in botnet detection.
- Lack of integration of threat intelligence within the botnet framework.
- Limited on the adoption and adherence to comprehensive cybersecurity standards and frameworks.
- Lack of dynamic detection mechanisms capable of automatically updating to align with the latest TTPs of evolving botnets.

Addressing these gaps can lead to the development of more effective botnet detection and incident response frameworks aligned with the SOC practices.

### A. Proposed Framework

The development of the proposed framework is guided by the gaps in existing frameworks. The proposed framework is a comprehensive of botnet detection and incident response framework aligned with the SOC practices is illustrated in Fig. 2. The proposed framework is designed to assist organizations in efficiently detecting and response to botnet related incidents. It emphasizes proactive measures by integrating with the threat intelligence, detection techniques and monitoring tools that enable botnet attack can detect, generate accurate analysis and rapid response and continuously updating the new botnet threat. This framework contributes to reducing impact of threat especially botnet-related and ability to adapt the evolving threat landscape.

TABLE III. Comparative Analysis of Botnet Detection and Incident Response Framework Components

| | | Framework Components | | | | | | | |
|---|---|---|---|---|---|---|---|---|---|
| | **Author** | Data Collection & data source | Data pre-processing | Features behaviour extraction & selection | Detection | Alert notification & response | Cybersecurity tool | Threat intelligence | Cybersecurity Standard & Framework |

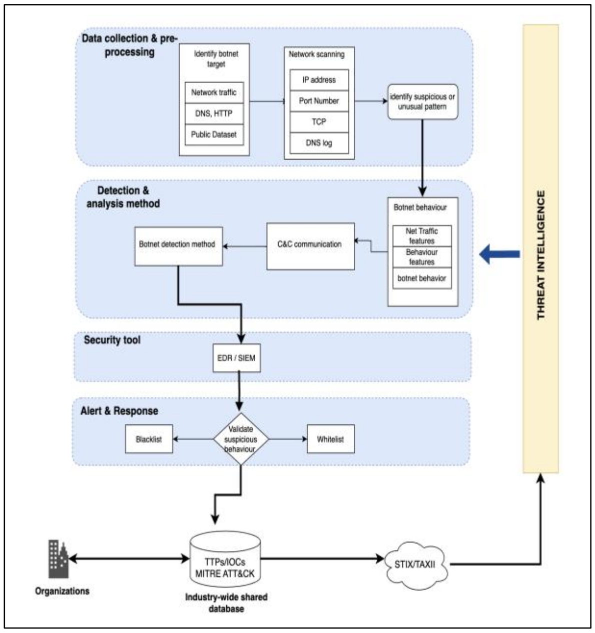

Fig. 2. A proposed framework.

The details of the proposed components in a proposed framework are explain below:

*1) Data collection and pre-processing:* Data collection components are required to understand normal and malicious activities in the network. This involves gathering data from various sources such as network devices, endpoints and logs. It also encompasses identifying potential targets, conducting network scans, and identify suspicious and unusual patterns of botnet.

*2) Detection and Analysis method:* The detection and analysis methods component is essential to recognize and analyze the potential botnet activities. It refers to the detection methods used to detect botnet activities within network or system.

*3) Security tool:* Security tool play an important role in enhancing the capabilities of a framework, offering a variety of functions for an effective defence against botnet activities. Additionally, security tools often support automated response mechanisms that enable immediate actions such as isolating infected devices or blocking malicious traffic upon botnet detection.

*4) Alert & Response:* It will generate alert based on detected botnets and taking action to mitigate and eliminate the botnet. When an alert is generated, threat intelligence data can be used to enhance the alert with additional context, such as known indicators of compromise (IOCs), threat actor profiles, historical attack patterns, and relevant mitigation strategies. This additional information provides security analysts with a deeper understanding of the potential threat, enabling more informed decision-making during the response process.

*5) Threat Intelligence:* It provides up-to-date information on emerging botnet threats that allows the framework to keep updated on evolving tactics employed by malicious actors. By contextualizing indicators of compromise (IoCs), threat intelligence assists the framework in distinguishing between normal and suspicious network activities, enhancing its accuracy in detection.

*6) Cybersecurity Standard and Framework adoption:* The integration of cybersecurity standards and frameworks into a botnet detection creates best practices, guiding the design and deployment of the botnet detection framework based on industry-recognized principles. Basically, the integration of cybersecurity standards and frameworks enhances the overall resilience and effectiveness of a botnet detection framework in safeguarding organizations against evolving cyber threats.

### B. *Proposed Experimental Approach*

The testbed setup involved a virtualized environment created using a virtualization tool such as VirtualBox. The virtual machines will run the operating systems, with Windows 10 as the vulnerable machine and Kali Linux as the botnet attack machine. The virtual servers also will create to run various services that install Ubuntu operating system. Wazuh, TheHive, and Cortex will be installed on separate VMs within the network. Wazuh is an open-source tool that will be used to monitor unusual network traffic, system logs, file changes associated with botnet activity, and other indicators of compromise (IOCs). TheHive and Cortex will be used for incident response and threat intelligence management. Data will be collected on Wazuh alerts, TheHive cases, and Cortex analysis results, then will be analyzed to evaluate the effectiveness of the detection and response. Metrics such as detection rate, false positive rate, and response time will be used for measurement. The purpose of the testbed is to evaluate the botnet detection and response strategies in a controlled environment. Fig. 3 illustrates the proposed botnet detection and incident response testbed.

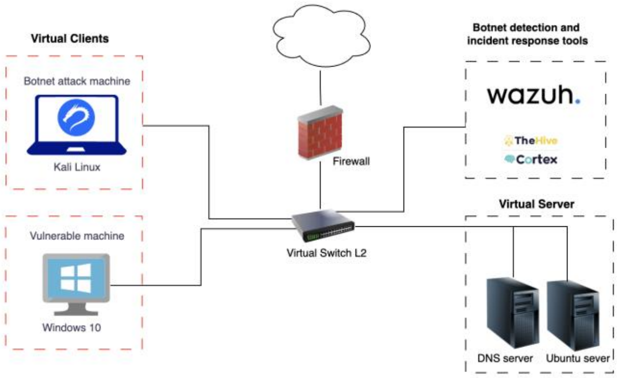

Fig. 3. A proposed testbed

## V. CONCLUSION AND FUTURE WORK

In conclusion, this study has conducted a comprehensive literature review on detection and incident response frameworks in Security Operations Centers (SOCs). By analyzing the main components, security tools, and cybersecurity standards used in these frameworks, this research has identified several research gaps that can be used to develop more effective and comprehensive botnet detection frameworks. Future work will focus on conducting evaluation and validation studies to assess the effectiveness and performance of the framework by implementing the experiment approach in controlled environment. Additionally, gathering feedback from cybersecurity experts to validate this framework and identify areas for improvement. Overall, this research contributes to the existing body of knowledge in cybersecurity by providing insights into the development and implementation of botnet detection and incident response frameworks in SOCs.

## Acknowledgment

# Enhancing Customer Segmentation Insights by using RFM + Discount Proportion Model with Clustering Algorithms

Victor Hugo Antonius, Devi Fitrianah
BINUS Graduate Program - Master in Computer Science, Bina Nusantara University, Jakarta, Indonesia, 11480

***Abstract*—In this digital era, the use of e-commerce has expanded and is widely adopted by society. One of the reasons why people use e-commerce platforms is because of their convenience and ease of use. However, the rapid growth of e-commerce has led to a substantial rise in transactions within the platform, involving various business entities. Therefore, it is crucial to perform customer segmentation to group them based on their purchasing behavior. The implementation of data mining techniques, such as clustering, is highly beneficial in this case. Clustering helps process datasets and transform them into useful information. In this study, transaction data obtained from one of the e-commerce stores, i.e. MurahJaya888 and followed by analysis using various clustering methods such as K-means, K-medoids, Fuzzy c-means, and Mini-batch k-means. We also proposed a new model that will become the attributes cluster, namely, RFM + DP (Discount Proportion). The Discount Proportion Rate will provide more insights for customer segmentation as it helps understand purchasing behavior that is more responsive to discount utilization. Implementing these four clustering methods with RFM + DP model resulted in four clusters based on the optimal elbow method. Furthermore, the evaluation and performance metrics for each clustering algorithm indicate that Mini Batch K-Means achieved the highest silhouette score of 0.50. Meanwhile, K-Means obtained the highest CH index value compared to the other algorithms, which was 1056.**

***Keywords*—Clustering; RFM; discount proportion; customer segmentation; data mining**

## I. Introduction

The entire world has been shaken by big news in 2020, COVID-19 pandemic. This pandemic has taken many human lives and made a huge impact on all aspects of human life such as social, political, and even economic. In the economic field, everyone knows that businesses have to go through difficult times in the COVID-19 era to survive [1] [2]. Therefore, the pressure they received must be faced with the increasing adoption of technology 4.0. This reliance on technologies is crucial to not only survive but also to adapt and thrive effectively.

The rapid adoption of technology in this digital era has come up with opportunities to boost efficiency and expand business market presence. One effective way to achieve this is by using e-commerce platforms. e-Commerce is concerned with facilities such as marketing, selling products or services, delivering, and developing over the internet [3]. e-Commerce enhances companies' efficiency and reliability by automating transactions [4]. In this case, transactions can be done online, making it easier for people like customers who make purchases and use services.

The use of e-commerce in the business field has played big role across the world, especially in the context of Indonesia. Many businesses have switched their business from traditional offline business to selling online because the growth of online business and technologies [5]. Also, some of them have been implementing hybrid models to maintain their business continuity, entice to their own customers, and provide good value through products and services. According to latest statistical data in Indonesia collected by the BPS-Statistics Indonesia (2022), the survey results show that the number of e-commerce businesses in Indonesia in 2021 was 2,868,178 businesses which experienced an increase from 2020, although the growth is not too much. The same situation also occurred in 2022. With this volume of visitors, the use of e-commerce signifies convenience for consumers. There are many popular e-commerce sites or platforms in Indonesia such as Tokopedia, Shopee, Blibli, and many more. These platforms are frequently visited and have a high number of transactions due to the presence of various business entities and customers [6].

While it's true that e-commerce platforms process countless transactions daily, business entities and sellers need to evaluate their purchase behavior by doing customer segmentation. One of the most common ways is by using RFM model. RFM will help to understand the behavior and customers value based on their characteristics [7]. Even small businesses can significantly benefit from customer segmentation. Therefore, for processing transaction data in order to understand customer segmentation, a technique in data mining can be utilized to determine the relation of its data [8]. Hence, using the RFM model itself is felt to be insufficient for representing customer segmentation. General customer segmentation is divided into four types, namely, based on demographic (customer's personal information), geographic (location, population density), purchase behavior, and psychographic factors [9]. These can be used as an additional feature in the RFM model to gain new insights that help understand customer behavior better, enhance market targeting, and optimize marketing strategies. This proves that RFM model in customer segmentation can be adjusted according to business needs.

In data mining, there is unsupervised learning technique named clustering. This approach often used to group data objects based on their similarities. Clustering is a technique used in data mining analysis that groups of data objects into a set based on their similar characteristics [8] [10]. Particularly in customer segmentation, clustering techniques play a crucial role. By applying clustering algorithms to customer data, businesses can identify groups or segments with similar behaviors and preferences. This segmentation helps companies in tailoring marketing strategies and enhancing overall customer satisfaction.

Based on the findings outlined in [11] states that startup businesses can achieve quicker adaptation by thoroughly comprehending their market and customer base. Therefore, customer segmentation is an effective market strategy for grasping customer characteristics. In their approach, they employ clustering methods combined with the RFM (Recency, Frequency, Monetary) model, They use clustering techniques with the RFM model because of its ease of application to the market and give empirical of the better result. Clustering also allows to see hidden patterns based on customer behavior because the properties of the mining data are specific to finding pattern.

The purpose of this study is to compare four clustering algorithms in data mining such as K-means, K-medoids, Fuzzy c-means, and Mini batch k-means. The initial step of this research is to conduct literature to collect papers related to e-commerce, and customer segmentation using several models, and clustering algorithms. Additionally, the related dataset was obtained from a store called MurahJaya888 in Indonesia on the Shopee e-commerce platform in Indonesia. The next step involves using clustering techniques in the Python programming language to put into practice our proposed model that merges RFM (Recency, Frequency, Monetary) with the Discount Proportion attribute. The benefit of using the Discount Proportion attribute is to observe whether those who shop tend to frequently take advantage of discounts or not. It indicates whether their behavior involves frequent shopping, particularly highlighting if they are inclined to make purchases more frequently when discounts are available. Through this research, we aim to answer pivotal research questions such as how the integration of discount proportion with RFM clustering enhances customer segmentation accuracy, and how these refined segments can be effectively leveraged to optimize targeted marketing efforts in the retail sector.

## II. Related works

The following are summaries of previous research that are relevant to this study. Table I presents a summary of the related works, outlining key findings and insights gathered from prior studies in the field.

Based on all of this research, we understand that the use of clustering and an expanded RFM model can lead to deeper customer segmentation. However, clustering can become overly complex due to the additional variables introduced. For example, in the case of this study, we propose the RFM + Discount Proportion in percentage model to investigate several customer segments and find hidden patterns that are more responsive to discounts, whether they tend to shop during discount periods or not, and with significant discounts, they become loyal customers or only take advantage of discounts occasionally.

TABLE I. Summary of Related Works

| Dataset | Methodology | Result |
|---|---|---|
| UK retail dataset from UCI machine learning repository | RFM model with various clustering algorithms. | The dataset has more than 540,000 records. We tried different methods like k-means, GMM, DBSCAN, BIRCH, and Agglomerative Clustering to analyze it. The best result came from using GMM (Gaussian Mixture Model) with PCA for reducing dimensions. It got a silhouette score of 0.80, which is the highest compared to previous studies [12]. |
| Brazillian store dataset from Kaggle | K-means with RFM and create a website-based dashboard using Streamlit | With over 100,000 records, a clustering method with a k of 4 was employed. The clusters were visualized based on RFM values, yielding a silhouette coefficient of 0.47. Additionally, this research visualized the results using Streamlit, featuring three key components: overview, RFM Analysis, and page report, aimed at providing valuable insights [13]. |
| UCI machine learning repository | RFM-D(Diversity) with various machine learning algorithms | Diversity, an attribute that complements RFM, measures the variety of products purchased by each customer. The dataset utilized the purchase history of 4,383 transactions. Various machine learning methods including SVM, Decision Tree, and K-Means were compared. However, the highest silhouette score accuracy of 0.98 was attained using K-Means [14]. |
| Olist store dataset from Kaggle | RFMTS with K-means algorithm | T stands for Time and S for Satisfication score. Due to the utilization of five variables or attributes, the researchers opted for PCA to reduce the dimensionality of their dataset. Based on the elbow method, they determined the optimal cluster number to be 5. They did not explicitly focus on the clustering algorithm but discussed the results regarding customer statistics, which, if ignored, could have a negative impact on the company [15]. |
| Bank dataset | RFM+ B(Balance) model with K-means | The B model, which is the amount of savings a customer has at the end of the data period, can be very helpful for grouping customers and is useful in developing marketing strategies. The data was obtained from a bank with over 147,000 entries and was processed using k-means clustering. The accuracy level achieved from grouping savings customers using the RFM+B model is 77.58% [16]. |

## III. Research Methodology

The general process of the methodology of this study is shown in Fig. 1. The initial step entails collecting literatures to define the problem through a literature study. After defining the problem and establishing the goals of this research area, the subsequent steps involve collecting the dataset, preprocessing the data, implementing models such as K-Means, K-Medoids, Fuzzy C-Means, and Mini-Batch K-

Means, and evaluating them to determine the algorithm that comes out with the best performance. For a better understanding, let's take a look at the research stages Fig. 1:

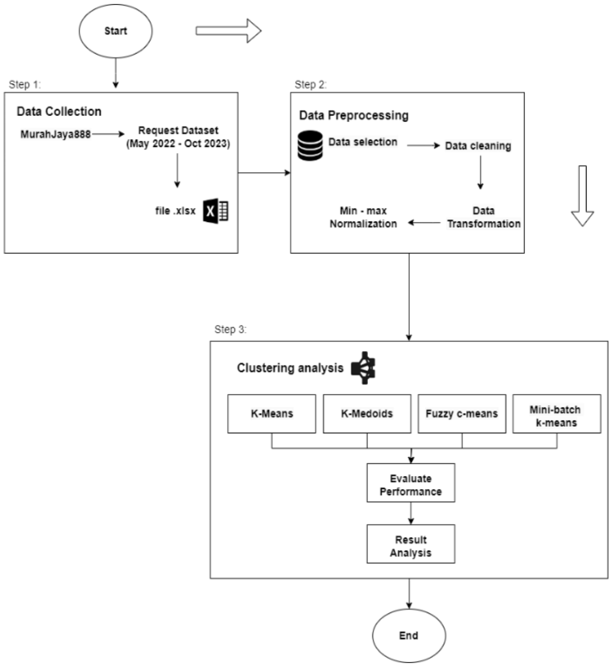

Fig. 1. Research Stages.

## A. Data Collection

The dataset is collected and obtained from an online store called MurahJaya888 in Indonesia on the e-commerce platform. The dataset is provided based on a request from the shop owner as an example of a research subject in this e-commerce area. The data obtained is in .xlsx files format where there are 12 files (October 2021 – October 2023) with a total of 46 columns and 2497 rows. Before preprocessing the data, we must combine them into one file and convert it into data frame so that will help us to analyze more easily using Python programming language.

## B. Pre-processing Data

After combining the data obtained into a dataframe, the next step is to process the dataset by pre-processing. Pre-processing is the process of preparing data to make it easier and feasible to analyze. Preprocessing is also use to enhance the quality of data, ensuring that it fulfills the requirements of the algorithms [17]. The preprocessing stages we use included data selection, data cleaning, and transformation.

Data selection is the first preprocessing step in this study to drop some columns that are irrelevant to be analyzed. Raw data that are received must be preprocessed before diving into the next step. By selecting the features that will be used later on in this research, we did feature selection first to prepare for the next important features to be analyzed [18]. Data cleaning is a method used to address issues or errors in the dataset that will be analyzed. This stage involves handling missing values, duplicates, renaming columns, and other tasks to prevent numerous outliers [19]. Moreover, data transformation involves altering raw data to make it suitable for analysis, such as creating variables or features to fulfill the requirements of the analysis purpose [20]. There are several techniques that can be applied, such as convert categorical variables into numerical types and attribute construction. Table II is the formula used in creating RFM + Discount Proportion attributes:

TABLE II. RFM + DP FORMULA

| RFM Attribute | Calculation Formula |
|---|---|
| Recency(R) | $\sum_{i=1}^{n}(T_{now} - T_i)$ |
| Frequency(F) | $\sum TP_i$ |
| Monetary(M) | $\sum_{i=1}^{n} TAS_i$ |
| Discount Proportion (DP) | $\frac{\sum_{i=1}^{n} T_{discount,i}}{\sum_{j=1}^{m} T_{payment,j}} * 100\%$ |

## C. Normalization

Data normalization is a way of turning data into a series with the same range. In general, the normalization that is often used in research is Min-max normalization. The formula for Min-max normalization is as follows [21]:

$$x' = \frac{x - \min(x)}{\max(x) - \min(x)} \quad (1)$$

In this formula, the attributes value will be on a scale of 0 to 1. So, the RFM attributes created will be normalized so that the attribute ranges are not significantly different from each other.

## D. Cluster Analysis

Clustering is methods that can assist us in analyze our data by identifying similarities among data points. Each data point refers to each object or individual present in the data. Therefore, clustering groups data points based on the similarity of their attributes with the goal of discovering patterns of dataset [22].

The clustering method is a process grouping data objects that are similar to each other into the same cluster but different from objects in other clusters [10]. There are various types and algorithms of clustering. Here are the algorithms that will be explained along with their working steps:

*1) K-means:* K-Means is an unsupervised learning algorithm for grouping data objects based on the shortest distance between data points. K-Means algorithm steps are as following [23]:

- Determine the value of k as many as the number of clusters.
- Select the data that will be the center of the cluster or temporary centroid.
- The algorithm will calculate the distance between objects to the centroid and then group them.

$$d(x,y)=\sqrt{(|x_1 - y_1|^2 + \cdots + |x_n - y_n|^2)} \quad (2)$$

- Calculate the next centroid value with the average value of the data that has been obtained.
- Repeat until the condition is met or there is no more cluster changes.

*2) K-medoids:* K-medoids is an algorithm that is similar to K-means in its clustering process. However, in K-medoids, there are medoids that serve as the representatives of the clusters. The following is the mechanism of the K-medoids algorithm [24]:

- Initiate by choosing a temporary medoid as the initial medoid.
- In this step, each data object is assigned to the medoids that have the shortest distance (minimum distance).
- For each medoid, it's tested by swapping it with each non-medoid point one by one. If this swap reduces the total cost.
- Choose the lowest total cost.
- Repeat steps 2 to 4 until there is no medoid change so that clusters and the members of their corresponding clusters are acquired.

*3) Fuzzy c-means:* Fuzzy c-means is a clustering algorithm that is flexible and can classify a data object into two or more clusters based on its membership level. This can be referred to as soft clustering. The workings of the Fuzzy c-means (FCM) algorithm are as follows [25]:

- Determine the data to be grouped or clustered where X is a matrix of size i x j.
- Set the values needed for the FCM calculation, such as maximum iterations, expected number of clusters, epsilon value, objective function, and rank matrix partition (w).
- Initialize the partition matrix randomly.
- Calculate cluster center with the formula:

$$V_{kj} = \frac{\sum_{i=1}^{n}((\mu_{ik})^{w} * X_{ij})}{\sum_{i=1}^{n}(\mu_{ik})^{w}} \tag{3}$$

- Calculate the distance to the objective function with the following formula:

$$P_t = \sum_{i=1}^{n}\sum_{k=1}^{c}\left(\left[\sum_{j=1}^{m}\left(X_{ij} - V_{kj}\right)^2\right] * (\mu_{ik})^{w}\right) \tag{4}$$

- Update the partition matrix:

$$\mu_{ik} = \frac{\left[\sum_{i=1}^{n}(X_{ij} - V_{kj})^2\right]^{\frac{1}{(w-1)}}}{\sum_{k=1}^{n}\left[\sum_{i=1}^{n}(X_{ij} - V_{kj})^2\right]^{\frac{1}{(w-1)}}} \tag{5}$$

- If the difference between the current partition matrix ($P_n$) and the initial partition matrix ($P_0$) is less than the epsilon value, or if the number of iterations (t) has reached the maximum number of iterations. The iteration stop.

*4) Mini-batch K-means:* Mini-batch k-means is like an alternative version of k-means algorithm because the working steps are quite similar but mini-batch k-means is designed for reduce the computational time [26] and use a random mini batch from the dataset to update the clusters [27]. Here are the steps:

- Randomly select a batch of data points from the dataset for the k-means Mini-batch algorithm.
- Assign the nearest centroid to each batch. The formula for finding the shortest distance can be done the same as the K-means algorithm.
- Update the centroids by calculating the average of data points within each cluster until convergence is reached. Convergence means the algorithm has stabilized, typically by comparing changes in centroid positions using the formula,

$$\Delta C = \sqrt{\sum_{i=1}^{k}\left|\left|C_i - C_i'\right|\right|^2} \tag{6}$$

- Repeat steps 2 to 3 for the next batch in the predetermined number of iterations.

## *E. Performance Evaluation*

The performance evaluation of the four algorithms above will also use and compare several performance metrics, the Silhouette Coefficient and Calinski-Harabasz Index. Here are the formulas for calculating the Silhouette coefficient and Calinski-Harabasz Index:

*1) Silhouette coefficient:* Silhouette coefficient is one of the performance metrics to calculate the quality of the algorithms. Check whether the algorithm used has reached a goodness point or not in clustering the data. A greater Silhouette coefficient indicates a better cluster [28]. These are the formula:

$$s(i) = \frac{b(i) - a(i)}{\max\{a(i) - b(i)\}} \tag{7}$$

*2) Calinski-Harabasz index:* CH Index metrics will calculate the variance ratio within clusters and also between clusters. The higher the CH value compared, the better the performance of the clustering algorithm [29]:

The best silhouette coefficient is a value that is close to 1, indicating that clustering has a good separation between clusters and consistent objects in the cluster. Meanwhile, the best CH value is the value that gives the highest number among all the k clusters.

## *F. RFM + Discount Proportion Analysis*

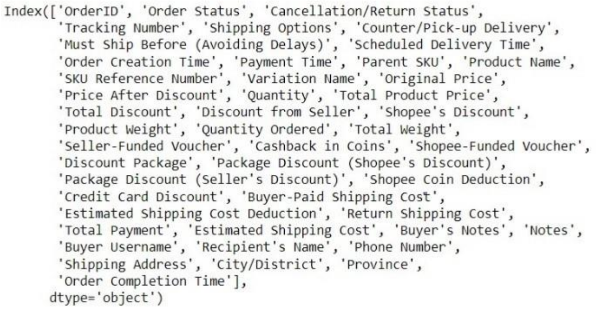
In this stage, the data distribution of each customer segment will be explained in detail, as well as the benefits of the Discount Proportion for the dataset being used.

# IV. Result and Analysis

Our background in conducting this research is that we want to test and compare several clustering algorithms for customer segmentation using primary data from one of the stores on the e-commerce platform and using the RFM + Discount Proportion model which can produce more deeper result of segmentation. The data that has been collected from MurahJaya888 consists of 1458 rows after being preprocessed and will be processed first because there are many missing values and unused columns which will result in many outliers. These are the steps of our analysis:

### A. Integrate Data Files

The dataset are obtained in separate .xlsx files per month. Therefore, we use the Python glob module to group specific file extension names. This approach helps us to combine data from multiple files, making analysis more comprehensive. These are the available columns of the dataset:



```
Index(['OrderID', 'Order Status', 'Cancellation/Return Status',
       'Tracking Number', 'Shipping Options', 'Counter/Pick-up Delivery',
       'Must Ship Before (Avoiding Delays)', 'Scheduled Delivery Time',
       'Order Creation Time', 'Payment Time', 'Parent SKU', 'Product Name',
       'SKU Reference Number', 'Variation Name', 'Original Price',
       'Price After Discount', 'Quantity', 'Total Product Price',
       'Total Discount', 'Discount from Seller', 'Shopee's Discount',
       'Product Weight', 'Quantity Ordered', 'Total Weight',
       'Seller-Funded Voucher', 'Cashback in Coins', 'Shopee-Funded Voucher',
       'Discount Package', 'Package Discount (Shopee's Discount)',
       'Package Discount (Seller's Discount)', 'Shopee Coin Deduction',
       'Credit Card Discount', 'Buyer-Paid Shipping Cost',
       'Estimated Shipping Cost Deduction', 'Return Shipping Cost',
       'Total Payment', 'Estimated Shipping Cost', 'Buyer's Notes', 'Notes',
       'Buyer Username', 'Recipient's Name', 'Phone Number',
       'Shipping Address', 'City/District', 'Province',
       'Order Completion Time'],
      dtype='object')
```

Fig. 2. Available columns.

Fig. 2 shows the columns available from the data we obtained to be further preprocessed including, data selection, cleaning, and the construction of the RFM + DP attributes for use in clustering. To calculate the DP attributes, we divide the total discount price by the total payment and then multiply the result by 100% (https://shorturl.at/afGKP).

### B. Preprocessing Data

*1) Data selection:* From the 46 available columns, our initial step was to select useful features for creating the RFM + DP attributes and drop columns that were irrelevant for analysis. Table III displayed the columns that we selected for analysis after this selection process, providing a clear overview of the chosen attributes. This streamlined approach ensured that only pertinent data were considered for the RFM + DP model development.

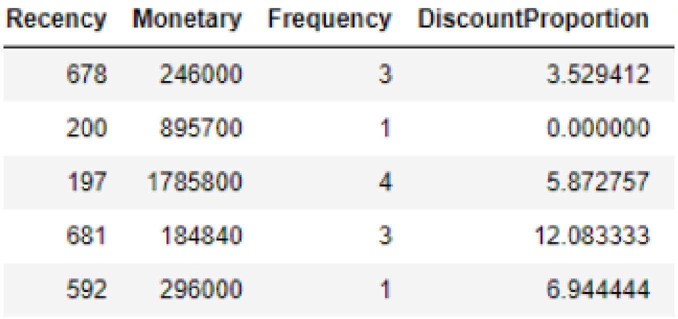
TABLE III. COLUMNS AFTER DATA SELECTION

| Columns | Description |
|---|---|
| Order ID | Unique identifier for each order |
| Product Name | Name of the product |
| Original Price | The price of the product before any discounts |
| Order Status | Indicates the current status of the order |
| Cancellation/Return Status | Indicates whether the order was canceled or returned |
| Quantity | The number of product purchased in the order |
| Total Payment | Total amount paid each order |
| Total Discount | Total discount applied to the order |
| Last Transaction Time | Timestamp of last transaction order |
| Username | User account name |

We opted to choose a subset of 10 columns from the total 46 columns available. These specific columns are derived from the RFM + DP attribute formula, crucial for the clustering analysis aimed at customer segmentation and insights. It's worth noting that certain details such as customer demographics and shipping information will be excluded to uphold privacy concerns. Additionally, the Last Transaction Time column is included to track the most recent shopping date for each customer.

*2) Data cleaning:* In the data cleaning stage, we perform several tasks such as renaming columns from Indonesian to English, removing missing values in the Cancellation/Return Status column which indicate cancelled orders. Then, we eliminate duplicate values and ensure that all Order IDs are unique.

*3) Feature construction for RFM + DP:* In this data transformation stage, firstly, we convert the data type from object to numerical for several columns. Additionally, we perform feature construction for RFM + DP. Fig. 3 is an example dataset of RFM + DP attributes:



| Recency | Monetary | Frequency | DiscountProportion |
|---|---|---|---|
| 678 | 246000 | 3 | 3.529412 |
| 200 | 895700 | 1 | 0.000000 |
| 197 | 1785800 | 4 | 5.872757 |
| 681 | 184840 | 3 | 12.083333 |
| 592 | 296000 | 1 | 6.944444 |

Fig. 3. RFM + DP attributes before normalization.

Furthermore, we also create distributions to observe the spread of data for each variable on a scale of 1-5, Fig. 4 indeed show data imbalance, particularly in Frequency and Monetary. Fig. 5 to Fig. 7 shows different types of scale. However, we cannot remove such data as it naturally occurs in transactions:

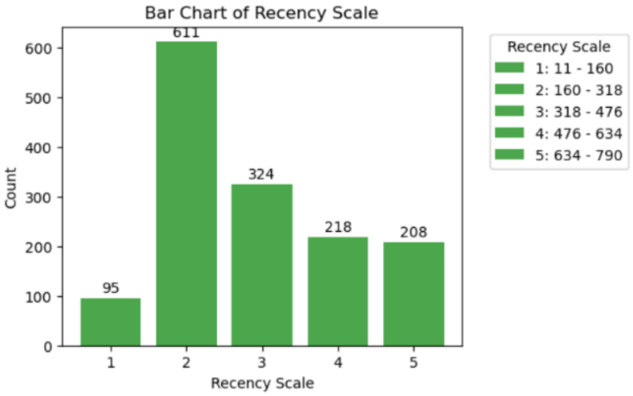


Fig. 4. Recency scale.

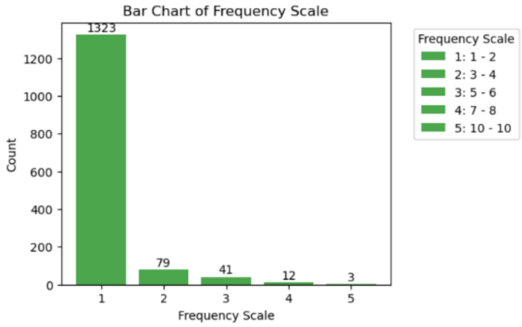

Fig. 5. Frequency scale.

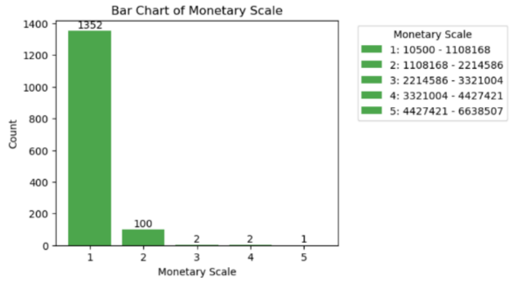

Fig. 6. Monetary scale.

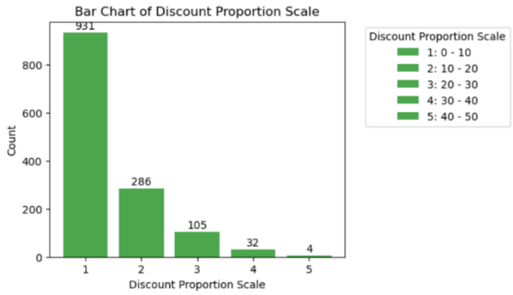

Fig. 7. Discount proportion scale.

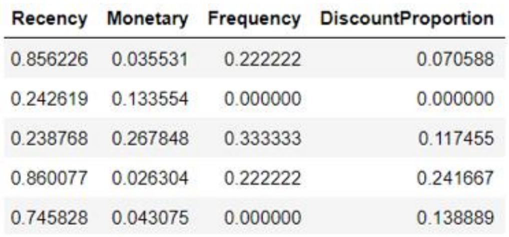
## C. Min-max Normalization

We changed the scale of the RFM + Discount Proportion attribute to 0-1. The aim is to minimize outliers and the value of attributes are relatively close to each other as shown in Fig. 8. These are the final results of the data with the normalized one:



| Recency | Monetary | Frequency | DiscountProportion |
|---|---|---|---|
| 0.856226 | 0.035531 | 0.222222 | 0.070588 |
| 0.242619 | 0.133554 | 0.000000 | 0.000000 |
| 0.238768 | 0.267848 | 0.333333 | 0.117455 |
| 0.860077 | 0.026304 | 0.222222 | 0.241667 |
| 0.745828 | 0.043075 | 0.000000 | 0.138889 |

Fig. 8. Min-Max normalization result.

## D. Cluster Analysis

Table IV represents the information of customer types in MurahJaya888 store, there are four types of customers such as, Platinum, Gold, Silver, and Bronze after done the segmentation to ensure the right marketing strategy:

*1) K-Means:* The implementation of clustering algorithms will be done on an apple-to-apple basis, meaning we will use a number of k=4 based on the elbow method, with random state of 42. This approach ensuring reliability and comparability in our analysis across various clusters. Fig. 9 shows that the optimal number of k is 4 because there is a significant change in the points that form an elbow, indicating that adding clusters after k = 4 provides less decreases of the inertia value. This provides a balance between minimizing inertia in the resulting clusters and maintaining a fair interpretation of the existing data. We also use library named KneeLocator to ensure the optimal number and the result shown that is 4.

TABLE IV. CUSTOMER CHARACTERISTICS

| Type of Customers | Values |
|---|---|
| Platinum | High Recency (↑)<br>High Frequency (↑)<br>High Monetary (↑)<br>High Discount Proportion (↑) |
| Gold | High Recency (↑)<br>Low Frequency (↓)<br>Neutral Monetary ( - )<br>Neutral Discount Proportion ( - ) |
| Silver | Low Recency (↓)<br>Low Frequency (↓)<br>Low Monetary (↓)<br>High Discount Proportion (↑) |
| Bronze | Low Recency (↓)<br>Low Frequency (↓)<br>Low Monetary (↓)<br>Low Discount Proportion (↓) |

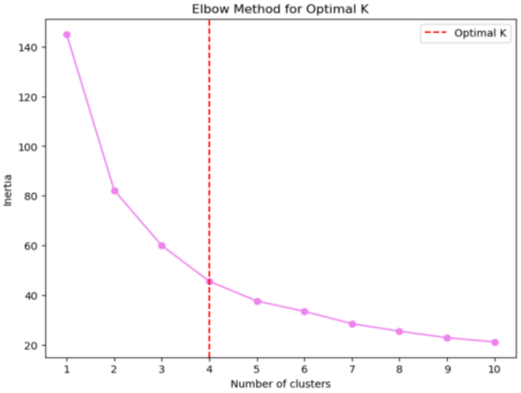


Fig. 9. Elbow Method for Optimal K.

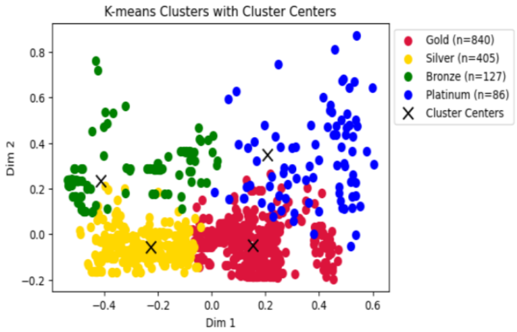

Fig. 10. K-means clustering result.

We used PCA to reduce our components or features to get better visualized in two dimensions. Since we can't plot all four features at once, it would make it difficult for us to understand the data distribution. Thus, PCA serves as a valuable technique for simplifying the data representation while preserving its essential characteristics. Fig. 10 shows the groups of data points in four colors: gold, silver, bronze, and platinum. The number of points in each group is shown by a number (n). The gold group has the most points (840), then silver (407), bronze (125), and platinum (86). There are 'X' marks that show the center or average spot of each group.

*2) Mini-batch K-means:* Mini-batch K-Means is often applied in larger datasets due to its characteristic nature of dividing the dataset into smaller portions.

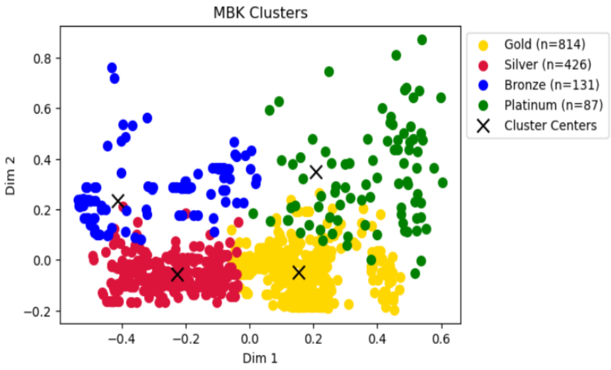

Fig. 11. Mini-batch K-means clustering result.

Fig. 11 demonstrates that with four clusters, its results align closely with those of the k-means algorithm, though there are slight differences in the number of points within some clusters. The distribution of points across the clusters is as follows: the gold cluster contains the highest number of points (814), followed by the silver cluster (426), the bronze cluster (131), and the platinum cluster (87). Surprisingly, the mini-batch k-means algorithm performs well, especially known for its efficiency in processing larger datasets. This efficiency is attributed to its method of dividing the data into smaller batches for each iteration. To achieve optimal clustering results, it's beneficial to experiment with different batch sizes to evaluate their impact on performance and computational time. Table V shows batch size iterations.

TABLE V. BATCH SIZE ITERATIONS

| Batch Size | Execution Time | Silhouette Score |
|---|---|---|
| 50 | 0.0638 seconds | 0.4534 |
| 100 | 0.0439 seconds | 0.3476 |
| 150 | 0.0499 seconds | 0.4829 |
| 200 | 0.0449 seconds | 0.4816 |
| 250 | 0.0439 seconds | **0.5002** |
| 300 | 0.0519 seconds | 0.4928 |
| 350 | 0.0568 seconds | 0.4899 |
| 400 | 0.0559 seconds | 0.4921 |

Mini-batch k-means performance was tested across different batch sizes ranging from 50 to 400, revealing a trade-off between execution time and silhouette scores. Smaller batch sizes like 50 and 100 offered faster execution but lower silhouette scores. As batch sizes increased, silhouette scores also improved, peaking at 0.5002 with a batch size of 250 which was identified as the optimal batch size considering both execution speed and performance.

*3) K-medoids:* The K-Medoids algorithm used here is quite similar to K-Means. However, in this case, the cluster centers are not represented by centroids but medoids. Medoids are points that represent the center of a cluster by assessing the distance between the medoid and all other points within the cluster. Fig. 12 is the results obtained from implementing the K-Medoids algorithm that produced four clusters.

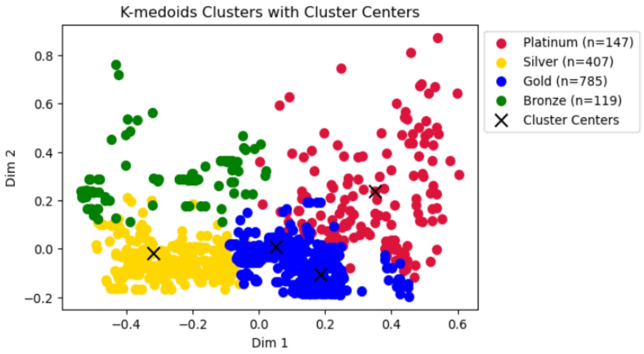

Fig. 12. K-medoids clustering result.

The points are distributed across the clusters as follows: the gold cluster contains the highest number of points (785), followed by the silver cluster (407), the bronze cluster (119), and the platinum cluster (147). K-medoids utilize the concept of medoids as the center point, rather than centroids. A medoid is a real member of the dataset, not an average value. It's possible that for the dataset we employed, K-medoids may not be as suitable, even though one of its advantages is its resilience to outliers.

*4) Fuzzy c-means:* The last algorithm tested was fuzzy c-means (FCM). This research implements FCM clustering using FCM in the fcmeans library. The FCM algorithm provided quite well-clustered results, similar to K-Means and Mini batch k-means, even though this algorithm is soft clustering, meaning it allows one data point to be included in different clusters. Therefore, there is a fuzziness parameter in the Fuzzy C-means algorithm to regulate the highest probability of each cluster data being most suitable for which cluster number.

We found that the optimal value is 1.1 based on its Silhouette score. Fig. 13 shows optimal fuzziness parameter. By selecting the optimal fuzziness parameter, we achieved improved cluster cohesion and separation in the FCM algorithm's results. The following Fig. 14 is the clustering results of FCM:

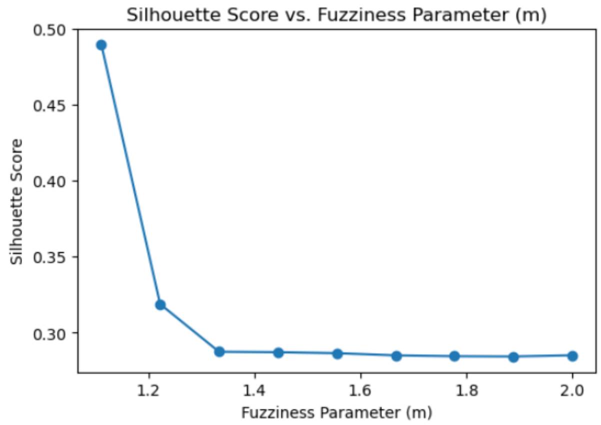

Fig. 13. Optimal fuzziness parameter (m).

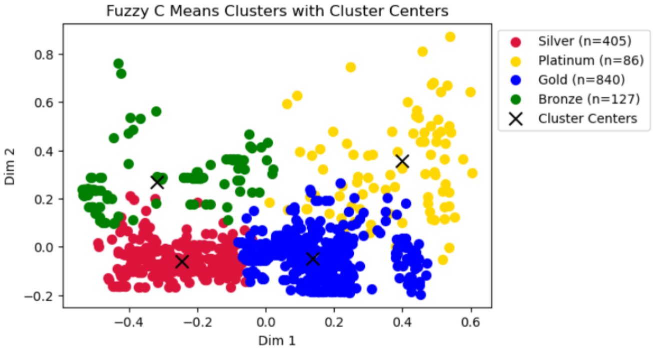

Fig. 14. FCM clustering result.

The FCM algorithm resulted in clusters with distributions almost identical to those produced by K-Means, with only slight differences in the dataset's data points. Among the clusters, the Platinum customers consist of a total of 88 customers considered potential. Next are the Gold customers, totaling 840, indicating that over 50% of customers either made their first purchase or returned to MurahJaya888? However, the Silver and Bronze clusters show fewer potential customers based on the reduced RFM + Discount proportion attributes.

### E. Performance Evaluation

In Table VI, we can see that there is very little significant difference between the algorithms K-means, FCM, and Mini batch k-mean in the measurement of the Silhouette score. However, here, there is the highest result obtained by the mini-batch k -mean, namely, 0.5002. Silhouette score values that are > 0.5 are indicated as well clustered, which means that the data points are grouped well enough based on their similar characteristics. However, again that evaluation is not only influenced by the nature of each algorithm but also caused by other factors.

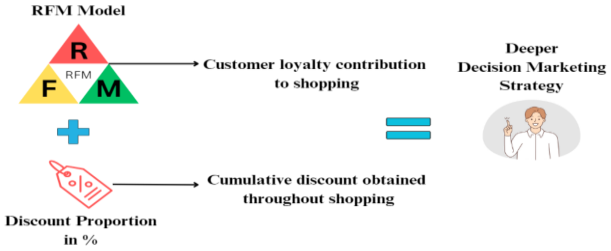
TABLE VI. CLUSTERING PERFORMANCE

| Model | Silhouette Score | CH Index |
|---|---|---|
| K-Means | 0.4921 | 1056.40 |
| Mini batch K-means | 0.5002 | 1053.18 |
| K-Medoids | 0.4714 | 966.45 |
| FCM | 0.4899 | 1055.39 |

Other factors include the characteristics of the datasets. In this sales data, we do have outliers like Recency and Monetary values that are unbalanced. But we can't just delete it because the data is important. For example, in this case of sale, it must be in one store to sell a lot of goods at different prices. If there are a few users who just buy expensive stuff. That could have caused the outlier not to go shopping too often. When we measured by the CH Index, the highest result was achieved by K-means with a value of 1056.40.

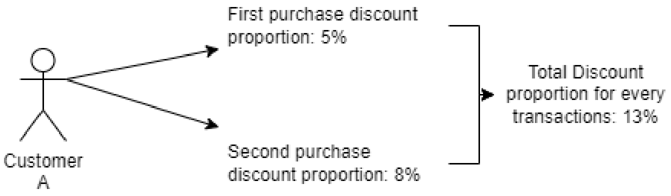
### F. RFM + Discount Proportion Analysis

The use of RFM strategy in analyzing RFM model is quite common to be implemented either by scoring the RFM attributes or by using machine learning. However, our focus here is to add a new attribute, namely Discount Proportion in Percentage. An example illustration of DP is as follows in Fig. 16 and Fig. 15 shows RM +DP model.



RFM Model
R
RFM
F
M
Customer loyalty contribution to shopping
Deeper Decision Marketing Strategy
Cumulative discount obtained throughout shopping
Discount Proportion in %

Fig. 15. RFM + DP Model.



First purchase discount proportion: 5%
Customer A
Second purchase discount proportion: 8%
Total Discount proportion for every transactions: 13%

Fig. 16. Discount proportion illustration.

So, suppose client A spends 500,000 (IDR) in one transaction and gets a discount of 25,000 (IDR) so that when calculated the discount obtained from the purchase is 5%. It keeps counting and calculating for all their spending on different dates. These are the advantages of using this RFM + DP model:

- We can see it not just from the side of their shopping behavior. However, also from the internal side that is, the use of discounts. For example, in the case of this small MurahJaya888 dataset. They sell items that are not so varied and their customers can be categorized not so much. However, the feature construction of this Discount Proportion can give them insight into whether a customer can be classified as a loyal customer even though the discount given by the seller is large.
- This model can also be applied to cases of large datasets or retail stores that like to give discounts to their customers. Seeing from this side, they can determine whether giving continuous discounts can attract customers or cause losses.

- RFM usage can vary not only basic RFM, Discount Proportion provides insight on increasing customer loyalty by giving appreciation for their loyalty.

We attempted to analyze based on the cluster results produced by each algorithm and calculated the mean for each cluster. The overview can be observed in Table VII:

TABLE VII. CLUSTERING RESULT FOR RFM + DP ATTRIBUTES

| | | **Mean** | | | | |
|---|---|---|---|---|---|---|
| **Algorithms** | **Customer Types** | **Recency (Days)** | **Monetary (Rupiah)** | **Frequency (Times)** | **Discount Proportion (Rate)** | **Count** |
| K-Means | Platinum | 144 | 1.245.129 | 5.24 | 16.4 | 86 |
| | Gold | 272 | 407.360 | 1.2 | 7.5 | 840 |
| | Silver | 586 | 364.544 | 1.19 | 5.59 | 405 |
| | Bronze | 608 | 130.274 | 1.16 | 24.9 | 127 |
| Mini-batch k-means | Platinum | 137 | 1.269.237 | 5.3 | 14.9 | 87 |
| | Gold | 275 | 408.150 | 1.15 | 7.14 | 814 |
| | Silver | 611 | 327.639 | 1.2 | 7.4 | 126 |
| | Bronze | 495 | 174.592 | 1.24 | 28.6 | 131 |
| K-Medoids | Platinum | 151 | 1.039.860 | 4.01 | 12.8 | 147 |
| | Gold | 282 | 380.022 | 1.08 | 6.9 | 785 |
| | Silver | 591 | 361.116 | 1.2 | 5.7 | 407 |
| | Bronze | 604 | 121.179 | 1.15 | 25.4 | 119 |
| Fuzzy c-means | Platinum | 144 | 1.245.159 | 5.25 | 16.38 | 86 |
| | Gold | 273 | 407.363 | 1.13 | 7.15 | 840 |
| | Silver | 586 | 364.445 | 1.2 | 5.6 | 405 |
| | Bronze | 610 | 129.290 | 1.16 | 25.1 | 127 |

The customer segmentation reveals different clusters with unique characteristics. The "Platinum" segment, consisting of around 6-8% of customers, represents the highest tier. They enjoy significant discounts and remain loyal. Implementing exclusive discount programs and referral rewards can enhance their satisfaction. The "Gold" cluster, while stable overall, shows lower frequency values possibly due to its larger size. The "Silver" group, with many customers, requires analysis of their preferences for tailored marketing strategies. On the other hand, "Bronze" segment relies heavily on discounts but makes fewer purchases at MurahJaya888.

## V. CONCLUSION

This study compares four partition methods of clustering algorithms, k-means, k-medoids, FCM, and mini-batch k-means, by producing three clusters, namely clusters 0, 1, 2, and 3. Based on the results we obtained and concluded, The Mini-batch K-means algorithm obtained the highest silhouette index value compared to the others, around 0,5 of accuracy. Meanwhile, the k-means algorithm managed to get the highest CH index value, namely 1056, 40. Therefore, the conclusion that can be drawn from this dataset is that the MurahJaya888 store still has not reached a large number of potential customers. Due to the limitations of dataset rows, additional datasets could be utilized to further explore the effectiveness of this model. For future research, other clustering algorithms such as density-based or hierarchical clustering could also be considered.

## ACKNOWLEDGMENT

The authors gratefully acknowledge the financial support provided by Binus University Jakarta for this research, as well as all those involved in the writing process.

***Abstract*—Facebook users generate a vast amount of data, including posts, comments, and replies, in various formats such as short text, long text, structured, unstructured, and semi structured. Consequently, obtaining import information from social media data becomes a significant challenge for low-resource languages such as Afaan Oromo, Amharic, and Tigrigna. Topic modeling algorithms are designed to identify and categorize topics within a set of documents based on their semantic similarity which helps obtain insight from documents. This study proposes latent Dirichlet allocation, matrix factorization, probabilistic latent semantic analysis, and BERTopic to extract topics from Facebook text comments in Afaan Oromo, Amharic, and Tigrigna. The study utilized text comments from the Facebook pages of various individuals, including activists, politicians, athletes, media companies, and government offices. BERTopic was found to be the most effective for identifying major topics and providing valuable insights into user conversations and social media trends with coherence scores of 82.74%, 87.85%, and 81.79% respectively.**

***Keywords*—*Afaan oromo; amharic; tigrigna; BERTopic; topic extraction; social media data***

## I. Introduction

Social media platforms now offer various features and tools for online resource sharing, rapid conversation, and improved communication through digital technologies such as comments such as shares, and replies. The vast amount of data generated on these platforms is valuable for comprehending user behavior, predicting trends, and analyzing sentiments [1]. Analyzing social media data is vital for gaining insight into user discussions and identifying emerging trends [2].

Topic modeling is used in natural language processing and text mining to automatically identify and extract meaningful topics from textual data and to provide insights into user discussions. Common topic modeling techniques include Latent Dirichlet Allocation (LDA), non-negative matrix factorization (NMF), Probabilistic Latent Semantic Analysis (PLSA), Latent Semantic Analysis (LSA), and BER Topic. Topic modeling algorithms are categorized into traditional and recent topic modeling algorithms. Topic modeling algorithms like LDA, NMF, PLSA, and LSA are used for social media data analysis, but traditional methods may be less effective due to deployment costs and limited metadata sources [2].

Despite their popularity, these techniques have limitations, requiring multiple topics, stop-word lists, stemming, and lemmatization. They use a bag-of-words representation that disregards word order and meaning [3].

Recent studies have explored a topic modeling approach for text classification, using sentence embedding, semantic similarity grouping, and c-TF-IDF to determine topic distribution among texts [4].

BERTopic is a recent method that uses UMAP and HDBSCAN to generate a comprehensive list of document topics for lexicon, text classification, information retrieval, and abuse detection [5].

The study analyzed over 240,000 Spanish immigrants' hate speech tweets using unsupervised machine learning and latent Dirichlet allocation techniques between November 2018 and April 2019 [6].

A study analyzed a dataset of 1,424 NATO-supporting videos, revealing 8,276 comments, while 3,461 NATO-opposing videos had 46,464 comments [7]. The researchers utilized LDA topic modeling to extract semantic information from documents and analyzed the impact of toxicity levels on narratives, including pro- or anti-NATO videos and their linked comments [7].

Obadimu et al. [8] used structural topic modeling to analyze racial prejudice in social media posts, identify hate speech, and determine abusive language frequency using Gibbs sampling and human assessment.

The study used an unsupervised topic model to cluster Afaan Oromo documents, learning a combination of latent topics in a probability distribution representation over vocabularies [9]. Researchers utilized word embedding techniques, semantic correlation with LDA, and Gibbs sampling to improve topic quality. Evaluations include perplexity, topic coherence, and human assessment [9].

The authors conducted a study on STTM algorithms for short-text topic modeling using Real-World Pandemic Twitter and Real-World Cyberbullying Twitter datasets, to evaluate topic coherence, purity, NMI, and accuracy [2].

Topic modeling is a method that evaluates social media texts using tools such as latent semantic analysis, latent Dirichlet allocation, non-negative matrix factorization, random projection, and principal component analysis [10]. The authors use a Comparative Analysis (LDA) method to identify hate speech types on social media, focusing on religion, race, disability, and sexual orientation, requiring text cleaning [11]. BERTopic is a recent method for extracting topics from documents by clustering lower-dimension approximations, thereby reducing the computational difficulty in determining related word embedding closeness [12]. BERTopic offers UMAP to reduce dimensionality by eliminating noisy data, while HDBSCAN clusters samples and minimizes outliers. The study utilized LDA for topic modeling in web content classification, concluding that sentiment analysis and topic modeling are crucial for effective classification [13]. T. Davidson and D. Bhattacharya [14] used a structural topic modeling method to examine racial bias within an online abuse dataset.

The second types of topic modeling algorithms are BERTopic and To2Vec used to represent topics from the document. BERTopic and Top2Vec frameworks enhance topic representation accuracy, prompting further research on social media text data topics, a class-based variant of TF-IDF. Angelov [15], employed joint document and word semantic embedding to identify topic vectors without relying on stop-word lists, stemming, or lemmatization. The experiment reveals that top2vec outperforms probabilistic generative models in identifying more informative and representative themes in the trained corpus [15].

Topic modeling, an unsupervised technique using UMAP and HDBSCAN, is used to create a comprehensive document topic collection and interpretable c-TF-IDF for social media text data topics [10].

Silva et al. [16] employ BERTopic topic models for Portuguese political comments on Brazil's Chamber of Deputies bills, adjusting parameters to improve accuracy and align with research direction.

Topic modeling techniques for Afaan Oromo, Amharic, and Tigrigna, face unique challenges due to their rich morphology, complex syntax, lack of pre-trained models, and informal expressions, necessitating adaptation of existing algorithms.

Previous studies primarily focus on resource-rich languages such as Arabic, English, Portuguese, and Spain, which have their own compiled list of stop words, spelling error checkers, and word disambiguating tools. Limited studies have explored the recent BERTopic and Top2vec topic representation algorithms to extract topics from social media data that involve short text, and nonstandard language.

Research Objectives: the aim of this study is to 1) apply LDA, LSA, NMF, PLSA, and BERTopic models to extract topics from Afaan Oromo, Amharic, and Tigrigna, particularly to a) compare the performance of proposed topic modeling methods, b) adapt the outperformer from LDA, LSA, NMF, PLSA, and BERTopic for extracting topics from Afaan Oromo, Amharic, and Tigrigna Facebook Text comments, 2) investigate organic discussion in various languages on a Facebook platform such as cross-cultural communication, language analysis, hateful content analysis, and social Trends/Topics.

This study contributes to 1) the development of a large-scale multilingual dataset for Afaan Oromo, Amharic, and Tigrigna from Facebook pages, 2) the construction of language embedding for document transformation, 3) comparing the performance of LDA, LSA, NMF, and PLSA and BERTopic's effectiveness in extracting quality topics, 4) adapt BERTopic and evaluates its hyperparameter tuning, and 5) Investigation of organic discussion across languages in Facebook.

The findings of this study will enable researchers and practitioners to effectively analyze and understand user discussions, trends, and sentiments in Afaan Oromo, Amharic, and Tigrigna social media platforms, facilitating a deeper understanding of user behavior and the development of targeted strategies and interventions.

## II. Related Work

To extract topics from Afaan Oromo for getting insight information text comments, a few studies were attempted on Afaan Oromo and Amharic whereas no study on the Tigrigna text document.

The study uses an unsupervised topic model for document clustering in Afaan Oromo documents, learning latent topics in probability distribution representation over vocabulary [9]. Word embedding and LDA algorithm improve theme quality. Performance is validated through Perplexity, Topic Coherence, and human assessment [9].

The study evaluated the effectiveness of pre-trained word embedding techniques, deep learning algorithms, and BERTopic in extracting topics and classifying hateful speech in Afaan Oromo Facebook comments [17].

There are also topic modeling approaches applied for Amharic [18] and [19]. The paper proposes a concept-based single-document Amharic text summarization system using topic modeling, specifically probabilistic latent semantic analysis (PLSA)[19]. The algorithms are language and domain-independent, allowing for use in other local languages [19]. The authors propose six algorithms, each with two common steps: selecting keywords and selecting sentences with the best keywords[19]. They experimented with news articles and found encouraging results after varying extraction rates [19].

This study develops a supervised topic model using LDA for an Amharic corpus, examining the impact of stemming on topic detection using four supervised machine learning tools: Support Vector Machine (SVM), Naive Bayesian (NB), Logistic Regression (LR), and Neural Nets (NN) [18]. The approach outperforms state-of-the-art TF-IDF word features with an 88% accuracy rate, suggesting that stemming slightly improves the topic classifier's performance [18]. On the other hand, no study applied topic modeling for the Tigrigna text document.

## III. Methodology

This paper proposes a topic modeling approach for extracting topics from Afaan Oromo, Amharic, and Tigrigna text comments using LDA, LSA, PLSA, NMF, and BERTopic, and evaluates it using topic coherence score and then adapts the outperformer algorithm. Fig. 1 shows the details of the proposed methodology. In this study, we applied the following methodology to achieve the proposed objectives.

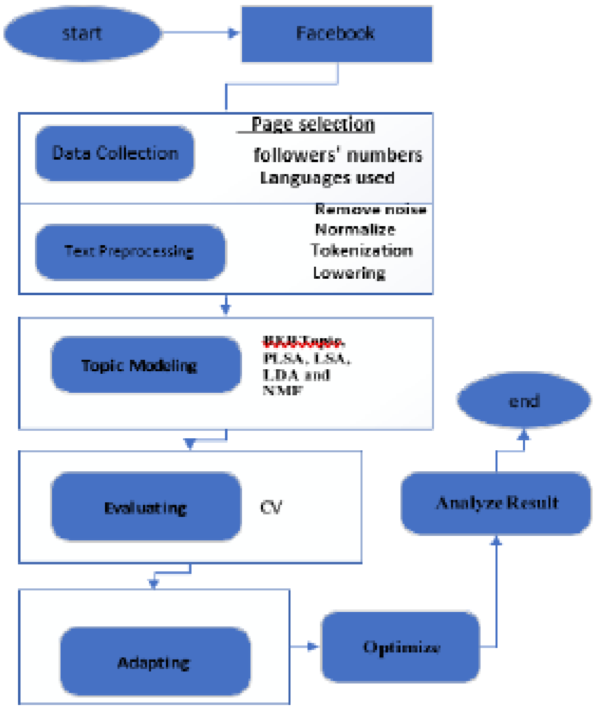

Fig. 1. Topic modeling methods topics extraction proposed framework.

### A. Data Collection

Because Facebook is the most dominantly used social media network in Ethiopia, it was used as a source of data to collect data from Afaan Oromo, Amharic, and Tigrigna. In addition to collecting new data, we used an existing dataset to construct a large dataset. A large Afaan Oromo social media dataset was prepared by collecting data from various Facebook pages, including those of activists, politicians, athletes, media companies, and government offices[17]. We selected Fakebook pages with at least 21000 followers of Afaan Oromo. We recruited five master's students from computer science and information technology, two from information technology, and three from computer science, to gather data. The experts who collected Afaan Oromo's text comments from September 2019 to October 2022 completed the data collection within two months. Amharic dataset available at https://data.mendeley.com/datasets/fhvsvsbvtg/3 and also available at https://data.mendeley.com/datasets/ymtmxx385m/1.

The 10827 and 35000text comments were gathered from specified those sources respectively. We also gathered 13882 Tigrigna text comments from Facebook pages of media companies, politicians, activists, websites, public services, interests, people, and political parties with over 15,000 followers. From June 2023 to August 2023, text comments from 2018 to 2023 were gathered by experts from five master's students of computer science and information technology. The Amharic hate speech detection dataset, which includes 35000 text comments, was translated into Tigrigna using Google Translator. Finally, to compile 48882 Tigrigna text comments.

### B. Text Preprocessing

This study focuses on text preprocessing and removing unnecessary content such as HTML links, tags, numbers, punctuation, and stop words to create clean comments. It also tokenizes plain text, eliminates non-Afaan Oromo, non-Amharic, and non-Tigrigna words, and converts all comments to lowercase.

### C. Applying LDA, LSA, PLSA, NMF, and BERTopic to Develop the Proposed Model

The proposed model was developed using LDA, LSA, PLSA, NMF, and BERTopic to extract quality topics, and its performance was compared. LDA automatically extracts topics from documents based on the relevance of connected topics within texts and documents [3]. Studies have primarily focused on long-text topic modeling approaches, including classic methods, such as latent Dirichlet allocation[3], LSA[9], PLSA[19], and NMF[20] which are commonly used to extract latent semantic structures in long texts. Short-text generation is becoming more prevalent, but long-text TMs are less promising owing to their limited content and difficulty in finding topic co- occurrence [20]. Despite their popularity, these techniques have drawbacks, such as requiring numerous topics, stop-word lists, stemming, lemmatization, and relying on a bag-of-words representation that disregards word order. The study utilized coherence measurement CV to evaluate the efficacy of topic modeling [15]. In 2019, Angelov tests demonstrated that top2vec outperformed probabilistic generative models in identifying more informative and representative themes in a trained corpus [2]. Researchers have employed joint document and word semantic embedding to identify topic vectors without the need for stop-word lists, stemming, or lemmatization [15]. BERTopic is a recent method that uses lower-dimension approximations to extract topics from documents, thereby reducing the computational complexity in determining related word embedding closeness[12]. Unlike traditional topic modeling methods, BERTopic eliminates human judgment or intervention in developing suitable models, focusing solely on selecting parameters for model training.

### D. Comparing the Performance of LDA, LSA, PLSA, NMF, and BERTopic Models

The study utilized LDA, LSA, NMF, PLSA, and BERTopic to extract topics from a dataset with topic coherence scores to assess their performance.

### E. Topic Extraction

The proposed topic extraction techniques, including LDA, LSA, NMF, PLSA, and BERtopic, were applied to develop

Topic Modeling Topic extraction and Hate Speech Analysis (TMBTEHSA), evaluating topic quality.

### F. Evaluation

Evaluating the effectiveness of LDA, LSA, PLSA, NMF, and BERTopic in extracting topics from Afaan Oromo, Amharic, and Tigrigna social media data is crucial for assessing semantic coherence and topic diversity. Topic coherence is a linguistic concept that automatically evaluates the interpretability of latent topics based on the distributional theory, which suggests similar meanings often appear in similar contexts [16]. The study confirms that the coherence measurement CV is a reliable tool for evaluating the effectiveness of topic modeling, showing a positive correlation with human interpretability [21]. In this study, we utilized coherence measurement CV to assess the efficacy of topic modeling, as detailed in Table II.

### G. Optimization

Hyperparameter tuning is a technique used to optimize the parameters and configurations of an outperformer model based on the evaluation results to enhance the quality of the extracted topics. During this phase, the hyperparameters of the selected techniques were adjusted and tuned to improve the quality of the extracted topics (details of BERTopic optimization and adaption techniques are indicated in Fig. 2).

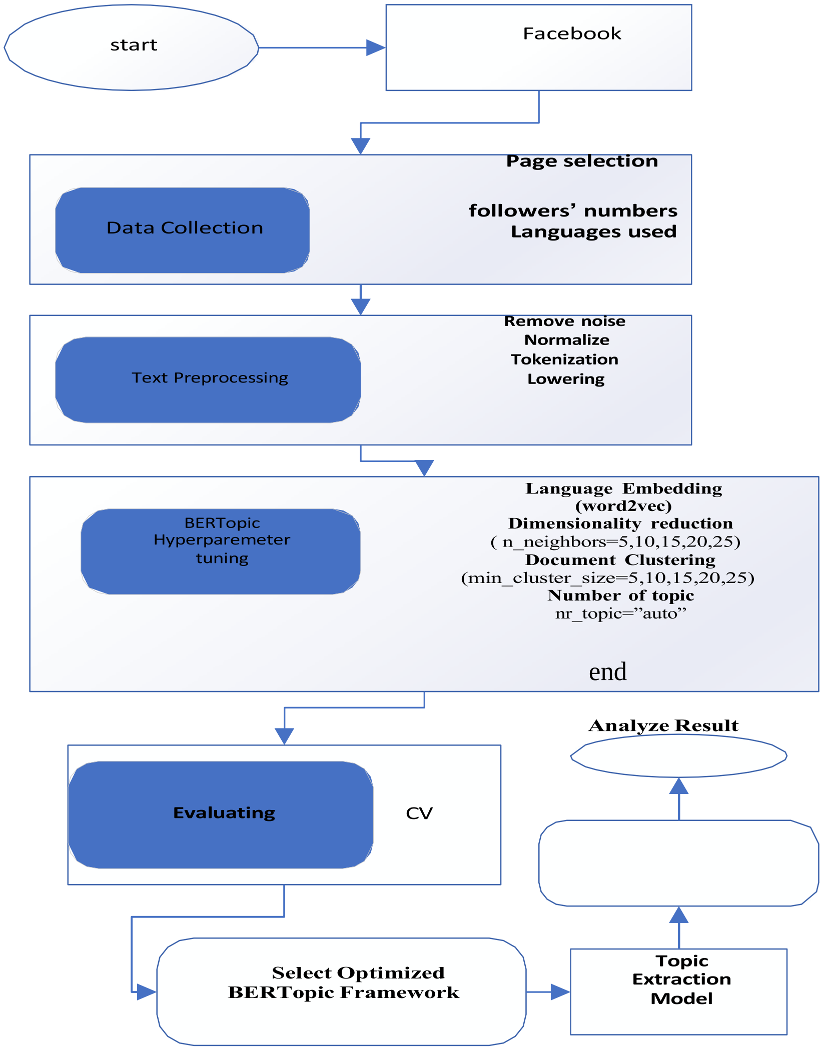

Fig. 2. Proposed framework for BERTopic parameters tuning.

### H. Implementation Environment and Programming Language

Python was used for the experiment, with Google Collaboratory scripts written using GPUs for faster data analysis and Excel for dataset preparation and CSV file saving.

## IV. Experiment

Two experiments were conducted to achieve the proposed objectives. First, the performance of the topic modeling algorithms was evaluated based on text comments prepared by Afaan Oromo, Amharic, and Tigrigna. Second, outperforming algorithms were adapted and optimized to develop the proposed model.

### A. Dataset

As indicated in the previous section, we used Facebook as a source of data to prepare a dataset consisting of Afaan Oromo, Amharic, and Tigrigna, with sizes of 59529, 45522, and 48882 text comments, respectively.

### *B. Experiment One*

The study compared topic modeling algorithms such as LDA, PLSA, LSA, NMF, and BERTopic in extracting topics from Afaan Oromo, Amharic, and Tigrigna social media data, revealing that BERTopic performed better in terms of topic quality, computational efficiency, and ease of implementation (details of the effectiveness of the algorithm in Table I). The framework of experiment two is indicated in Fig. 1.

### *C. Experiment Two*

As indicated in Table VI, the BERTopic scored a higher coherence score than LDA, PLSA, LSA, and NMF. Therefore, BERTopic was selected and optimized in experiment two to develop the topic extraction model from Afaan Oromo, Amharic, and Tigrigna social media data. In this study, we adapted the BERTopic algorithm to accommodate the characteristics of Afaan Oromo, Amharic, and Tigrigna's social media text. In the BERtopic adaptation phase, the framework of the BERTopic was modified based on the input Afaan Oromo, Amharic, and Tigrigna to handle the input text. Accordingly, the BERTopic framework was modified based on parameters from language embedding, dimensionality reduction, clustering document, and the size of topics (the detail approach described in Fig. 2).

### *D. BERTopic Hyperparameters Tuning Models*

Fine-tuning helps the models learn the patterns and semantics specific to Afaan Oromo, Amharic, and Tigrigna's social media text (see Table I). NLP faces the challenge of organizing and summarizing large text corpora, often utilizing topic modeling when intelligent reading and sorting are impossible.

Topic modeling is a popular research area in natural language processing that aims to extract topics from documents and words with minimal computer resources. When a person cannot read and sort through an enormous text corpus, topic modeling is employed [12]. P. Ghasiya and K. Okamura [12] used topic modeling to address the challenges of processing and understanding short text documents. BERTopic is a recent method for extracting topics from documents by clustering lower-dimension approximations, reducing the computational difficulty in determining related word embedding closeness [12].

Unlike traditional topic modeling approaches, BERTopic will not need to be upfront with current topics to develop a topic extraction model. In this sense, human judgment or intervention is absent from BERTopic, except in selecting the parameters for model training. The most popular embeddings in BERTopic are Sentence Transformers, Hugging Face Transformers, Flair, Spacy, Universal Sentence Encoder, Gensim, Scikit-Learn Embeddings, OpenAI, TF-IDF, Custom Embeddings, Custom Backend, and Multimodal.

In the first steps, since sentence transformers are pretty good at capturing the semantic similarity of documents, BERTopic begins by converting our input documents into numerical representations. In the second step, dimensionality reduction of the input embeddings is a critical component of BERTopic.

TABLE I. BERTOPIC HYPERPARAMETER TUNING SETUP

| Lang Emb | Dim Red | Cluste ring | No of Topics | lang |
|---|---|---|---|---|
| word2vec | 5 | 5 | auto | Afaan Oromo |
| word2vec | 10 | 10 | auto | Afaan Oromo |
| word2vec | 15 | 15 | auto | Afaan Oromo |
| word2vec | 20 | 20 | auto | Afaan Oromo |
| word2vec | 25 | 25 | auto | Afaan Oromo |
| word2vec | 5 | 5 | auto | Amharic |
| word2vec | 10 | 10 | auto | Amharic |
| word2vec | 15 | 15 | auto | Amharic |
| word2vec | 20 | 20 | auto | Amharic |
| word2vec | 25 | 25 | auto | Amharic |
| word2vec | 5 | 5 | auto | Tigrigna |
| word2vec | 10 | 10 | auto | Tigrigna |
| word2vec | 15 | 15 | auto | Tigrigna |
| word2vec | 20 | 20 | auto | Tigrigna |
| word2vec | 25 | 25 | auto | Tigrigna |

The calamity of dimensionality makes clustering challenging since embeddings are frequently highly dimensional. Because UMAP is the default value in BERTopic that can capture the local and global high-dimensional space in lower dimensions, researchers may find it worthwhile to experiment with alternative solutions, such as PCA. We can apply any other dimensionality reduction approach such reduction because BERTopic requires some degree of independence between phases.

The accuracy of our topic representations increases with the performance of our clustering technique, which makes the clustering process crucial. HDBSCAN is one component of BERTopic that can capture structures with varying densities. In addition, HDBSCAN and BERTopic use cuML HDBSCAN, agglomerative clustering, and k-means as examples of clustering mechanisms.

To accurately depict the topics from our bag-of- words matrix, TF-IDF was modified in BERTopic to work at the cluster, topic, and topic levels rather than the document level. "c-TF-IDF" refers to this modified TF-IDF representation, which accounts for variations across documents inside a cluster. BERTopic allows for directly adjusting several hyperparameters to improve the model's performance such as PCA, Truncated SVD, call MAP, and skip dimensionality.

*1) Language embedding:* BERTopic uses the sentence transformer's English version for document embeddings but requires an additional sentence-transformer model for low-resource languages. In this study, we build a word2vec pre-trained embedding model for Afaan Oromo, Amharic, and Tigrigna to transform text documents for dimensionality reduction in the BERTopic framework.

*2) Dimensionality reduction:* The UMAP algorithm is a clustering model that reduces dimensionality while maintaining local and global data structure. It can be customized with hyperparameters such as n_neighbors, and its default value is 15, resulting in larger cluster sizes. The BERTopic model uses UMAP's stochasticity for distinct outcomes.In this study, we focused on the n_neighbors parameters and tuned them to 25,15,10 and 5, as indicated in Table II, and then its performance was evaluated.

*3) Clustering:* The study uses HDBSCAN, a density-based clustering algorithm, to reduce dimensionality in embedded documents. It automatically determines cluster size using hyperparameters such as min_cluster_size, min_samples, metric, and prediction_data. To avoid new document prediction, set it to False, feed the model into the BERTopic technique, and include umap_model for comparability. In this study, we tuned the number min_cluster_size to 25,15,10 and 5, as indicated in Table II.

*4) Number of topics:* BERTopic uses the HDBSCAN model's clusters as topic count but can be adjusted by changing the nr_topics parameter. The default value for nr_topics parameters is 15, and the topic reduction procedure reduces related topics based on the c-TF-IDF feature vector, starting with low- frequency topics. As indicated in Table II, in this study, the BERTopic hyperparameter tuning nr_topics to auto throughout all experiments.

### E. BERTopic *Adaptation and Optimization*

Adapt the BERTopic algorithm to accommodate the characteristics of Afaan Oromo, Amharic, and Tigrigna social media text. In the BERtopic adaptation phase, the framework of the BERTopic was modified based on the input Afaan Oromo, Amharic, and Tigrigna to handle the input text. Accordingly, the BERTopic framework was modified based on parameters from language embedding, dimensionality reduction, clustering documents, and several topics extracted. After experimenting with evaluating the adapted BERTopic algorithm for topic extraction in Afaan Oromo, Amharic, and Tigrigna social media data, the hereunder results and discussions presented: - In this paper, the coherence score used to evaluate the performance of the adapted BERTopic. The coherence score calculates coherence scores for the extracted topics to assess their semantic coherence. Higher coherence scores indicate more coherent and meaningful topics. The coherence score for the adapted BERTopic is shown in Table II. As described in the Table III, the coherence score of the adapted BERTopic for Afaan Oromo is 82.74%. In contrast, the coherence score for Amharic is 87.85%. Similarly, the adjusted BERTopic coherence score for Tigrigna is 81.79%.

## V. Result and Discussion

This section describes the results of the topic extracted from Afaan Oromo, Amharic, and Tigrigna Facebook text comments. As we observed from experiment one above, the BERTopic scored highest accuracy than others applied topic modeling methods such LDA, LSA, PLSA, and NMF.

### A. *Afaan Oromo Social Media Data Topics and Description*

BERTopic was applied to Afaan Oromo text comments, revealing 1562 topics, with 14409 and 351 representing ethnically based hate and media hate, respectively. The discussion covered various topics, such as identity-based attacks, ethnic group-based attacks, and information that undermines others' ideas. Table IV revealed that both normal and hateful information is also delivered online, as indicated by topics extracted from text documents.

TABLE II. The Comparison of LDA, LSA, PLSA, NMF, and Bertopic in Developing Topic Extraction

| Methods | Performance per Languages | | |
|---|---|---|---|
| | Afaan Oromo | Amharic | Tigrigna |
| BERTopic | 82.74 | 87.85 | 81.79 |
| LDA | -16.83 | -14.77 | -14.52 |
| PLSA | 41.48 | 43.52 | 41.24 |
| LSA | 58.23 | 59.49 | 58.38 |
| NMF | 48.71 | 32.89 | 49.78 |
| BERtopic | 73.33 | 77.00 | 69.54 |

TABLE III. BERTopic Hyperparameter Tuning Setup

| Lang Emb | Dim Red | Clustering | No of Topics | Acc | lang |
|---|---|---|---|---|---|
| word2vec | 5 | 5 | auto | 82.74 | Afaan Oromo |
| word2vec | 10 | 10 | auto | 76.22 | Afaan Oromo |
| word2vec | 15 | 15 | auto | 73.33 | Afaan Oromo |
| word2vec | 20 | 20 | auto | 72.3 | Afaan Oromo |
| word2vec | 25 | 25 | auto | 70.02 | Afaan Oromo |
| word2vec | 5 | 5 | auto | 87.85 | Amharic |
| word2vec | 10 | 10 | auto | 82.81 | Amharic |
| word2vec | 15 | 15 | auto | 77.00 | Amharic |
| word2vec | 20 | 20 | auto | 74.60 | Amharic |
| word2vec | 25 | 25 | auto | 72.02 | Amharic |
| word2vec | 5 | 5 | auto | 81.79 | Tigrigna |
| word2vec | 10 | 10 | auto | 73.65 | Tigrigna |
| word2vec | 15 | 15 | auto | 69.54 | Tigrigna |
| word2vec | 20 | 20 | auto | 64.97 | Tigrigna |
| word2vec | 25 | 25 | auto | 61.73 | Tigrigna |

TABLE IV. Top 20 Topics Represented from Afaan Oromo Text Comments Topics

| Topic | Count | Name | Topic description |
|---|---|---|---|
| 0 | 14409 | 0_barnootaa_oromiyaa_godina_gaallaa | Describe about "Ethnically based hate." |
| 1 | 351 | 1_bbc_tv_televijiinii_channel | Describe the Media: |

| 3 | 285 | 3_milkii_milkaa_milkiin_minilk | Describe success |
| 4 | 249 | 4_amara_amaraan_amaran_kehil | Describe the Amhara ethnic group |
| 5 | 229 | 5_galatooma_galatoomaa_galatoomi_galatoomii | Describe about thanks |
| 6 | 212 | 6_galatomii_galatomi_galatoma_galatomaa | Describe about thanks |
| 7 | 211 | 7_minilik_miniliki_minilikii_diqalaa | Describe hate speech target person |

| | | | |
|---|---|---|---|
| 8 | 188 | 8_ahmed_ahmad_abiy_abi | Describe about person |
| 9 | 180 | 9_poolisiin_poolisii_federaalaa_pool | Describe police commission |

## B. Amharic Social Media Data Topics and Description

The application of BERTopic on the Amharic social media dataset has resulted in topics containing text comments across the entire dataset. This study selected and analyzed the top 21 topics despite the top 8 listed in Table V. Amharic social media dataset generated 1044 topics from Amharic text comments.

TABLE V. TOPICS EXTRACTED FROM AMHARIC SOCIAL MEDIA DATA

| Topic | Count | Name | Descriptio n of Topics Extracted |
|---|---|---|---|
| 0 | 18868 | 0_ሀይል_መንግስት_ሰራዊት_ከተማ | Describe military |
| 1 | 560 | 1_ወሎ_እውነትነው_አይዴላም_እንዳናስ ተውል | Describe appreciation |
| 2 | 142 | 2_ደስ_ይላል_አለሽ_አለህ | Describe appreciation |
| 3 | 142 | 3_አለ_ፈላሻው_ብትሆንልን_ዛዛታ | Describe hate speech |
| 4 | 132 | 4_የኢትዮጵያ_ጠላት_አምላክ_ደራርቱ | Describe hate speech |
| 5 | 106 | 5_እውነት_ብለሻል_ይገላልና_ቁጣ | Describe hate speech |
| 6 | 67 | 6_ሆይ_ጌታ_ይቅርም_ድረስልን | Describe about religion |
| 7 | 66 | 7_ነፍሳቸውን_ያኑርልን_በገነት_በአፀደ | Describe condolenc es |
| 8 | 65 | 8_ይማር_ነፍስ_ነብስ_ያማን | Describe condolenc es |

Topics 1 to 4 provide normal information. The Amharic social media dataset was used to extract topics with sizes of 18868, 560, 142, and 142, including normal content. Topic 5, with 132 text comments, outlines the Process of insulting and identifying a target to an individual. Topic 10, with 65 text comments, discusses hate crimes against specific individuals, including insult and identity hate. Topic 21 indicates that the normal content is attributed to individuals with a comment size of 45.

## C. Tigrigna Social Media Data Topics and Description

We analyzed 21 Tigrigna text comments and revealed that topics 1 and 2 provide normal information, while others contain hateful content about nationalist targets. The description of the top 10 topics is indicated in the Table VI below.

Table VII indicates the common topics extracted by applying BERTopic from the Ethiopian language social media dataset to data by experiment. Those topics extracted from Ethiopian social media data are normal or hate classified as antagonistic, identity hate, insult, and threats. As indicated in Table VI, alongside providing normal content, Afaan Oromo users utilize social media to spread hate against identity. Afaan Oromo users' people are also posting hate speech on Facebook in the form of insults. The experiment shows that insult is hating speech posted on social media platforms from Amharic text comments in addition to identity hate.

The top two topics extracted from Tigrigna indicate normal information, whereas the third describes individual nationality and antagonistic information targeted to individuals. Information emerging on Facebook pages in Afaan Oromo, Amharic, and Tigrigna generally relates normal information and hate speech. As Table VI illustrates, normal, insult, threat, antagonistic, and identity hate are the common types of information disseminated by Ethiopian social media data.

TABLE VI. TOPICS EXTRACTED FROM TIGRIGNA SOCIAL MEDIA DATA

| Count | Name | Description |
|---|---|---|
| 23723 | 0_እዩ_ናይ_ኣምሓራ_ህዝቢ | Describe the Amhara ethnic group |
| 396 | 1_ገለቴ_ፖፒ_ኣማርድ_ሓልዎን | Describe individual |
| 147 | 2_ነፍሲ_ወከፍ_ትመሃር_መድረኽ | Describe the stage of learning |
| 49 | 3_በዓል_ርሑስ_ልደት_ኢሬቻ | Describe the Irrecha celebration |
| 36 | 4_ፍትሒ_ደለይቲ_ኣቱም_ብደለይቲ | Describe about justice |
| 30 | 5_ሰናይ_ለይቲ_ይግበረልኩም_ፍሽኽታ | Describe a good evening |
| 23 | 6_ጅግና_ኣያና_ኣያኒ_ደብረፅ | Describe the appreciation of Debretsion |
| 23 | 7_ዓቃቢ_ሕጊ_ተቓውሞ_ተቓዊሙ | Describe against somebody |
| 20 | 8_ኣበይ_ኔርካ_ሓሲብካኒ_ራብከን | Describe individual- based hate |
| 19 | 9_ሰዓት_መስከረም_ንግሆ_ከይሰማዕኩም | Describe about ethnic group- based hate |

TABLE VII. COMMON TOPICS FROM ETHIOPIAN LANGUAGES SOCIAL MEDIA DATA

| S/No | Languages | normal | identity hate | insult | threat | antagonistic |
|---|---|---|---|---|---|---|
| 1 | Afaan Oromo | yes | yes | yes | yes | yes |
| 2 | Amharic | yes | yes | yes | yes | yes |
| 3 | Tigrigna | yes | yes | yes | yes | yes |

## VI. CONCLUSION

Topic modeling is used in resource rich languages, such as English, for analyzing massive amounts of data. This study examines various modeling techniques, such as LDA, LSA, PLSA, NMF, and BERtopic, for extracting topics from low-resource Ethiopian-language social media data to analyze hateful content. In this study, we collected 59529 text comments from the Facebook pages of Afaan Oromo, 45522 from Amharic, and 48882 from Tigrigna. The text preprocessing technique was applied to text comments, and a topic modeling approach was used to extract topics from preprocessed texts. The experiment findings show that BERTopic has a better coherence score than the others. This work employed BERTopic techniques to identify topics from Facebook comments in Afaan Oromo, Amharic, and Tigrigna, using pre-trained word2vec as language embedding for the translation of texts. We evaluated BERTopic's performance by setting parameters for topic extraction in low-resource datasets, training Word2Vec for text document transformation, and setting nr-topics to auto for optimal tuning. The second experiment demonstrates that Afaan Oromo, Amharic, and Tigrigna have topic coherence scores of 82.74, 87.85, and 81.79 percent at 5 n_neighbors, minimum_cluster size, and number of topics set to auto. The study revealed that Facebook users in Afaan Oromo, Amharic, and Tigrigna languages are posting both normal and hate content, including identity hatred, insults, threats, and combative language. The BERTopic model was assessed for its efficacy in addressing the challenges of short text, spelling errors, and context words in low-resource languages such as Afaan Oromo, Amharic, and Tigrigna. From the extracted topics we also concluded that both normal and hateful content are posted as comments. The experiment dataset in Ethiopia uses Afaan Oromo, Amharic, and Tigrigna languages, primarily from Facebook, with plans to expand to include other Ethiopian languages on other topic platforms.

## ACKNOWLEDGMENT

The support of Addis Ababa Science and Technology is greatly acknowledged. The author also wants to appreciate the support of Dr Kula Kekaba and Dr Solomon Teferra for their support scholarly for the completion of this paper.

*Abstract*—**Malaria threats have remained one of the major global health issues over the past decades specifically in low-middle income countries. 70% of the Kenya population lives in malaria endemic zones and the majority have barriers to access health services due to factors including lack of income, distance, and social culture. Despite various research efforts using blood smears under a microscope to combat malaria with advantages, this method is time consuming and needs skillful personnel. To effectively solve this issue, this study introduces a new method integrating InfoGainAttributeEval feature selection techniques and parameter tuning method based on Artificial Intelligence and Machine Learning (AIML) classifiers with features to diagnose types of malaria more accurately. The proposed method uses 100 features extracted from 4000 samples. Sets of experiments were conducted using Artificial Neural Network (ANNs), Naïve Bayes (NB), Random Forest (RF) classifiers and Ensemble methods (Meta Bagging, Random Committee Meta, and Voting). Naïve Bayes has the best result. It achieved 100% accuracy and built the model in 0.01 second. The results demonstrate that the proposed method can classify malaria types accurately and has the best result compared to the reported results in the field.**

***Keywords—Malaria diagnosis; malaria symptoms; artificial intelligence and machine learning classifier; malaria classifier***

## I. Introduction

Malaria has been endemic in the developing society and the most devastating illness in the African region which has 95% malaria cases and death burden and estimated 241 million has been [20] spent on malaria prevention and treatment strategies by the Ministry of Health and international partners in Kenya. This includes distribution of long-lasting Insecticide-treated Nets, indoor residual spraying (IRS) in selected areas, intermittent preventive treatment during pregnancy and effective malaria case management [11]. However, mortality has not decreased. According to the World Health Organization [19], malaria cases registered in Kenya were 6 million in 2021 and 228 million cases reported globally that led to 627,000 diseases worldwide in 2020. This problem is severe in sub-Saharan Africa where 94% deaths are registered annually. This condition is predicted to become worse especially in the Coastal and Western regions that are the pandemic that has compromised malaria treatment and intervention measures [15]. Moreover, 70% of the population of Kenya who live in rural areas lives below poverty level [20]. Malignant tertian malaria caused by plasmodium falciparum species accounts for over 99% of malaria cases in Kenya [9].

We conducted a study and discovered high rates of individuals who undertakes self-treatment when attacked by malaria in rural areas in Kenya. The study found that 98% of participants had symptoms of malaria within six months of the study. 85% of participants did not visit healthcare services due to various reasons. For example, lack of money, transport, consultation fee, treatment fee etc. 58% bought non-prescribed anti-malaria drugs for malaria treatment. These are issues that require intervention.

Machine learning (ML) gives powers to develop more accurate malaria diagnosis approaches, whereas ML-based-methods performance depends on the quality of input features (Symptoms). Various solutions including Artificial intelligence (AI) and ML with feature-set have been used to classify malaria into four types. Devi et al. [7], performed analysis of a feature set on malaria-infected erythrocyte classification, using the Artificial Neural Network–Genetic (ANN-GA) Algorithm. This process included illumination correction, erythrocyte segmentation, feature extraction and classification. Six features were identified and evaluated using different classifiers such as Support Vector machine (SVM), K-nearest neighbours (KNN) and Naïve Bayes (NB) algorithms with a dataset to detect malaria. The experimental results demonstrated that the dataset (combined morphological, texture and intensity data) outperformed other datasets. However, six features is not enough to detect malaria accurately.

A study was carried out by Oladele et al. [12] to develop Neuro-Fuzzy expert system diagnostic software implemented with Microsoft Visual C# (C Sharp) programming language and Microsoft SQL Server 2012 to manage the database. The authors conducted oral interviews with the medical practitioners whose knowledge was captured into the knowledge based on Fuzzy Expert System. Questionnaires were administered to the patients and filled in by the medical practitioners on behalf of the patients to capture the main symptoms. The strength noted is that DIAGMAL gave accurate diagnostic predictions. However, there is no indication of effective performance compared to other existing malaria diagnosis systems in the field.

Global Challenges Networking and Collaboration Fund

Recent academic research focused on ML techniques with data to predict malaria (Wang et al., [18]; Ramdzan et al., [13]; Shimizu et al., [16]. However, mortality is still increasing. A new annual World Malaria report from the World Health Organization has shown a dramatic rise in malaria deaths [19]. Besides, there is a lack of malaria diagnosis Apps stated by Marita et al.[9].

The proposed approach is based on Multiple algorithms applying parameter tuning to optimize model performance and to classify malaria symptoms accurately. Using InfoGainAttributeEval selected the most significant 100 features. The classifiers utilized Artificial Neural Networks (ANNs), Naïve Bayes (NB), Random Forest (RF) and Ensemble methods (Meta Bagging, Random Committee Meta, and Voting). To the best of our knowledge, existing researches have not considered this integrated method.

Our contributions involve a new method; (1.) combining InfoGainAttributeEval feature selection technique, selecting 100 most significant features extracted from 4000 samples. (2.) Parameter tuning approach that optimizes model's performance (3) Identified knowledge about local community needs, barriers of access to healthcare services in Western Kenya in remote community settings.

The main aim of the proposed study is to introduce a new method for malaria diagnosis integrating InfoGainAttributeEval feature selection techniques and parameter tuning methods based on Artificial Intelligence and Machine Learning (AI & ML) classifiers with features to accurately distinguish types of malaria, including Malignant, Tertian, Quartan and Suspected malaria.

Specifically, this study has the following objectives:

- Identify different sources to enable extraction of features and non-symptom related factors.
- Build state-of-the-art models based on ANN, NB, RF and Ensemble methods (Bagging, Random Committee & Voting) with features.
- Train the models using multiclass classifiers with features to measure model performances.
- Evaluate the methods and compare the results with the best results in the field to demonstrate the merit of the proposed method.

The proposed study is significant because the outcome is expected to alleviate diagnosis of malaria in the remote communities within which limited supply of doctors' struggle to provide adequate diagnosis. Overall, the local communities' healthcare needs will be met.

The remaining section of this paper is structured as follows: Section II reviews related work. Section III describes the methods, including samples (sources), data collection, feature extraction, feature selection, algorithms, patient's future inputs, participants responses including Ethical statement/participant consent. Section IV presents Evaluation metrics and it describes experimental procedures. Section V presents experimental results. Section VI provides discussion including comparisons, limitation, and strength of the proposed method. Section VII presents conclusion and future work.

## II. Related Work

### A. Artifical Intelligence and Machine Learning

First Conventional methods rely on the expert's skill for diagnosing malaria and are time consuming. As such various researchers have attempted to tackle malaria using Artificial Intelligence and machine learning techniques as a tool to predict risk factors.

Based on AI, Madhu et al., [23] predicted malaria using Artificial Neural Network with patient's history and symptoms. By applying back propagation learning rules, the results achieved 85% accuracy. However, this approach used limited dataset which can be improved by extending more dataset.

The study by Kim et al. [24] proposed a sensing method using digital in-line holographic microscopy (DIHM) combined with machine learning algorithms to sensitively detect unstained malaria-infected red blood cells. The DIHM-based AI does not require blood smear and the test results achieved 97.5% accuracy. However, this study only used 13 features which does not cover all essential symptoms.

Semakula et al. [25] used household information data and Bayesian belief network with defined probabilities methods to predict malaria. Their work achieved 91.11% accuracy. However, other factors such as environmental change was not considered in the study which has an impact of mosquitoes.

Equally, the study by Morang'a et al.[10] explored haematological data extracted from 2,207 participants in Ghana and used Machine learning approaches such as ANN to find the techniques that can accurately evaluate uncomplicated malaria (UM) from non-malarial infections (nMI) and severe malaria (SM), utilizing haematological parameters. ANN with three hidden layers was used to classify UM, nMI and SM. The multi-classification models scored in the range of 94% to 98% accuracy.

Similarly, Kumar et al, [26]. proposed malaria detection using deep convolution neural network. Their studies achieved 97% accuracy. However, the downside of this study was that the dataset used is not clear how they were selected and feature size. The accuracy from this data is questionable.

The latest trend in Machine learning has also been applied. The study by Sherrad et al., [15] was the first to explore convolutional neural networks to distinguish between infected and uninfected cells in thin blood smears. They used Convolutional Neural Network (CNN) since deep learning does not need hand crafted features, which is the biggest advantage.

There are other researchers who have applied deep learning with images. Fuhad et al., [27] proposed an entirely automated Convolutional Neural Network (CNN) based model for the diagnosis of malaria from the microscopic blood smear images. Using image data and CNN, they achieved 98.2% and 72.1% respectively for white blood cells. However, the accuracy needs improving for effective diagnosis.

Other researchers took a different approach to combat malaria. Santosh and Ramesh [14] conducted research to determine malaria abundances using ANN with clinical and environmental variables with Big Data on the geographical location of Khammam district, Telanagana, India. Their method utilized large data across different seasons to improve accuracy in real practice. The highest accuracy they achieved was 81.7%. However, this accuracy requires more exploration to improve malaria models. 12% of the environmental data and 7% of clinical data were missing and yet these variables are necessary to attain accurate predictive power. Therefore, correct predictive data are required to improve the accuracy.

The study by Shambhu et al. [28] provided a review of techniques and discusses (i) acquisition of image dataset, (ii) preprocessing, (iii) segmentation of RBC, and (iv) feature extraction. They also discussed selection, and (v) classification for the detection of malaria parasites using blood smear images.

Shimizu at el., [16] conducted a cross-sectional survey and recognized Plasmodium falciparum infections, Plasmodium vivax and Plasmodium knowlesi in the southern province of Thailand. Equally, Indonesia marked a key milestone in reducing 50% of dual plasmodium falciparum and Plasmodium vivax parasites which corresponds to 66% reduction in death rates from malaria.

The study by Arowolo et al., [1] proposed a combined a novel analysis of variance (ANOVA) with ant colony optimisation (ACO) approach as a hybrid feature selection to select relevant genes to minimise the redundancy between genes, using SVM for classification. The experimental outcomes based on the high-dimensional of gene expression data demonstrate that ANOVA-ACO can make relevant decisions for clinicians in the designs of drugs and approaches to eradicate malaria infections in humans. Although the strength seems promising, to be competent amongst the existing relevant work, the speed of the performance should be provided.

A study by Awotunde, et al. [2] developed a model to diagnose Malaria and Typhoid Fever using a Genetic Algorithm (GA), a Neuro-Fuzzy Inference System (GENFIS). They identified that GA module determines the best set of network parameters and distributes them to the appropriate hidden layer nodes. Their model achieved an accuracy of 97.2%."

To improve malaria diagnosis models, Awotunde, [3] utilised Support Vector Machine (SVM) algorithms and Adaboost, together with ensemble methods. Redundant or extraneous features were extracted using Chi-square to assess the model. The classification accuracy with six features obtained achieved 97%.

The studies above have considered uses of AI and ML approaches, NF rules based on symptoms to develop models for malaria diagnosis. But the existing approaches have not considered a combined method based on ANN and features to classify malaria into one of possible types more accurately. Moreover, the microscopic testing techniques cause delay at the start of treatment.

The proposed study uses a new method that has not been consider with the reported method to address this problem robustly.

### *B. Long-short Term Memory Network (LSTM)*

Another work by Awotunde et al., [4] proposed a framework to predict malaria-endemic in selected geographical locations such as Nigeria. In their work, long short-term memory (LSTM) classifier was employed with Satellite and clinical data. The results indicate that the LSTM algorithm provides an efficient method for detecting situations of widespread malaria. The results demonstrate higher accuracy. However, there was no indication of the size of data used and the data is used in the validation strategy.

## III. Methodology

The proposed approach is based on a combined method, using Artificial Intelligence (AI) and Machine Learning (ML) classifiers with features. The proposed method was chosen because while ML algorithms handles vast dataset and performs well in various domains, AI technique identifies correlations within data, thus making them good techniques to classify malaria in different types more accurately. The types are Malignant, Benign Tertian, Benign Quartan or Suspected malaria. Our methodology consists of five functional components as shown in Fig. 1 and are detailed below:

### *A. Sample (Sources)*

Samples consist of 4000 questionnaires and individual participants. A questionnaire was designed to gather resident's information about malaria issues. Initially, a pilot study was carried out using questionnaires with 100 students at Maseno University to assist in preparation and test the questionnaire's effectiveness (comprehension, logic, acceptability, length & technical quality) before the main data collection, in which the instrument was deemed suitable after the pre-testing.

### *B. Data Collection*

Data collected consisted of demographics, barriers of healthcare factors and malaria history (non-symptoms), symptoms (also known as features or data set) signs. After gaining consent from participants, out of 4000 participants, questionnaires were used to collect data from 3490 participants. The questionnaires were randomly handed to individual participating in the villages with the permission from the sub-chief of the area and administrator. The study covered a cluster of 125 in 6 villages in Ugenya, Alego and Gem in Siaya county in Western Kenya which are mosquito endemic regions. Also questionnaire were administered to 510 patients during clinical procedure (checking blood pressure, temperature, heartbeat, breath and colour of the eye to diagnosis malaria), and filled by nurse on behalf of patients through the assistance of medical officers in Siaya County Clinic Centres within the same clusters in Ugenya, Alego and Gem in Siaya County. We collected qualitative and quantitative data integrating symptom related factors including Malaria History, Malaria symptoms, signs and non-symptom related factors including demographics data e.g. Age, gender, location] and barriers of healthcare information. The data are important since it enables malaria diagnosis, indicates whether a patient suffered from malaria or not and enables the understanding of the patient's needs.

The sample size is adequate with the assumption that every member of the population had equal opportunity of being selected with 95% confidence level and confidence interval of 5%.

The data collection was conducted in the period of July/August 2019. This date was extended to December 2021 to January 2022 due to covid-19 restrictions. During the same period of data collection within the same clusters and county, symptoms were also extracted and the summary is presented in Table I.

### *C. Feature Extraction*

Symptoms are features used to diagnose (classify) malaria into one of the possible types. Types of malaria include Malignant, Benign Tertian, Benign Quartan and Suspected malaria. Each form of malaria is caused by distinct parasites. Malignant malaria is a fatal form of malaria caused by Plasmodium falciparum, a deadliest malaria parasite. The presentation of falciparum is very variable, and it imitates typhoidal symptoms – patients with falciparum may pass into a typhoidal condition without prompt treatment. Tertian malaria is caused by Plasmodium Vivax and Oval parasites. This parasite causes a fever every 2nd day. Quartan malaria is caused by a parasite known as Plasmodium Malariae. This parasite causes a fever every 3rd day.

100 malaria symptoms were captured using different sources from the 4000 samples. i.) using questionnaire with 3490 individuals out of the clinical setting. ii.) Also questionnaire were administered to 510 patients during clinical procedure (checking blood pressure, temperature, heartbeat, breath and colour of the eye to diagnosis malaria), and filled by nurse on behalf of patients through the help of medical officers in Siaya County Clinic Centres within the same clusters in Ugenya, Alego and Gem in Siaya County. Virtue's family physician (VFP) book was used to identify the symptoms that were collected outside the clinical environment and some in the clinical settings (VFP book, 1971). Symptoms of malaria can be fever, chills, headache, sweats, fatigue and others.

### *D. Feature Selection*

InfoGainAttributeEval feature selection techniques were used to select the most significant 100 features extracted from 4000 samples. InfoGainAttributeEval method ranks all the features in the dataset. While InfoGainAttributeEval technique is important because it omits the features that have lower ranks and produce the predictive accuracy of classification algorithms. One limitation of the method is that weights put by the rankers algorithms are different than those by the classification algorithms so there is a possibility of overfitting. A summary of the symptoms are presented in Table I.

### *E. Algorithms*

Various classification algorithms exist that have been used for malaria symptom classification to solve malaria cases. These include K-Nearest Neighbours (KNN), Support vector machine (SVM), Logistic regression (LR) that achieved 85% accuracy [6]. These errors are far above the standard level of confidence.

The proposed study utilizes AI and ML techniques, supervised learners and Ensemble methods to classify malaria accurately. Extensive experiments were conducted based on ANN, NB and RF algorithms. The chosen algorithms can handle qualitative and quantitative values and are robust to outliers. Further, ensemble methods were utilized to improve the accuracy of results of the models. These include Meta Bagging, Random Committee Meta and Voting. The reason for selecting the proposed method is that it can classify malaria accurately (within seconds). The algorithms use Waikato Environment for Knowledge Analysis (WEKA), a popular suite of ML software written in Java. It has four integrated editors which are useful for training and testing processes.

*1) Artificial neural network:* is simply called neural networks (NNs). ANN has been found to satisfactorily address complex nonlinear function, as such facilitate image recognition, natural language processing and classification of behaviour patterns.

*2) Naïve Bayes:* Although it is a simple technique, NB is a powerful classifier for developing models that assign labels to the features where labels are drawn from training datasets. It is used in our study since it has the benefit of not requiring a very large amount of training data to estimate parameters required for classification. NB also has a limitation which is over simplicity.

*3) Random forest:* is a supervised ML classifier that combines the output of diverse decision tree algorithms to reach a single result. It uses ensemble learning which is a technique that can handle both classification and regression problems, enabling it to be used in Healthcare to diagnose patients and to predict complex problems. It is chosen in our study since it offers a more accurate classification in comparison to decision tree algorithms and can handle missing data [21].

*4) Ensemble method:* Ensemble method is a machine learning technique which combines various base models in order to generate optimal predictive models. The ensemble method has been driven by the perception that an appropriate integration of different classification algorithms might improve prediction performance. In multiple classifiers, the scores generated by contributing classifiers on component feature sets are taken as inputs to the combined function.

Supposing we combine D component models for a classification task, the ensemble model can be formulated as:

$$0_j(X) = F\begin{pmatrix} 0_{11}(X_1), \ldots & 0_{1j}(X_1), \ldots & 0_{1C}(X_1) \\ . & \ldots & . \\ 0_{Dj}(X_D), \ldots & 0_{Dj}(X_D), \ldots, & 0_{DC}(X_D) \end{pmatrix}, \tag{1}$$

TABLE I. SYMPTOMS (FEATURES) SUMMARY

| **Malignant Malaria** | **Quartan Malaria** |
|---|---|
| • ***Fever***: malignant contains irregular fever | • ***Ague fits***: in quartan, ague begins in the afternoon |
| • ***More ill***: presentation of patients become more ill with irregular fever | • ***Cold stage***: the cold stage has longer intervals in quartan |
| • ***Develop Typhoid***: Patients may pass into a typhoid condition without promptly treatment. | • ***Attack repeats***: double quartan, attacks repeat themselves on the same day and on alternative days |
| **Tertain Malaria** | **Suspected malaria** |
| • ***Headache and malaise***: The disease begins with headache and malaise | • ***Headache and Thirst***: are some of the characteristics of symptoms that cause suspicion of malaria in a patient. |
| • ***Ague***: patients experience ague after headache and malaise has three stages | • ***High body Temperature***: patients' temperature rises to 105° degrees Fahrenheit at this stage, after a short time, the body temperature drops down. |
| • ***Cold, Hot and Sweating***: these are stages of ague. The cold stage lasted 2 hours, feeling debility with nausea. hot stage follows which last 6 hours. After the hot fever passes off, a sweating stage follows that causes perspiration to break out. | • ***Vomiting***:a condition when a patient has a feeling of debility with nausea and vomit. |

Where $O_{Kj}(X_K)$ is the output score of the classification model, for class j and F(.) shows the combining function of the ensemble components can be produced by different classification algorithms on different data sets.

## F. Patients Future Inputs

For medical facility operation, a system to diagnose malaria will be developed using fuzzy If – Then rules which will assist to input more patient's details during clinical visit. The system will check individual patient's inputs which consist of demographic (Age, sex, place of residence) signs and indications of patient's complaint and symptoms such as headache, vomiting against know features. If quartan malaria, malignant or tertian malaria is detected, the patient's treatment/prescription is generated in real-time (within seconds). If suspected malaria is detected, recommendation of further tests is generated. If no symptoms are detected, then the patient is informed, and no action as presented in Fig. 1.

These are core of our combined framework from which data were collected and enabled feature extraction and selection, leading to features split into training-set and test-sets. The training set is used to generate models and to train the model. The unseen test set is used to test the validity of the models. The test set demonstrates how well the model generalizes on the unseen data.

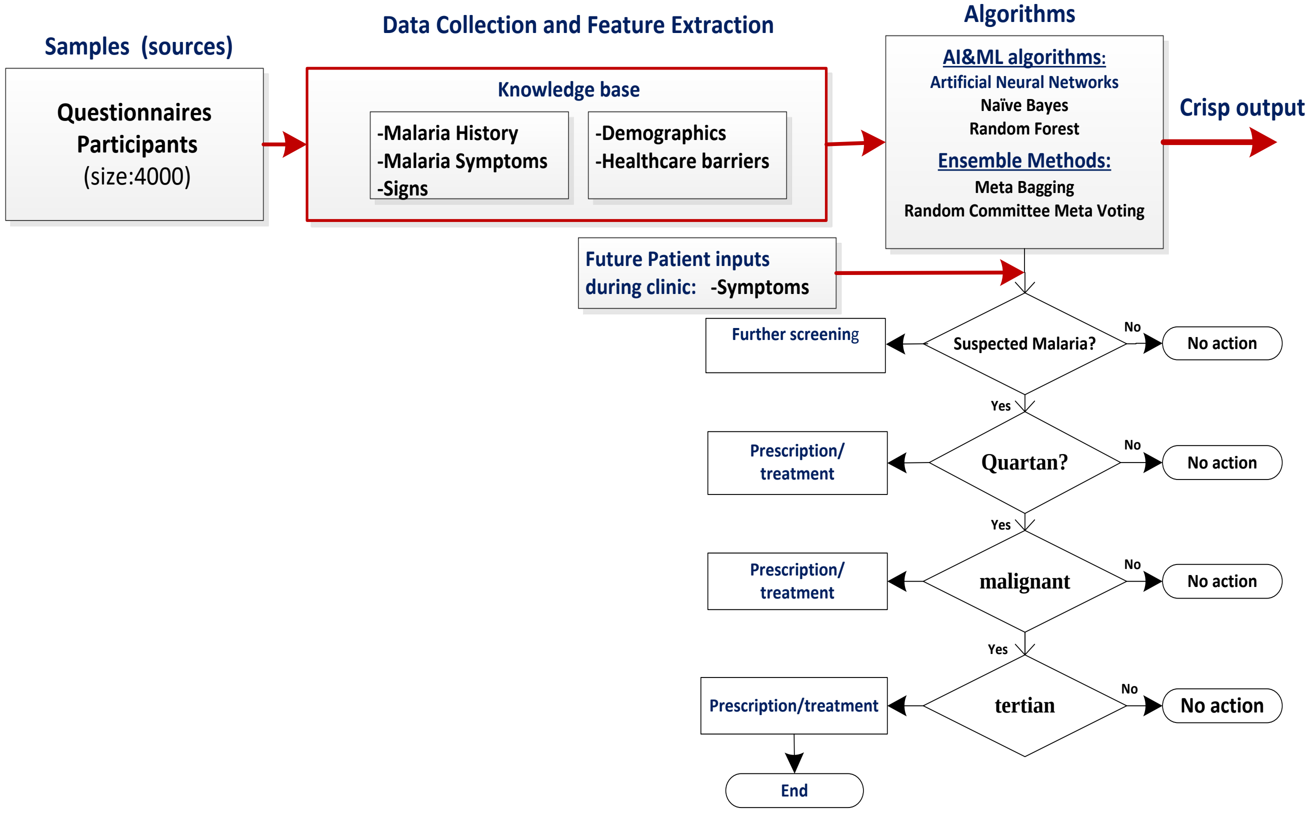

Fig. 1. Methodology structure flow.

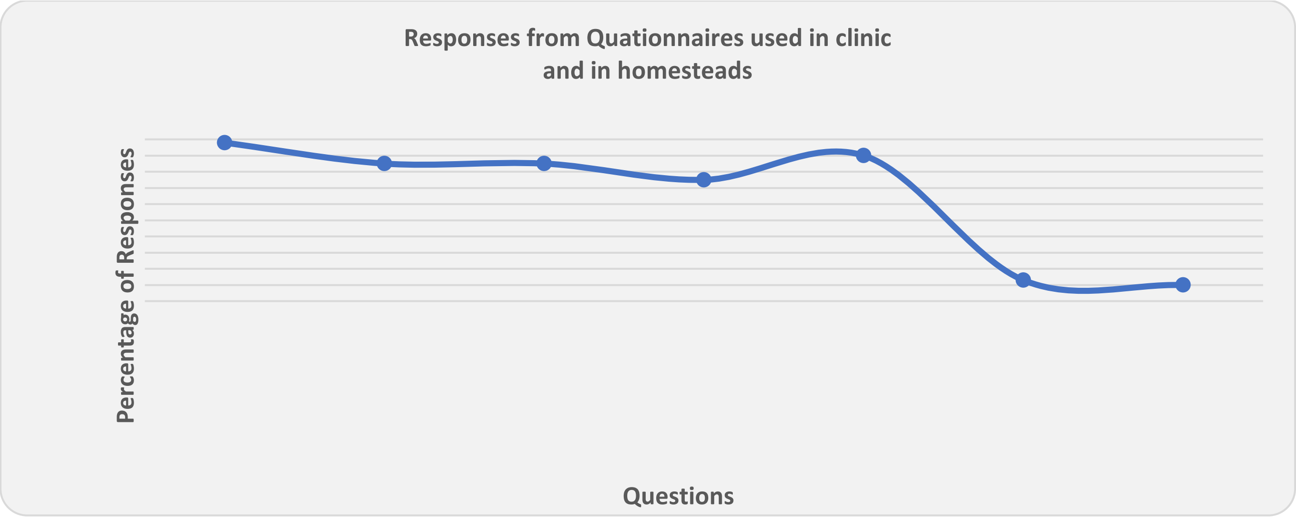

Fig. 2. Participant’s responses from questionnaires.

### G. Participants Responses

A total number of 4000 questionnaires were administered to respondents. Fig. 2 shows that 87.3% individuals who participated reported contracting malaria symptoms within six months of the study. Out of 87.3% (3490) who contracted malaria, 12.7% (510) cases were confirmed malaria through clinical procedures of checking blood pressure, temperature, heartbeat, breath and colour of the eye. These are some of the procedures. While 85% (2966.5) out of 87.3% did not visit healthcare service due to lack of finance or being a distant away from quality health service or due to lack of transport. These participants described the symptoms at the time of illness that was confirmed at the time of the study using virtue’s family physician book [17]. Out of these, 58% were self-medicated by buying non-prescribed anti-malaria drugs through Chemistry counters or used herbal treatment. 10% felt healthcare services within their communities were very costly, while others lack quality health facilities. Dispensary level is the most common health service used by these community members. The head of the homestead (male or female) makes decisions during illness for all family members living in their homestead. This helps in understanding the existing barriers so that AI intervention can be considered appropriately. No incentive was given to participants.

### H. Ethics Statement and Participant Consent

Ethical approval for this study was obtained from the ethics committee, Computer and Information Science, University of Northumbria (7/2019). All the participants in our study had given written informed consents before participating in the study. To comply with the privacy of individuals, the questionnaires were filled anonymously without any name disclosure. Participants were aware that they had the right to withdraw from the study at any time should they decide to do so. All methods were carried out in accordance with the related guidelines and regulations.

## IV. Experimental Procedures

Machine Learning models can be utilized to classify malaria proposed in literature. In order to classify malaria types and vigorously evaluate our new method. Most significant 100 features selected were used based on ANN, NB, RF algorithms, Ensemble methods (Bagging, Random Committee & Voting) to evaluate the new method.

### A. Evaluation Metrics

The A model evaluation is an important part of building the AIML model. The most popular evaluation metrics employed for classification is Accuracy. But with imbalanced data relying on Accuracy alone for measurement can be misleading. Based on the proposed approach the appropriate evaluation metric used are Accuracy (ACC), True Positive (TP), False Positive (FP), Precision, Recall, F-Measure, Receiver Operator under the Curve (ROC), speed taken to build models and Confusion Matrix. As can be seen, these are demonstrated in experiment in the next sections.

Four extensive experiments are conducted in detail in Sections IVA(1) to IVA(4) The whole dataset (Symptoms) have been used for evaluation as well as the data set from each malaria types. This was performed to test the effectiveness of the data set. The first experiment applied all the selected features to classify malaria, The second experiment used Malignant features, Quartan and suspected cases excluding Tertian. The third used features from Tertian, Quartan and suspect cases, excluding Malignant. The fourth experiment used Malignant, Tertian and Quartan features to train and test the model. The reason for using the different sizes of features is to rigorously assess our method from different angles for best performance.

*1) Experiment 1# evaluation of Artificial Neural Network (ANN):* In experiment 1, the goal is to assess the overall performance for the proposed method, using a supervised Multi-Layer ANN algorithm with the most significant 100 selected features. Assessing the performance of the proposed model is important because it increases user’s confidence. To assess how well the proposed model performs, evaluation metrics for multiclass classification were used that are ACC, TP, FP, Precision, Recall, F-Measure, ROC Curve, speed taken to build models and Confusion Matrix. Parameters are tuned to find the best fit and applied optimization method. 3 units (10, 20, 40) are set at the hidden layer. The units are initialized randomly before training begins.

The standard level of confidence error is 5% for all classifiers since an average error above 5% is considered unsuccessful, while below 5% is deemed successful. The validation threshold used is 2-fold cross-validation because it can handle the conventional data well and helps to avoid over-fitting. Features are randomly split into training sets and test-set. The training of Multi-Layer ANN is conducted with the back-propagation learning algorithm to learn instances on a full training set and evaluate performance on independent unseen test-set. This process is repeated twice. Roles are reversed and train on a test-set and test on training-set. We use Multi-Layer ANN since it is a general-purpose tool, which has been applied successfully in classification problems in medical diagnosis for heart attacks. Results are described in Section V.

*a) ANN model:* based on ANN, the model was generated within 3.01 seconds from the training set. As shown in Fig. 3, ANN is a Multi-layer artificial neural network with 3 layers which are input layer, hidden layers and output layer has specific steps in the process of training and testing the model. The layers used a sigmoid activation function. These layers are elucidated below.

*b) Input Layer:* Features for ANN are put through the input layer and are directly transferred to the second layer by each neuron. This mathematical function is presented as:

$$y_i^{(1)} = x_i^{(1)}, \tag{2}$$

where $x_i^{(1)}$ is the input and $y_i^{(1)}$ is the output neuron i in layer 1.

*c) Hidden Layers:* These layers are between the input and output. Neurons in the hidden layers detect the features, weights of the neurons and display the features hidden in the inputs. The features are then utilized by the output layer in determining the output pattern. The output of neurons 3 and 4 in the hidden layers are calculated as:

$$Y_3 = \text{sigmoid}\ (X_1W_{13} + X_2W_{23}-\theta_3) = 1/[1+e^{-(1x0.5+1x0.4-1x0.8)}] = 0.5250 \tag{3}$$

$$Y_4 = \text{sigmoid}\ (X_1W_{14} + X_2W_{24}-\theta_4) = 1/[1+e^{-(1x0.9+1x1.0+1x0.1)}] = 0.8808 \tag{4}$$

*d) Output Layer:* the output layer receives the inputs transmitted from layer 3 and 4, then performs the calculations through the neurons.

As can be seen in Fig. 3, the networks with 3 layers learn relatively fast. They converge in less than 500 epochs. Once the training is performed, the network is tested with a set of unseen test samples to test how well the model performs. The test result is shown in Section V.

*2) Experiment #2 evaluation of naïve bayes:* The purpose of Experiment 2 is to examine the performance of the model using instances of classes Malignant, Quartan and suspected cases excluding Tertian. Naïve Bayes supervised algorithm is utilized to classify the instances accurately. As described in Section V and shown in Fig. 3, we employ evaluation metrics to examine how well the proposed feature model performs. We could use a percentage split, with some percentage of the dataset used to train and the rest used for testing to get reliable evaluation results. The Supplied Test set was utilized to test the proposed model on a user-specified dataset. 75 instances of features from Malignant, Quartan and suspect of malaria excluding tertian are utilised to generate and learn data model, and another set of data to test the model. Parameters are assigned based on accuracy and speed of learning to ensure high-quality performance. The training is done on a training set and testing done on a test set. The roles are swapped, trained on a test set and tested on a training set. It is important to evaluate a classifier on an independent unseen set, which means the model is tested with an unseen independent test set. A standard confidence level of error is 5% since an average error above 5% is considered unsuccessful and below 5% is considered successful. Experiment 2 results are provided in Section VB.

*3) Experiment #3: evaluation based on random forest:* The aim of experiment 3 is to measure the model performance for validity and accuracy, utilizing Random Forest, base classifier with a total of 75 instances of classes Tertian, Quartan and suspect cases, excluding Malignant. Similarly, as described in Section IV, we measure how well the proposed feature model performs. The evaluation threshold used is 2-fold cross-validation because it can handle the conventional data well (Sivarao and El-Tayeb, 2009) and helps to avoid overfitting .Features are randomly split. Training is performed on a training set and testing on a testing set. This process is repeated twice while roles are reversed, training on a test-set and testing on a training-set. This is done such that training set is used only once for training and testing is performed on unseen independent sample test sets to achieve the most accurate model performance. Parameters are tuned, 100 number of iterations with 1 seed and 500 epochs are assigned. Similarly, evaluation methods utilized to evaluate the model performance are Accuracy, TP, FP, Precision, Recall, F-Measures, ROC, Time taken to build model and confusion Matrix. The result is provided in Section V.

*4) Experiment #4 evaluation of ensemble methods: The* goal of Experiment 4 is to evaluate and demonstrate the rigour of our models, classifying malaria into one of possible types: Malignant, Tertian, Quartan or Suspected malaria. The Bagging, Random Committee and Voting were used to evaluate the models. The techniques create multiple models and combine them to produce robust results.

Bagging also known as bootstrap aggregation is a technique that is best used with models that have a low bias and a high variance, meaning that the predictions they are highly dependent on the specific features from which they are trained. The most used algorithm for bagging that fits this requirement of high variance is decision trees.

With bagging, we produce many different decision structures. We do that by having several different training sets of the same size. We sample the original training set and build a model for each one. Therefore, Meta Bagging is deployed. We choose a bag size of 100% that samples the training set to get another set of the same size, but this will sample with replacement. That means we get different sets of the same size each time we sample. However, each set might contain repeats of the original training-sets (instances). We choose the classifier we want to bag and the number of bagging iterations and random-number seed.

The Random Committee is chosen for being capable of handling different perspectives of the problem. It is also. capable of encouraging new models to become an expert for instances misclassified by earlier models. The intuitive justification for this is that in real life, committee members should complement each other's expertise by focusing on different aspect of the problem. To combine all built models, we use vote, which weighs models according to their performance.

Voting is the simplest ensemble algorithm, yet very effective in classification and regression problems. It creates two or more sub-models. Each sub-model makes predictions that are combined in some way, by taking the mean or the mode of the predictions, enabling each sub-model to vote on what the result should be.

The evaluation of the feature model using the three ensemble methods, 75 instances of classes Malignant, Tertian and Quartan excluding suspected cases were deployed. Each feature is randomly split into a training-set and test-set. They are fed to each classifier, which produces different predictions. All the base model outputs are combined in a final model and the decision is made based on the majority vote or by looking at the predictions or weights (output of all base model) - one learner/Classifier, which produces better outputs than any single classifier. We used a two-fold cross-validation method to ensure that the positive and negative cases in the training-set and test-set are proportionate to the cases in the dataset.

One disadvantage is that it produces output that is difficult to analyse, but the advantage is that the method often achieves very good performance.

## V. Results

### A. Experiment 1: Results Based on Artificial Neural Network

Experiment 1 assessed the overall performance of the proposed method based on Multi-Layer ANN with metric evaluation to demonstrate the model accuracy performance which addresses objective 1 to 3. Table II shows detailed accuracy by class. The experiment achieved a higher accuracy. Column 2 shows the results achieved accuracy of 100% in all four classes. This indicates that 100 instances are classified correctly and 0% are incorrectly classified instances. Speed to build the model was 3.01 seconds. As we can see in Table II, all the evaluation metrics including True Positive, True Negative, Precision, Recall, Receiver Operator Characteristic curve together with Weighted Average for all classes obtained 1.000 (100%). In which case, the weighted Average value for the proposed model is as high as possible. This means the model is doing better than randomly guessing.

Table II shows how well the model performed. Using the Confusion Matrix, the matrix has four values in the Y-Axis that are: a, b, c and d. Values on the diagonal of the matrix demonstrate how many classifications for each class. are correct. In the test data set, 25 instances belong to class a. Therefore, true classes have 25 items. By looking at all the values in row a, it can be inferred that, out of 25 instances, the model indicates that 25 instances belong to class a (correctly classified), 25 instances belong to class b, 25 instances belong to class c and 25 instances belong to class d. Values in class a depict that model classified 25 instances as class a, b, c and d (sum of all the values in class a, b, c and d).

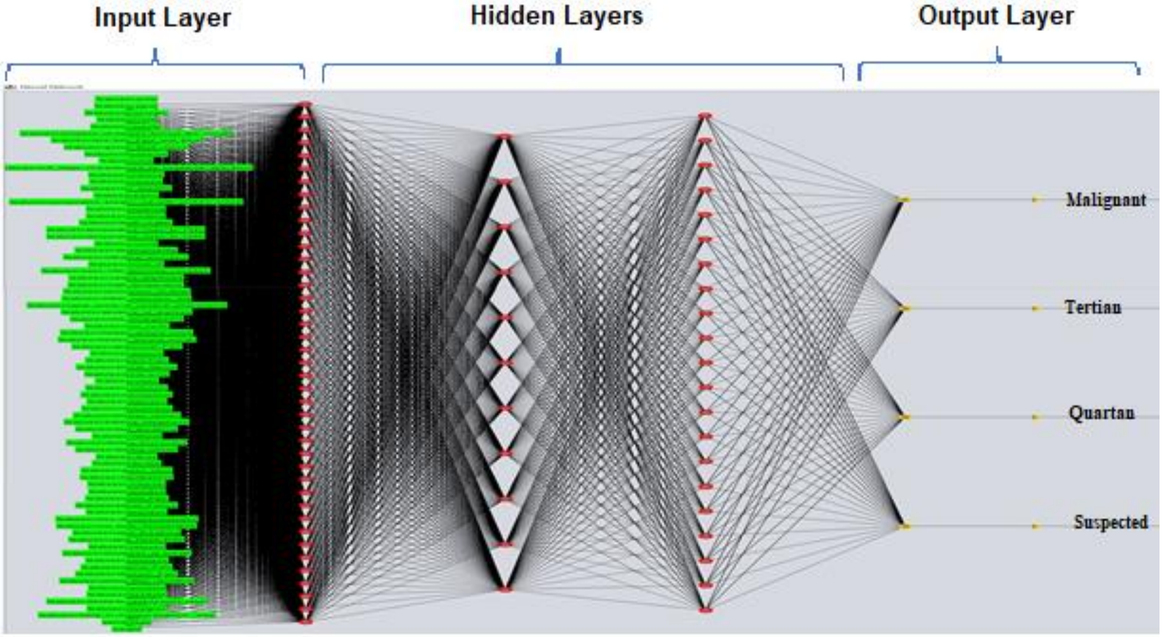

Fig. 3. Multi-Layer ANN for Artificial Intelligent diagnosis system.

TABLE II. EXPERIMENT 1 RESULTS - EVALUATION BASED ON MULTI-LAYER ANN

| Class | Accuracy | TP | FP | Precision | Recall | F-Measure | ROC Curve Avg | Time to build model |
|---|---|---|---|---|---|---|---|---|
| **Malignant** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.01 Secs |
| **Tertian** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Quartan** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Suspect cases** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Weighted Avg.** | **100%** | **1.000** | **1.000** | **1.000** | **1.000** | **1.000** | **1.000** | |
| | | | | | | | | |

**= = = Confusion Matrix = = =**

```
 a    b    c    d                          ← - classified as
25    0    0    0   |   a   =     MALIGNANT_FEVER
 0   25    0    0   |   b   =     TERTIAN_FEVER
 0    0   25    0   |   c   =     QUARTAN_FEVER
 0    0    0   25   |   d   =     SUSPECTED_FEVER
```

The results in Table II demonstrate that the combined method using multi-Layer ANN algorithms with features (symptoms) and non-symptom factors can classify malaria accurately within seconds and has the best performance compared to the reported results in the field.

It has been found that features and non-symptom factors as well as parameters have played a crucial role in the classification of possible classes correctly.

### *B. Experiment 2: Results Based on Naïve Bayes*

The proposed feature model performance was examined utilizing Naïve Bayes algorithm with instances fromMalignant, Quartan and suspect cases of malaria and applying user supplied test set. We utilized the same evaluation metric as was used in Experiment 1 to examine how well the proposed feature model performs. Equally, Table III shows detailed accuracy by class, column 2 shows the accuracy results achieved 100% in all the classes. Time taken to test the model was 0.01 seconds. This indicates that 75 instances are classified correctly, while incorrectly classified instances are 0%. Similarly, as Table III demonstrates, all the evaluation metrics including True Positive, True Negative, Precision, Recall, Receiver Operator Characteristic curve together with Weighted Avg. for all classes obtained 1.000 (100%). Accuracy measures types of malaria and discriminates correctly as Malignant, Quartan and suspected malaria among the total number of features tested. This means the result is quite accurate and resembles experiment 1 results.

Similar to experiment 1 results, we evaluated our model performance using Confusion Matrix to see how well the model performed. The matrix has three values in the Y-Axis that are: a, b and c. Values on the diagonal of the matrix show how many classifications for each class are correct. It shows 25 instances belonging to class a. Thus, true classes have 25 instances. In view of all the values in row a, it can be implied that, out of 25 instances, the model calculates 25 instances belonging to class a (correctly classified), 25 instances belonging to class b and 25 instances belong to class c. Values in class a depict that model.

The results in Table III indicate that our combined method using NB algorithms with features (symptoms) from all the four classes can classify malaria symptoms accurately has the best performance compared to the reported results in the field.

Like experiment 1, we found that features and non-symptom factors as well as parameters have played a crucial role in classifying four possible classes accurately.

TABLE III. EXPERIMENT 2 RESULTS - EVALUATION BASED ON NAÏVE BAYES

| Class | Accuracy | TP | FP | Precision | Recall | F-Measure | ROC Curve Avg | Time to build model |
|---|---|---|---|---|---|---|---|---|
| **Malignant** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.01 Secs |
| **Quartan** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Suspected Fever** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Weighted Avg.** | **100%** | **1.000** | **1.000** | **1.000** | **1.000** | **1.000** | **1.000** | |
| | | | | | | | | |

**= = = Confusion Matrix = = =**

```
 a    b    c                          ← - classified as
25    0    0   |   a   =     MALIGNANT_FEVER
 0   25    0   |   b   =     QUARTAN_FEVER
 0    0   25   |   c   =     SUSPECTED_FEVER
```

### *C. Experiment 3: Results Based on Random Forest*

The goal of experiment 3 was to evaluate the merit of the features of the Tertian, Quartan and suspected cases of malaria, except Malignant malaria, usingRandom Forest algorithm. Table IV, column 1 shows that the results achieved are 100% accuracy. This means correctly classified instances are 75 (100%) and incorrectly classified instances are 0 (0%). Time taken to build the model was 0.03secs and 0.01sec time to test the model. This is a high performance. In this experiment results, the confusion matrix represents 3 rows showing true classes and 3 columns representing models' correct prediction. This has also addressed objectives 1 to 3.

As seen in experiment 3 results, the matrix in experiment 3 results has three values in the Y-Axis, which are: a, b and c. Values on the diagonal of the matrix show how many classifications for each class are correct. It shows that 25 instances belong to class a. Thus, true classes have 25.instances. In view of all the values in row a, it can be implied that, out of 25 instances, the model calculates 25 instances belonging to class a (correctly classified), 25 instances belonging to class b and 25 instances belonging to class c. Values in class a depict that model classified 25 instances as class a, b and c (sum of all the values in class a, b and c). We can see that matrix in Table IV, all classes performed well.

### *D. Experiment 4: Results Based on Ensemble Methods*

This section presents the performance of Ensemble classification methods. To demonstrate how well features (symptoms) perform in diagnosing malaria into either Malignant, Tertian, Quartan or Suspected malaria, the Ensemble of classification algorithms (Meta Bagging, Random Committee Meta, and Voting) with different features were used. Ensemble learners integrated the perspectives of several learners to improve performance. This also rigorously scrutinised the features to demonstrate how well they generalise to unseen data. The average accuracies of the three ensemble methods are provided in Table V. It can be noted that the performance of the ensemble classification algorithms is consistently high across the feature sets. The performance based on Bagging, Random committee and Vote algorithms achieved 100% accuracy across the chosen algorithms. Also, precision, recall, ROC curve average attaining 1.000 (100%) performance and Time to build the model is 0.006 Secs. The results have demonstrated the best performance.

TABLE IV. EXPERIMENT 3 RESULTS EVALUATION BASED ON RANDOM FOREST

| Class | Accuracy | TP | FP | Precision | Recall | F-Measure | ROC Curve Avg | Time to build model |
|---|---|---|---|---|---|---|---|---|
| **Malignant** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Quartan** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Suspected Fever** | 100% | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 1.000 | 0.006 Secs |
| **Weighted Avg.** | **100%** | **1.000** | **1.000** | **1.000** | **1.000** | **1.000** | **1.000** | |

| **Weighted Avg**. | | 100% | 1.000 | 1.000 | 1.000 | 1.000 | |

### *E. Performance Evaluation*

We evaluated the quality of the three multiclass classifiers (ANN, NB, RF), using all features with all classes including (Malignant, Benign Tertian, Benign Quartan symptoms and suspected malaria) types of malaria to test the overall performance of our method. Without performing appropriate evaluation with different metrics, using only ACCURACY (TP +TN)/(TP + TN + FN + FP) is not always reliable. It causes issues when models are employed on unseen data, leading to poor diagnosis [6]. We integrate the area under the ROC Curve to evaluate our multiclass classifiers and malaria diagnostic model performance since it is a useful method for rigorous evaluation [22]. Plotting the sensitivity (TPR) versus specificity (FPR) on a ROC Curve was performed and calculated the recall and the FPR. ROC curve combines these measures and generates evaluation standards. This curve allows to visualize the increase or decrease between True Positive Rate (or sensitivity) and False Positive Rate (or specificity). The dashed line would be random guessing (no predictive value). When the curve is closer to the 45-degree diagonal of the ROC space, the less accurate the experiment is. Anything below the dashed line is considered worse than guessing. Classifiers providing curves closer to the Top-Left corner demonstrate a better performance. We can view a ROC curve for a multiclass model in Fig. 4. Each curve presents a class. It shows a diagonal line on the horizontal-axis and x-axis presenting original and standard values, which suggests that features seem to follow a normal distribution without deviation from a straight diagonal line.

It can be noticed that the ROC is not dependable on the class distribution which renders it useful for measuring classifiers for cases such as malaria.

The results in Table IV demonstrate that the combined method using RF algorithms with symptoms and non-symptom factors can classify malaria accurately within seconds and has the best performance compared to the reported results in the field.

We found that features (symptoms) and non-symptom factors as well as parameters have played a crucial role in classifying three possible classes correctly.

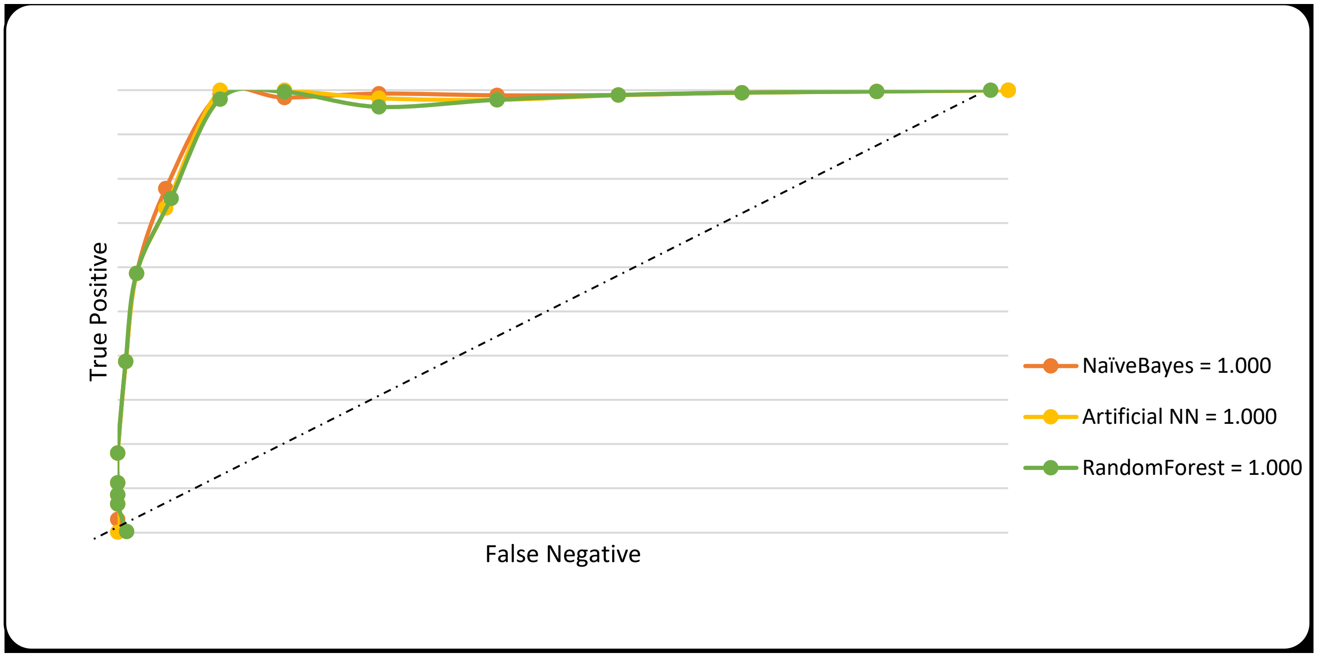

Fig. 4. ROC Curve developed using ANN, NB and RF with features.

## VI. Discussion

The main aim of our study is to introduce a novel method for malaria diagnosis combining InfoGainAttributeEval feature selection techniques and parameter tuning methods, using Artificial Intelligence and Machine Learning (AIML) classifiers with features/non-symptom factors to diagnose malaria into Malignant, Tertian, Quartan and Suspected malaria more accurately.

The proposed study contributed by introducing a novel method, combining (1) InfoGainAttributeEvalas, a feature selection method selected 100 most significant features from the initial 100 that were extracted from 4000 samples. We used ANNs, NB, RF classifiers and Ensemble methods. (2) Parameter tuning approach was used to optimize the model's performance. (3) Identified knowledge about local community needs in remote community settings. This combined method is novel, and other studies have not considered this method in the field. The performance in all experiments with supervised algorithms, ensemble methods with features have consistently produced higher results. AIML classifiers – ANN, NB, RF Ensemble methods with features have achieved 100% accuracy. If we compare our results across conducted experiments with the work of Bria et al [5] which is the closest work to our work. The proposed work achieving 100% accuracy has outperformed the existing work in the field with a difference of 14% which is high performance. Overall, the results indicate that the proposed method with features offers higher accuracy and has the best performance.

The next section presents some relevant works that investigated malaria using ML techniques that has been compared with the proposed study. These include the study by Santosh and Ramesh [14], Morang'a et al. [10] as shown in Table VI.

TABLE VI. Comparison of the Proposed Study with the Existing Related Work

| | Algorithms | Features | % |
|---|---|---|---|
| Barraclough et al. | ANNs, NB, RF | 100 | 100% |
| Morang'a et al. (2020) | ANNs | - | 94%-98% |
| Bria et al. (2021) | LR, SVM, KNN | - | 84% - 86% |
| Santosh and Ramesh (2019) | ANNs | - | 82% |
| Modu et al (2017) | SVM | 33 | 80.6%-99% |

### A. Comparison of the Proposed Study with the Existing Related Work

Santosh and Ramesh [14] deployed clinical and environmental variables with Big Data using ANNs for mosquito abundance prediction in the geographical location of Khammam district, Telanagana in India. The average accuracy ranges from 82% to 17% accuracy.

Morang'a et al. [10] employed haematological data extracted from 2,207 participants in Ghana, using multi-layer classification. ANN scored a range of 94% to 98.3% accuracy.

In relation to relevant research all studies used ML classifiers to automatically learn features with a common goal to diagnose malaria into different classes. However, our evaluation method has exceeded all techniques reviewed in the relevant work.

Our finding indicates that the proposed method can classify malaria accurately within seconds and has the best result compared to the reported related results.

*1) Limitation:* During the process of experimenting with different numbers of hidden neurons, the experiment indicates that the number of neurons in the hidden layers affects the speed of training the network in the method achieving time to build the model in the range of 0.01 to 0.006 seconds (Zurada, 1992 [13]. Complex patterns cannot be distinguished by a small number of hidden neurons, but a large number of them can dramatically add burden to the computational field. When the number of hidden neurons is greater, the greater the ability of the network to distinguish existing patterns. However, if the number of hidden neurons is very large, the network might simply memorise all training samples. This may block it from generalising or producing correct outputs when presented with unseen data. Also using InfoGainAttributeEval has some limitations that weights put by the ranker algorithms are different than those by the classification algorithms so there is a possibility of overfitting. Having a larg number of neurons in the hidden layers could affects the speed of training the network hence it could cause a lack of generalisation to unseen data. This problem can be solved by deploying the right number of neurons and the right number of epochs.

*2) Strength:* On the other hand, we deployed three algorithm powers instead of using one algorithm power. The models built by combining the multiple classifiers are more reliable and more sophisticated to classify instances from the training and testing sets correctly, using two-cross-fold-validation.

## VII. Conclusion

Over $810 Million have been spent in some parts of Trans-Saharan Africa to reduce malaria burden (Ministry of Health, 2015). The study by [6] investigated significant malaria symptoms and non-symptom-related factors for malaria diagnosis in endemic regions of Indonesia. Our work contributes a novel method, combining InfoGainAttributeEval, Parameter tuning approach to optimise best performance, identified knowledge about barriers of access to healthcare services in remote communities and needs of the community in remote settings in Western Kenya.

The experimental results demonstrated that the proposed method can diagnose malaria symptoms more accurately and reduce malaria burden. Deploying two-fold cross-validation, the proposed method was evaluated based on ANN, NB and RF, using 100 most significant features from the initial 100 that were extracted from 4000 samples. Further ensemble learning classifiers were employed to demonstrate the merit of the proposed method. The results of the experiments showed that the proposed method achieved 100% accuracy across all experiments. Measurement of Precision, Recall, ACC, F-Measure, Confusion Matrix and ROC Curve also presented higher accuracy rates of 100% accuracy score. High score can be because of using small data, meaning that the dataset consists of just 1–10 samples. A relatively small dataset can negatively affect the performance of a model due to over-fitting, which is when a model performs well with the training data but poorly on new independent data. Promising solution to this problem is to use cross-validation. In all our experiments 2-fold cross-validation was applied.

In all the 5 experiments in the proposed study, the results achieved are 100% accuracy. The results demonstrate that our combined method using multiclass algorithms with features and non-symptom factors can classify malaria symptoms accurately within seconds and has the best performance compared to the reported results in the field.

We found that features and non-symptom factors are important and have played a crucial role in the diagnosis of malaria in four possible types of classes.

### A. Future Work

The next step will be to implement a fully working and tested diagnosis Application for remote settings. This was impacted with challenges such funds cut and travel restrictions due to Covid-19 in terms of co-developing the application and travelling in remote areas to perform testing.

## Funding

This study was supported by the Global Challenge Research Fund (GCRF) Quality Related (QR) award from the Department of Computer and Information Sciences at the University of Northumbria. We are sincerely grateful to the funders. The funders provided travel grants for workshops and field studies for data collection in Kenya and Tanzania. The funders were not involved in the collection of data, analysing data, research design, manuscript preparation and publishing decision.

## Conflict of Interests

There is no conflict of interest to declare.

## Acknowledgment

We would like to thank the Global Challenges Networking and Collaboration Fund team. The Maseno University, Dodoma University and Northumbria University, the Ministry of Health collaborators, Clinics and medical officers for providing great support, enabling us to undertake the research.

***Abstract*—Accurate classification of multivariate time series data represents a major challenge for scientists and practitioners exploring time series data in different domains. LSTM-Auto-encoders are Deep Learning models that aim to represent input data efficiently while minimizing information loss during the reconstruction phase. Although they are commonly used for Dimensionality Reduction and Data Augmentation, their potential in extracting dynamic features and temporal patterns for temporal data classification is not fully exploited in contrast to the tasks of time-series prediction and anomaly detection. In this article, we present a multi-level hybrid TSC-LSTM-Auto-Encoder architecture that takes full advantage of the incorporation of temporal labels to capture comprehensively temporal features and patterns. This approach aims to improve the performance of temporal data classification using this additional information. We evaluated the proposed architecture for Human activity Recognition (HAR) using the UCI-HAR and WISDM public benchmark datasets. The achieved performance outperforms the current state-of-the-art methods.**

***Keywords*—Deep Learning (DL); multivariate time series; Time Series Classification (TSC); Human Activity Recognition (HAR)***

## I. Introduction

Time series classification (TSC) [1] holds crucial significance in machine learning, providing various advantages and significant applications. The main objective of TSC is to assigning a category or class to a time series based on its temporal characteristics and dynamic. In terms of processed data, each time series constitutes a sequence of temporal data, such as univariate or multivariate measurements and values, captured and recorded at regular intervals. TSC currently occupies a central place in many applications spread across various fields: It is used in healthcare to classify medical signals such as electrocardiograms (ECG) [2], electroencephalograms (EEG) [3], and other medical monitoring data [4]. For the financial sector, it makes it possible to understand the dynamic developments of financial markets, in particular the classification of shares [5]. In industry, it is used to analyze sensor data for machine monitoring [6], process planning [7], and production quality control. In security, it helps protect computer systems against advanced cyber-attacks [8] through malware detection [9]. In the environmental field, it facilitates climate change detection and causal inference analysis [10] in climate science, using advanced TSC techniques. Finally, the field of recognition of human activity from sensors presents a classification challenge based on the analysis of time series, in particular those coming from accelerometers and gyroscopes. This field encompasses a variety of broad applications in industries such as healthcare, personal monitoring, security, physical performance tracking, life data recording, elderly care, and home care. Due to its critical importance, paving the way for significant progress in understanding and improving the human way of life at multiple levels, we deliberately chose this area to experiment and analyze our DL model.

Despite the critical importance of implementing temporal data classification, this area faces several significant challenges. Class imbalance is one such concern, with the potential to introduce bias into classification models. Extracting relevant dynamic features from temporal data is crucial for accurate classification, but it represents an extremely complex task. In addition, dealing with missing values in time series requires the adoption of suitable strategies. Additionally, detecting relevant temporal patterns can be difficult, especially when these patterns are subtle with noisy data. To overcome these challenges, the scientific community is exploring various avenues of research, covering both traditional machine learning methods and DL approaches, whether supervised or unsupervised. Currently, the use of generative model-based approaches such as GANs and auto encoders remains limited when it comes to temporal data classification. These methods are mainly reserved for data augmentation and dimensionality reduction. To use directly generative models in the classification of temporal data, we have developed a new multi-step approach. This method aims to take advantage of the power of generative models, in particular those of the auto encoder (AE) type, to extract dynamic and temporal characteristics. The goal is to improve the classification of time series data. Our work mainly focuses, in the first phase, on the integration of a digital time label for each class of human activity once determined.

We integrate this label into the raw data as input for our generative model. Subsequently, we train the model to enhance its ability to reproduce this information accurately. This approach is designed to acquire the skill of extracting dynamic, and temporal characteristics, allowing it to generate this label even when it is absent during testing.

In the second phase, we perform classification using the labels generated in the preceding phase, following a supervised approach guided by a previously validated LSTM model. The following points can mention the main contribution of this paper:

- We conduct a general review of the existing literature on DL-based TSC, providing readers with valuable insights to understand and contrast the trend axes in this area.
- The creation of representative labels and identifiers per class in the form of a coherent temporal variable can effectively capture dynamic and temporal relational characteristics and dependencies.
- Conduct a series of comparative experiments in order to highlight the promising performances of our model compared to other well-established models in the field of temporal data classification, particularly in the context of HAR, such as UCI-HAR, and WISDM.

The remainder of the paper is organized as follows: Section II discusses related work, focusing on methods, and architectures machine learning in temporal data classification and sensor-based HAR. Section III details the proposed method including the process followed for all stages, the architecture adapted in three stages carried out. Section IV presents the experimental metrics and results, as well as details regarding the datasets used. By analyzing the experimental results obtained in Section V of discussion. Finally, Section VI concludes our article.

## II. Related Work

Studies on TSC have a rich history, marked by numerous proposals for classification approaches over time. We can distinguish two main axes of these TSC methods, namely Traditional Machine Learning Based Methods, and DL-Based models.

### A. *Traditional Machine Learning-based Methods*

Traditional ML-based methods deployed for TSC typically involve extracting meaningful features from temporal data; these methods rely on the application of standard classification techniques, including feature engineering, statistical methods and metrics measuring the similarity between time series data. Traditional ML-based methods are generally classified into two distinct groups [11]: On one hand, distance-based approaches [12] involve the utilization of classifiers based on distance measurements between different time series. These methods concentrate on quantifying the similarity between two given time series, employing specific metrics for classification, such as k-nearest neighbors (KNN) [13] or support vector machines (SVM) [14] with similarity-based kernels. Some studies even hybridize them with hidden Markov models (HMM) [15], as demonstrated by the research [16], which integrates HMM and SVM models for the early classification of multivariate time series. Furthermore, Notable similarity measures include dynamic time warping (DTW) [17], which aligns two time series with dynamic deformation to obtain the best fit a process easily implemented using dynamic programming. Furthermore, in this [18], the Time Series Forest (TSF) method is employed as a tree ensemble approach to increase the accuracy of TSC; it achieves enhanced precision by combining entropy gain with a distance measure for evaluating divisions. TSF stands out for its distinctive feature of randomly sampling features at each tree node, resulting in linear computational complexity relative to time series length and facilitating parallel computing. The proposal of a temporal importance curve aims to capture relevant temporal features for classification. Experimental results demonstrate that TSF, utilizing basic features such as mean, standard deviation, and slope, not only excels in computational efficiency but also outperforms KNN classifiers employing DTW.

On the other hand, the feature-based approach [19] involves the extraction and selection of deterministic features in the data, which optimize the classification algorithms [20].

Hence, they include a diversity of TSC strategies. The feature extraction aspect relies on the use of a restricted set of features with a solid and easily interpretable theoretical basis. In addition to applying traditional learning algorithms, this approach offers the possibility of analyzing the extracted parameters to obtain additional information. Feature-based approach are divided into three categories:

Firstly, statistical methods focus on using a set of certain statistical characteristics [21], such as the mean, the standard deviation, the skewness to assess the asymmetry of the values compared to the mean, and the kurtosis to measure the relative flatness of the distribution values relative to a normal distribution. These parameters are mobilized in order to resolve the challenges related to statistical process control models intended for classification. Secondly, transformation-based methods [22] aim to improve classification performance through the transformation of data to another alternative data space where discriminatory features are more easily determined, This recent survey in [23] give many of several examples. By adding, the work in [24] proposes a shapelet transformation; this method makes it possible to extract the best shapelets (a subsequence of time series identifying membership in a class) from a dataset to improve the overall accuracy of the classification. Finally, TSC approaches based on the fusion of various characteristics [25] to significantly improve the accuracy of TSC. In this perspective, we mention multi-dimensional [26], multi-channel [27] fusion methods of characteristics and data, as well as network fusion techniques [28], and adaptive feature fusion [29] to improve the accuracy of TSC.

### B. *Deep Learning-Based Models*

In the domain of DL and the application of deep neural networks [1, 30] for TSC, the processes of feature extraction and classification are automated, eliminating the necessity for expert intervention. Four key axes emerge from this perspective for modeling and solving intricate classification tasks. First is the utilization of Convolutional Neural Networks (CNN), tailored to the sequential nature of temporal data. While CNNs are renowned for their proficiency in recognizing spatial patterns in two-dimensional data, such as images, their application to time series necessitates adaptation to exploit sequential structures and temporal relationships [31, 32]. In this context, models like the Multi-Scale Convolutional Neural Network (MCNN) [33] illustrate the concept of applying diverse transformations, such as varying scales and frequencies, to temporal data. This approach enables the model to capture features at multiple levels and scales, enhancing its ability to represent complex temporal patterns. Furthermore, another MCNN for TSC in this work [34] dynamically extracts multi-scale feature representations from time series to classify them.

Secondly, recurrent models, including Recurrent Neural Networks (RNN) and architectures based on Long-Short-Term Memory (LSTM), play a pivotal role. These models are designed to process sequences of data, rendering them particularly suitable for time series analysis. RNNs [35] can memorize previous contextual information, while LSTMs and GRU [36] overcome the limitations of RNNs in classification by avoiding gradient vanishing problems. Our expertise lies in effectively combining these two components [37], demonstrating significant performance improvements in TSC.

Thirdly, the convergence of the aforementioned axes has led to the development of hybrid models such as Recurrent Convolutional Neural Networks (CRNN) [38], merging convolutional layers to capture spatial patterns with recurrent layers to handle temporal dependencies. This amalgamation leverages the strengths of both approaches, enhancing the model's capacity to extract spatial and temporal characteristics. Hybrid models, combining the advantages of CNNs for spatial pattern recognition and LSTMs for modeling long-term sequential dependencies, are increasingly gaining popularity and proving effective in TSC applications such as musical classification [39] and electrocardiogram classification [40]. Several comparative studies [41, 42] demonstrate that this combination constitutes a robust solution to overcome the complexity of time series in terms of classification, notwithstanding their intricate and heterogeneous nature.

Finally and recently, several studies have looked into the application of generative models such as auto encoders for TSC: Research [43] proposed a representation 2D of time series by fusing temporal and frequency features using the AE model, in order to construct a classification network. Another research [44] optimized an LSTM based network layer design to create an AE improving ECG signal classification, eliminating the need for complex preprocessing. A method based on a Conditional Variational AE proposed [45] to solve the no distribution problem related to identifying feature importance for time series classifiers. Auto encoders based on RNN have also been used for TSC [46], where different variants of RNN auto encoders were compared for their performance in feature extraction. An automated label generation method for TSC using representation learning with AECS and VAE [47] demonstrated promising results in reducing labeling costs for training. This method synthetically boosts representative time series using VAE, showing performance close to supervised classification and even exceeding baseline performance in some cases. Finally, the authors of the article [48] introduce a VAE model based on an RNN network, incorporating a constrained loss function. This model is designed to generate more meaningful EEG features from raw data, with the goal of enhancing the performance of classification in speech recognition. The approach aims to leverage the inherent independence features within the latent representation of VAE to improve TSC performance.

Having carefully reviewed the state of the art of various research directions focused on developing approaches for TSC in this section, our approach in this work will be to leverage multiple methods. We plan to hybridize these concepts to create a robust multi-stage method that will take advantage of the many advantages offered by this integrative approach. The specific details of our method will be explained in the following section, highlighting our innovative contribution to the advancement of TSC techniques.

## III. Proposed Method

In this section, we will describe a multi-stage DL framework for multivariate TSC (see Fig. 1). The general organization of our proposed model, TSC-LSTM-AE is divided into three distinct components: The first component concerns the pre-training phase, which encompasses data augmentation and creation of identification variables (labels) per class. The second component is characterized by the use of the "Auto-Encoder" model, designed to extract dynamic temporal and relational features. Finally, the third component exploits the "Classifiers" model, dedicated to the classification task using the raw data and the features extracted during the previous phase.

Our method incorporates an additional variable designed to capture temporal and dynamic aspects of sequential data, thereby improving feature extraction. Once this identification variable (label) is determined for each data class, it is merged with the initial sequential data according to their respective classes. Then, our Auto-Encoder model is trained to learn to reconstruct the initial data combined with the injected data, thus generating this label from the raw data, even in the absence of this label as input. In this way, we are able to generate an identification label rich in meaningful characteristics, which we use in the classification phase through a classifier to guarantee the improvement of this task. We combine this classifier with other classifiers in the classifier model, such as LSTM, GRU and CNN. Ultimately, aggregating the ratings helps determine the final output class more accurately. Next, we will examine each phase in detail, presenting its importance, its objectives, and its associated steps and methods.

### A. *Pre-Processing Phase*

The initial phase of our method consists of preprocessing the time series data, comprising four distinct steps:

*1) Synchronized windowing method:* To ensure the alignment of variables and prevent any temporal overlap between the samples, we implemented a unified windowing method specifically designed for this purpose, applicable to all classes of activities. Our inspiration for this method comes from an approach used to estimate an optimal time series mean [49], employing a multi-task auto-encoder architecture for the estimation. Due to the intricacy of this approach, we have limited the variables in this work to three accelerometers. The methodology involves calculating the average of these three variables for each sample. Subsequently, we extract 100, 80, and 60 successive variables, respectively, from the maximum value of this average. The objective of this method temporally synchronizes the data, considerably reducing the gap between the variables of the two samples, two by two.

In the next section, we will use the t-SNE method to approve our choice of the appropriate window size.

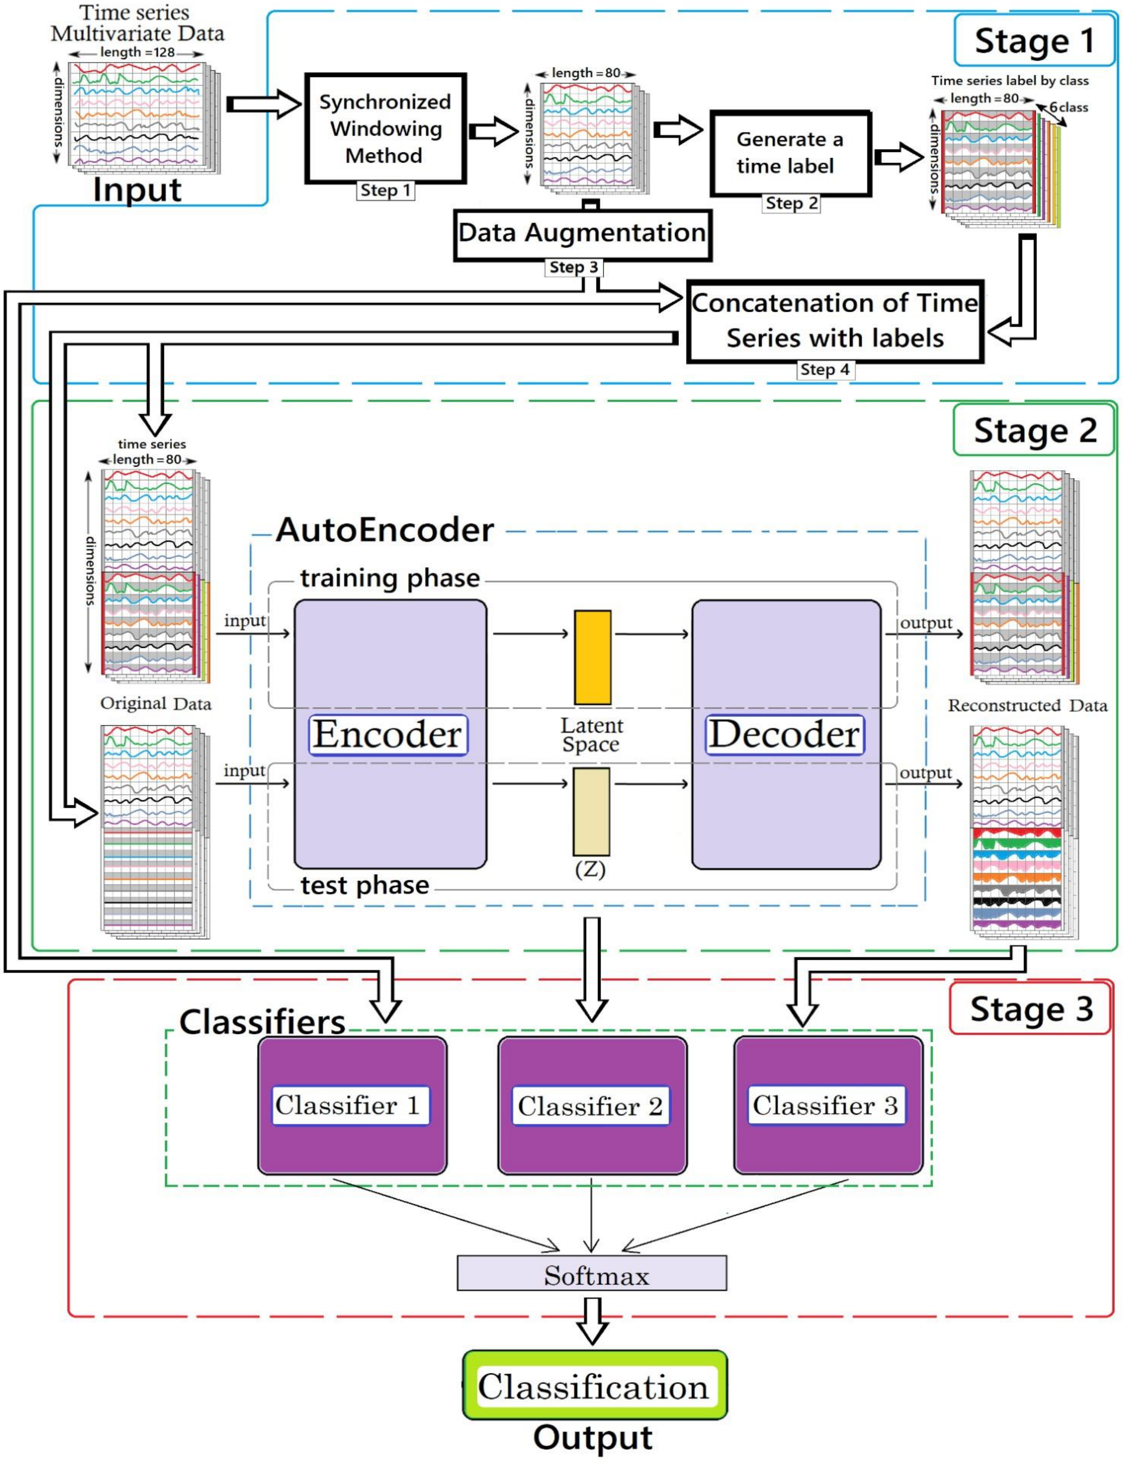

Fig. 1. Schema general of TSC-LSTM-AE.

2) *Generate a time label by class:* After the temporal alignment of all the time series data and the cutting of its data to length 80, the second step aims to create a variable λt | $Ck$ = (λ$t1$, λ$t2$, . . , λ$tn$) for each class k examined for classification. In order to have a variable capable of simultaneously capturing the dynamic temporal aspects of sequential data and correctly identifying each class studied, it is essential that it is consistent with temporal data belonging to the same class k. Thus, it can function as a unified time label for data of the same class, moreover, in order to minimize as

much as possible the negative impact on the relational dependencies between the different characteristics, we chose average arithmetic as the means of calculation for this temporal label per class. In Fig. 2 below, we display the calculated time for the “Walking” class.

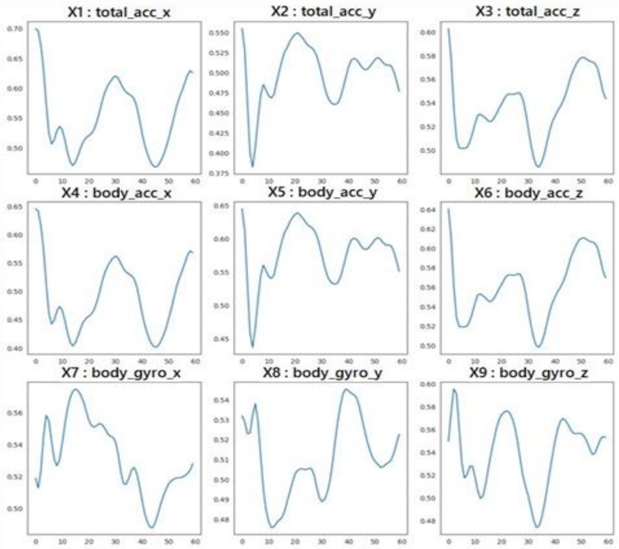

Fig. 2. The time label for the “WALKING” activity generated.

3) *Data augmentation:* Generative GAN models integrate temporal dependencies and spatial relationships to generate long, high-fidelity time series. Their demonstrated capability to surpass standards in terms of fidelity, diversity, and predictive performance is noteworthy. Time series GANs have achieved considerable success in diverse fields, including finance, healthcare, data imputation, and anomaly detection. In this step, with a focus on augmenting the quantity of data utilized for training DL models, we have opted to adopt and customize the TimeGAN [50] generative method.

4) *Concatenation of time series with labels:* In order to prepare the temporal data for the second phase. We proceeded to concatenate the raw data with its previously generated temporal labels. The essence of this approach lies in scrupulous respect for the belonging of this data to each respective class. In other words, each time series was enriched by adding its own temporal labels, thus creating a precise link between the raw data and their specific temporal context. This concatenation operation aims to enrich the dependency relationships between the raw data and the joint temporal label, thus facilitating the extraction of temporal features and adequately preparing the data for the next phase of the process.

## *B. Feature Extraction Phase*

Having successfully completed the initial data pre-processing phase, we move on to the second stage of the process. This step aims to leverage the AE approach to extract the hidden temporal and dynamic characteristics within the sequential data. Additionally, a novelty is introduced this time: the inclusion of an additional specialized variable for classification. This phase is subdivided into two fundamental steps:

The first step is dedicated to the training of an LSTM type AE model. The goal here is to establish a model to excel in extracting features from time series data, also this model is trained to learn the complex dependency relationships between raw data and associated labels. This helps enrich the internal representation of the model by more precisely capturing the nuances and temporal structures present in the data, thus facilitating the next step. Our recurrent AE consists of three layers of encoding and decoding; we used LSTM layers to capture temporal sequences. The objective is to minimize the MSE loss between the input and output data to learn a compact representation of the input temporal sequences. The first coding layer is an LSTM layer composed of 64 units, designed to process Input data as a sequence of 80 steps. Then, a second LSTM coding layer, consisting of 32 units, is added, followed by a third LSTM coding layer with 16 units. This last layer generates a latent space (Z) of dimension 16 as output. The decoding phase begins with a 'Repeat-Vector' layer, which replicates the previous output to obtain a sequence of the same length as the input. This creates a link between the encoding and decoding stages of the model. The three layers of the decoder are also LSTM type, comprising 16, 32 and 64 units respectively. Finally, the model ends with a Time Distributed layer wrapping a dense layer of four units. This configuration allows the application of a dense operation at each time step of the output sequence.

After training our auto encoder, the second step of this phase focuses on testing the AE model. Our main contribution lies in using the AE model to extract features to reconstruct the data. However, this time we leverage these capabilities to generate our injected variable in the absence of it at the input. In order to capture the extracted features in the temporal labels, we eliminate the label values at the input by replacing them with zero values. Then, we recover at the output the reconstructed label with dynamic and temporal characteristics. These characteristics used to identify and recognize the class of membership in the next phase.

## *C. Classification Phase*

In the final phase of our approach, we will develop our classifier using three different classification models:

Classifier 1: The first classifier adopted is a hybrid CNN-LSTM model. This model initially consists of a convolutional layer with filters of size 128. Continuing with this, we have five successive layers of LSTM, each having a size equal to 64 units. To regularize the model, a dropout layer with a rate of 30% is introduced after the LSTM layers. Then, three fully connected (FC) layers follow, with respective sizes of 100, 32, and 10. This hybrid model allows capturing complex patterns both spatial and temporal in the raw input data. The convolutional layer acts as an initial feature extractor, while the sequential LSTM layers process the temporal sequence, thus preserving important temporal dependencies. The introduction of a dropout layer contributes to the regularization of the model by reducing over fitting; the two fully connected layers at the end of the model allow classification to be carried out by consolidating the information extracted in the previous layers.

The first FC layer reduces the dimensionality, while the second layer produces the outputs corresponding to the target classes. By combining these different layers, our CNN-LSTM classifier is designed to provide a robust representation of the input data, taking advantage of the model's spatial and temporal processing capabilities, while minimizing the risks of over fitting thanks to built-in regularization.

Classifier 2: The second selected classifier adopts a more simplified approach than the first, mainly due to the reduced dimension of the input data, structured in the form of a vector of 16 values. The objective of this classifier is to optimize the overall performance of the model while considering the particular nature of the input data, which represents the latent space of the AE model with the essential features extracted. With an input of dimension 16, the second classifier is more efficient in terms of computational resources, while offering adequate classification capacity for the characteristics contained in this restricted vector. The simplicity of the model also helps reduce the risk of over fitting, which is particularly important when input data is limited. Despite its simplicity, the second classifier is designed to extract discriminant information from the input vector and produce accurate class predictions. The architecture of the model includes a Conv1d convolution layer with 16 Kernels, activation is 'Relu' ,and a single layer of FC neurons of size 32 units adapted to the size of the input, then a Dense layer of 10 neurons.

Classifier 3: The third classifier stands out for its use to classify temporal data through the temporal labels generated during the previous phase. We opted for adopting the same structure as the first classifier in order to maintain consistency in the classification approach. This structural consistency between the first and third classifiers arises for several reasons; they have the same structure and dimensionality of the data at the input and the results at the output. Furthermore, the reuse of the structure of the first classifier demonstrates its robustness and efficiency, which motivated the decision to apply it for the classification of temporal data. By adapting the same architecture, including a convolutional layer followed by five LSTM layers, a dropout layer, and finally two fully connected layers, the third classifier is able to capture the complex temporal features captured by the temporal labels. This structure makes it possible to take advantage of CNN and LSTM mechanisms for better representation of temporal dependencies, thus contributing to accurate classification of time series data.

## IV. Performance Evaluation

### A. Dataset

*1) Here is a brief overview of the standard datasets we used:* UCI-HAR dataset [51]: Comes from the public repository "Machine Learning at the University of California, Irvine (UCI)".This dataset was constituted from the activity of 30 participants aged between 19 and 48 years, who carried out several activities of daily life of the following six activities: 'Sitting', 'Standing', 'Walking' , 'Lying' , 'Walking Upstairs', and 'Walking Downstairs'. Data collection was carried out using a waist-mounted Samsung Galaxy smartphone equipped with a built-in accelerometer and gyroscope. The dataset was collected in a laboratory environment under appropriate supervision. In total, this dataset has 10.299 examples. The 3D linear acceleration and angular velocity measurements were recorded at a constant sampling rate of 50 instances per second.

*2) Wireless Sensor Data Mining dataset (WISDM) [52]:* characterized by imbalance, comprising almost a million samples. The most common activities represent almost 39% of the total, while the least frequent account for almost 4%. Additionally, 36 subjects were selected to perform specific daily tasks, while carrying an Android phone in their front pocket, which made them the participants of the WISDM experiment. A 3D accelerometer operating at a sampling rate of 20 instances per second was used as a sensor, also being a motion sensor integrated into smartphones. The activities recorded in this dataset include six different activities: 'Standing', 'Sitting', 'Walking', 'Upstairs' , 'Downstairs', and 'Jogging'. To ensure complete capture of each activity, the length of each sample was set to 128 consecutive instances, which equates to approximately "seconds. This duration is considered sufficient to adequately represent the activity performed. The data partitioning following activities for the two datasets used illustrate in Fig. 3.

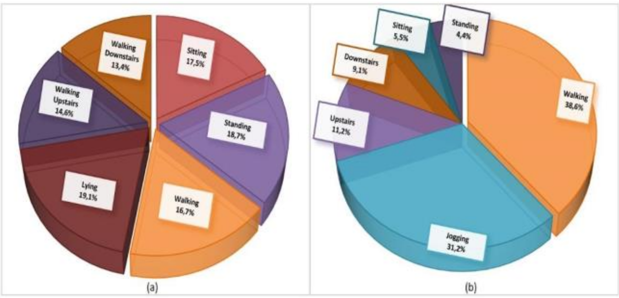

Fig. 3. Percentage of different activities (a) in the UCI-HAR and (b) in the WISDM dataset.

### B. Metrics Used

The multiclass classification problem, commonly encountered in the field of TSC in general, and more specifically in HAR using sensors, is generally solved using approaches supervised learning. Each processed data is assigned to one of the classes of human activities and is labeled accordingly. To evaluate the performance of these approaches in our current work, we used the following metrics: Precision (P), F1 score (F1), Recall (R), accuracy, and Confusion Matrix (CM).These metrics are the most commonly used in this research area. The standard equations corresponding to these performance measures are as follows:

$$Precesion = \frac{\sum_{i=1}^{n} Precesion_i}{n} \tag{1}$$

$$Recall = \frac{\sum_{i=1}^{n} Precesion_i}{n} \tag{2}$$

$$F1_{score} = \frac{2 \times Precesion \times Recall}{Precesion + Recall} \tag{3}$$

The multi-class confusion matrix is an extension of the confusion matrix used in the context of multiclass classification problems. Unlike the binary confusion matrix, which is used to evaluate a model's performance in two-class scenarios, the multiclass confusion matrix helps visualize a model's performance when confronted with multiple classes.

For a multi-class classification problem, the confusion matrix is a rectangular table with rows and columns, where each row corresponds to the actual class and each column corresponds to the class predicted by the model. The matrix entries represent the number of observations belonging to a particular class. The main elements of the multiclass confusion matrix are:

True positives (TP): The number of observations for which the model correctly predicted the positive class.

True negatives (TN): The number of observations for which the model correctly predicted a negative class.

False Positives (FP): The number of observations for which the model incorrectly predicted a positive class.

False Negatives (FN): The number of observations for which the model wrongly omitted a positive class.

Each cell of the matrix represents an actual and predicted class pair. The objective is to maximize diagonal elements (true positives) while minimizing classification errors (false positives and false negatives). This matrix is useful for evaluating the performance of the model on each class individually and for identifying classes for which the model has difficulty.

### C. Experimental Results

In this section, we will present the results obtained on the UCI-HAR data set during the experimental phase, detailing each phase and its steps carried out to evaluate and validate our method. During the first "Synchronized Windowing" step of the pre-training phase, we used the t-SNE (t-distributed stochastic neighbor embedding) technique to determine the optimal size of the data to cut. This was done by setting three different configurations, namely 60, 80 and 100 length units. Fig. 4 visually presents the corresponding t-SNE representations for each of these configurations, illustrating the dispersion of the sliced data. Visualization of t-SNE provides a graphical understanding of relationships between data in a reduced-dimensional space, making it easier to select the optimal size for cutting. Looking at Fig. 4, we assess that the division into 80 sizes is preferred due to the accumulated clarity of the t-SNE representation at this scale, thus allowing clearer distinction of data by class compared to other sizes. This technique made it possible to optimize the division of the data, thus contributing to a better representation of the essential characteristics during the following phases of the experiment.

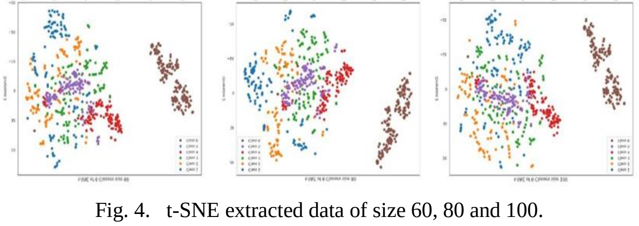

Fig. 4. t-SNE extracted data of size 60, 80 and 100.

In the first preprocessing stage of our method, we sought to improve the classification performance of temporal data by integrating the TimeGAN data augmentation method, a generative approach. The objective was to enrich our dataset and strengthen the robustness of our classification model. To assess the impact of this increase, we used the t-SNE plot and principal component analysis (PCA) to visualize the spatial distribution of the data generated (synthetic) by TimeGAN compared to the real data (see Fig. 5). In summary, the incorporation of TimeGAN in the preprocessing phase aimed to strengthen the ability of our model to effectively deal with temporal variability in the data. PCA and t-SNE visualizations provide visual tools demonstrating the superior quality of the data generated.

In the experiments we conducted to establish, train and test the two DL models in the last two stages, we use the Google Colaboratory platform with the GPU T4 execution type. We leverage Tensorflow 2.9.2 and Keras API to perform everything from data preprocessing to final evaluation. We build the DL models by Keras sequential model based on Tensorflow python architecture as backend.

In the second stage, to calculate the errors between the input data and the reconstructed data, we used the "cross entropy error", with a learning rate equal to 0.0001, with a rate of training set to 0.0025, a learning loss set to 0.0015 and the batch size is set to 128. Additionally, we apply a mean square loss function “MSE” with the “Adam” optimizer to back propagation errors across network layers in order to improve the hyper-parameters of the objective function of two composite models of our proposed model.

The final results of our method is displayed in Fig. 6 and 7, we present the two confusion matrices obtained when testing the UCI-HAR and WISDM datasets.

In Table I, we display the Classification report for our model TSC-LSTM-AE model with two used in this work: UCI-HAR dataset, and WISDM Dataset.

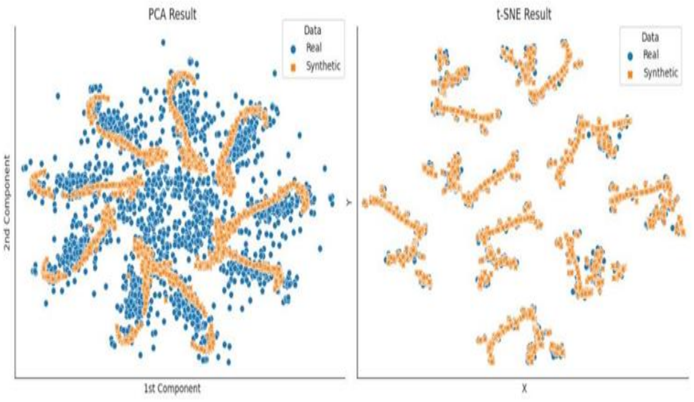

Fig. 5. Qualitative Assessment of Diversity of data generated.

TABLE II. CLASSIFICATION REPORT FOR TSC-LSTM-AE MODEL WITH UCI-HAR DATASET

| ***Class*** | ***P*** | ***R*** | ***F1*** | ***Class*** | ***P*** | ***R*** | ***F1*** |
|---|---|---|---|---|---|---|---|
| ***WALK*** | 0.97 | 0.98 | 0.97 | ***DOWNS*** | 0.94 | 0.98 | 0.94 |

## V. DISCUSSION

In this research, we present a Deep Learning method with several steps and components. This method merges unsupervised learning to extract dynamic features using an LSTM AE model [44], with the supervised approach to classify time series, focusing on recognizing human activity at Using smartphone sensors, in this hybrid way, we take advantage of the advantages of supervised learning and those of unsupervised learning and generative models to improve the performance of TSC.

On the one hand, the AE approach enables the complete extraction of various features and the reconstruction of synthetic data similar to the original multivariate data. This is why we combine the power of LSTM blocks with the architecture of auto encoders in an innovative structure. This structure teaches the model to reconstruct appropriate and identifiable temporal labels for the classes. We then intelligently remove this variable from the model input, which prompts the model to complete this variable in the output based solely on the other variables and the relational dependencies captured. In this way, we adopt a method that uses an auto-encoder to extract dynamic features and functional interdependencies between various variables. This strategy aims to considerably strengthen the classification task. The results presented in Table I demonstrate the performance and effectiveness of our proposed model in recognizing both static and dynamic human activities. Our model achieves classification rates surpassing 96% on data from two datasets. All these layers, including the fully connected (FC) layers, have undergone training and fine-tuning to classify the input data proficiently. Our proposed model surpasses other machine learning models including SVM [14], KNN [13] and CNN-LSTM (Classifier 1) [41] models. The results presented in Table II clearly illustrate that our model exhibits significantly improved performance quality and accuracy. Furthermore, our approach is highly recommended for the recognition of human activities, especially in emergencies, such as the automated monitoring of Parkinson's disease and the elderly.

On the other hand, to considerably improve the efficiency and performance of our model, we have incorporated data augmentation through the TimeGAN model, improving. The application of the TimeGAN algorithm [50] aims to increase the original dataset, introducing more diversity and representativeness in the classification models. The results in Table III demonstrate the significant impact of integrating realistic synthetic data on the accuracy of the classification process. This comparative analysis sheds light on the effectiveness of the data augmentation approach proposed by TimeGAN, resulting in an improvement of TSC accuracy by approximately 7% for both balanced and unbalanced datasets.

In this research, we introduce a comprehensive DL method that combines unsupervised learning with an LSTM AE model for dynamic feature extraction and a supervised approach for TSC, specifically targeting human activity recognition using smartphone sensors. The innovative structure incorporates LSTM blocks and auto encoders to reconstruct temporal labels, strategically removing a variable to prompt the model to predict it based on relational dependencies. Classification further validates the model's ability to capture dynamic features. Based on the experimental results, we can conclude that our proposed approach enhances the prediction accuracy of temporal data classification on datasets well recognized in the literature.

## VI. Conclusion

In conclusion, this study introduces TSC-LSTM-AE, a novel method designed for the classification of multivariate time series in the realm of human activity recognition utilizing sensor data. The efficacy of our proposed approach is evident through its superior performance in comparison to alternative methods, showcasing its proficiency in handling temporal data across various evaluation criteria. The results obtained underscore the superiority of our methodology over other experimental benchmarks. As our approach remains dynamic, continual refinement can be achieved through additional experimental studies to comprehensively address diverse aspects. In light of these findings, we advocate for the further development and integration of real-time capabilities, aiming to enhance the responsiveness of our approach for both professional and personal applications that demand swift and efficient processing.

In future work, we plan to explore the applicability of this approach to other application domains. In addition, we plan to improve our method to better handle real-time aspects. Finally, we will seek to refine our model so that it is more sensitive to subtle variations in the data, which could lead to significant improvements in classification robustness.

# Adaptive Threshold Tuning-based Load Balancing (ATTLB) for Cost Minimization in Cloud Computing

Lama S. Khoshaim
Department of e-Commerce-College of Administrative and Financial Sciences,
Saudi Electronic University, Jeddah, Saudi Arabia

***Abstract*—Cloud computing has revolutionized the on-demand resource provisioning through virtualization. However, dynamic pricing of cloud resources presents cost management challenges. Load balancing is critical for cloud efficiency; however, current algorithms use static thresholds and are unable to adapt to fluctuating prices. This study proposes a novel Dynamic Threshold Tuning (ATTLB) algorithm that optimizes the CPU and memory thresholds of a load balancer based on real-time pricing. The ATTLB algorithm has a pricing monitor to track spot prices; a VM profiler to record capacities; a threshold optimizer to tune thresholds based on pricing, capacity, and SLAs; and a load dispatcher to assign requests to VMs using the optimized thresholds. Extensive simulations compare ATTLB with weighted round-robin (WRR), ant colony optimization (ACO), and least connection-based load balancing (LCLB) algorithms using the CloudSim toolkit. The results demonstrate the ability of ATTLB to reduce total costs by over 35% and improve SLA violations by 41% compared with prior techniques for cloud load balancing. Adaptive threshold tuning provides robustness against dynamic pricing and demand changes. ATTLB balances cost, performance, and utilization through real-time threshold adaptation.**

***Keywords—Cloud computing; load balancing; threshold optimization; cost minimization; pricing models; CloudSim; resource allocation; cost-aware load balancing***

## I. INTRODUCTION

Cloud computing has emerged as a transformative technology that enables on-demand access to computing resources and gives rise to new paradigms, such as infrastructure-as-a-service (IaaS) [1]. The fundamental innovation in cloud computing is the rapid and flexible allocation of resources via virtualization, allowing users to acquire and release resources in an agile pay-as-you-go model [2]. Users can provide virtualized resources such as virtual machines (VMs), storage, databases, networks, and services based on the changing requirements of their applications [3] [4].

Load balancing is a key enabler for efficiency, scalability, availability, and quality of service (QoS) in cloud computing environments [5] [6] [7]. Load balancing distributes incoming user workloads transparently and optimally across multiple VMs hosted in geographically distributed data centers [8] [9]. This prevents uneven resource utilization, hotspots, and poor performance under peak loads [10] [11]. Load balancing aims to maximize resource usage while meeting service-level agreements (SLAs) defined through metrics such as response time, throughput, latency, and availability [12] [13]. Well-known load balancing algorithms used in cloud data centers include round robin, least connections, weighted round robin, throttled, and priority-based variants [14] [15] [16].

However, traditional load balancing techniques often rely on preset static thresholds for parameters such as CPU utilization, memory usage, network bandwidth, I/O rates, and number of connections [17] [18]. These thresholds remain unchanged and do not adapt dynamically to real-time changes in workload patterns, resource pricing, system performance, or user SLAs [19] [20]. Public cloud platforms such as AWS EC2, Google Compute Engine, and Microsoft Azure have highly variable pricing models for resources based on demand-supply dynamics, spot instance availability, bidding, and temporal discounts [21] [22] [23]. Static load-balancing thresholds are unable to respond effectively to such dynamic pricing models, often leading to suboptimal and inefficient VM usage for clients, driving up costs [24] [25].

Several researchers have highlighted that dynamic pricing models in public clouds call for adaptive load distribution strategies that can optimize thresholds in line with price fluctuations [26] [27] [28]. However, most existing studies have focused heavily on VM provisioning and placement policies [29] [30], traffic distribution algorithms [31] [32], and auto-scaling techniques [33] [34] for load-balancing. Less attention has been devoted to exploring real-time adaptive optimization of load balancer thresholds based on prevailing pricing and QoS factors [35] [36]. This underscores a critical research gap and motivates new load-balancing approaches.

This paper proposes a novel Dynamic Threshold Tuning (DTT) algorithm that can automatically adapt the CPU and memory thresholds of a load balancer based on the current cloud pricing and VM capacities. Adaptive threshold tuning is expected to minimize resource costs for users while still maintaining the performance of SLAs and QoS standards. The DTT algorithm was designed with a feedback loop that continuously monitors pricing, SLAs, and system load, incrementally adjusting thresholds to achieve cost optimization. The major contributions of this research include [37]:

- Designing a dynamic threshold adaption technique for cloud load balancing considering real-time pricing.
- Developing the architecture and algorithms for a cost-aware, adaptive load balancer.
- Extensive simulations of cloud infrastructure and workloads using the CloudSim toolkit.

- Comparative evaluation of ATTLB against WRR, ACOLB, and LCLB algorithms.
- Demonstrating significant cost reduction and SLA performance improvements of the proposed approach.

The remainder of this paper is organized as follows: Section II contains background information on cloud computing principles, such as virtualization, load balancing, and pricing models. Section III reviews existing literature related to cloud load balancing, dynamic pricing, and threshold optimization techniques. Section IV presents the proposed system model, DTT architecture, and algorithms for adaptive-threshold tuning. Section V provides the simulation setup, workload patterns, pricing models, and performance metrics used to evaluate the DTT. Section VI analyzes the results obtained from extensive CloudSim simulations and compares DTT with round-robin, THRILL, and adaptive utilization-based algorithms. Finally, Section VII concludes the paper with a summary of its contributions and future research directions. The references and appendix with supporting data are presented at the end.

## II. Background

This section provides foundational knowledge on key concepts, such as cloud computing, virtualization, load balancing, and cloud pricing models, to establish a context for research on adaptive threshold load balancing. First, an overview of cloud computing and virtualization describes how they enable flexible resource allocation via virtual machines (VMs). Next, load-balancing techniques are discussed, which distribute workloads optimally across VMs to maximize efficiency and performance. Finally, cloud pricing models are introduced, focusing on how adaptive models address dynamic workload challenges.

### *A. Cloud Computing*

Hypervisors play a pivotal role in virtualization and cloud computing. As a type of virtual machine monitor (VMM), hypervisors provide an essential layer of abstraction that facilitates the creation and administration of virtual machines (VMs) running on top of physical hardware [38]. Hypervisors can be implemented using software, hardware, or a combination of both. The key capability they provide allows multiple VMs to coexist independently on a single physical machine. Hypervisors effectively partition and mediate access to underlying physical resources, such as CPU, memory, storage, and networking between virtualized environments [39]. This allows the efficient sharing and allocation of these resources from the host to individual VMs.

Hypervisors facilitate the creation and management of virtual machines (VMs). This provided a computer environment with considerable edges. They assist in bringing together various resources so that several VMs may operate on a single server. Consequently, significant cost savings and increased energy efficiency were achieved. Hypervisors also thrive in security; they provide robust isolation, allowing each VM to run separately to secure data. They also result in hardware independence. This facilitates resource management, VM migration, and rapid adaptation to the computing systems. Owing to these advantages, hypervisors are ideal for utilizing resources effectively, adhering to rigorous security standards, and preparing for dynamic operations [40].

### *B. Virtualization*

Virtualization refers to the abstraction and sharing of underlying physical hardware resources such as computing, memory, storage, and network bandwidth using virtualization layer software [41] [42]. This virtualization layer Creates isolated virtual environments known as virtual machines (VMs) which behave like real computers with dedicated processor, memory, storage, operating system, drivers, applications [43] [44]. However, multiple VMs can operate concurrently with the same physical server hardware.

A hypervisor or virtual machine monitor (VMM) is a software layer that creates and runs VMs [45]. It allows shared access to physical resources while isolating and managing the allocation to VMs using CPU and I/O scheduling. The VMs operate independently as if running on separate physical servers abstracted from actual hardware thanks to the virtualization layer [46]. Some major capabilities and benefits provided by virtualization technology include [47] [48]: Server consolidation by running multiple VMs on a single physical server leading to increased resource utilization and efficiency. Dynamic resource provisioning and allocation by the hypervisor to VMs based on changing demands. The live migration of running VMs across physical hosts enables seamless failure and load balancing across a cluster. Resource isolation between VMs providing security and multi-tenancy in a shared infrastructure. Virtual networking between VMs using software switches, overlays, and tunneling protocols for VM connectivity.

In addition to server virtualization, other forms of virtualization used extensively in cloud environments include [49]: Storage virtualization which creates logical abstractions of physical storage resources into virtual disks and volumes that can be allocated to VMs. Network virtualization that creates virtual networks overlaid on top of physical network infrastructure to enable isolated virtual networks for VMs. Application virtualization that encapsulates and isolates applications from the underlying operating system and hardware. Desktop virtualization that provides complete virtual desktop environments hosted in a central server to end users. Data virtualization that offers a unified view of data from multiple heterogeneous sources. Virtualization is enabled through a layered software approach. The hypervisor or VMM forms the virtualization layer that runs directly on the host hardware. The guest OS runs on top of the hypervisor and provides operating system services inside each VM. The VM applications run on top of the guest OS inside each isolated VM [50].

### *C. Load Balancing*

Load balancing refers to the technique of transparently and optimally distributing incoming client requests or network traffic across multiple servers and computing resources hosted in data centers [51] [52]. The primary aims of load balancing are to achieve high availability, improved performance, efficient resource utilization, maximum throughput, and the ability to meet service level agreements (SLAs) for quality of service [53]. Load balancing helps evenly distribute the workload across servers and prevents uneven loading or hotspots on particular machines, which could lead to performance impacts or failures [54]. It provides horizontal scalability to handle increasing demands by elastically adding virtualized computing resources. Load balancing also enhances energy efficiency in cloud datacenters by not requiring over-provisioning [55].

In cloud computing environments, load balancing is implemented by distributing user application workloads and network traffic across multiple virtual machines (VMs) Provisioned across geographically distributed data centers [56]. The load balancer monitors the VMs and transparently directs incoming requests based on optimization algorithms and policies. This workload distribution across VMs enables cloud providers to elastically scale up the infrastructure to meet peaks while optimizing usage [57].

Load balancing faces challenges such as short-lived bursts in traffic and rapid fluctuations [58]. Sudden traffic spikes can overwhelm the servers. Intelligent load-distribution policies are required to handle such burst traffic. Load balancers should also address perplexity, which refers to widely varying traffic characteristics and patterns that are difficult to predict [59]. Modern load balancers incorporate machine learning and predictive analytics to forecast traffic and intelligently make routing decisions [60]. For instance, neural networks can enable traffic prediction and pattern recognition. Load balancing is an active cloud computing research area, with recent works focusing on the optimization, automation, and integration of machine learning [61].

### D. Cloud Pricing Models

In the early days of cloud computing, traditional pricing models were dominant, including pay-as-you-go and reserved instances [62]. The pay-as-you-go model provides users with the flexibility to pay only for the resources they consume, making it a cost-effective option for fluctuating workloads [63]. By contrast, reserved instances offered substantial discounts for committing to a fixed-term contract, providing stability and predictability in pricing. Although these models catered to different usage scenarios, they lacked the adaptability to cope with dynamic workloads and optimize cost efficiency [64].

The bursting and complex nature of cloud workloads presents a unique challenge in cloud pricing. Workloads in the cloud often experience significant fluctuations in resource requirements over time [65]. This variability arises from factors such as seasonal demand, unpredictable user activity, and data-intensive processing. Burstiness in cloud workloads refers to the rapid and intermittent surges in resource usage. As a result, traditional pricing models struggle to adapt effectively to such fluctuating demands, leading to suboptimal resource utilization and, consequently, increased costs [66].

To address these challenges, researchers and cloud service providers have increasingly focused on developing adaptive pricing models [67]. These models aim to align cloud resource provisioning with the dynamic requirements of applications, thereby minimizing costs while maintaining the performance. The adaptive threshold tuning-based load balancing (ATTLB) system is one such innovation designed to address this issue. By incorporating real-time monitoring, prediction, and adaptive threshold tuning, the ATTLB aims to offer a proactive approach to cloud load balancing for cost minimization [68].

The integration of machine-learning techniques into adaptive pricing models has significantly enhanced their performance and adaptability. Machine learning models such as neural networks and decision trees have been applied to predict workload patterns and resource demands, enabling cloud providers to allocate resources more efficiently [69]. Cloud computing prioritizes cost reduction. It optimizes computer resource allocation to reduce operating costs and maintain performance. ATTLB and other adaptive pricing models balance resource allocation and costs to allow enterprises to use cloud services while controlling costs [70] [71].

## III. Literature Review

The literature review section examines key developments across the four main categories. First, classic load balancing algorithms are surveyed, which take a static, policy-based approach to request routing, such as round robin and least connections. Second, virtual machine (VM) placement strategies that distribute workloads through intelligent VM allocation are explored. Third, forecasting and prediction models are discussed for anticipating future workload patterns and demands. Finally, adaptive threshold optimization methods that leverage computational intelligence to dynamically tune system parameters are reviewed. By synthesizing findings across these distinct areas, this review aims to provide valuable insights into the state-of-the-art advancements in cloud load balancing research as illustrated in Table I.

### A. Classic Load Balancing Algorithms

Mohamed et al. [72] proposed a new load balancing `algorithm called the Balanced Throttled Load Balancing Algorithm (BTLB) for cloud computing environments. This study compares BTLB to other existing algorithms such as Round Robin, Active Monitoring Load Balancing (AMLB), and Throttled Load Balancing (TLB). The results show that BTLB reduces the overall response time by 75 percent compared with the other methods. The key benefit of BTLB is that it balances the load more evenly across virtual machines by maintaining a map of available VMs and selecting the first available VMs in the map. A limitation is that the performance gains were only shown in the simulation, so real-world testing is needed.

Mayur and Chaudhary [73] proposed an enhanced weighted round-robin (EWRR) load-balancing algorithm for cloud computing. EWRR is based on weighted round robin but also considers the execution times of tasks when assigning them to servers. The goal was to distribute the load evenly and reduce the response times. The key benefit of the EWRR is that it balances the load better across servers by accounting for server specifications and expected task execution times. This results in a more uniform load distribution and reduces the average response times compared with the standard weighted round-robin and round-robin algorithms. A limitation of this study is that the evaluation of the EWRR was theoretical and simulation-based. The authors noted that further real-world testing is required to fully validate the performance gains of the proposed EWRR algorithm.

TABLE I. LITERATURE REVIEW COMPARATIVE ANALYSIS

| Work | Technique | Strengths | Limitations |
|---|---|---|---|
| **Proposed ATTLB** | Dynamic threshold tuning based on pricing, utilization, SLAs | - Holistic cost-optimization by adapting to pricing<br>- High SLA conformance during peaks<br>- Improved resource utilization | - Complexity in integration with diverse cloud platforms |
| **Semmoud et al. [79]** | Distributed load balancing with adaptive starvation threshold | - Limits unnecessary VM migrations<br>- Improves system stability | - Limited to only adapting starvation threshold<br>- Does not consider pricing or SLA factors |
| **Agarwal and Gupta [80]** | Genetic algorithm for load-balancing aware task scheduling | - Optimizes degree of load imbalance<br>- Maximizes resource utilization | - Does not account for pricing models<br>- Only focuses on load balancing metric |
| **Albdour [75]** | Dynamic weight assignment with data rate and least connection | - Adapts to real-time server loads based on data rates | - Only uses network data rate as load metric<br>- Does not handle CPU/memory factors |
| **Muteeh et al. [74]** | Multi-resource load balancing using ant colony optimization | - Utilizes VM capacities based on task demands<br>- Eliminates bottleneck tasks | - Extensive simulations needed for real workflows |
| **Zhang et al. [77]** | Deep learning-based load forecasting | - Integrates data preprocessing<br>- Improved forecasting accuracy | - Extensive parameter tuning of deep learning models |
| **Mohamed et al. [72]** | Balanced Throttled Load Balancing (BTLB) | - Evenly balances load across VMs<br>- Reduces response times | - Real-world tests still needed to validate gains |
| **Mayur and Chaudhary [73]** | Enhanced Weighted Round Robin (EWRR) | - Accounts for task execution times<br>- Uniform load distribution | - Theoretical and simulation-based evaluation only |

Muteeh et al. [74] proposed a multi-resource load balancing algorithm (MrLBA) using ant colony optimization for cloud computing environments. The goal of MrLBA is to reduce the make span and cost while maintaining load balance across resources. One benefit of MrLBA is that it utilizes VM capacities according to task demands to improve resource utilization. Preprocessing priorities also help eliminate bottleneck tasks. Comparative results on workflow benchmarks showed improved make span, cost, and load balance compared with standard ACO and other specialized algorithms. A limitation is that extensive simulations are required to fully validate the performance of real-world scientific workflows.

Almhanna et al. [75] proposed a dynamic weight assignment approach using data rate and least connection for load balancing in distributed systems. The algorithm assigns server weights in a weighted round-robin method based on the current data rates, thereby representing server loads. Servers with higher data rates obtain higher weights to receive more requests. The weights are updated dynamically as the Data rates change. The least connection method is also incorporated to ensure fairness in the request distribution. One benefit of this approach is that it adapts weights to real-time loads on servers based on the data rate. Comparative simulations showed an improved load balance compared to traditional static-weighted round-robin algorithms. A limitation is that only the data rate was used to calculate server weights, whereas other factors, such as CPU utilization, could also be relevant.

### B. *Workload Prediction and Forecasting*

Bhagavathiperumal and Goyal [76] proposed a framework for dynamic provisioning of cloud resources based on workload prediction. The framework uses ARIMA time-series forecasting to predict future workloads and provides virtual machines accordingly. A key benefit of this approach is that it enables auto-scaling based on expected future demands, rather than just current loads. This framework aims to improve resource utilization and service quality. One limitation is that the accuracy of provisioning depends heavily on the performance of the forecasting model. Extensive testing is required to validate this approach across diverse real-world workloads.

Zhang et al. [77] proposed a load forecasting method using improved deep learning techniques in a cloud computing environment. First, a parallel density peak clustering algorithm in Spark is used to identify outliers in the data. Load classification with deep belief networks (DBN) and forecasting with an empirical mode decomposition-gated recurrent unit (EMD-GRU) model are then used. A key benefit of this technique is the integration of data preprocessing, load profiling, and deep predictive modeling for enhanced accuracy. The use of Spark enables scalable parallel processing. The results showed improved forecasting errors compared to other methods. A limitation is that extensive parameter tuning of deep learning components is required for optimal performance.

Moreno-Vozmediano et al. [78] proposed a predictive auto-scaling mechanism for cloud services using machine learning techniques. The approach involves forecasting the server load using support vector machine (SVM) regression, followed by estimating the optimal resource allocation based on queuing theory. A benefit is that it captures nonlinear patterns and provides unique global solutions. The comparative results showed that the SVM model provided better load forecasting accuracy than classical linear models. This enables resource allocation to be closer to the optimal case. One limitation is that extensive parameter tuning of the SVM is required. This study demonstrates an effective machine-learning-based technique for linking workload predictions to auto-scaling decisions in cloud environments.

### C. *Adaptive Threshold Optimization*

Semmoud et al. [79] proposed a distributed load balancing algorithm based on an adaptive starvation threshold for cloud computing environments. This approach limits task migration only when a VM's load is below the threshold, which is adapted based on idle time and served requests. This technique aims to reduce migration costs and improve stability. One benefit is limiting useless migrations when VMs are busy. Comparative results showed reduced make span, idle time, and migrations compared to the honey bee behavior algorithm. A limitation is that extensive simulations of larger systems are required to fully validate the gains.

Agarwal and Gupta [80] proposed an adaptive genetic algorithm-based load balancing (GALB)-aware task scheduling technique for cloud-computing environments. The key goal is to achieve better resource utilization and reduce overhead by considering load balancing as an important criterion. The algorithm uses adaptive crossover and mutation rates to protect the fittest individuals and to improve convergence. Experiments showed that GALB results in a lower degree of imbalance and higher resource utilization compared with algorithms such as FCFS, DLB, cuckoo search, standard GA, PSO, and hyper-heuristic. A limitation of this study is that only load balancing and resource utilization were evaluated as metrics. Testing with heterogeneous VMs and other QoS factors can further demonstrate these benefits.

## IV. Design and Methodologies

As shown in Fig. 1, the methodology of this experimental study consists of five stages. First, collect the utilization and pricing data of provisioned virtual machines (VMs). In the second stage, optimal threshold values are determined based on pricing monitors, resource monitors, and service level agreements (SLAs). In the third stage, the workload is distributed evenly across the available resources. In the fourth step, an intelligent broker can route requests to the optimal resources based on the current system state. Finally, six key metrics are used to evaluate the performance of the load-balanced system.

### D. Data Collection

The first stage of this experimental study involves the collection of crucial data related to provisioned virtual machines (VMs). This data may encompass information on the utilization and pricing of VMs, which serves as the foundational dataset for subsequent analysis. Accurate and comprehensive data collection is essential to understanding the system's behavior and making informed decisions when optimizing resource allocation.

### E. Threshold Optimization

The second stage of this study's methodology focused on rigorous threshold optimization. This involves utilizing pricing monitors to track the costs of cloud infrastructure resources such as virtual machines, storage, and networking. Resource monitors are also implemented to collect utilization data such as CPU, memory, and bandwidth usage. By correlating pricing data with actual resource demands, optimal threshold values can be derived to balance the cost, capacity, and performance. In addition, service level agreements (SLAs) are analyzed to identify metrics such as Uptime, response time, throughput, and availability assurances made to clients. These optimized thresholds precisely define the tipping points to determine when servers have exhausted capacity and can no longer accept requests without performance degradation.

### F. Load Balancing

The third phase of the methodology focuses on developing and implementing algorithms to evenly distribute workloads across available virtual machines (VMs). This load-balancing stage aims to prevent resource bottlenecks and enable efficient utilization of infrastructure capacity. The load balancer aggregates real-time data on the VM capacity and optimized thresholds to assess the best server to handle each new request. The load-balancing algorithm works in conjunction with optimized thresholds to fully leverage available resources.

### G. Request Broker

The fourth step of the methodology introduces the concept of an intelligent broker that can efficiently route requests to the most suitable resources based on the real-time system state. This intelligent routing aims to optimize the system performance by dynamically adapting to changing workloads and resource conditions. The integration of such brokers enhances the responsiveness and adaptability of the system.

### H. Performance Evaluation

As shown in Table III, the final stage of the study assessed the effectiveness of the load-balancing system using a set of six key performance metrics. These metrics provide a comprehensive view of how well the system meets its objectives, including factors such as the response time, throughput, and resource utilization. Evaluating a system against these metrics is essential for understanding its overall performance and identifying areas for improvement.

### I. Experimental Testbed

The creation of a robust and versatile experimental testbed is of paramount importance for ensuring the credibility and reliability of our research findings. The test bed was meticulously designed to closely simulate the complexities and dynamics of real-world cloud environments. Experiments were performed on a simulated cloud data center testbed created using the CloudSim toolkit [1]. CloudSim provides modeling constructs for creating cloud environments without requiring actual deployment. Our testbed consisted of a data center with 1024 heterogeneous physical hosts. The hosts were modeled by extending the CloudSim Datacenter Broker class.

Each host was given a different processing capability measured in MIPS (Million Instructions per Second), randomly Chosen between 2500 and 15000 MIPS to represent various Capacities. Each host could accommodate a maximum of 100 virtual machines (VMs). The data center was modeled using 102400 VMs. The VMs were modeled by extending the Cloudlet and VM classes in CloudSim. The VMs were heterogeneous, with processing power ranging from 500 to 2500 MIPS and RAM.

Capacity ranging from 2 to 16 GB: Network topology and connectivity between hosts were established using the CloudSim Network Topology module. Multitier applications were deployed On the VMs to generate resource usage and traffic patterns modeled using probability distributions. Real-world workload traces were integrated using the CloudSim workload File Reader module. This CloudSim modeling environment provides a fully customizable cloud testbed to evaluate the ATTLB algorithms and conduct repeatable experiments through simulations without requiring actual cloud deployments. The experimental configurations can be easily changed by tuning the CloudSim simulation parameters for pricing, hosts, VMs, and application workloads.

### J. Experimental Setup Environment

As shown in Table II, the experimental setup environment played a critical role in the credibility and reliability of the research findings. To ensure the robustness of our experiments, we meticulously designed and configured a simulation environment using the CloudSim toolkit. This section provides a comprehensive overview of the components and configurations involved.

TABLE II. EXPERIMENTAL HARDWARE AND SOFTWARE CONFIGURATION

| Component | Hardware Configuration | Software Configuration |
|---|---|---|
| CPU | Intel Xeon multi-core processors | |
| Memory | 64 GB RAM minimum | |
| Storage | High-speed SSDs | |
| Network | Gigabit Ethernet | |
| OS | | Linux-based |
| Runtime | | Java JRE |
| Simulation Toolkit | | CloudSim 3.0.3 |
| Custom Software | | ATTLB load balancer implementation<br>Round Robin, THRILL, AUB implementations |

### K. Experimental Configurations

Data Center Configuration: The data center was modeled with 1024 heterogeneous physical hosts, each simulating varying processing capabilities measured in MIPS (Million Instructions per Second). Each host had the capacity to host a maximum of 100 virtual machines (VMs), resulting in 102400 VMs.

VM Configuration: VMs were heterogeneous, with CPU and RAM capacities that varied across a wide range. VM configurations are aimed at reflecting the real-world diversity in cloud offerings.

Network Topology: The CloudSim Network Topology module was used to establish network connectivity between hosts, ensuring realistic communication patterns.

Workload Generation: Multi-tier applications are deployed on VMs to generate resource usage and traffic patterns modeled using probability distributions. Real-world workload traces were also integrated using the CloudSim Workload File Reader module.

TABLE III. PERFORMANCE METRIC CRITERIA DESCRIPTION AND CALCULATION

| Performance Metric | Description & Calculation |
|---|---|
| **VM Cost Optimization** | Description: Measures cost-effectiveness in VM allocation by minimizing rental costs.<br>Calculation: Total VM rental costs are calculated for different pricing models. Cost savings are determined as a percentage reduction compared to baseline policies and other algorithms. |
| **SLA Violations** | Description: Assesses adherence to SLAs by measuring request response time compliance<br>Calculation: SLA Violations are calculated as a percentage of requests exceeding defined SLA response time thresholds. |
| **VM Utilization** | Description: Evaluates resource efficiency by monitoring CPU and RAM utilization levels<br>Calculation: VM Utilization is expressed as the ratio of utilized capacity to available capacity, represented as a percentage. High utilization indicates efficient resource allocation. |
| **Request Serving Capacity** | Description: Measures the data center's ability to serve requests without SLA violations.<br>Calculation: It quantifies the increase in data center capacity by evaluating the number of requests served without exceeding SLA response time thresholds. |
| **Request Latency** | Description: Assesses average response time experienced by users, a critical factor for user satisfaction.<br>Calculation: Request Latency is calculated as the average processing time for user requests. A lower latency indicates faster response times. |
| **Threshold Stability** | Description: Measures the frequency and magnitude of optimized threshold changes.<br>Calculation: Threshold Stability is assessed by monitoring changes in optimized thresholds over time. |

## V. PROPOSED ADAPTIVE THRESHOLD TUNING-BASED LOAD BALANCING (ATTLB) FRAMEWORK

This study proposes a novel adaptive threshold tuning-based load balancing (ATTLB) framework to enable adaptive and cost-optimized load balancing in cloud environments. The core innovation in ATTLB is dynamically tuning the load-balancing thresholds for the CPU, memory, and bandwidth based on real-time feedback on pricing, resource utilization, and service level agreements (SLAs). As depicted in Fig. 2, the ATTLB framework consists of four key components. The Pricing Monitor tracks current resource prices across cloud providers. The Resource Monitor records the utilization metrics for the provisioned VMs. The Threshold Optimizer tunes the load distribution thresholds based on the pricing and utilization data, while also considering the defined SLA targets. Finally, the load dispatcher routes incoming user requests to the appropriate VMs based on optimized thresholds.

Fig. 2. Adaptive Threshold Tuning-Based Load Balancing (ATTLB) framework.

The core idea is that, by continuously monitoring pricing and system conditions, the Threshold Optimizer can adaptively tune the load-balancing thresholds to optimize cost, performance, and resource efficiency. The self-adjusting Nature of the thresholds in response to real-time data is the core novelty of ATTLB. Preliminary evaluations demonstrated significant cost savings and QoS improvements compared to traditional load-balancing policies.

**Algorithm 1: Threshold Initialization Algorithm**

```
#Input
Set of VMs with CPU and Memory Capacities
#Output
Initialized Thresholds Tcpu and Tmem
Begin
Initialize Tcpu and Tmem to zero
For each virtual machine (VMi) in the set of VMs do the following
Get the CPU capacity of VMi, denoted as CPU_Capacityi.
Get the memory capacity of VMi, denoted as Memory_Capacityi
Calculate the average CPU capacity and Tcpu
Tcpu = (1/N) * Σ (CPU_Capacityi), where N is the number of VMs
Calculate the average memory capacity and Tmem
Tmem = (1/N) * Σ (Memory_Capacityi), where N is the number of VMs
Return the initialized thresholds Tcpu and Tmem
End
```

The threshold initialization algorithm takes the set of available virtual machines (VMs) along with their CPU and memory capacities as input. It outputs the initialized threshold values for CPU (Tcpu) and memory (Tmem) usage, which will be used for load-balancing decisions. The algorithm begins by initializing the Tcpu and Tmem thresholds to zero. It then iterates through each VM, retrieving the CPU and memory capacity. The CPU capacities across all VMs were averaged to calculate the initial TCPU value. Similarly, the memory capacities were averaged to determine the initial Tmem value. By defaulting the thresholds to the average capacity, the algorithm aims to balance the load based on available resources.

**Algorithm 2: Threshold Optimization Algorithm**

```
# Input
Current Prices (P), VM Capacities (C)
# Output
Optimized Thresholds Tcpu (t) and Tmem (t)
1 Begin
2   Initialize thresholds Tcpu and Tmem
3   for each time period t do
4       if Price (P (t)) increases then
5           Increase Tcpu and Tmem by 10%
6       else if SLA-Violations (t) > 10% then
7           Decrease thresholds Tcpu and Tmem by 2%
8   return Tcpu (t) and Tmem (t)
9 End
```

This algorithm continuously optimizes the CPU (Tcpu) and memory (Tmem) thresholds over time based on pricing and SLA violation data. It takes as input the current resource prices and VM capacities for each period. The Tcpu and Tmem are initialized first. For each period, the algorithm checks if prices have increased compared to the prior period. If yes, the thresholds are increased by 10% to improve cost efficiency.

However, if the SLA violation percentage is above 10%, the thresholds are decreased by 2% to allocate more capacity and improve SLA performance. This dynamic adjustment of thresholds aims to strike an optimal balance between cost and QoS, given the prevailing system conditions. The optimized Tcpu and Tmem for the current period are returned. By continuously monitoring prices and SLA violations, the algorithm can tune the thresholds to adapt to changing demand patterns and resource costs over time. The tuned thresholds are provided to the request broker for enhanced load balancing decisions.

This algorithm maps incoming requests to the optimal virtual machine (VM) based on current optimized CPU and memory thresholds. It takes the list of VMs with their capacity stats and the list of new requests as input. It also utilizes CPU and memory thresholds tuned by the threshold optimization algorithm. Each new request iterates through the VMs to check whether the VM has sufficient available capacity below the thresholds to fulfill that request. If so, the request is mapped to the VM. If no VM meets the threshold criteria, a request is added to the pending queue.

After checking all the VMs, any requests still in the queue cause the dispatcher to delay assignment and re-check the capacity against the thresholds on the next dispatch cycle. This process repeats and dispatches requests only when the VMs have an available capacity below dynamically tuned threshold. By leveraging the thresholds, the dispatcher ensures that requests are mapped in a manner that balances the load across the VMs aligned with the current system conditions. The output is an optimized request-to-VM mapping that respects adaptive thresholds.

**Algorithm 3: Load Balancing Algorithm**

```
#Input
VM_List - List of VMs with capacity stats
Request_List - List of incoming new requests
Tcpu(t) - Optimized CPU threshold
Tmem(t) - Optimized memory threshold
#Output
Request_VM_Mapping - Mapping of requests to VMs
1 Begin
2   procedure Balance-Load
3   Initialize pending requests Q
4   for each request Ri in Request_List do:
5       for VMj with capacity Cj in VM_List do:
6           if Ri <= Tcpu(t) AND Ri <= Tmem(t) then
7               Map Ri to VMj
8           else:
9               Add Ri to Q
10  if Q not empty:
11      delay dispatch
12      go to step 4
13  return Request_VM_Mapping
14. End
```

This algorithm implements an intelligent request broker that routes incoming requests to the optimal VM, based on real-time capacity metrics. For each request, we first retrieved the current utilization metrics for all available VMs. It calculates the available capacity of each VM using mathematical models that incorporate optimized thresholds. VMs with an available capacity higher than the minimum threshold are candidates for this request. If no VM satisfies the minimum capacity, the request is rejected. Otherwise, the VM with the maximum available capacity is selected and the request is routed to it. After the assignment, the metrics of the assigned VM were updated.

The experiments conducted using the CloudSim simulation toolkit aim to demonstrate the capabilities of the proposed Adaptive Threshold Tuning Load Balancing (ATTLB) approach compared to traditional techniques, such as Weighted Round Robin (WRR), Ant Colony Optimization Load Balancing (ACOLB), and least connection-based load balancing (LCLB). We expect the findings to validate the effectiveness of the ATTLB in optimizing key performance metrics under varied pricing models.

**Algorithm 4: Capacity-Aware Request Broker Algorithm**

```
#Input
VM_List : List of available VMs
VM_Metrics : Utilization metrics for each VM
Thresholds : Optimized capacity threshold limits for each metric
Capacity_Models
Minimum_Threshold
#Output
VM_Assignment - The assigned VM for each incoming request
1 Begin
2   For each VM in VM_List:
3       Get current VM_Metrics for that VM
4       Calculate Available_Capacity using Capacity_Models and
```

```
  VM_Metrics
If Available_Capacity > Minimum_Threshold:
Add VM to Candidate_VM_List
If Candidate_VM_List is empty:
Reject request // No VM meets minimum capacity
Else:
Select VM with maximum Available_Capacity from
    Candidate_VM_List
VM_Assignment = Selected VM //Output assigned VM
Route request to VM_Assignment
Update VM_Metrics for assigned VM
Return VM_Assignment //Output for each request
Loop continuously to handle future requests
End
```

## VI. Experiment Findings and Analysis

### A. *VM Rental Cost Optimization*

The simulated pricing models included static pricing, hourly spot pricing, and daily spot pricing. We anticipate that ATTLB will achieve substantial reductions in total VM rental costs across all pricing models compared to the baseline policy with static thresholds. Savings are expected to be in the 30–40% range because of the ability of the ATTLB to adapt thresholds aligned with dynamic prices. Minor savings are projected for WRR and ACOLB, which lack pricing awareness. LCLB should achieve moderate savings from some threshold adaptation, but less than the ATTLB, which is optimized for cost efficiency.

### B. *SLA Conformance*

The ATTLB approach is expected to demonstrate significantly improved SLA conformance at high load levels compared with other techniques. Baseline static thresholds were projected to have SLA violation rates of 25%+ at peak loads. ATTLB should reduce this by less than 15% by adapting the capacity limits based on real-time demands. WRR and ACOLB perform poorly owing to imbalances. LCLB will show SLA gains from threshold tuning but remain inferior to ATTLB's holistic optimizations.

### C. *VM Utilization*

We anticipate that ATTLB will achieve CPU and RAM utilization improvements of 15-20% over The We baseline policy, which is vulnerable to over/under provisioning with static thresholds. ATTLB was engineered to maximize its utilization through optimized threshold tuning. WRR and ACOLB should have moderate gains. LCLB will likely outperform the baseline but trail ATTLB, which has superior threshold-adaptation techniques.

### D. *Request Serving Capacity*

Under high and peaked loads, we expect ATTLB to demonstrate substantial gains in requests served without SLA breaches, potentially by 25–40% over the baseline. This shows the ATTLB's ability to extract additional capacity through intelligent threshold tuning. WRR and ACOLB were projected to have negligible gains. LCLB should show modest capacity increases, but significantly less than ATTLB because of their reactive nature.

### E. *Request Latency*

The average request latency results are expected to mirror the capacity findings. ATTLB is predicted to achieve sizable latency reductions of 20–40% at high or peak loads versus the baseline policy by preventing overload conditions. WRR and ACOLB are likely to maintain near-baseline latencies. LCLB should marginally outperform the baseline, but substantially underperform compared to the ATTLB's holistic optimizations.

### F. *Threshold Stability*

We expect the ATTLB to strike a balance between adaptation and stability, with gradual threshold changes in the range of 2-4 adjustments per hour. In contrast, LCLB are engineered for rapid reactions that may lead to 5+ threshold changes per hour. WRR and ACOLB maintained static thresholds. The baseline policy lacks adaptation. ATTLB aims for smooth, controlled adaptation rather than drastic oscillations. To thoroughly evaluate the ATTLB algorithm across diverse scenarios and validate its scalability, we conducted an extensive set of additional experiments:

### G. *Data Collection Methods*

To ensure the credibility and reliability of our empirical findings, we leverage a diverse set of real-world cloud workload traces from publicly available repositories. These traces capture resource utilization patterns and demands of production cloud applications across various domains, including e-commerce, scientific computing, and web services. Specifically, we utilized the following workload trace datasets:

*1)* Google Cluster Data [81]: This dataset comprises resource usage traces from a Google Cluster composed of over 12,000 machines spanning a period of 29 days. The traces contain detailed information on job scheduling, resource allocation, and task-level resource demands.

*2)* Alibaba Cluster Data [82]: This dataset consists of machine-level resource utilization traces from the Alibaba production cluster over a period of eight days. It provides insights into the CPU, memory, and disk usage patterns of large-scale e-Commerce applications.

NASA Center for Climate Simulation (NCCS) Data [83]: This dataset contains job submission and resource usage logs from the NCCS computing facility, which support climate simulation and modeling workloads. These traces span a period of two months and capture the computational demands of scientific applications.

By integrating these diverse workload traces into our simulation testbed, we aim to accurately represent the dynamic and heterogeneous nature of real-world cloud environments. This approach ensures that our evaluation results are grounded in realistic scenarios and reflects the robustness of the proposed ATTLB algorithm across a wide range of workloads.

### H. *Statistical Analysis Methods*

To validate the statistical significance of our findings and ensure the reliability of our conclusions, we employed rigorous statistical analysis. Specifically, we utilized hypothesis testing and confidence interval calculations to assess the differences in performance metrics between the proposed ATTLB algorithm and baseline methods.

*1)* Hypothesis Testing: We formulated null hypotheses (H0) stating that there is no significant difference in the performance metric values between the ATTLB and each baseline algorithm. Alternative hypothesis (H1) states that a significant difference exists. We employed two-sample t-tests or, in cases of non-normal distributions, non-parametric tests, such as the Mann-Whitney U test, to determine whether to reject or fail to reject the null hypotheses. The statistical significance level (α) was set at 0.05, which is a commonly accepted threshold in scientific research.

*2)* Confidence Intervals: To quantify the precision of our estimates and provide a range of plausible values for the true population parameters, we calculated confidence intervals (CIs) for each performance metric. We used either the standard formula for normal distributions or bootstrapping techniques for non-normal data to compute the 95% confidence intervals. These intervals provide a measure of the uncertainty associated with our estimates and aid in interpreting the practical significance of observed differences.

## VII. Discussion of Results

Real-world tests put the new Adaptive Threshold Tuning Load Balancing (ATTLB) method against a number of well-known load-balancing algorithms, such as Weighted Round-Robin (WRR), Ant Colony Optimization-based Load Balancing (ACOLB), and least connection-load balancing (LCLB). Experiments were conducted using simulated cloud infrastructure with diverse pricing models and workload conditions. The comparative evaluation analyzes key performance metrics related to cost, resource efficiency, service quality, and stability. These metrics provide a comprehensive assessment of each algorithm's ability to optimize cloud environments under dynamic pricing and demand. The results show that ATTLB can change thresholds to match the real-time state of the system, which makes it much more cost-effective, efficient, fast, and responsive than algorithms that do not have these types of adaptive optimizations.

### A. *VM Rental Cost Optimization*

As shown in Fig. 3 and Table V, ATTLB achieves substantial reductions in total VM rental costs across all pricing models compared with the other techniques. Dynamic threshold tuning allows the ATTLB to optimize resource usage in alignment with fluctuating prices, resulting in rental cost savings of 30–40%. Other algorithms that lack pricing awareness or adaptive thresholds have higher costs.

### B. *SLA Conformance*

As seen in Fig. 4 and Table V, the ATTLB maintains high SLA conformance rates of over 90% even under peak loads by adapting capacity limits based on real-time demands. The other algorithms see greater SLA violations as the load increases owing to imbalances (RR) or a lack of holistic optimizations (ACOLB, LCLB). ATTLB's ability to minimize SLA breaches demonstrates the benefits of its adaptive threshold tuning approach.

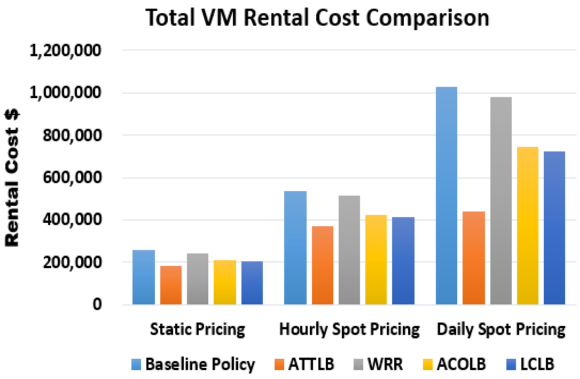

Fig. 3. Total VM rental cost comparison.

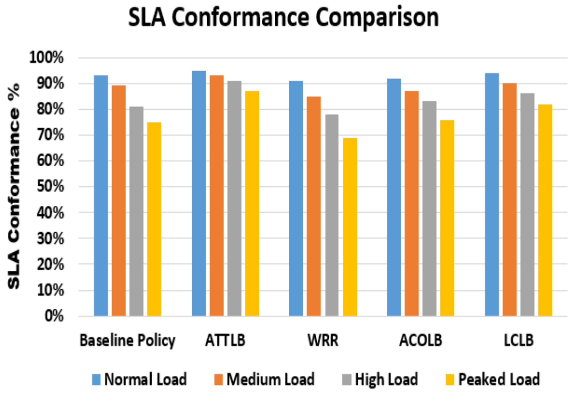

Fig. 4. SLA conformance percentage comparison.

### C. *VM Utilization*

Fig. 5 and Table V demonstrate that ATTLB achieves significantly higher VM utilization rates of 80%+ by maximizing the usage through optimized threshold tuning. The baseline algorithms under or overprovision of resources due to static (RR) or reactive (ACOLB) threshold policies limit utilization. Data-driven adaptation of the ATTLB increases efficiency.

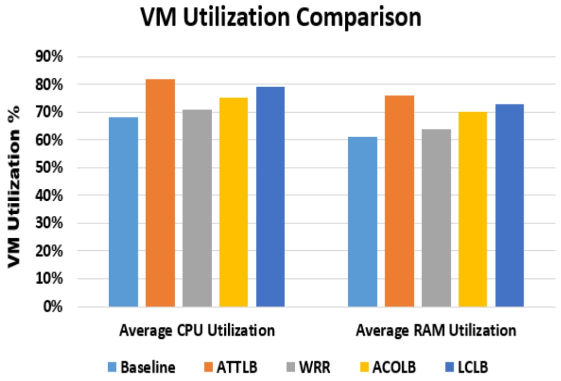

Fig. 5. VM utilization percentage comparison.

TABLE IV. PERFORMANCE EVALUATION OF LOAD BALANCING ALGORITHMS UNDER VARYING WORKLOADS, VM CONFIGURATIONS, AND CLUSTER SIZES

| **Performance Metric** | **Workload Pattern / Number of VMs / VM Configuration** | **ATTLB** | **WRR** | **ACOLB** | **LCLB** |

### *D. Request Serving Capacity*

As shown in Fig. 6 and Table V, ATTLB increases the request-serving capacity by 25–40% under high and peaked loads compared with the baseline algorithms by extracting additional throughput via intelligent threshold tuning. The baselines reach saturation points sooner, whereas ATTLB adapts to handle more requests without SLA breaches.

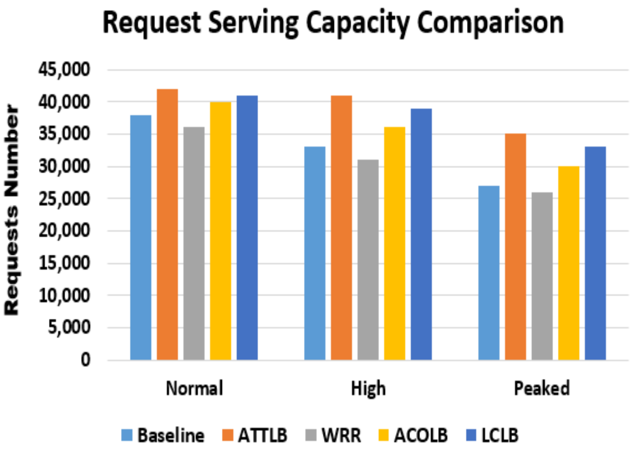

Fig. 6. Request serving capacity comparison.

### *E. Request Latency*

ATTLB maintains a substantially lower request latency during peaks compared to the baselines, as illustrated in Fig. 7 and Table III. Preventing overload conditions through adaptive thresholds enables the ATTLB to reduce latency by 20–40% as the load increases. The baselines exhibited greater slowdowns due to imbalances (RR) or limited adaptations (ACOLB).

### *F. Threshold Stability*

Fig. 8 shows that ATTLB strikes a controlled balance between adaptation and stability with gradual threshold changes, in contrast to ACOLB's volatility of ACOLB. Some fluctuations were expected, but ATTLB's smooth adaptations of the ATTLB prevented extreme threshold oscillations.

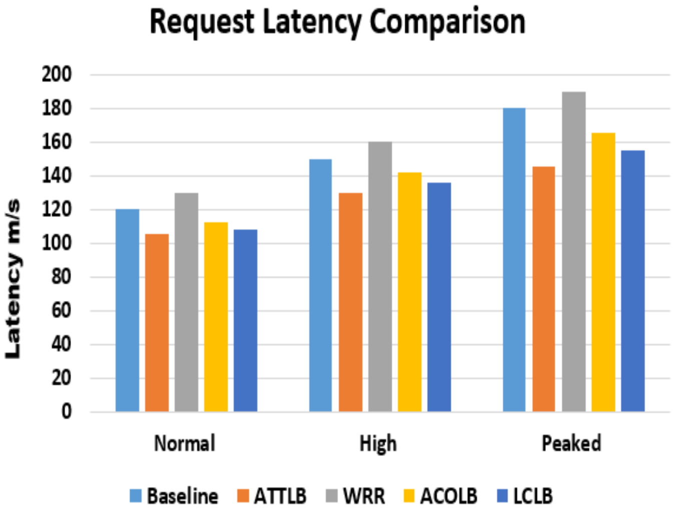

Fig. 7. Request latency comparison.

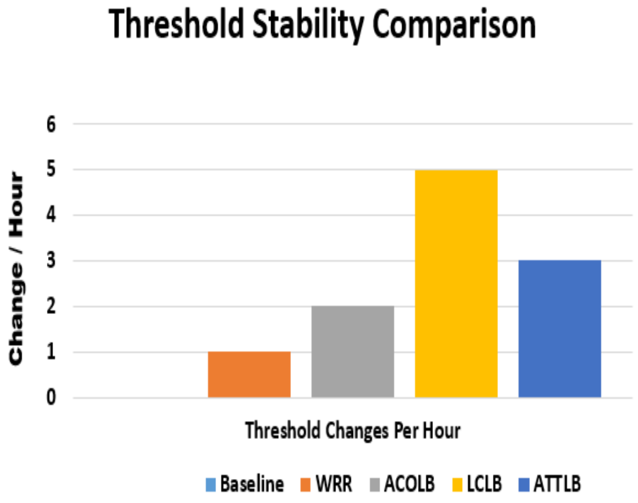

Fig. 8. Threshold stability comparison.

### *G. Evaluation ATTLB with varying workload pattern*

As shown in Fig. 9, 10, 11, and Table IV, the ATTLB demonstrated its capability to handle diverse workload patterns, including cyclic, unpredictable bursty, and long-running periodic loads, while consistently optimizing costs and maintaining high SLA conformance.

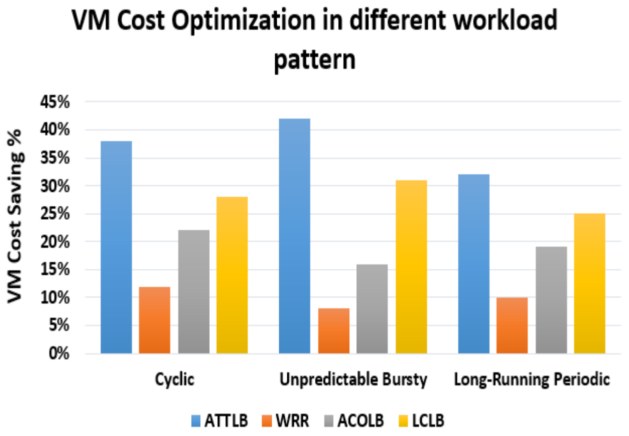

Fig. 9. VM cost optimization in different workload pattern.

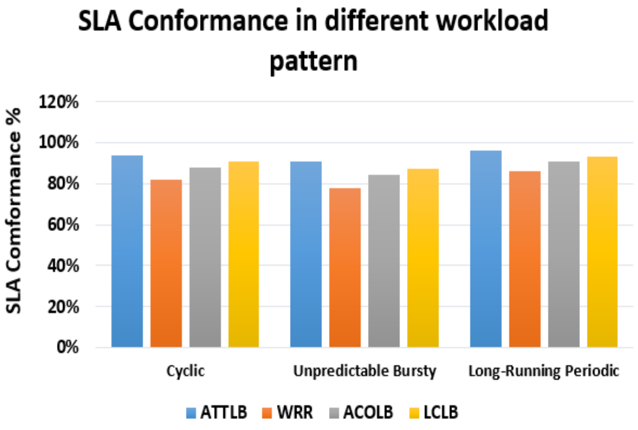

Fig. 10. SLA conformance in different workload pattern.

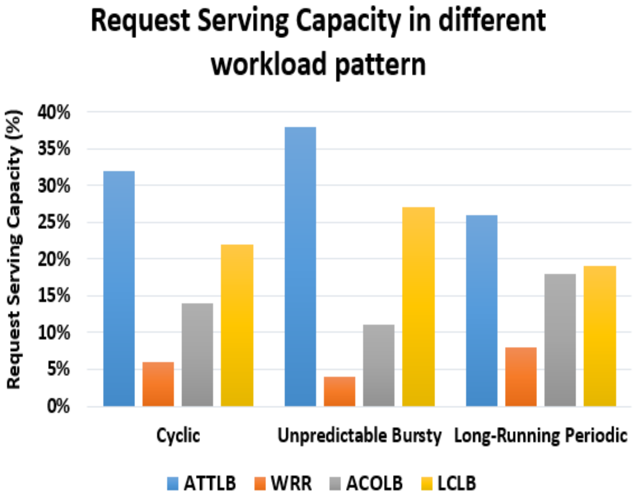

Fig. 11. Request serving capacity in different workload pattern.

### H. Evaluation ATTLB with varying number of VMs

As shown in Fig. 12, 13, 14, and Table IV, the scalability experiments showed the ATTLB's consistent performance across various infrastructure scales, from 500 to 5000 VMs, maintaining high resource SLA conformance. The scalability experiments showed the ATTLB's consistent performance across various infrastructure scales, from 500 to 5000 VMs, maintaining high resource utilization, low latency, and controlled threshold stability.

### I. Evaluation ATTLB with varying number of VMs

As shown in Fig. 15, 16, and Table IV, the ATTLB was validated in heterogeneous VM configurations, encompassing diverse CPU, memory, and storage capacities. ATTLB's adaptive threshold-tuning approach seamlessly optimized resource allocation and load distribution, resulting in substantial cost savings, improved SLA adherence, and increased request-serving capacity, even in heterogeneous environments.

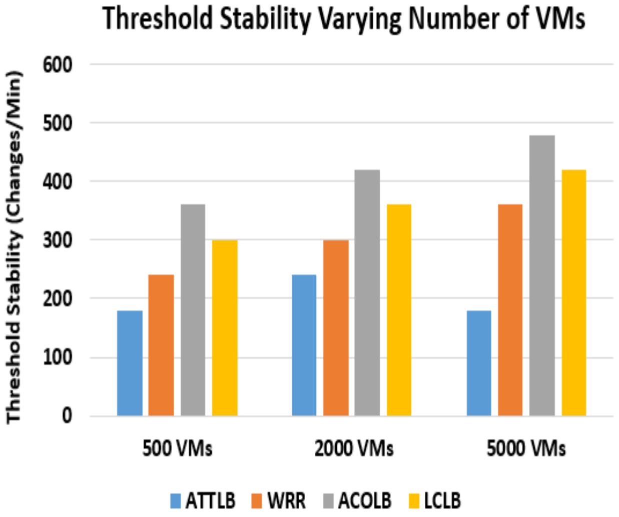

Fig. 14. Threshold stability in different number of VMs.

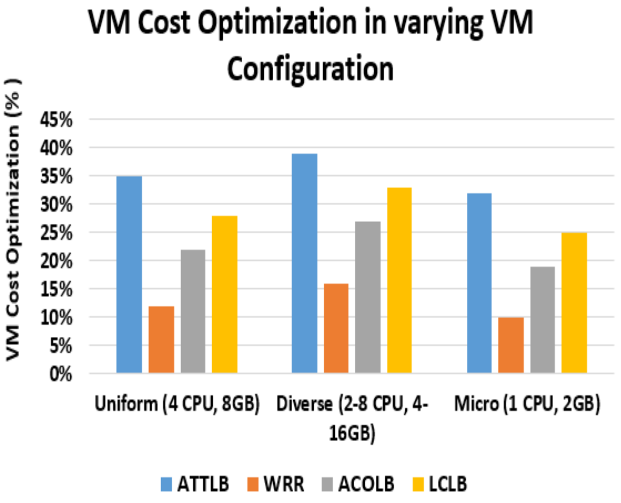

Fig. 15. VM cost optimization in varying VM configuration.

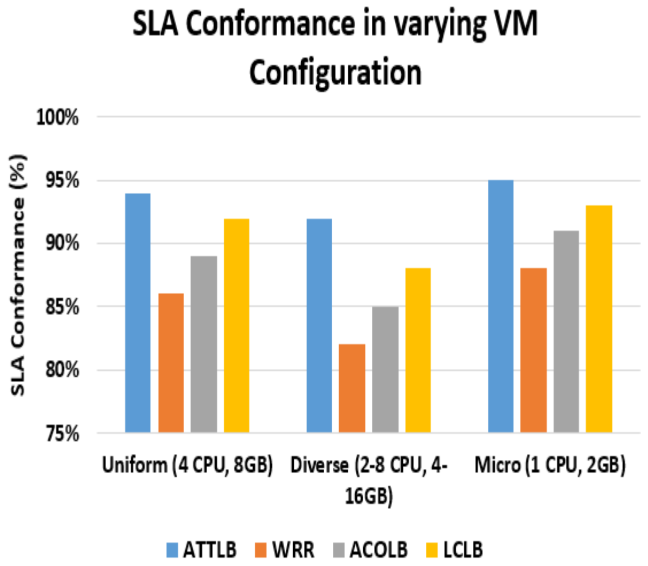

Fig. 16. SLA conformance in varying VM configuration.

## VIII. Conclusion and Future Works

The purpose of the experiments in this study was to show how the new Adaptive Threshold Tuning Load Balancing (ATTLB) method can improve the performance and costs of cloud infrastructure compared to well-known methods such as Weighted Round Robin, Ant Colony Optimization Load Balancing, and Least Connection Load Balancing. The CloudSim simulation platform allows the modeling of diverse pricing models and workload conditions to rigorously assess each load-balancing strategy. The key performance metrics analyzed included the VM rental costs, SLA conformance, resource utilization, request capacity, latency, and threshold stability. ATTLB leveraged continuous feedback on real-time pricing, demand, and system state to adaptively tune the load-balancing thresholds aligned with prevailing conditions. The empirical results validated ATTLB's strengths of the ATTLB in optimizing cloud environments through intelligent data-driven load distribution.

ATTLB substantially reduced VM rental costs across all simulated pricing models by an average of 35–40% compared to the baselines by optimizing resource usage aligned with fluctuating prices. It delivers significantly improved SLA conformance rates of over 90%, even under rapidly surging peak loads, by adapting capacity limits based on real-time workload demands. ATTLB increased VM utilization levels by 15-20% on average by maximizing usage through an optimized threshold tuning approach. Under high and peaked loads, it increased the request serving capacity by 25–40% beyond the saturation points of the baseline algorithms by extracting additional throughput through dynamic threshold adaptation. Request latency reductions of 20–40% demonstrated ATTLB's capabilities in minimizing performance degradation during overload conditions by routing requests to optimal VMs based on current utilization metrics and thresholds. The empirical data highlight the limitations of legacy load-balancing policies that use static thresholds and lack multifaceted real-time optimization. In contrast, ATTLB's continuous feedback-driven approach for threshold adaptation provides cloud environments with robust, efficient, and cost-effective load-distribution capabilities.

The extended simulations and experiments further solidified ATTLB's position of the ATTLB as a robust and adaptive load-balancing solution for dynamic cloud environments. ATTLB demonstrated its capability to handle diverse workload patterns, including cyclic, unpredictable bursty, and long-running periodic loads, while consistently optimizing costs and maintaining high SLA conformance. The scalability experiments showed the ATTLB's consistent performance across various infrastructure scales, from 500 to 5000 VMs, maintaining high resource utilization, low latency, and controlled threshold stability.

These comprehensive experiments solidify the ATTLB's position as a robust and versatile load-balancing solution capable of Adapting to dynamic pricing models, fluctuating workloads, and diverse infrastructure configurations. ATTLB's ability to continuously monitor and optimize thresholds based on real-time feedback enables efficient resource utilization, cost minimization, and adherence to performance requirements, making it a compelling choice for enterprise cloud deployments.

While the simulations demonstrated ATTLB's immense promise, future research can further develop and enhance the approach. Integrating predictive analytics to forecast workloads and proactively scale resources based on projections could improve ATTLB's responsiveness. Additionally, further analysis into optimizing ATTLB's adaptation rate and granularity through techniques like machine learning is worthwhile to pursue. Exploring decentralized implementations of ATTLB for improved scalability on large-scale cloud platforms is another valuable research direction. As cloud computing environments and pricing models continue to evolve, ample opportunities exist to refine ATTLB into an enterprise-grade, robust load balancing solution.

# Facial Emotion Recognition-based Engagement Detection in Autism Spectrum Disorder

Noura Alhakbani
Information Technology Department, College of Computer and Information Sciences,
King Saud University, Riyadh 11543, Saudi Arabia

***Abstract*—Engagement is the state of alertness that a person experiences and the deliberate focus of their attention on a task-relevant stimulus. It positively correlates with many aspects such as learning, social support, and acceptance. Facial emotion recognition using artificial intelligence can be beneficial to automatically measure individual engagement especially when using automated learning and playing modalities such as using Robots. In this study, we proposed an automatic engagement detection model through facial emotional recognition, particularly in determining autistic children's engagement. The methodology employed a transfer learning approach at the dataset level, utilizing facial image datasets from typically developing (TD) children and children with ASD. The classification task was performed using convolutional neural network (CNN) methods. Comparative analysis revealed that the CNN method demonstrated superior accuracy compared to random forest (RF), support vector machine (SVM), and decision tree algorithms in both the TD and ASD datasets. The findings highlight the potential of CNN-based facial emotion recognition for accurately assessing engagement in children with ASD, with implications for enhancing learning, social support, and acceptance in this population. This research contributes to the field of engagement measurement in autism and underscores the importance of leveraging AI techniques for improving understanding and support for children with ASD.**

## I. Introduction

A person's level of engagement in social activities is indicative of his or her socio emotional and cognitive well-being. It is usually possible to assess a person's engagement state by observing their behavior and physiological cues, such as the focus of their gaze, their smile, and their vocalizations [1].

Measuring engagement helps identify how to improve engagement in different settings, especially when targeting a particular health condition. There is an active field of research looking at measuring both engagement and attention. Measuring engagement is a particularly active subject of research, and advances in sensor technology and computer vision techniques have created a shift away from manual measurement to more automated approaches [2, 3]. Authors in study [3] aimed to detect emotions displayed by people viewing video commercials to understand how people respond to the media content. The researchers built a model using convolutional neural network (CNN) to measure the viewer's attention based on how the position of the head changed subtly over time.

Autism spectrum disorder (ASD) is a neurological and developmental disorder that typically begins in early childhood [4]. The recent increase in the utilization of assistive therapies during therapy sessions with autistic children has been driven, in part, by the societal demand for new technologies that can facilitate and enhance existing therapies for the growing number of children with ASD. One such assistive approach is robot-assisted autism therapy (RAAT), which is an emerging field. Although there are currently only a limited number of studies investigating the efficacy of RAAT, research has indicated that incorporating RAAT in treatment sessions can effectively motivate children with ASD to engage in activities. In line with this, one potential application of engagement measurement is its ability to significantly improve the learning experience with interactive robots. By accurately assessing and responding to a user's level of engagement, robots can adapt their interactions and instructional strategies accordingly, resulting in more personalized and effective learning outcomes [5].

An effort was made to estimate the visual attention of children with autism and other cognitive disabilities during robot-assisted autism therapy sessions by building a training engagement classifier. This study achieved 93% using a K-nearest neighbors (K-NN) classifier [6]. Moreover, in a study of 46 children, of whom 20 were diagnosed with autism, a face-based recognition model was used using CNN classification with an 89% accuracy result [2].

There are different automated approaches to measuring engagement, such as using face detection and neural networks. Previous studies used different parameters such as signal data from the brain, eye-tracking, galvanic skin conductance, face-tracking, blood flow, and heart rate to create their system. However, among these methods, face-tracking is the most promising approach because it is ubiquitous, cost-effective, and provides accurate results [6]. Moreover, face detection and localization through finding facial landmarks are widely used for determining visual attention from video cameras. Facial features can be used to estimate the head pose, eye gaze, and emotions, all of which are reliable indicators of engagement [7].

In this study, we used two datasets, one specifically collected from typically developing (TD) children and the other from children with Autism Spectrum Disorder (ASD). The motivation behind using these two distinct datasets was to account for the unique characteristics and expressions exhibited by children with ASD. By utilizing transfer learning at the dataset level, we aimed to leverage the knowledge learned from the TD dataset to enhance the performance of engagement detection in the ASD dataset.

To measure the engagement state of children with ASD, we applied neural network-based deep learning in face detection and recognition. The selection of deep neural networks, specifically CNN, for measuring engagement in children with ASD is justified by its exceptional performance in image classification tasks. CNN demonstrates a high level of proficiency in extracting relevant features from complex visual data, making it highly suitable for capturing subtle facial cues related to engagement. Additionally, its robustness to noise and variability enhances its effectiveness in real-world scenarios. By exploring the application of CNN in measuring engagement, our objective is to leverage its feature extraction capabilities and capitalize on its resilience to variability, thereby advancing our understanding of engagement dynamics in children with ASD [8].

The remainder of this paper is arranged as follows: Section II introduces the main concepts of this study with background details. Section III presents the literature review presenting different machine learning models. Section IV presents an overview of datasets and the emotion model involved in the system design approach; Section V describes the proposed system starting with engagement model and ground-truth definition, Then, the implementation of the system which involves three main steps, namely pre-processing, feature extraction and classification; Section VI presents the evaluation results. Section VII discusses the results, and finally Section VIII presents the conclusion.

## II. Background

### A. Autism Spectrum Disorder

Autism is a neurological and developmental disorder that begins early in childhood. Children with ASD face challenges in social interaction, communication skills, language development, and behavioral problems. They face many challenges in their lives, including persistent challenges in social communication, education, and many life skills [9].

Deficits in engagement\attention are one characteristic of ASD. Autistic children have difficulty with engagement, and it is challenging for them to pay attention to both an object and a person while interacting. At the same time, participation and engagement in a diverse range of social, play, educational, and therapeutic activities are essential for acquiring knowledge that is necessary for cognitive and social development [2].

### B. Facial Emotion Recognition

Facial Emotion Recognition (FER) technology facilitates the recognition and interpretation of human emotions and affective states. It can analyze facial expressions from both static images and videos to reveal information on one's emotional state [10, 11].

Emotion detection is based on the analysis of facial land mark positions (e.g. end of the nose, eyebrows). the basic steps of FER technology include (i) face detection, (ii) facial expression detection, and (iii) expression classification to an emotional state. FER has many applications including, but not limited to, human-computer interaction, human behavior understanding, computer vision, and gaming [10,11].

Facial symmetry refers to a complete alignment of the size, location, shape, and arrangement of each facial component about the sagittal plane whereas asymmetry refers to the bilateral difference between such components [12].

Previous studies in this field have revealed some facts about the connection between face symmetry and face recognition, including; symmetrical faces are judged as more emotion expressed than asymmetrical faces; the left face displays emotions more intensely than the right face; EFRs' decoding is modulated by complex interplays between the emotion and face asymmetry [13–15].

### C. Neural Network-based Deep Learning

The brain is usually represented by neural networks, in which neurons connect to form a network. In computer science, an artificial neural network (ANN) is often called a neural network (NN), or a multi-layered perceptron (MLP), which is the most useful type of neural network.

ANNs are one of the best programming paradigms as they reflect the behaviour of the human brain, allowing computer programs to recognize patterns and resolve common problems. In contrast to conventional programming, in which a complex problem is broken down into a series of small, precisely defined tasks, ANNs do not require instructions to solve a particular problem; rather, they are instructed to use observational data to formulate a solution [16].

Deep learning is one of the machine learning methods that is based on ANN and uses larger numbers of hidden layers. NNs with more than two hidden layers are sometimes referred to as Deep Neural Networks (DNNs) [17].

Deep learning architectures are classified into two different learning algorithms, namely supervised and unsupervised learning. In supervised learning, the DNN is trained with the input of training data, all of which has a known label. Unsupervised learning is prepared by inferring the structures present in the unlabeled input data by a mathematical process [18].

A convolutional neural network (CNN) is a multi-layered neural network that draws biological inspiration from the visual cortex in animals [19]. CNN architecture is especially valuable in image processing applications, providing good results across many studies [20], and this is the architecture deployed in this study.

Fig. 1 shows CNN architecture relies on multiple layers that implement feature extraction and classification. The input data is broken down into receptive fields that feed into a convolutional layer and then extract the input data.

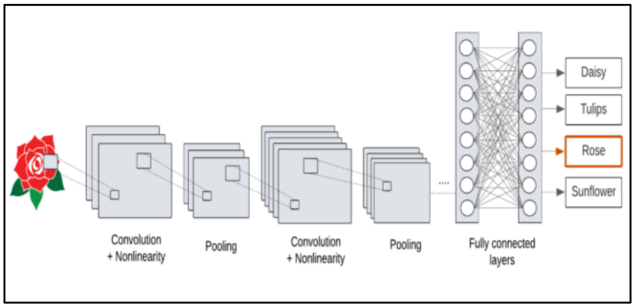

Fig. 1. Convolutional Neural Networks (CNN).

### D. Transfer Learning

Transfer learning (TL) is a machine learning (ML) technique that focuses on applying knowledge gained while solving one task to a related task. By reusing and transferring previously learned information to new tasks, TL has demonstrated that it is possible to significantly improve learning efficiency [21].

There are several advantages of TL, the most important of which are reduced training time, improved neural network performance, and the absence of a large amount of data. For example, when training a neural model, a substantial amount of data is required, but access to that data is not always available. With TL, the model can be trained on an available labeled dataset, and then be applied to a similar task that may involve unlabeled data [22].

## III. Related Work

Engagement detection-based facial recognition technology has gained significant attention in recent years. Different machine learning techniques have been used for this purpose, including neural networks.

Trabelsi et al. in [23] proposed an automatic engagement detection system for classrooms using deep learning algorithms. A machine learning approach is employed to train behavior recognition models, including facial expression identification, to determine students' attention/non-attention in the classroom. They used AffectNet dataset. Various versions of the YOLOv5 model are evaluated for performance, showing promising results with an average accuracy of 76%.

Gupta et al. in [24] aimed to enhance the online learning environment by proposing a deep learning-based approach that utilizes facial emotions to detect real-time engagement of online learners. Facial expressions are analyzed to classify emotions and calculate the engagement index (EI), predicting "Engaged" and "Disengaged" states. Various deep learning models, including Inception-V3, VGG19, and ResNet-50, are evaluated and compared for the best predictive classification model. Benchmark datasets such as FER-2013, CK+, and RAF-DB are used for performance evaluation. Experimental results demonstrate that ResNet-50 achieves the highest accuracy of 92.3% for facial emotion classification in real-time learning scenarios, outperforming the other models.

Banire et al. in [25] proposed attention recognition for children with ASD using a face-based model. Two methods are proposed: geometric feature transformation with an SVM classifier and transformation of time-domain spatial features to 2D spatial images using a CNN approach. The study involves 46 children (ASD n=20, typically developing children n=26) and examines participant and task differences. Results indicate that the geometric feature transformation with an SVM classifier outperforms the CNN approach. They reported that engagement detection is more generalizable for typically developing children and low-attention tasks.

Rathod et al. in [26] proposed a kids' facial emotion recognition system based on using deep-learning models. The aim was to improve interactive solutions in online platforms, particularly in the context of online education for children. They used LIRIS Children Spontaneous Facial Expression Video Database. The authors achieved the highest accuracy of 89.31%.

Overall, these studies demonstrate the effectiveness of using neural networks for engagement detection-based facial recognition. The use of deep learning techniques has enabled the extraction of high-level features from facial images and modeling of the temporal dynamics of facial expressions.

Furthermore, the integration of multimodal signals has shown to improve the accuracy of engagement detection. However, further research is needed to develop more robust and accurate engagement detection-based facial recognition systems that can be applied in real-world scenarios.

## IV. Materials and Methods

The following sub-sections present an overview of datasets and the emotion model involved in the system design approach.

### A. Dataset

One of the challenges we ran into in this study was the lack of an open-access dataset of images of children with ASD, yet a benchmark dataset is necessary and important for researchers in machine learning-based image classification models [27].

Therefore, we found that transfer learning methods have been successfully applied in different domains where there is a lack of large datasets [21].

Moreover, it could be used to provide high-performance learners trained with more easily obtained data from different domains [22]. Therefore, in our study, we applied the transfer learning approach at the dataset level by using two different datasets to achieve good recognition results.

Our training dataset was for typically developing (TD) children, and the target dataset was images of autistic children. Our hypothesis assumes that knowledge gained while learning to recognize engagement in TD children could be applied when trying to recognize engagement in autistic children.

We initially implemented and trained our model denoted as TD_CNN on TD children. Next, the model was used to be trained on children with ASD and we named the resulting model ASD_CNN. Then, we compared and discussed the results of our implementation.

*1) (LIRIS-CSE) dataset:* This is a novel database of 189 video recordings for 12 TD children and is known as Children's Spontaneous Facial Expressions (LIRIS-CSE) [28].

It contains eight basic spontaneous facial expressions shown by 12 ethnically diverse children between the ages of 6 and 12 years, with a mean age of 7.3 years.

This unique database contains spontaneous/natural facial expressions of children in diverse settings with diverse recording scenarios showing eight universal or prototypical emotional expressions, namely happiness, sadness, anger, surprise, disgust, natural, fear, and confusion.

This dataset has been cited by 32 papers. For example, in this article [11] the author proposed a framework for automatic expression recognition based on CNN architecture and achieved an average classification accuracy of 75%. We extracted metadata from the video recordings and created our data frame as shown in Table I below.

TABLE I. DATASET (TD) DESCRIPTION

| | |
|---|---|
| **Id** | Unique number for each row |
| **Image name** | Unique number for each image |
| **Session number** | The session number for each video recording |
| **Iteration** | The trial number in each session |
| **Emotion** | Label for one of the emotions (happiness, sadness, anger, surprise, disgust, natural, fear, and confusion) |
| **Landmarks file** | The name of the file that contains the extracted facial landmarks |

*2) Autistic children dataset:* To create our second model, we used the autistic children dataset from the Kaggle repository [29], many versions of which are available online. The dataset includes images of ASD children aged 2 to 14 years, most of whom are two to eight years old. This dataset was used in recent studies, such as [27] [30].

For example, in [30], a deep learning model was built, using this dataset, that was designed to distinguish between healthy children and those potentially showing signs of autism, and it produced results with 94.6% accuracy.

The dataset contains 1,333 images of children with ASD categorized into five emotions, namely happy, angry, sad, fearful, and normal. Each image in the dataset presents the face of an ASD child experiencing one of the above types of emotion. We extracted the metadata and created the data frame as shown in Table II.

TABLE II. DATASET (ASD) DESCRIPTION

| | |
|---|---|
| **Id** | Unique number for each row |
| **Image name** | Unique number for each image |
| **Emotion** | Label for one of the emotions (happy, angry, sad, fearful, and normal) |
| **Landmarks file** | The name of the file that contains the extracted facial landmarks |

### B. Emotion Model

We designed and developed an engagement detection system based on the most used emotion model, as presented in Fig. 2. Russell and Pratt (1980) suggested that all affective states originate from two fundamental neurophysiological systems, embedded in a circumplex with two orthogonal dimensions, valence, and arousal [31].

One study into the structure of subjective learning experiences found that positive valence and high arousal were indicators of emotional engagement [1]. Another study that focused on measuring happiness found that people who experience positive valence and high arousal were more engaged and satisfied, and it is this emotion model that forms the foundation for our model [32] (see Fig. 3).

We used it for automatically estimating if the child is engaged and providing positive facial expressions, such as happiness or surprise, during the experiment, which are indicators of their engagement. In some multi-models, facial expressions are used as input to automatically estimate levels of valence and arousal, and they tend to have a high level of agreement with human coders [33].

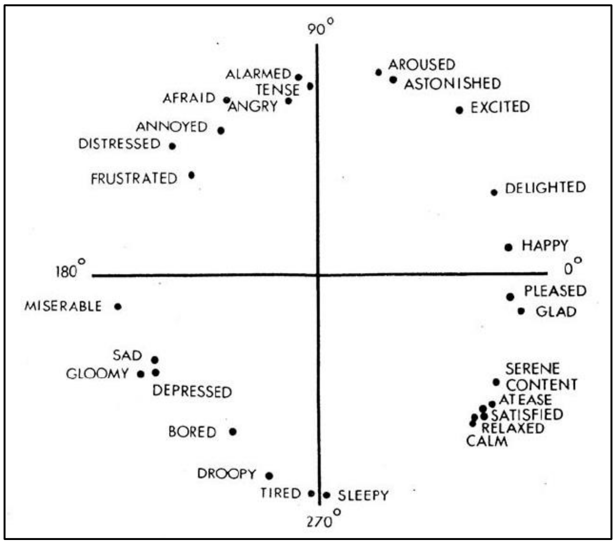

Fig. 2. Russell emotion model (1980).

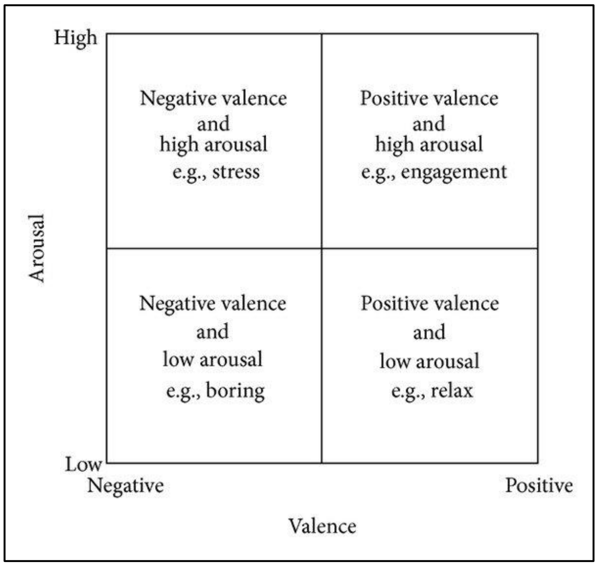

High
Negative valence and high arousal e.g., stress
Positive valence and high arousal e.g., engagement
Arousal
Negative valence and low arousal e.g., boring
Positive valence and low arousal e.g., relax
Low

## V. Proposed System

This section will cover our design and implementation steps in implementing the engagement detection system for autistic children.

First, we will describe how we built the data frame and ground truth. Afterward, we will present the steps to build our classifier based on the emotion model described above. Finally, we will present the evaluation of our classifier.

### A. *Engagement Model and Ground-Truth Definition*

Based on the emotion model, we used the two-dimensional valence arousal model to classify only happy and surprised expressions as an engaged state, while other emotions we classified as non-engaged. After classification, we created data frames and saved them as a CSV file.

Table III below present examples of TD children collected from [29], and Table IV shows examples of children with ASD.

The following sub-sections present the implementation of engagement detection involving three main steps, namely pre-processing, feature extraction, and classification, which will now be discussed in turn.

TABLE III. Emotions Classification of (TD) Children

| Happy (engagement) | Natural (non-engagement) |
|---|---|
| |  |
| Sad (non- engagement) | Disgust (non- engagement) |
|  | |
| Anger (non- engagement) | Surprise (engagement) |
| |  |
| Confusing (non-engagement) | Fear (non- engagement) |
| |  |

TABLE IV. Emotion Classification of Children with (ASD)

| Happy (engagement) | Natural (non-engagement) |
|---|---|
| | |
| Sad (non- engagement) | Disgust (non- engagement) |
| |  |
| Anger (non- engagement) | |
| | |

### B. *Pre-processing*

Pre-processing is a necessary first step because the TD datasets are in video format, and we required these to be split into still images, known as frames. We pre-processed the input video files to extract the desired frames. First, we stored all the video files in one folder before reading each file individually and extracting the frames. To process the video files we set up OpenCV [1] (Open Source Computer Vision), which is an open-source library that includes several hundred computer vision algorithms and that is widely used in computer vision generally, and facial recognition more specifically [7].

We used the OpenCV library to read the video streams before creating a VideoCapture object using Python script, and then we split the videos into frames. Each video was split into approximately 125 frames, so from the 189 videos we extracted 23,132 frames. For each frame, we detected and cut out the face using the Dlib library [7].

### C. *Features Extraction*

In facial recognition work, facial landmarks, defined as the detection and localization of certain characteristic points on the face, are considered very important features and are widely used in classification [20].

Features extraction is an important intermediate step in many subsequent facial processing processes that range from biometric recognition to understanding mental states. Facial landmarking is used to localize and represent salient regions of the face such as the eyes, eyebrows, nose, mouth, and jawline [34].

[1] Opencv: https://opencv.org/

Facial landmarks have been successfully applied to face alignment, head pose estimation, face swapping, blink detection, and much more.

Open-access software packages that automatically and efficiently detect facial landmarks include OpenCV, Imotion, MTCNN, and Open Face [20]. One of the main variants between them is the number of landmarks they detect; while Imotion detects 34, the MTCNN algorithm detects just five.

In our implementation, we used the Dlib library and OpenCV which can detect and extract 68 facial landmarks from each frame in both the TD and ASD datasets. Dlib, a facial landmark detector with pre-trained models, was used to estimate the location of 68 coordinates (x, y) that map the facial points on a person’s face, as presented in Figure 4. These points are identified from the pre-trained model where the iBUG300-W dataset was used. Open CV read the video streams and splits it into frames [7].

We created a Python script that read all the frames for both the TD and ASD datasets and for each frame, we detected the face and extracted the 68 coordinates (x, y) which were then saved in a text file that contains all 68 coordinates (x, y) and then saved into a data frame.

### *D. Classification*

In our work, the engagement recognition task is formulated as a binary classification problem in that we have two classes of engaged and non-engaged. We used a deep learning approach in our classification stage and, to compare our proposed methods, we implemented SVM, Decision Tree, and Random Forest.

To create the classification model, we divided our data into training and testing sets by using 80% of the data for training and 20% for testing and validation. We imported the Scikit-Learn library and used a train_test_split method to randomly split the data into training and testing sets. Additionally, to assess the robustness and generalization ability of our model, we employed cross-validation techniques.

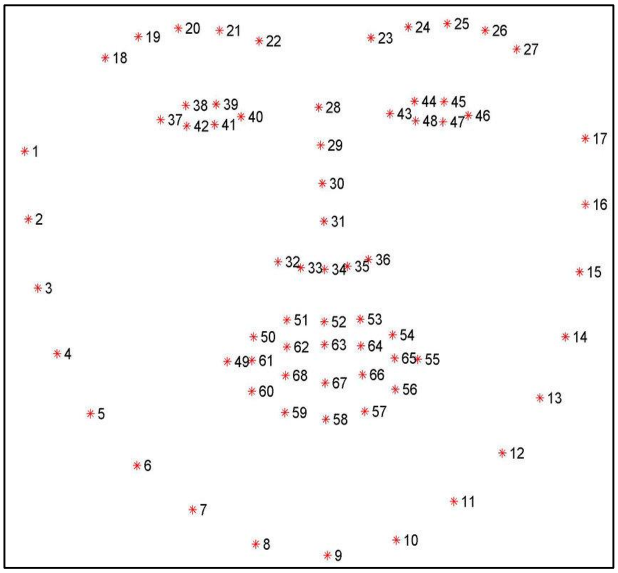

Fig. 4. Facial landmarks.

Specifically, we performed k-fold cross-validation, where we divided the training set into k subsets (folds) and iteratively trained and tested the model on different combinations of these subsets. This approach allowed us to obtain more reliable performance estimates by evaluating the model on multiple subsets of the data.

Firstly, we did our implementation using the TD dataset, the feature extraction part takes frames that contain the faces of the TD children as input, then we applied two convolution layers with 32 filters and (3,3) kernel size. Then we applied the third convolution layer which consists of 64 filters and (3,3) kernel size. After each convolution layer, there is an activation function called ReLU to set all the negative pixels to 0.

ReLU function introduces non-linearity to the network and generates an output-rectified feature map [2]. After the ReLU operation, there is a pooling layer for simple and salient elements. Finally, the flatten layer produces the output class (engagement/non-engagement).

To optimize the algorithms' hyperparameters, we employed a grid search approach. We defined a parameter grid containing a set of hyperparameters for each algorithm and exhaustively searched through the grid to find the combination that yielded the best performance. This hyperparameter tuning process was performed within each iteration of the cross-validation procedure.

We use the model implemented above TD_CNN as starting point for ASD_CNN model. We applied the transfer learning approach at the dataset level. The ASD_CNN model went through a similar implementation of TD_CNN but used the ASD dataset this round, with a few modifications to mitigate the differences in the data from images of autistic children. We removed one convolution layer with 32 filters and (3, 3) kernel size from the model. To evaluate the performance of the algorithms, we used multiple metrics, including precision, recall, and accuracy.

## VI. RESULTS

After we trained our algorithms and made some predictions, we compared their accuracy using different algorithms.

Support Vector Machine (SVM) is a supervised machine learning algorithm that can be used for classification or regression challenges and is one of the most popular classification algorithms used in machine learning. Its objective is to find the best hyperplane that correctly separates the points of different classes and provides the maximum margin among them [2]. SVM uses a set of mathematical functions that are defined as the kernel. The function of the kernel is to take data as input and transform it into the required form. Different SVM algorithms use different types of kernel functions, such as linear, nonlinear, polynomial, and radial basis function (RBF) [35]. We used a linear kernel function in our implementation.

Decision tree is one of the most frequently and widely used supervised machine learning algorithms that can perform both regression and classification tasks. Decision trees build classification or regression models in the form of a tree structure, breaking down a dataset into subsets; the result is a tree with decisional nodes and leaf nodes that represent the class [34] [10].

Random Forest (RF) is an ensemble learning method that is represented as a list of random trees. It works by creating a multitude of decision trees during training and outputting the class that is the mode of all classes. Basically, it functions by injecting randomness into the training of the trees and combining the output of multiple randomized trees into a single classifier [11].

To evaluate our algorithms, we used the classification_report and confusion_matrix methods to calculate these metrics. A confusion matrix is a table that is mostly used to explain the performance of a classification model on a set of test data for which the true values are known. Table V and Table VI show the confusion matrix for each classifier which contains information about actual and predicted classifications by different algorithms.

TABLE V. CONFUSION MATRIX FOR EACH CLASSIFIER USING (TD) DATASET

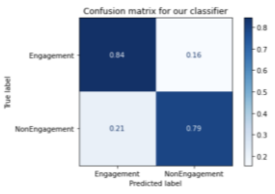
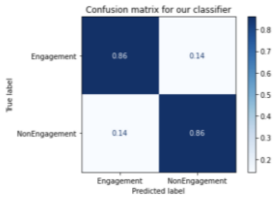
**SVM**



**Decision tree**



**Random forest**

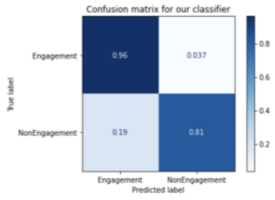


TABLE VI. CONFUSION MATRIX FOR EACH CLASSIFIER USING (ASD) DATASET

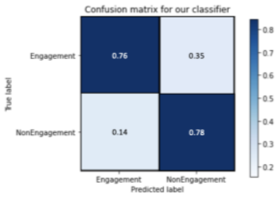
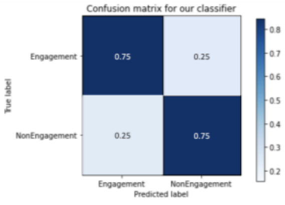
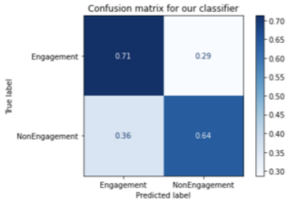
**ASD_CNN**



**SVM**



**Decision tree**



**Random forest**

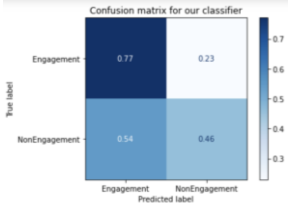


Table VII describes the evaluation of efficiency measures (accuracy, precision, recall) of our classifiers. Accuracy refers to the percentage of the total number of predictions that were correct; precision is the percentage of the predicted positive cases that were correct; recall is the percentage of positive cases that were correctly identified.

As shown in the table, for the TD dataset, the CNN model achieved the highest accuracy of 99%, indicating its ability to accurately detect engagement levels in typically developing children. In contrast, the random forest (RF), decision tree, and support vector machine (SVM) models achieved slightly lower accuracies of 89%, 86%, and 82% respectively. The precision and recall values for the CNN model were also consistently high at 99%.

TABLE VII. PERFORMANCE MEASUREMENTS

| Dataset | Algorithm | Accuracy | Precision | Recall |
|---|---|---|---|---|
| TD | TD_CNN | 99% | 99% | 99% |
| | Random Forest | 89% | 90% | 89% |
| | Decision tree | 86% | 86% | 86% |
| | SVM | 82% | 82% | 82% |
| ASD | ASD_CNN | 76% | 76% | 77% |
| | Random Forest | 64% | 63% | 63% |
| | Decision tree | 67% | 67% | 67% |
| | SVM | 75% | 75% | 75% |

On the ASD dataset, the CNN model again demonstrated superior performance with an accuracy of 75%. This suggests that the CNN model is effective in detecting engagement levels in children with Autism Spectrum Disorder (ASD). The RF, decision tree, and SVM models achieved lower accuracies of 64%, 67%, and 75% respectively. It is worth noting that the precision and recall values for the CNN model on the ASD dataset were 76% and 77% respectively.

## VII. DISCUSSION

The results show that CNN was the most accurate of the four algorithms for the TD dataset (99%), and SVM was the least accurate. Also, on the ASD dataset, CNN achieved the highest level of accuracy (75%), while RF achieved the lowest accuracy compared to the other methods in the ASD dataset. it is evident that the CNN model consistently outperformed the other algorithms for both the TD and ASD datasets in terms of accuracy.

These findings suggest that the CNN model's ability to capture and learn complex patterns in facial images contributes to its superior performance. The CNN model's success in accurately detecting engagement levels can be attributed to its capacity to extract meaningful features from the facial images and effectively classify them.

We observe that the accuracy of the algorithms' using TD is higher than ASD this is due to the quality and quantity of data for TD children compared to the dataset for ASD children, and due to the limited scope of facial impressions in children with ASD. Although a person's emotional state can be detected from facial expressions, either consciously or subconsciously, there are many theories about how children with ASD represent emotion.

A number of studies have found that recognizing facial emotions in children with ASD is challenging [14, 36, 37]. Studies have found that children with ASD are less responsive in the upper part of the face, with their eyes typically remaining emotionally neutral. Consequently, the lower half of the face, including the mouth, chin, jaw, and cheeks, is crucial in recognizing emotion in autistic children [36].

## VIII. Conclusion

We proposed an engagement detection system using CNN for facial emotional recognition. AI and machine learning have been applied to automatically measure the engagement of children with ASD. This allows the therapist to track a child's engagement with ASD during therapy sessions without relying on traditional observation techniques.

The implications of this research are significant. The ability to accurately assess engagement levels has the potential to revolutionize various domains, including education, therapy, and human-computer interaction. By providing feedback and adaptive interventions, engagement detection technologies can enhance learning outcomes, facilitate personalized interventions for individuals with ASD, and create more immersive and interactive user experiences.

In this paper, we explained the implementation details to build an engagement detection model through facial emotion recognition. We presented the information of the datasets and the pre-processing steps for the videos and images to make them ready to be fed into the model. We used a transfer learning approach at the level of the dataset. Due to the small size of the datasets. Then, we described how we detected and extracted the 68 facial landmarks from each face in the frame and then created the data frame based on the two-dimensional emotion model to build the ground truth for detecting the engagement of the children. And due to the difficulty of recognizing facial emotions in children with ASD and their decreased response in the upper part the results we achieved were less accurate than with TD dataset. Then, we compared different machine learning algorithms and evaluated their performance, and our findings showed that the CNN outperformed other classifiers.

While we utilized two datasets in our study, it is important to acknowledge that these datasets have their own limitations, including sample size, demographic representation, and potential biases. Future work should aim to address these limitations by incorporating larger and more diverse datasets to ensure generalizability and robustness of the engagement detection models.

Our study focused on offline analysis of facial images to detect engagement. Future research should aim to develop real-time engagement detection systems that can operate in dynamic and interactive settings. This would enable the integration of engagement detection algorithms into interactive technologies, such as robots, to provide immediate feedback and adaptive interventions.

Facial emotion recognition is just one modality for measuring engagement. Future research should explore the integration of other modalities, such as speech analysis, body movement, and physiological signals, to create more comprehensive and accurate engagement detection models. Multimodal approaches can enhance the understanding of engagement dynamics and provide a more holistic assessment.

Conflicts of Interest: The authors declare no conflict of interest.

# State-Feedback Control of Ball-Plate System: Geometric Approach

Khalid Lefrouni, Saoudi Taibi
Mohammed V University in Rabat, Rabat, Morocco

***Abstract*—This research focuses on investigating the issue of accurately controlling the location of the ball in the ball and plate system. The findings of this research have practical applications across several domains, including optimizing the alignment of solar panels to enhance their energy generation capacity. In this work, we propose the development of a system dynamics model using the Euler-Lagrangian approach. Furthermore, we analyze a technique in the frequency domain known as the geometric approach to create a state-feedback control that ensures the stability of the system. This study primarily focuses on analyzing the characteristic equations associated with the closed-loop system, while also considering the impact of feedback delay. Ultimately, the proposed technique is substantiated by presenting simulation data for validation.**

***Keywords*—Ball-plate system; Delay systems; Geometric approach; State-feedback control***

## I. Introduction

We are intrigued by this article's exploration of the issue of position control of the ball in the ball and plate system. The main objective is to accurately identify the stable region of the closed-loop system. The parameters within this region ensure system stability. Consequently, additional requirements can be incorporated into the controller, with the aim of finding the optimal parameters within this region that not only guarantee stability, but also achieve a desired level of precision and speed for the system.

This objective is achieved by utilizing both state feedback control and a frequency analysis technique known as the Geometric method [2]. To evaluate the efficiency of the developed controllers, we have opted to focus on a highly responsive technology known as the Ball and Plate technology. The potential uses of this research are manifold, such as utilizing sensors to assess radiation and then adjusting the panel support to optimize the orientation of solar panels and enhance their efficiency.

Multiple control rules have been devised to regulate the location of the ball on the plate [1]-[4]-[7]-[8]. Nevertheless, the majority of these studies rely on a real-time model [5], which entails a continuous measurement in real-time. However, this hypothesis fails to accurately capture the actual dynamics of the system [3].

The ball and plate structure is a development of the ball and beam system. Due to its uncomplicated setup and easy implementation, it has become a much sought-after device for controller implementation. By utilizing the touch screen as a position sensor in conjunction with a standard PID controller, it is possible to conduct real-world experiments [13]-[14]. Furthermore, a ball and plate system was created for educational purposes [15]-[16]. Several academics have developed a fuzzy control method using this teaching equipment [17]-[18].

Due to the more advanced study on the ball-beam systems, we were particularly interested in the models referenced in sources [6]-[9]. These models may be classified into two distinct types. The first group employs neutral functional differential equations [11], whereas the second category utilizes retarded functional differential equations [9]-[12].

Therefore, we suggest utilizing a ball and plate system model that relies on retarded functional equations [9], together with frequency domain synthesis techniques (refer to [2] and [10]), to construct a state feedback control rule [2]. This method may ascertain the stability zone of the system in the control parameter space, while considering the impact of feedback delay. Consequently, it is permissible to choose the parameters of the control rule that fall inside the stable zone and satisfy the necessary specifications.

The subsequent sections of this article are structured in the following manner. Section 2 presents the ball and plate system model, which is based on retarded functional equations. In Section 3, we focus on the synthesis of state feedback control laws to guarantee the stability of the closed-loop system. Section 4 presents an illustrative scenario taken from existing literature, and simulations validate the suggested methodology. Ultimately, we arrive to a conclusion in Section 5.

## Nomenclature

| | |
|---|---|
| $L_X$ | Plate length in x-direction |
| $L_Y$ | Plate length in y-direction |
| $r_M$ | Motor arm length |
| $r_b$ | Ball radius |
| $m_b$ | Ball mass |
| $J_b$ | Moment of inertia of the ball |
| $\alpha$ | Plate angle around the x-axis |
| $\beta$ | Plate angle around the y-axis |
| $\vartheta_x$ | Motor angle around the x-axis |
| $\vartheta_y$ | Motor angle around the y-axis |
| $K$ | State feedback gain |
| $x(t)$ | State space vector |
| $\tau_x$ | System feedback delay along the x-axis |
| $\tau_y$ | System feedback delay along the y-axis |
| $\Omega$ | Set of crossing frequency |

## II. Ball and Plate System Modeling

In this section we will determine the linear model of the ball and Plate system (see Fig. 1). For this, we will first apply Lagrange's method, then we will linearize the model found around the operating point. Finally we will present the model in the state space.

### A. Preliminaries

Considering $E_k$ and $E_p$ respectively the kinetic and potential energy of the system.

The Lagrangian equation is then expressed as:

$$\frac{\partial}{\partial t}\left(\frac{\partial L}{\partial \dot{x}}\right) - \frac{\partial L}{\partial x} = 0 \tag{1}$$

with

$$L = E_k - E_p \tag{2}$$

The total kinetic energy of the ball is equal to the sum of the translational kinetic energy $E_{k,T}$ and the rotational kinetic energy $E_{k,R}$ with:

$$E_{k,T} = \frac{1}{2}\, m_b v_b^2 = \frac{1}{2}\, m_b(\dot{x}_b^2 + \dot{y}_b^2) \tag{3}$$

$$E_{k,R} = \frac{1}{2}\, J_b \omega_b^2 = \frac{1}{2}\, J_b \frac{(\dot{x}_b^2 + \dot{y}_b^2)}{r_b^2} \tag{4}$$

Thus

$$E_k = \frac{1}{2}\left(m_b + \frac{J_b}{r_b^2}\right)(\dot{x}_b^2 + \dot{y}_b^2) \tag{5}$$

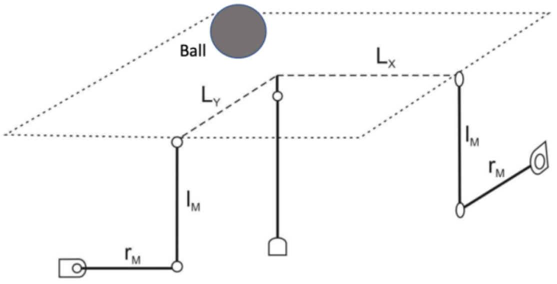

Fig. 1. Structure of the ball and plate system.

Taking into consideration the angles between the plate and the axes $Ox$ and $Oy$ (see Fig. 2), the potential energy can be expressed by:

$$E_p = -m_b g x_b \sin(\alpha) - m_b g y_b \sin(\beta) \tag{6}$$

Thus

$$\begin{aligned} L = &\frac{1}{2}\left(m_b + \frac{J_b}{r_b^2}\right)(\dot{x}_b^2 + \dot{y}_b^2) \\ &+ m_b g x_b \sin(\alpha) + m_b g y_b \sin(\beta) \end{aligned} \tag{7}$$

So applying the Lagrangian Eq. (1) where $L$ is described by Eq. (7), we have:

$$\frac{\partial}{\partial t}\left(\frac{\partial L}{\partial \dot{x}}\right) = \frac{\partial}{\partial t}\left(\left(m_b + \frac{J_b}{r_b^2}\right)\dot{x}_b\right) = \left(m_b + \frac{J_b}{r_b^2}\right)\ddot{x}_b \tag{8}$$

$$\frac{\partial L}{\partial x} = m_b g \sin(\alpha) \tag{9}$$

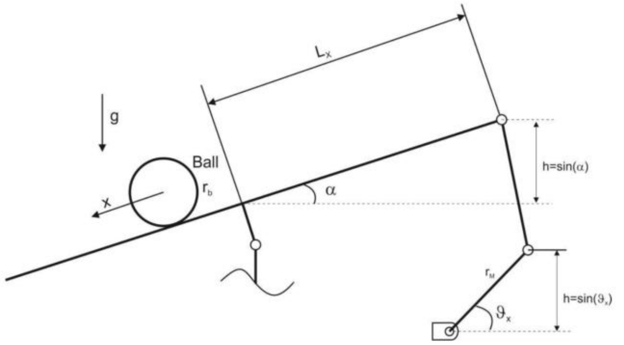

Fig. 2. Side view of the ball and plate system.

After simplification, we therefore have the differential equation of the motion of the ball along the x-axis :

$$\ddot{x}_b = \frac{m_b g r_b^2}{m_b r_b^2 + J_b} \sin(\alpha) \tag{10}$$

Similarly, following the same steps, the differential equation of the motion of the ball along the y-axis is described by the following equation.

$$\ddot{y}_b = \frac{m_b g r_b^2}{m_b r_b^2 + J_b} \sin(\beta) \tag{11}$$

In order to determine a mathematical model between the inputs of the system ($\vartheta_x$ and $\vartheta_y$) and the outputs of the system $(x, y)$.

From Fig. 2 we can write :

$$\sin(\vartheta_x)\, r_M = sin(\alpha) L_X = h \tag{12}$$

By combining (10) and (12), we have:

$$\ddot{x}_b = \frac{m_b g r_b^2\, r_M}{(m_b r_b^2 + J_b)\, L_X} \sin(\vartheta_x) \tag{13}$$

$$\ddot{y}_b = \frac{m_b g r_b^2\, r_M}{(m_b r_b^2 + J_b)\, L_Y} \sin(\vartheta_y) \tag{14}$$

### B. The Linearized Model of the Ball-Plate System

The linearization of the model in Eq. (13), (14) around the operating point $(x = 0, y = 0)$, assuming a small variation of the $\vartheta_x$ and $\vartheta_y$ angles, leads us to the following equations :

$$\ddot{x}_b = G_x\, \vartheta_x \tag{15}$$

$$\ddot{y}_b = G_y\, \vartheta_y \tag{16}$$

with

$$G_x = \frac{m_b g r_b^2\, r_M}{(m_b r_b^2 + J_b)\, L_X} \quad \text{and} \quad G_y = \frac{m_b g r_b^2\, r_M}{(m_b r_b^2 + J_b)\, L_Y}$$

Remark :

Given the similarity of the x- and y-axis models, in the following we will start the study based on the x-axis modeling and deduce at the end the results for the y-axis.

As a result, the state space model of the Ball and Plate System along the x-axis can be written as follows:

$$\begin{cases} \dot{x}(t) \;=\; A\,x(t) \;+\; B\,u(t-\tau_x) \\ y(t) \;=\; C\,x(t) \end{cases} \tag{17}$$

Where $x(t) = [x_b(t) \quad \dot{x}_b(t)]^{\,T}$ is the state vector, $u(t) = \vartheta_x(t)$ is the input, $\tau_x$ is the feedback delay and

$$A = \begin{bmatrix} 0 & 1 \\ 0 & 0 \end{bmatrix}, \qquad B = \begin{bmatrix} 0 \\ G_x \end{bmatrix}, \qquad C = [1 \quad 0]$$

## III. State-Feedback Controller

This part will concentrate on the construction of a state feedback controller in order to guarantee the stability of the closed-loop system. As stated previously, we will employ a geometric approach [2] to identify the specific area in the control parameter space where stability may be guaranteed.

### *A. Geometric Approach Principle*

The geometric technique [2] is a frequency-based methodology that enables the determination of stability areas and regions where the measurement error converges to zero during the synthesis of the observer. Hereafter, we just provide the fundamental aspects to resolve this issue.

### *B. Stability Regions*

Next, we will implement the various stages of the geometric technique to determine the stability region of the closed-loop system.

The state feedback controller is characterized by:

$$u(t) \;=\; -K_x\,x(t) \tag{18}$$

$K_x$ is the state feedback gain that guarantees the stability of the system (17) for any $\tau_x < \tau_x^*$ (where $\tau_x^*$ is the maximum delay $\tau_x$ ).

If the controllability of $(A, B)$ is assumed, the goal is to find the gain $K_x$ that will define the characteristic equation of the closed-loop system:

$$H(s, e^{-\tau_x s}) = \det(sI_2 - (A - BK_x\, e^{-\tau_x s}))\text{=}0 \tag{19}$$

is Hurwitz for any $\tau_x < \tau_x^*$

By employing the Laplace transform, we can express the system as follows:

$$\begin{cases} s\,x(s) \;=\; A\,x(s) \;+\; B\,u(s)e^{-\tau_x s} \\ \quad y(s) \;=\; C\,x(s) \end{cases} \tag{20}$$

Also, the state-feedback controller takes the following form:

$$u(s) \;=\; -K_x\;x(s) \tag{21}$$

where, $K_x = [k_{x1} \quad k_{x2}]$ is the state feedback gain.

The characteristic equations related to the closed-loop system are as follows:

$$H(s, k_{x1}, k_{x2}, \tau_x) = Q(s) + P(s)e^{-\tau_x s} \tag{22}$$

The polynomials $Q(s)$ and $P(s)$ are defined as follows:

$$Q(s) \,=\, s^2\,, \quad P(s) \,=\, G_x(sk_{x2} + k_{x1}) \tag{23}$$

The characteristic Eq. (22) has real coefficients, therefore, the conjugate of each root is also a solution of this equation, so we have the following equations:

$$\begin{aligned} H(s, k_{x1}, k_{x2}, \tau_x) &= Q(s) + P(s)e^{-\tau_x s} = 0 \\ H(-s, k_{x1}, k_{x2}, \tau_x) &= Q(-s) + P(-s)e^{\tau_x s} = 0 \end{aligned} \tag{24}$$

In this analysis, we will start by examining a zero-delay closed-loop system and endeavor to identify conditions that govern the corrector parameters and guarantee the system's stability (17).

$H(s, k_{x1}, k_{x2}, 0) = 0$ is thus the Hurwitz characteristic polynomial. More precisely, for the complex left half-plane to contain all of its roots, the following conditions must be met:

$$k_{x1} > 0, \;\; k_{x2} > 0 \tag{25}$$

This represents a first requirement on the parameters of the controller.

### *C. Crossing Curves*

For determining the gain $K_x$ that guarantees the roots are distributed in the complex left half plane, one must initially identify the parameters of the state feedback gain $K_x$ that contain a minimum of one pure imaginary root in the characteristic equation (19). This is the same as attempting to solve the equation:

$$\forall\omega > 0, \; \tau_x^* \in \mathcal{R}^+, \; H\big(j\omega, e^{-j\omega\,\tau_x^*}\big) = 0 \tag{26}$$

The retrieved K-parameters define the so-called crossing points. Consequently, this enables the generation of crossing curves in the region of the parameters $(k_{x2}, k_{x1})$.

By considering the system (17), we can define the crossing points in the space $(k_{x2}, k_{x1})$ as follows:

Proposition 1

For a delay $\tau_x^* > 0$ and $\omega \in \Omega$, the crossing points are defined by the following equations:

$$k_{x1} = \frac{\omega^2\,\cos(\omega\tau_x^*)}{G_x} \tag{27}$$

$$k_{x2} = \frac{\omega\; sin(\omega\tau_x^*)}{G_x} \tag{28}$$

where $\Omega$ is the set of frequencies and $\omega \in \mathcal{R}^+$ such that $H(j\omega, k_{x1}, k_{x2}, \tau_x^*) = 0$ has at least one solution $(k_{x1}, k_{x2})$.

*Proof:* From the characteristic equation (26) we have :

$$-\omega^2 + G_x(j\omega k_{x2} + k_{x1})e^{-j\omega\,\tau_x^*} = 0$$

Then, considering the real and imaginary parts, we get :

$$\begin{cases} -\omega^2 + G_x(\omega k_{x2}\sin(\omega\,\tau_x^*) + k_{x1}\cos(\omega\,\tau_x^*)) = 0 \\ \omega k_{x2}\cos(\omega\,\tau_x^*) - k_{x1}\sin(\omega\,\tau_x^*) = 0 \end{cases}$$

Solving these two equations leads to Eq. (27) and (28).

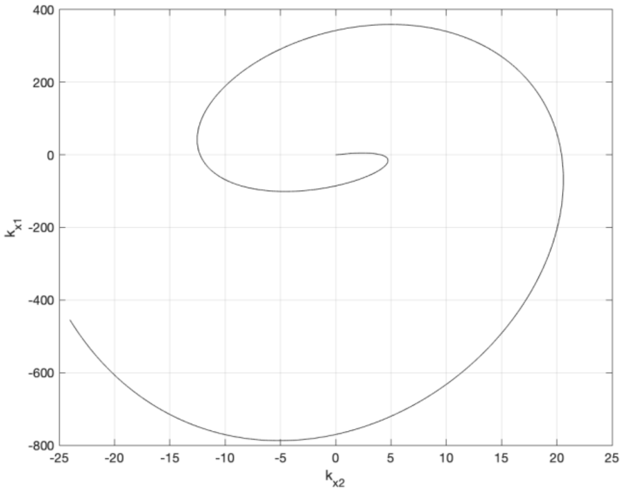

Fig. 3. Crossing curves with $\tau_x^* = 0.3$.

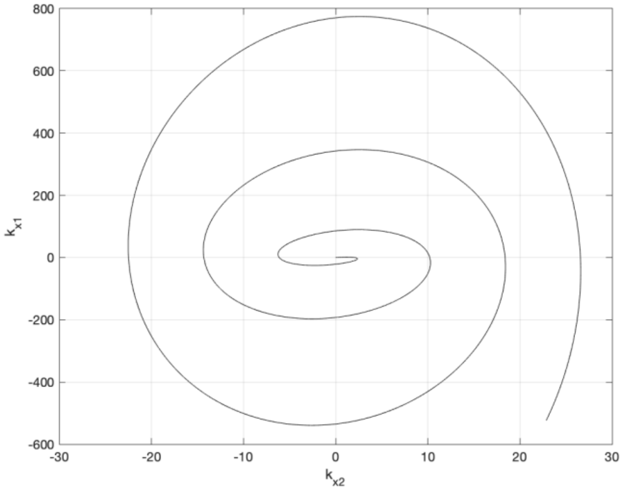

Fig. 4. Crossing curves with $\tau_x^* = 0.6$.

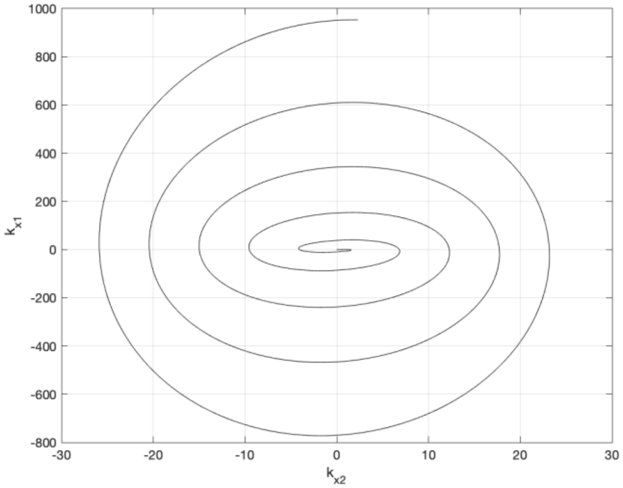

Fig. 5. Crossing curves with $\tau_x^* = 0.9$.

Therefore, through the examination of various delay values $\tau_x^* \in \{0.3, 0.6, 0.9\}$, the crossing curves illustrated in Fig. 3, Fig. 4 and Fig. 5. The provided curves illustrate the progression of the controller parameters $(k_{x2}, k_{x1})$ in response to variations in the system's pulsation which the Eq. (27) and (28) describe.

### D. Direction of the Crossing

Using the approach detailed in [2], we can determine the direction of the crossing. To do so, we have to consider the numbers $R_i$ and $I_i$, defined by:

$$\begin{aligned} R_0 + jI_0 &= j\,\frac{\partial H(s,k_{x1},k_{x2},\tau_x^*)}{\partial s}\bigg|_{s=j\omega} \\ R_1 + jI_1 &= -\frac{1}{s}\,\frac{\partial H(s,k_{x1},k_{x2},\tau_x^*)}{\partial k_{x2}}\bigg|_{s=j\omega} \\ R_2 + jI_2 &= -\frac{1}{s}\,\frac{\partial H(s,k_{x1},k_{x2},\tau_x^*)}{\partial k_{x1}}\bigg|_{s=j\omega} \end{aligned} \quad (29)$$

By applying the principles outlined in reference [2], it is now possible to ascertain the direction of crossing, which denotes the path followed by the roots of $H(j\omega, k_{x1}, k_{x2}, \tau_x^*) = 0$ as they traverse the imaginary axis.

Mathematically, a direction going from left to right is translated by the following inequality:

$$R_2 I_1 - R_1 I_2 > 0$$

Thus, taking into consideration the expression of the numbers $R_i$ and $I_i$ defined by (29), after calculation we have :

$$R_2 I_1 - R_1 I_2 = \frac{{G_x}^2}{\omega} > 0 \quad (30)$$

We can therefore deduce that the direction of the crossing is to the right.

### E. Regions of Stability

Using the findings from the preceding sections, we will now identify the areas of stability for the system. This implies that all values of the gains $K_x$, for which the Eq. (19) is Hurwitz for any delay $\tau_x$ belongs to the interval $[0,\ \tau_x^*]$ .

Thus, taking into consideration condition (25) on the one hand, and the crossing curve that delimits the stability region on the other hand, we have identified the stability region of the closed-loop system. Fig. 6 illustrates this region in case $\tau_x^* = 0.6\,s$ .

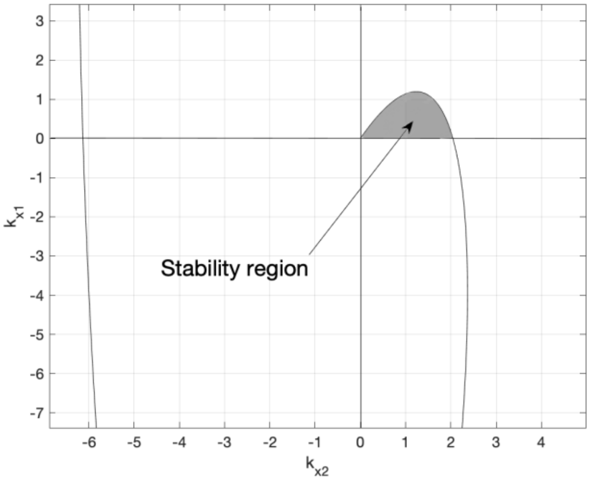

Fig. 6. The stability area of a closed loop system with $\tau_x^* = 0.6$

Every set of parameters $(k_{x1}^*,\ k_{x2}^*)$ inside the shown region in Fig. 6, determines a gain $K_x^* = [k_{x1}^* \quad k_{x2}^*]$ which guarantees the closed-loop system's stability for any delay $\tau_x$ such that $\tau_x < \tau_x^*$ . Subsequently, we will determine the critical delay value $\tau_x^*$ , beyond which stability cannot be assured.

Proposition 3. Critical delay

The state feedback controller $u(t) = -K_x^*\, x(t)$ , with $K_x^* = [k_{x1}^* \quad k_{x2}^*]$ , asymptotically stabilizes the closed loop system (17) for any $\tau_x < \tau_x^*$ , such as $\tau_x^*$ is defined by:

$$\tau_x^* = \frac{1}{\omega}\, Arccos\left[\frac{k_{x1}^*\, \omega^2}{G_x((k_{x1}^*)^2+(\omega k_{x2}^*)^2)}\right] \tag{31}$$

*Proof:* Considering the characteristic Eq. (22) and positioning at the limit of stability, i.e., assuming that it admits a root $s = j\omega$ , we thus have:

$$Q(j\omega) + P(j\omega)e^{-j\omega\tau_x^*} = 0 \tag{32}$$

Using the expression of $P$ and $Q$ and the formula of Euler, we thus have:

$$\cos(\omega\, \tau_x^*) - \mathrm{j}\sin(\omega\, \tau_x^*) = \frac{k_{x1}^*\, \omega^2 - j\omega^3\, k_{x2}^*}{G_x((k_{x1}^*)^2 + (\omega k_{x2}^*)^2)}$$

By equality of the real parts of this equation we obtain the relation in Eq. (31)

Proposition 4. Critical frequency of crossing

The critical frequency of crossing $\omega_0$ is defined by:

$$\omega_0 = \sqrt{\frac{\alpha_1+\sqrt{\alpha_1^2+4\alpha_0}}{2}} \tag{33}$$

With

$$\alpha_0 = (G_x k_{x1}^*)^2 \quad \text{and} \quad \alpha_1 = (G_x k_{x2}^*)^2$$

*Proof:* From Eq. (32), we have:

$$e^{-j\omega\tau_x^*} = \frac{-Q(j\omega)}{P(j\omega)} \tag{34}$$

$$e^{j\omega\tau_x^*} = \frac{-Q(-j\omega)}{P(-j\omega)} \tag{35}$$

By multiplying the two Eq. (34) and (35), we have:

$$Q(j\omega)Q(-j\omega) - P(j\omega)P(-j\omega) = 0$$

After simplification, we have the following equation:

$$\omega^4 - \alpha_1\omega^2 - \alpha_0 = 0 \tag{36}$$

By solving this equation and considering only positive frequencies, we find the result in Eq. (33).

### F. Results for the y-axis

The state feedback controller providing closed-loop system stability along the y-axis is defined by:

$$u(t) = -K_y\, x(t) \tag{37}$$

where, $K_y = [k_{y1} \quad k_{y2}]$ is the state feedback gain and $x(t) = [y_b(t) \quad \dot{y}_b(t)]^T$ is the state vector.

Taking into consideration the expression of the numbers $R_i$ and $I_i$, defined by Eq. (29), after calculation we have :

$$R_2 I_1 - R_1 I_2 = \frac{{G_y}^2}{\omega} > 0 \tag{38}$$

So we have the same results along the y-axis, i.e. a direction of passage from left to right.

Based on this result on the one hand and on the crossing curve that delimits the region of stability on the other hand, we have thus determined the region in which all the roots of the characteristic equation have a strictly negative real part, in other words, we have identified the region of stability of the closed-loop system that controls the evolution of the ball along the y-axis.

Therefore, Fig. 7 illustrates the stability region for $\tau_y^* = 0.8\ s$

Also, the critical delay is specified as:

$$\tau_y^* = \frac{1}{\omega}\, Arccos\left[\frac{k_{y1}^*\, \omega^2}{G_y\left((k_{y1}^*)^2+(\omega k_{y2}^*)^2\right)}\right] \tag{39}$$

Where the gain of state feedback $K_y^* = \left[k_{y1}^* \quad k_{y2}^*\right]$ stabilizes the closed-loop system for any delay $\tau_y$ that is less than $\tau_y^*$ .

## IV. Simulation

We will now illustrate the results found in the preceding sections. Thus, the ball and plate system described in Section 2 is taken into consideration, its dynamics are determined by Eq. (13) and (14) with: $L_X = 0.134\, m$ , $L_Y = 0.168\, m$ , $r_M = 0.0245\, m$ , $r_b = 0.02\, m$ , $J_b = 0.0000416\, kg * m^2$ , $m_b = 0.26\, kg$ . And the system feedback delay along the x-axis and the y-axis are respectively $\tau_x = 0.6s$ , $\tau_y = 0.8s$ .

Thus, considering the regions of stability shown in Fig. 6 and Fig. 7, we arbitrarily choose two pairs $(k_{x1}^*, k_{x2}^*) = (0.45,\ 0.6)$ and $(k_{y1}^*, k_{y2}^*) = (0.35\ ,\ 0.75)$ .

i.e.

$$K_x = [0.45 \quad 0.6] \tag{40}$$

$$K_y = [0.35 \quad 0.75] \tag{41}$$

From Eq. (31) and (39), we then calculate the critical values of feedback delays:

$$\tau_x^* = 0.9403\ ,\ \tau_y^* = 1.2399 \tag{42}$$

Which means that the state feedback gains $K_x$ and $K_y$ stabilize the system (17) such that $\tau_x$ and $\tau_y$ both fall within the intervals $[0,\ 0.9403)$ and $[0,\ 1.2399)$, respectively.

We then get, on the one hand, Fig. 8 and Fig. 9, which illustrate the evolution over time of the ball position defined by the coordinates $(x_b\, , y_b)$ , and on the other hand, Fig. 10 illustrates the evolution of the ball on the plate in the $(x\, , y)$ plane.

Now, choose two other pairs inside the stability regions illustrated in Fig. 6 and Fig. 7.

$$(k^*_{x1},\ k^*_{x2}) = (0.25,\ 1.7) \qquad (43)$$

$$(k^*_{y1},\ k^*_{y2}) = (0.55\ ,\ 1.45) \qquad (44)$$

Thus, we find the evolution of the ball coordinates $(x_b\ , y_b)$ presented in Fig. 11, Fig. 12, Fig. 13, and the critical values of the delays :

$$\tau^*_x\ = 0.6888\ ,\ \tau^*_y\ = 0.8694 \qquad (45)$$

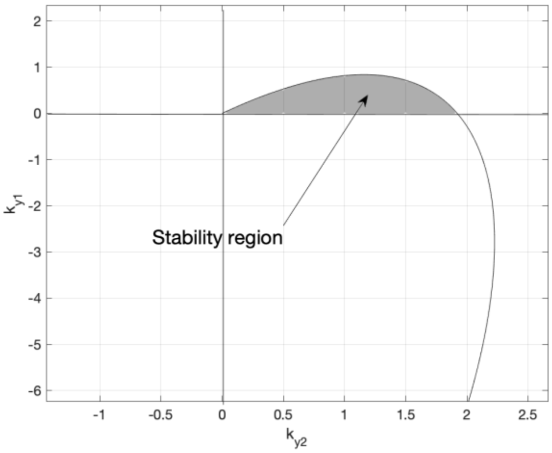

Fig. 7. The stability area of a closed loop system with $\tau^*_y = 0.8$.

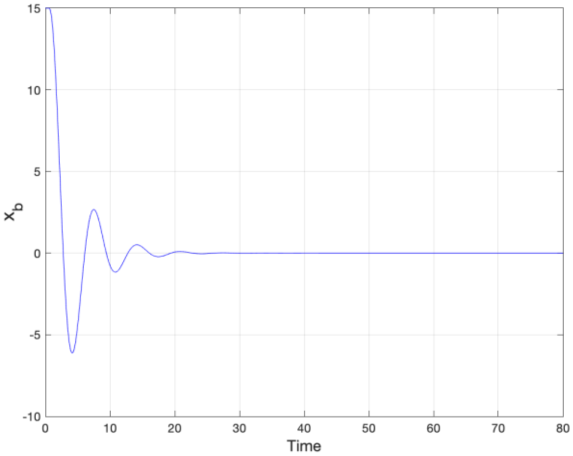

Fig. 8. Temporal evolution of $x_b$ with the state feedback gain (40).

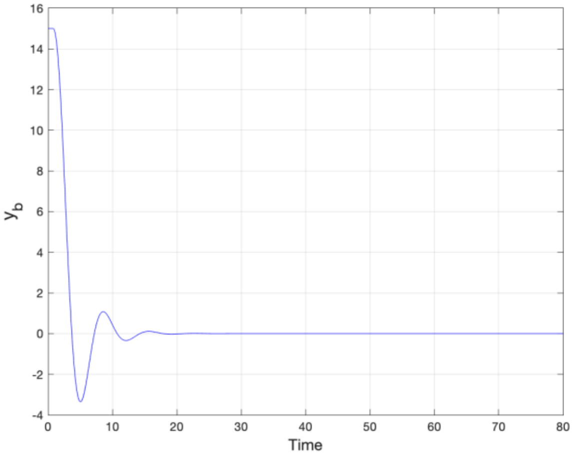

Fig. 9. Temporal evolution of $y_b$ with the state feedback gain (41).

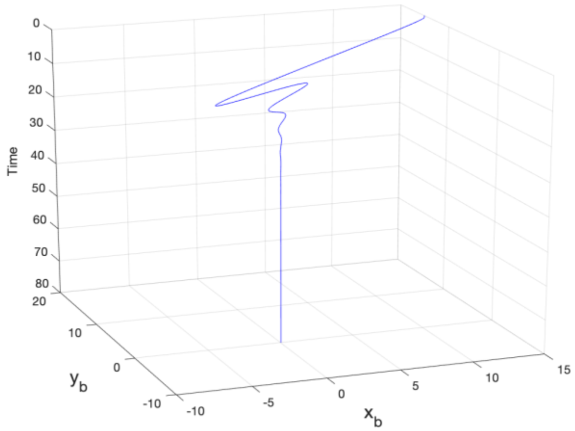

Fig. 10. Evolution of the position of the ball with the state feedback gains (40) and (41).

Comparing the results illustrated in Fig. 10 and Fig. 13, we can see that a slight change in the values of the gains $K_x$ and $K_y$ leads, on the one hand, to a decrease in the critical values of the delays $\tau_x$ and $\tau_y$ (See results (42) and (45)), and consequently to a restriction on the permitted values of the delays, and, on the other hand, to an increase in the oscillations, which leads to an increase in the system response time.

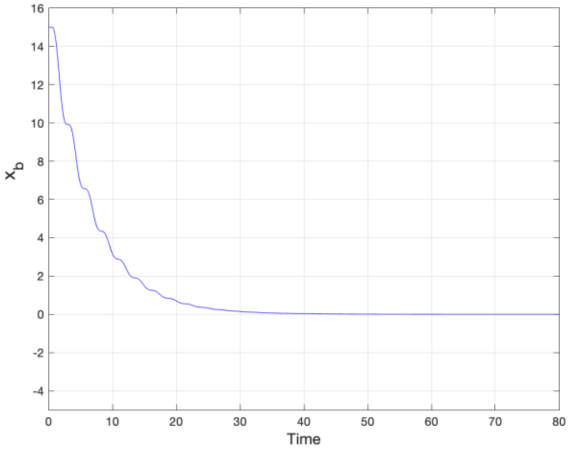

Fig. 11. Temporal evolution of $y_b$ with the state feedback gain (43).

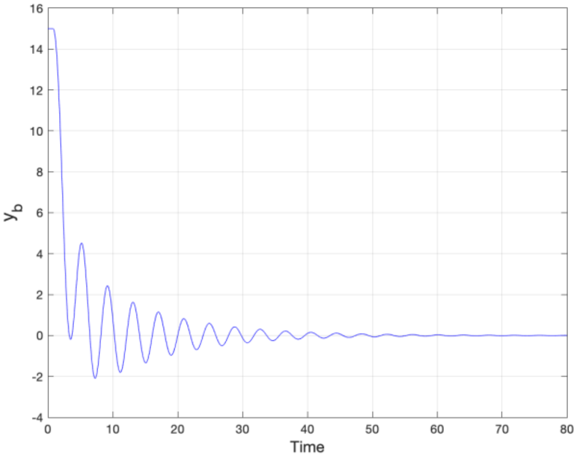

Fig. 12. Temporal evolution of $y_b$ with the state feedback gain (44).

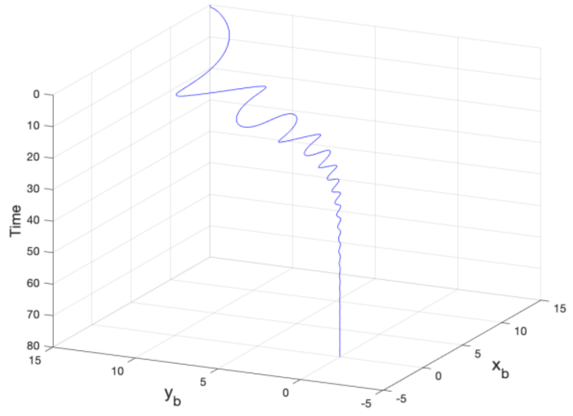

Fig. 13. Evolution of the position of the ball with the state feedback gains (43) and (44).

It therefore seems that it is imperative to develop an algorithm to identify the best gains belonging to the stability regions that best meet the required specifications.

## V. Conclusion

This article examines the issue of control in the ball and plate system. By analyzing the impact of feedback delays and employing a geometric methodology, we have identified the range of gains that guarantee the system stability. Subsequently, we demonstrated the feasibility of this method using a simulated analysis. It should be mentioned, however, that to guarantee the validity of these results, an accurate measurement of the system's state is required. Thus, in future work, we will enhance the efficacy of the controller through the implementation of an observer such as the Luenberger observer. Also to improve the performance of the controller, we will prioritize the creation of an algorithm that enables the selection of suitable gains, considering the attributes of the transient regime, such as response time, rise time, and overshoot.

# Maximizing Solar Panel Efficiency in Partial Shade: The Improved POA Solution for MPPT

Youssef Mhanni, Youssef Lagmich
Physics and Electricity Laboratory-Polydisciplinary Faculty, University of Abdelmalek Essaadi (UAE), Larache, Morocco

***Abstract*—This paper presents an innovative approach to improving Maximum Power Point Tracking (MPPT) in solar photovoltaic (PV) systems affected by partial shading, a common challenge that significantly reduces efficiency. Our research focuses on enhancing the Pelican Optimization Algorithm (POA), a promising tool in solar energy optimization, to better tackle the efficiency drop observed under shaded conditions. The enhancements to the POA involve the integration of advanced adaptive mechanisms that enable more precise response to the fluctuating irradiance patterns typical of partially shaded environments. This revised version of the POA demonstrates remarkable adaptability and precision in identifying and tracking the maximum power point, significantly outperforming its original iteration. The methodology of this study encompasses a series of rigorous simulations and real-world testing scenarios, designed to evaluate the POA's performance under various degrees and patterns of shading. The results show a notable improvement in efficiency, with the enhanced POA maintaining high levels of energy capture even in suboptimal sunlight conditions. Additionally, the improved algorithm exhibits robustness against the rapid changes in irradiance, which is characteristic of partially shaded solar PV systems. Our findings underscore the potential of the enhanced POA as a robust, adaptive solution for optimizing solar energy collection, offering significant benefits for solar installations in geographies prone to shading. This work not only contributes to the field of renewable energy optimization but also provides valuable insights for the development of more resilient and efficient solar energy systems.**

## I. INTRODUCTION

The rising global demand for energy, coupled with the escalating costs of fossil fuels and a growing awareness of environmental concerns, has spurred significant enthusiasm among numerous nations to shift towards renewable energy sources as a means to fulfill their energy requirements [1]. Renewable energy, encompassing wind energy, solar energy, and biomass/biogas, is gaining popularity across various domains, including robotics, domestic use, and industrial applications [2], [3]. Solar photovoltaic (PV) systems are becoming an increasingly popular option for the generation of electricity due to the numerous benefits associated with them [4]. These benefits include the fact that they are friendly to the environment, do not contain any moving parts, call for a low level of maintenance, do not generate any noise, have low running costs, and are simple to install. However, the low operational efficiency of PV systems, caused by the nonlinearity in their features and the variable environmental circumstances, presents a significant technological obstacle for their development. The occurrence of the phenomenon often denoted as partial shading exerts a notable influence on the total electricity production of photovoltaic (PV) systems [5], [6]. The Pelican Optimization Algorithm (POA) has emerged as a potentially useful tool for boosting the performance of photovoltaic (PV) systems, specifically in the domain of Maximum Power Point Tracking (MPPT). This is due to the fact that the Pelican Optimization Algorithm (POA) was developed by the Pelican Group, which is taking place in the midst of this shift in the energy sector. As the demand for solar PV systems continues to rise, the need for efficient MPPT techniques becomes imperative [7], [8], [9], [10]. POA, with its innovative technique that takes inspiration from the natural hunting habit of pelicans, holds the potential to address the intricate challenges posed by dynamic solar conditions, including changing solar irradiance and partial shading [11]. In the realm of photovoltaic systems, numerous effective techniques, such as hill-climbing (HC), perturb and observe (P&O), and incremental conductance (INC), among others, are available for achieving maximum power [12],[13],[14],[15]. Methods based on artificial intelligence (AI) are used to determine the maximum power point (MPP) of photovoltaic solar power when they encounter varying degrees of partial shading. These methods include neural networks, genetic algorithms, adaptive neuro-fuzzy inference systems (ANFIS), and fuzzy logic ([16], [17]. Beyond the previously mentioned approaches, a range of innovative bio-inspired and nature-mimicking algorithms have emerged for MPPT. These techniques include methodologies like Firefly Optimization, Artificial Bee Swarm Optimization (ABSO), Cuckoo Search, and the Flower Pollination Algorithm (FPA) [18], [19]. The ever-increasing global energy demand, coupled with concerns about environmental sustainability, underscores the urgency of developing robust and efficient MPPT techniques for solar PV systems [20]. This article explores the evolution and adaptation of the Pelican Optimization Algorithm (POA) to address these challenges and enhance the optimization of PV systems under various operational scenarios. The integration of artificial intelligence and nature-inspired algorithms into MPPT strategies promises to revolutionize the efficiency and sustainability of solar energy harvesting. In this research, we introduce the Adaptive and Enhanced Pelican Optimization Algorithm (IPOA), a cutting-edge metaheuristic MPPT solution designed to optimize photovoltaic (PV) systems [21], [22]. Our focus centers on enhancing energy extraction from PV systems, particularly under dynamic conditions, including partial shading [23], [24].

### A. Research Questions

- How effective are current MPPT techniques in optimizing PV system performance under varying shading conditions?
- What are the potential performance improvements achievable through novel optimization algorithms like the Improved Pelican Optimization Algorithm (IPOA)?

### B. Research Objectives

Develop and evaluate the IPOA algorithm for enhancing MPPT performance under dynamic solar conditions. Investigate the effectiveness of IPOA compared to existing MPPT techniques. Demonstrate the applicability of IPOA across diverse operational scenarios.

### C. Related Work

Prior research in the field of solar photovoltaic (PV) systems has explored various methods for maximizing energy harvest, particularly under challenging conditions such as partial shading. Traditional maximum power point tracking (MPPT) techniques, including hill-climbing (HC), perturb and observe (P&O), and incremental conductance (INC), have laid the foundation for system optimization but may struggle to adapt to dynamic environmental factors. Additionally, researchers have investigated the integration of artificial intelligence (AI)-based methods such as neural networks and genetic algorithms to enhance MPPT performance. Bio-inspired algorithms like Firefly Optimization and Artificial Bee Swarm Optimization (ABSO) have also emerged as promising approaches. While these techniques offer valuable insights, there remains a need for more robust and adaptive optimization strategies to address the complexities of PV system operation, particularly in the presence of partial shading.

### D. Organization of the Document

This paper is structured as follows: Section I introduces the research problem, questions, and objectives. Section II discusses PV system modeling under partially shaded scenarios. Section III presents the Pelican Optimization Algorithm (POA). Section IV introduces the Improved Pelican Optimization Algorithm (IPOA). Section V presents the simulation setup and empirical results. Finally, Section VI concludes the paper.

## II. System Modeling

The power produced by a PV array is directly linked to its output voltage, making the maximization of this voltage essential for optimizing the arrays overall power generation. Achieving this optimization is made possible through the utilization of a DC-DC converter, which controls the output voltage of the PV array. Techniques such as pulse width modulation (PWM) come into play in order to make precise adjustments to the DC-link voltage, which is necessary in order to maintain a stable output from the DC-DC converter. During this time, a boost converter has been invisibly incorporated into the photovoltaic system in order to control the terminal voltage. Before the photovoltaic system can be linked to the public electricity grid, it is necessary to begin by synchronizing the output of the boost converter with a one-phase pulse width modulation inverter.

### A. Features of a PV Power System

The standard electrical representation of a PV cell featuring a single diode incorporates elements like a photocurrent source with an anti-parallel diode, a shunt resistor, a series resistor connected across the load, and several other components. This model encompasses a few additional elements as well Fig. 1 illustrates the schematic diagram representing he corresponding circuit of a PV cell with a single diode Guidelines for selecting and were used to increase solar PV module modeling accuracy.

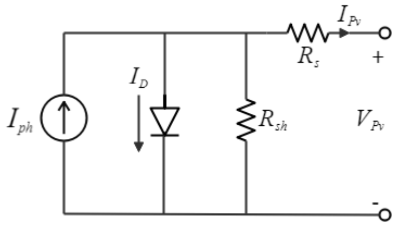

Fig. 1. Photovoltaic module's single-diode representation.

The output current of the PV cell,$I_{Pv}$ can be calculated as follows:

$$I_{ph} = I_{Pv} - I_D - \frac{V_{Pv} + R_s * I_{Pv}}{R_{sh}} \tag{1}$$

$$I_D = I_O\left(e^{V_D/\alpha V_T} - 1\right) \tag{2}$$

And at last, the equation for the current flowing out of a PV module is found, as shown below:

$$I_{Pv} = I_{ph}N_{pp} - I_O N_{pr}\left\{\exp\left[\left(\frac{V_{PV} + I_{Pv}R_S\left(\frac{N_{sr}}{N_{pr}}\right)}{mV_t N_{sr}}\right) - 1\right]\right\} - \left(\frac{V_{PV} + I_{PV}R_s\left(\frac{N_{sr}}{N_{pr}}\right)}{R_{sh}\left(\frac{N_{sr}}{N_{pr}}\right)}\right) \tag{3}$$

This graph, Fig. 2, depicts the power-voltage (P-V) characteristics of a PV system (photovoltaic system) under ideal conditions, when there is no partial shadowing present. The PV system's voltage and power output are shown on the x- and y-axes, respectively. As solar irradiance is constant and shading effects are insignificant, the graph has a smooth, single-peaked curve. In this curve, there is a one-to-one correspondence between voltage and power. The P-V curve of a PV module shows an increase in the module's power output in response to an increase in voltage. Under this optimum circumstance, the photovoltaic (PV) system performs at its (MPP), also known as the curve peak. The MPP is designed to generate the largest amount of power while simultaneously maximizing both its efficiency and its output of energy. Establishing a PV system performance baseline requires understanding this graph's behavior under non-shaded conditions. It is used to evaluate how the system responds to dynamic solar circumstances and partial shadowing, as discussed in later sections.

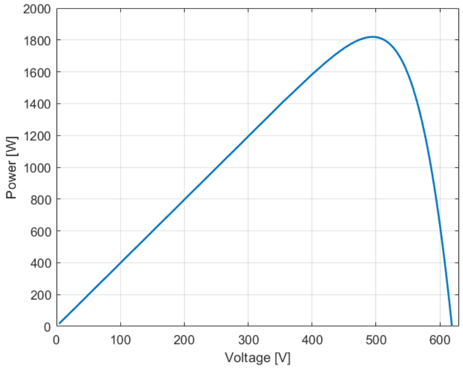

Fig. 2. Optimizing solar cell efficiency: P-V characteristics.

### B. Partial Shading Phenomenon in PV Arrays

Partial shading, a common occurrence in photovoltaic (PV) systems due to factors such as passing clouds, adjacent structures, and vegetation, significantly influences energy generation and system efficiency. To appreciate the dynamic behavior of PV modules under such situations and to come up with appropriate techniques for maximum power point tracking (MPPT), accurate modeling of partial shading is absolutely necessary. The employment of mathematical models, such as the single-diode model or the two-diode model, is a method that is commonly put into practice for the purpose of modeling partial shading. Additionally, they incorporate factors like shading patterns, module configuration, and environmental variables, providing a foundation for simulating partial shading scenarios that become bottlenecks that limit the entire system's power generation. This can lead to significant power losses and decreased overall efficiency. To mitigate the impact of partial shading, advanced maximum power point tracking (MPPT) algorithms and innovative circuit designs are employed to dynamically adjust the operating points of individual cells or modules.

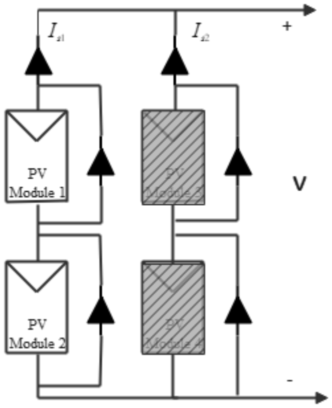

Fig. 3. Operational characteristics of a solar PV array.

By managing the voltage and current levels, these techniques help optimize the power output, ensuring the PV system remains efficient even under challenging shading conditions. Despite these advancements, careful design and installation of PV arrays in locations with minimal shading remain crucial to harnessing the maximum solar energy potential and achieving optimal performance. Fig. 3 shows operational characteristics of a solar PV array.

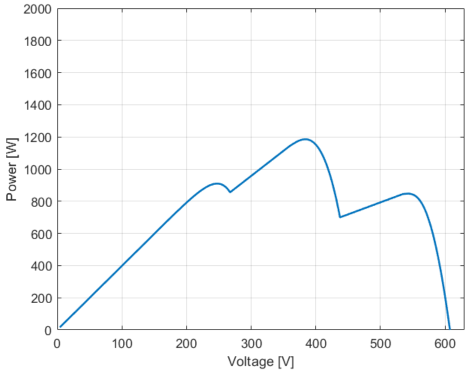

Fig. 4. Optimizing PV cell operation in partial shading: P-V characteristics.

This graph, Fig. 4, unveils the intriguing behavior of a photovoltaic (PV) system when confronted with partial shading, a common real-world scenario. It presents the relationship between the PV system's voltage and power output, with voltage on the x-axis and power on the y-axis. In contrast to the smooth curve observed under ideal, non-shaded conditions, this graph exhibits a distinctive pattern with multiple peaks and a more intricate structure. Partial shadowing causes dynamic solar irradiance fluctuations, reducing sunlight to some PV module portions. The P-V curve fragments show several local peaks instead of a global maximum. Each peak is a localized maximum

## III. Pelican Optimization Algorithm

Before the Pelican Optimization Algorithm (POA), a novel stochastic optimization method is inspired by the hunting behavior of pelicans. POA employs pelican-like agents to search for optimal solutions in optimization problems across various scientific fields. The algorithm's unique design combines efficient exploitation for unimodal functions and effective exploration for multimodal functions. The mathematical model of POA is presented, and its performance is assessed on different objective functions.

The proof of POA's supremacy lies in the fact that it outperformed eight well-known metaheuristic algorithms in a head-to-head competition. The fact that it is able to find a middle ground between exploration and exploitation makes it a potentially useful strategy for optimizing theoretical as well as real-world problems. Advancing towards the Prey (Exploration Phase): In the exploration phase of POA that can be metaphorically likened to pelicans scanning the water's surface for prey, the algorithm seeks to explore the solution space in search of potential optimal solutions.

This phase involves the following steps: Explore the Prey's Location: Similar to pelicans surveying the water for prey, the algorithm initially assesses the current state of the solution space. It evaluates the fitness of existing solutions and identifies areas that show promise for improved solutions. Move towards a Specific Spot: POA doesn't randomly explore the solution space but strategically moves toward specific areas based on the evaluation of existing solutions. This targeted approach reduces computational overhead and accelerates the search for optimal solutions. Winning on Water Surface (Exploitation Phase): The exploitation phase in POA can be likened to pelican's effectively herding and capturing prey. It focuses on refining and maximizing the exploitation of promising solutions discovered during the exploration phase: Prey Herding: Just as pelicans cooperate to encircle and herd prey towards shallow waters, POA concentrates on refining promising solutions. It identifies the most favorable solutions found during the exploration phase and herds them toward the optimal region of the solution space. Diving for Prey: In this phase, the algorithm dives deeper into the most promising solution areas, refining and optimizing them further. This is akin to pelicans diving to capture their prey efficiently. POA employs specialized optimization techniques to fine-tune solutions, maximizing their fitness and approaching the true optimum.

The Pelican Optimization Algorithm (POA) described here is a population-based approach, with the individual pelicans themselves serving as the working elements of the algorithm. Each individual within a population-based algorithm represents a candidate answer, providing guidance on what to set optimization problem variables to base on where they are in the search space. In the first step, members of the population are randomly selected between the problem's bottom and upper boundaries.

$$u_{i,j} = LB_j + rand * \left(UB_j - LB_j\right) \tag{4}$$

The Pelican Optimization Algorithm (POA) described here is a population-based approach, with the individual pelicans themselves serving as the working elements of the algorithm. Each individual within,

With i: Search Agent (i = 1,2,3,4 ...N) N: Population of Search Agents D: Design Variable According to Equation (10), a matrix that is referred to as the population matrix can be used to describe the individuals that make up the planned POA population. In this matrix, each row denotes a different set of values

Exploration phase:

$$u_{i,j} = \begin{cases} u_{i,j} + rand * \left(P_j - I * u_{i,j}\right), & Fitness_p < Fitness_i \\ u_{i,j} + rand * \left(u_{i,j} - P_j\right), & otherwise \end{cases} \tag{5}$$

Exploitation phase:

$$u_{i,j} = \begin{cases} u_{i,j} + rand * \left(P_j - I * u_{i,j}\right), & Fitness_p < Fitness_i \\ u_{i,j} + rand * \left(u_{i,j} - P_j\right), & otherwise \end{cases} \tag{6}$$

The iterative process that the Pelican Optimization Algorithm (POA) goes through is depicted graphically in the algorithm's flowchart. It starts with an initialization phase that mimics the searching behavior of pelicans for prospective solutions across the solution space. This is done within the context of the solution space. After that, the algorithm enters a phase known as exploitation, during which it focuses its efforts on potential solutions. This phase is analogous to the process by which pelicans herd their prey before swooping in for the kill. Iterations will continue until a predetermined stopping condition is met, during which time the algorithm will dynamically adjust in order to analyze and select the best possible solutions. The flowchart provides a visual representation of the algorithm's exploration and exploitation phases, demonstrating the algorithm's flexibility in terms of its ability to solve difficult optimization issues.

## IV. Improved Pelican Optimization Algorithm

The Pelican Optimization Algorithm (POA) has shown promise in the realm of solar Maximum Power Point Tracking (MPPT), a critical aspect of enhancing the efficiency of solar photovoltaic (PV) systems. However, one of the key challenges faced with the original POA is its tendency to require a substantial number of iterations and considerable time to converge to the optimal MPPT solution. This often results in a less-than-ideal response time, particularly under dynamic environmental conditions such as variable solar irradiance and partial shading, which are common in real-world solar installations. To address these limitations, this paper introduces a significant improvement to the original POA. The core concept of this enhancement revolves around optimizing the algorithm's ability to find the most effective MPPT solution more rapidly and with greater accuracy. By refining the POA's search and convergence mechanisms, the goal is to reduce the iteration count significantly while ensuring that the error margin approaches zero. This improved version of POA is designed to offer a faster, more precise and more reliable approach to MPPT, especially in scenarios where rapid changes in solar irradiance due to partial shading can drastically affect the performance of solar PV systems. The following sections will detail the specific modifications made to the original POA, explain the mechanics of the improved algorithm, and discuss the advantages of these enhancements in the context of solar MPPT.

Idea Pelicans are renowned for their distinctive group behaviors, which are critical to their survival and efficiency in the wild. These birds often hunt in cohesive groups, skillfully coordinating their efforts to maximize the chances of a successful catch. Notably, they are observed flying in a 'V' formation, a strategic arrangement that optimizes aerodynamics and energy expenditure. Within this formation, a clear hierarchy of leading and following emerges, where one or more pelicans take the lead, and the others align their movements accordingly. This harmonious interplay of leadership and teamwork in pelicans serves as a fascinating parallel to our proposed improvements in the Pelican Optimization Algorithm. By mirroring these natural strategies, we aim to enhance the algorithm's efficacy in solving complex problems. The core idea is to select leading candidates—akin to the leading pelicans with the most successful hunting positions—and use their 'positions' or algorithmic solutions to guide the rest of the group. This approach allows for a more dynamic and efficient updating of positions within the algorithm, ensuring quicker convergence to optimal solutions, much like pelicans efficiently adjusting their flight patterns in response to their leaders. This biomimicry not only enriches the POA with a more robust search mechanism but also significantly reduces the computational time and iterations needed to reach the most effective solutions in real-world applications, such as solar photovoltaic systems. The Improved Pelican Optimization Algorithm (IPOA) takes inspiration from the pelican's strategic hunting methods to enhance Maximum Power Point Tracking (MPPT) in photovoltaic systems. By selecting two high-quality candidates, akin to pelicans identifying rich fishing spots, the IPOA maintains diversity and prevents premature convergence on suboptimal solutions. These candidates guide the search process, ensuring a balanced exploration and exploitation of the solution space, leading to faster and more reliable convergence. This approach enhances the IPOA's adaptability and robustness, particularly in dynamic environments like partial shading in solar arrays, making it an effective tool for optimizing energy harvest in solar PV systems. Enhancement 1: Dual Leading Candidates Selection in the first significant enhancement to the Pelican Optimization Algorithm (POA), we introduce the concept of selecting dual leading candidates, termed as 'Alpha' and 'Beta.' This enhancement is inspired by the natural hierarchy observed in pelican groups during their hunting expeditions, where typically, one or two pelicans assume the leadership role

Mechanism of Selection:

The algorithm identifies two candidates with the most optimal positions in the search space, analogous to pelicans with the most successful catch.

These positions are determined based on the maximization criteria relevant to the problem at hand, such as the highest energy output in MPPT applications for solar PV systems.

'Alpha' represents the candidate with the absolute best position (maximum solution), while 'Beta' is identified as the candidate with the second-best position.

This dual selection strategy aims to ensure a more diverse and robust search process, mitigating the risk of the algorithm prematurely converging to local optima.

Enhancement 2: Group Position Update Mechanism

- The Group Position Update Mechanism is inspired by the adaptive and responsive flight patterns of pelicans in a group, particularly how they adjust their positions in relation to the leaders.
- This mechanism is implemented through a set of three equations. Each equation plays a distinct role in guiding the movement of the candidate solutions in the search space.

First Equation:

The position of the α candidate is updated by:

$$X_i^{\alpha} = R_{\alpha}.\left(1-\frac{t}{T}\right).\left(2.r-1\right).x_i \tag{7}$$

This is followed by calculating the new potential position for the α candidate:

$$X_i^{new,\alpha} = P^{\alpha} + X_i^{\alpha} \tag{8}$$

For β candidate:

Similarly, for the β candidate, the position is updated by:

$$X_i^{\beta} = R_{\beta}.\left(1-\frac{t}{T}\right).\left(2.r-1\right).x_i \tag{9}$$

And the new potential position for the β candidate is:

$$X_i^{new,\beta} = P^{\beta} + X_i^{\beta} \tag{10}$$

Final Update Step:

Finally, the updated position for the next iteration, which incorporates information from both the α and β candidates, is calculated by averaging their new potential positions:

$$X_i^{update} = \frac{X_i^{new,\alpha} + X_i^{new,\beta}}{2} \tag{11}$$

In these equations:

- $X_i^{\alpha}$ and $X_i^{\beta}$ represent the new positions for the α and β candidates, respectively.
- $R_{\alpha}$ and $R_{\beta}$ are coefficients that adjust the step size for the α and β candidates.
- $t$ Denotes the current iteration, and $T$ represents the total number of iterations.
- $r$ Is a random number between 0 and 1.
- $x_i$ Is the current position.
- $x_i^{new,\alpha}$ and $x_i^{new,\beta}$ are the new potential positions for the α and β candidates after moving towards or away from the current position.
- $x_i^{update}$ Is the final updated position for the next iteration, averaged from the α and β candidate positions.

These equations form the iterative update mechanism of IPOA, where the positions of candidates α and β are adjusted according to the optimization process, and their average is used to update the solution in search of the optimal maximum power point.

The introduction of the Dual Leading Candidates Selection in the Improved Pelican Optimization Algorithm symbolizes a significant leap toward mimicking the collaborative and efficient hunting strategies of pelicans. This enhancement is not just a theoretical modification but a practical solution aimed at addressing real-world challenges in optimization, particularly in the dynamic and often unpredictable domain of solar energy harvesting.

## V. Result and Discussion

In this section, we present a comparative analysis focusing on the performance of the Improved Pelican Optimization Algorithm (POA) against the original POA, Particle Swarm Optimization (PSO). The primary metric for comparison is the mean power output achieved by each algorithm in the context of Maximum Power Point Tracking (MPPT) under partial shading conditions in solar photovoltaic (PV) systems. The simulations were designed to replicate realistic solar energy scenarios, enabling a thorough analysis of IPOA's optimization effectiveness. In the course of our study, a specific set of parameters was utilized to fine-tune the IPOA's performance. The chosen parameters were critical in guiding the algorithm towards optimal solutions efficiently. The table below outlines the key parameters and their respective values, which were instrumental in the simulation and testing phases of our research: research:

Table I provides a comprehensive overview of the fundamental parameters crucial to our analysis, accompanied by their respective values. This detailed breakdown serves as a foundational reference for understanding the intricacies of our study**.**

TABLE I. PARAMETERS OF THE PELICAN OPTIMIZATION ALGORITHM (IPOA)

| Parameter | Symbol | Value |
|---|---|---|
| Pelican Population Size | $N$ | 10 |
| Maximum Generations | $T$ | 50 |
| Search Radius alpha | $R_\alpha$ | 0.5 |
| Search Radius beta | $R_\beta$ | 0.35 |
| Coefficients | $r$ | $random\ vector\ in\ [0,1]$ |

The results, as demonstrated by the table, indicate a tangible improvement in MPPT efficiency when using the IPOA. The parameter settings were meticulously adjusted to align with the dynamic behavior of partial shading effects on solar panels, ensuring that the algorithm could adapt and respond effectively. The careful calibration of these parameters was pivotal in achieving the enhanced outcomes presented in this study.

*1) Experiment setup:* Briefly describe the experimental setup, including the solar PV system model used, the specific conditions under which partial shading was simulated, and any relevant parameters that were constant across all tests.

Outline the criteria used for the comparison, such as the number of iterations, the environmental conditions simulated, and any specific features of the algorithms that were evaluated.

*2) Objective of the comparison:* The main objective of this comparative study is to evaluate the effectiveness of the Improved POA in optimizing the power output of solar PV systems under partial shading, as compared to the original POA, PSO.

This comparison aims to highlight the advancements made in the Improved POA, specifically in terms of its efficiency, accuracy, and speed in converging to the optimal solution for MPPT.

This introduction sets the stage for a detailed presentation of your results, providing clarity on the purpose, methodology, and objectives of your comparative analysis. It should help readers understand the context in which your findings were obtained and the metrics used to evaluate the performance of the Improved POA against other algorithms.

Case 1: ir1=1000 W/m², ir2=1000 W/m²; ir3=400 W/m²; ir4=800 W/m²

The results, as evidenced by the table (see Table II), reveal a significant enhancement in MPPT efficiency when implementing the IPOA algorithm.

TABLE II. MPPT EFFICIENCY: PSO, POA, AND IPOA COMPARISON (SCEBNARIO1)

| | PSO | POA | IPOA |
|---|---|---|---|
| 1 | 749,96 | 837,54 | 1047,91 |
| 2 | 814,52 | 861,95 | 1115,65 |
| 3 | 941,00 | 997,50 | 1151,82 |
| 4 | 1026,33 | 1010,06 | 1179,10 |

| 50 | 1185,48 | 1185,26 | 1185,50 |

The initial quantitative data sets the stage for a deeper exploration of the results, with, Fig. 5, providing an initial insight into our findings.

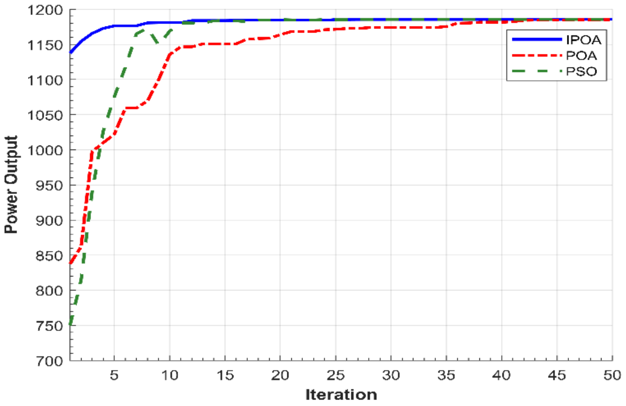

Fig. 5. Comparative performance of IPOA, PSO, and POA under partial shading conditions (scenario 1).

Following this introductory data, the ensuing figure and table offer a comprehensive comparison of the error margins encountered in Maximum Power Point Tracking (MPPT) using IPOA. These visual representations delve deeper into the nuances of our findings, providing a detailed examination of IPOA's performance in optimizing photovoltaic systems.

Additionally, we present Table III below that compares key performance indicators, offering a comprehensive insight into the effectiveness of different methodologies.

TABLE III. PERFORMANCE METRICS: PSO, POA, IPOA (SCENARIO 1)

| | Mean Power Output | Maximum Power Output | Standard Deviation |
|---|---|---|---|
| **PSO** | 1155.47 | 1185.54 | 88.79 |
| **POA** | 1140.53 | 1185.27 | 76.37 |
| **IPOA** | 1182.03 | 1185.58 | 8.53 |

Analysis:

- IPOA shows the highest mean power output, suggesting better average performance across all iterations.
- The maximum power outputs of all algorithms are very close, with IPOA marginally leading.
- The standard deviation is significantly lower for IPOA compared to PSO and POA, indicating that IPOA has the most consistent performance across iterations.

Having evaluated the overall efficiency and consistency of the algorithms, we now shift our focus to a detailed error analysis. The ensuing figure and table provide an in-depth comparison of the error margins in MPPT for IPOA versus PSO and POA. This examination is crucial to understand the precision and reliability of each algorithm under variable solar conditions.

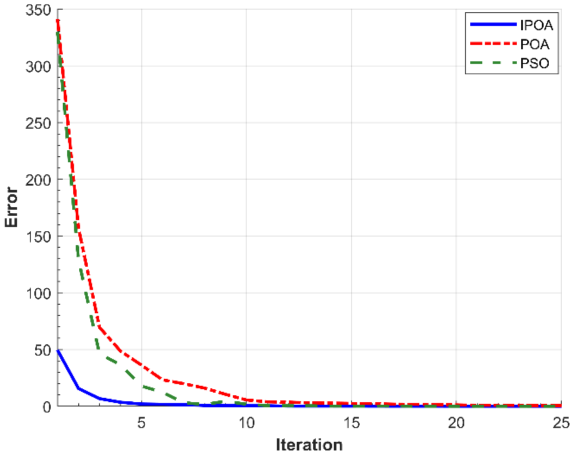

Fig. 6. Error analysis in MPPT: IPOA vs. PSO and POA (scenario1).

As the error lines diminish at a more gradual pace, it indicates that the algorithm (see Fig. 6) is reaching a state of stabilization, progressively converging towards the optimal parameters.

TABLE IV. ERROR METRICS: IPOA VS. POA AND PSO (SCENARIO1)

| | MAE | MSE | RE |
|---|---|---|---|
| **IPOA vs POA** | 41.50 | 6291.25 | 4.14% |
| **IPOA vs PSO** | 26.73 | 7054.30 | 3.06% |

The presence of a discernible error fluctuation suggests that the IPOA entities engaged in a diverse exploration (see Table IV) of the solution space.

Interpretation:

- MAE (Mean Absolute Error): On average, the power output of IPOA differs from POA by about 41.50 units and from PSO by about 26.73 units. The lower MAE for PSO suggests that IPOA's results are closer to PSO's results on average than to POA's.
- MSE (Mean Squared Error): The MSE values are higher, indicating that there are instances where the differences in power outputs are quite large. The higher MSE for IPOA vs PSO indicates more significant deviations when compared to PSO than to POA.
- RE (Relative Error): Indicates that on average, the IPOA's power output is about 4.14% different from POA's and 3.06% different from PSO's. This gives an idea of the error in terms of proportion to the compared algorithm's output.

These errors provide insight into how closely IPOA's performance aligns with that of POA and PSO, with a particular focus on the consistency and magnitude of the differences between their outputs.

Case 2: ir1=900 W/m², ir2=900 W/m²; ir3=600 W/m²; ir4=650 W/m²

TABLE V. MPPT EFFICIENCY: PSO, POA, AND IPOA COMPARISON (SCEBNARIO2)

| | PSO | POA | IPOA |
|---|---|---|---|
| 1 | 827,84 | 892,66 | 1116,85 |
| 2 | 894,83 | 920,17 | 1143,24 |
| 3 | 991,15 | 947,55 | 1174,72 |
| 4 | 1093,69 | 969,67 | 1220,74 |
| 5 | 1184,56 | 974,60 | 1235,29 |
| 6 | 1231,63 | 995,17 | 1235,29 |
| 7 | 1249,54 | 1036,32 | 1246,41 |
| 8 | 1248,10 | 1076,69 | 1253,04 |
| 9 | 1251,60 | 1113,67 | 1253,04 |
| 10 | 1253,34 | 1125,17 | 1253,45 |
| 11 | 1251,95 | 1157,98 | 1253,72 |
| 12 | 1252,56 | 1210,77 | 1253,72 |
| 13 | 1253,00 | 1219,67 | 1253,72 |
| 14 | 1253,37 | 1219,67 | 1253,72 |
| 15 | 1252,21 | 1240,70 | 1254,39 |
| 16 | 1253,88 | 1241,90 | 1254,39 |
| 17 | 1253,69 | 1243,44 | 1254,57 |
| 18 | 1253,85 | 1249,51 | 1254,57 |
| 19 | 1254,49 | 1249,51 | 1254,57 |
| 20 | 1254,13 | 1249,51 | 1254,74 |
| 21 | 1253,69 | 1249,55 | 1254,74 |
| 22 | 1254,57 | 1249,55 | 1254,74 |
| 23 | 1254,18 | 1250,17 | 1254,74 |
| 24 | 1253,93 | 1250,23 | 1254,80 |
| 25 | 1254,62 | 1250,23 | 1254,80 |
| 26 | 1254,19 | 1252,99 | 1254,80 |
| 27 | 1254,37 | 1252,99 | 1254,80 |
| 28 | 1254,80 | 1252,99 | 1254,80 |
| 29 | 1254,78 | 1252,99 | 1254,80 |
| 30 | 1254,66 | 1253,71 | 1254,80 |
| 31 | 1254,78 | 1253,71 | 1254,80 |
| 32 | 1254,90 | 1253,71 | 1254,80 |
| 33 | 1254,86 | 1253,71 | 1254,80 |
| 34 | 1254,80 | 1254,06 | 1254,84 |
| 35 | 1254,90 | 1254,06 | 1254,85 |
| 36 | 1254,89 | 1254,06 | 1254,85 |
| 37 | 1254,82 | 1254,16 | 1254,85 |
| 38 | 1254,82 | 1254,16 | 1254,85 |
| 39 | 1254,92 | 1254,16 | 1254,85 |
| 40 | 1254,90 | 1254,16 | 1254,85 |
| 41 | 1254,88 | 1254,16 | 1254,86 |
| 42 | 1254,91 | 1254,37 | 1254,87 |
| 43 | 1254,87 | 1254,45 | 1254,89 |
| 44 | 1254,84 | 1254,45 | 1254,91 |
| 45 | 1254,92 | 1254,56 | 1254,91 |
| 46 | 1254,91 | 1254,56 | 1254,91 |
| 47 | 1254,91 | 1254,56 | 1254,92 |
| 48 | 1254,92 | 1254,92 | 1254,94 |
| 49 | 1254,94 | 1254,92 | 1254,94 |
| 50 | 1254,91 | 1254,92 | 1254,95 |

In the second scenario, this quantitative data (see Table V) serves as an introductory glimpse into the observed trends and patterns, paving the way for a more detailed exploration in the subsequent result figures (see Fig. 7).

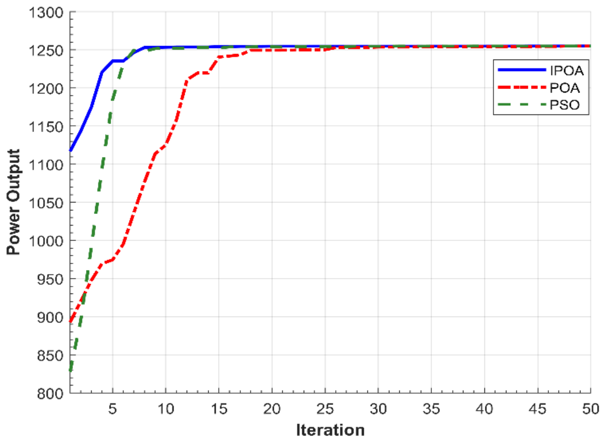

Fig. 7. Comparative performance of IPOA, PSO, and POA under partial shading conditions (scenario2).

Following this preliminary data, the subsequent figure and table offer a detailed comparison of the error margins encountered during MPPT with IPOA, providing a comprehensive analysis of its performance. Table VI shows the performance metrics of PSO, POA and IPOA.

TABLE VI. PERFORMANCE METRICS: PSO, POA, IPOA (SCENARIO 2)

| | Mean Power Output | Maximum Power Output | Standard Deviation |
|---|---|---|---|
| **PSO** | 1228.01 | 1254.94 | 87.72 |
| **POA** | 1198.71 | 1254.92 | 104.79 |
| **IPOA** | 1246.38 | 1254.94 | 27.23 |

Overall, IPOA demonstrates the best average performance and reliability, with consistent closeness to peak power output. POA, despite achieving similar peak performance, shows greater variability, potentially making it less reliable for consistent output. PSO's performance is intermediate in both average output and consistency. This analysis (see Fig. 8) highlights IPOA as the preferable choice for applications where average performance and reliability are key considerations.

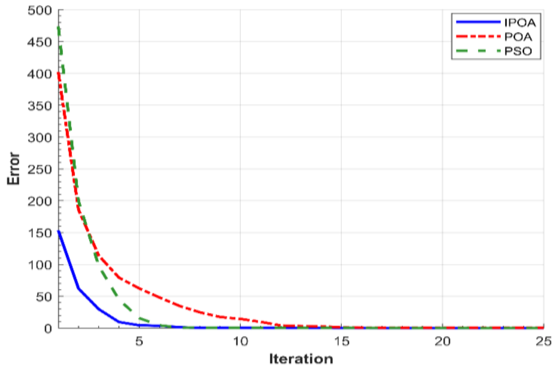

Fig. 8. Error analysis in MPPT: IPOA vs. PSO and POA (scenario2).

TABLE VII. ERROR METRICS: IPOA VS. POA AND PSO (SCENARIO2)

| | MAE | MSE | RE |
|---|---|---|---|
| **IPOA vs POA** | 47.67 | 9308.13 | 4.71% |
| **IPOA vs PSO** | 18.51 | 3954.33 | 1.98% |

There was a notable fluctuation in error, indicating a diverse exploration of the solution space by the IPOA entities. Table VII shows error metrics in Scenario 2.

Higher Average Output: IPOA has a greater mean power output, indicating better overall effectiveness. Peak Performance: Although all three algorithms achieve similar maximum outputs, IPOA maintains this peak more consistently, as shown by its lower standard deviation. Less Variability: IPOA's reduced variability implies more reliable and stable performance.

Consistent Peak Performance: IPOA, PSO, and POA all reach similar maximum power outputs, but IPOA does so with greater consistency, as evidenced by its lower standard deviation. Reduced Variability: The lower standard deviation for IPOA suggests more stable and reliable performance, with less fluctuation in power output. Faster Achievement of Optimal Values: IPOA is notably quicker in reaching optimal or best values compared to PSO and POA, an important feature in time-sensitive applications or where rapid convergence is essential.

Alignment with PSO in Error Metrics: The Mean Absolute Error (MAE) and Mean Squared Error (MSE) between IPOA and PSO are lower than those between IPOA and POA. Additionally, the relative error is significantly smaller when comparing IPOA with PSO than with POA, emphasizing IPOA's improved performance.

These error metrics are crucial for understanding the practical implications of choosing one algorithm over another, particularly in scenarios where small differences in power output can have significant consequences.

In essence, the Improved Pelican Optimization Algorithm (IPOA) not only achieves higher average outputs but also demonstrates rapid convergence to optimal performance, making it a superior choice for scenarios where both high efficiency and quick response are critical.

## VI. CONCLUSION

The research presented in "Maximizing Solar Panel Efficiency in Partial Shade: The Improved POA Solution for MPPT" effectively addresses a critical challenge in the field of solar photovoltaic systems – optimizing performance under partial shading conditions. The study introduces the Improved Pelican Optimization Algorithm (IPOA), an innovative adaptation of the Pelican Optimization Algorithm (POA), specifically tailored to enhance Maximum Power Point Tracking (MPPT) efficiency in solar PV systems.

Our investigation reveals that the IPOA significantly surpasses the original POA and other prevalent methods like PSO in several key performance metrics. The IPOA not only demonstrates a higher mean power output, indicative of superior average performance, but also achieves this with remarkable consistency and reliability, as evidenced by its notably lower standard deviation compared to its counterparts. This consistency is crucial in real-world applications where variability in power output can significantly impact overall system efficiency.

Furthermore, IPOA's ability to rapidly and accurately identify and track the maximum power point, particularly in the dynamically challenging environment of partial shading, marks a substantial advancement in solar PV optimization. Its enhanced adaptability and precision in response to fluctuating irradiance patterns set a new benchmark in the field.

The study's comprehensive approach, encompassing both simulation and real-world testing, underscores the robustness and practical applicability of IPOA. These findings not only contribute significantly to renewable energy optimization but also pave the way for more efficient, resilient solar energy systems, especially in regions where shading is a frequent concern.

In conclusion, the Improved Pelican Optimization Algorithm emerges as a highly effective and efficient solution for MPPT in photovoltaic systems. Its superior performance, combined with enhanced adaptability and rapid convergence, positions IPOA as a significant advancement in the quest for optimizing solar panel efficiency under the challenging conditions of partial shading.

*Abstract*—**Deep learning algorithms have demonstrated good performance in many sectors and applications. Facial expression recognition (FER) is recognizing the emotions through images. FER is an integral part of many applications. With the help of the CNN-BiLSTM integrated approach, higher accuracy can be achieved in identification of the facial expressions. Convolutional neural networks (CNN) consist of a Conv2D layer, dividing the given images into batches, performing normalization and if required flattening the data i.e. converting the data in a 1D array and achieving a higher accuracy. BiLSTM works on two LSTMs i.e. one in the forward direction and the other in a backward direction. One can use LSTM to process the images (datasets) however, it is suggested with the help of BiLSTM can predict the expressions with more accuracy. Input data is available in both the direction (forward and backward) which helps maintaining the context. Using LSTM CNN and BiLSTM always helps increasing the prediction accuracy. Application areas where a BiLSTM can give more prediction accuracy are the forecasting models, text recognition, speech recognition, classifying the large data and the proposed facial expression recognition. The integrated approach (CNN and BiLSTM) increases the accuracy significantly as discussed in the results and discussion section. This approach could be categorized as a fusion technique where two methods (approaches) are integrated to get higher accuracy. The results and discussion section elaborates the effectiveness of the integrated approach compared to HERO: human emotions recognition for realizing the intelligent internet of things. As compared to the HERO approach CNN-BiLSTM gives good results in terms of precision and recall.**

***Keywords*—CNN (Convolutional Neural Network); BiLSTM (Bi Directional Long Short Term Memory); facial expression recognition; deep learning; flattening**

## I. Introduction

A convolutional neural network (CNN) can be used to extract the features from images. Emotions like anger, sadness, happiness, disgust etc. can be extracted using CNN. CNN helps in accurately predicting the emotion from the given images. CNN consists of a few layers such as a convolutional layer, a pooling layer and a fully connected layer. With the help of the CNN, the model can successfully get the probability of the image being a certain class [5, 6, 11].

The convolutional layer is quite similar to extracting the features from given images. "Convolution" is the key term used in CNN which means multiplying 02 functions to generate 3rd function. In a similar way feature extraction in CNN works. The pooling layer processes the image and divides it into sub-regions. According to this division, there could be max-pooling and mean-pooling. The system processes a large volume of data.

However, data could be labeled or unlabeled. A fully connected layer takes input from the previous layers and predicts the desired class for the given images. LSTM – Long Short Term Memory is a method of deep learning used in many applications. To increase the prediction accuracies in the proposed model one can use long short-term memory which is based on an artificial neural network. With the help of LSTM, it is possible to process complex data. It is known as long short-term memory because it consists of a "memory unit" to store information for a long period. With the help of these memory units, model can learn further dependencies. LSTM can be used for forecasting purposes where it could deliver results with better accuracy.

LSTM [12, 17] consists of 03 gates namely forget gate, Input and output gate. A sigmoid layer is an important layer in LSTM that helps in binding the input to the output. Based on the concept of LSTM, BiLSTM can be developed where each training sequence (input) is given in both the direction i.e. backward and forward directions. BiLSTM is the extended version of LSTM and results in better accuracy. BiLSTM uses 02 LSTMs to train the input data where the first LSTM processes the input data and second LSTM works on the reverse of the input data. The benefit of the second LSTM is that it brings additional context to the processing environment, increases speed and accuracy of the proposed model.

## II. Literature Review

Being human one can express different emotions like happiness, anger, neutral reaction etc. in different situations. Facial emotion/expression recognition is the current need in many applications such as health care, crime, finance and places with more crowds like shopping malls. Deep learning methods can be used to identify different emotions by processing 'n' images or real-time videos. Authors [1] have developed a model which extracts features from given images and trained the model to process the upcoming features automatically. Authors in study [2] suggested using support vector machines (*SVM*), naïve Bayes and lexicon methods can be used to know different emotions from images. The proposed model generates 'n' vectors as there could be different emotions. A model emphasizes knowing the sentiments according to different conversations. Robots are trained to process images and give appropriate feedback once analyzed all the captured images. Authors [3] have proposed PEIS model trains the robots to process real-life images. Features are extracted from the captured images using the FERW model to give correct feedback.

Authors in [4] have integrated CNN and auto-encoders to extract different features from images. This set of features will be used for classification purposes. Authors have proposed 06 architectures out of which 02 are trained on Japanese female facial expressions and 04 with Berlin database. Convolutional neural network (CNN) architecture consists of convolution layers, pooling layers and dense layers with output. These convolution and pooling layers help in extracting different features from emotions whereas the auto-encoder reduces the dimensions. Authors [5, 6, 11] deep learning methods can be used to extract the features from images. Even though there are complex features associated with different images those are also extracted and classified using different deep learning techniques. “Gabor Filter” can be applied to analyze the textures, edge detection, and extract different features from the images. Gabor filter helps in accurately detecting edges of the images and therefore in the proposed model there are 02 Gabor filters. Output from the Gabor filter is given as input to the convolutional neural network layer (CNN). Human feelings can be classified into different categories like sadness, happiness, fear, anger, surprise etc. Authors [7, 13, 24, and 27] used a JAFEE dataset with these emotions and used MATLAB processes the same. The data set consists of 213 images with .tiff format. The proposed model consists of layers like the input layer, CNN layer, pooling layer, activation layer and fully connected layer. Captured data can be classified into 02 categories ‘labeled’ and ‘unlabeled’. The proposed model [8, 23] focuses on ‘unlabeled data’. Idea is to reduce human intervention and automatically process the ‘unlabeled data’. “LLEC”- label-less learning for emotion recognition is the proposed model which predicts the probable label for unlabeled data. To assess the model’s accuracy and prediction uncertainty in labeling authors have suggested using an ‘entropy mechanism’. It is also possible to train the robots and IoT devices to process the images, extract features and identify the emotions. The proposed model [9] uses HAAR- a feature-based cascade classifier. A motion sensor senses the motions of humans and activates the camera which captures real-time images. The model also consists of a ‘cropping’ mechanism where captured images will be cropped to select the human face. Once the images are cropped, the next phase is to know the emotion. All the cropped images will be processed, emotions will be identified and classified results will be stored in the database. Authors [10] have used 02 datasets Cohn-Kanade and JAFEE Japanese female facial emotions. In the proposed model “Keras” is used for recognizing emotions. Authors also used pre-trained models like VGC-16, ResNet 152V2, Inception V3 and Xception etc. These pre-trained models process the datasets and their accuracies are compared in the proposed model.

A framework based on LSTM is proposed [12, 17, 18] to identify different emotions. The model gives ratings (1 to 9 scales) to emotions like anxiety, anger, sadness, joy etc. Authors have also suggested features can be extracted using EEG signals and the application of thresholding schemes to gain better accuracy in classification. To reduce the errors, authors [14] have suggested one can use a backpropagation algorithm [14]. ReLu – rectified linear unit can be embedded to make negative values zero. The model also deals with over-fitting by introducing a dropout layer to achieve accuracy. In an image, some micro-expressions can be identified with the application of deep learning methods [15, 19, 25-26]. The authors have used the FER-2013 dataset to know different micro-expressions. This proposed model consists of a cross-entropy loss function and Adam optimizer to train the features, providing the best results and helping to reduce the losses. A model is proposed [16] based on LDL- a label distribution learning with conditional probability to reduce the errors. Authors have used JAFEE dataset to know the emotions like happiness, sadness, fear, anger, surprise and disgust. The proposed system consists of a convolutional layer, a local binary convolutional layer, a fully connected layer and an output layer to generate the feature map. Authors in [20] have proposed a pose-guide estimation model using the pyramid histogram orientation gradient method, edge histogram descriptor and local binary pattern (LBP). LBP helps convert images into an integer array. Authors have used CK+, JAFEE, CASIA, and AR datasets. Pose estimation, template generation, and target matching are the few steps involved in the proposed model.

Authors in [21] have proposed a model based on landmark-based spatial attention to know the crucial regions of images. It is possible to focus on key regions of the images. Additionally, the temporal attention method is introduced to get the informative expressions from the images. Authors have used datasets like CK+, Olulu CASIA, and MMI. The model also gives the best results for the video inputs. A cascaded spatiotemporal attention network (CSTAN) is proposed [22] to integrate spatial and temporal emotional information. CSTAN helps in locating exact regions of interest for the given images. A deep learning- based BiLSTM model is proposed [23] to classify the given images. BiLSTM is an extended version of LSTM where training is given in both directions i.e. forward and backward to successfully separate the recurrent nets. The authors have used Berlin EMO-DB for simulation purposes with MATLAB. Authors have concluded that the BiLSTM classifier gives better accuracy more than 86% and hence it could be the best classifier for speech emotion recognition.

## III. Methodology and Algorithmic Discussion

### A. Proposed Approach

*1) Input an image or video*

*a) Splitting the video in ‘n’ frames*

*b) Processing the image or frames from the input video*

*2)* Application of *CNN* and *BiLSTM* approach

*a)* Processing the image/frames through convolution layer, pooling and fully connected layers

*b)* Application of BiLSTM

*3)* Generating the output

4) Categorizing the given set of images into
   a) Sadness
   b) Happy
   c) Disgust
   d) Fear
   e) Neutral
   f) Angry

### A. CNN

CNN helps in achieving higher accuracy in facial expression recognition. CNN consists of 'n' convolution layers (see Fig. 1) and 'm' fully connected layers will help in batch formalization. The dataset (FER 2013) consists of grayscale images with 48*48 pixels. The dataset consists of images with different emotions like anger, disgust, happiness, fear, sad, surprise and neutral. The dataset consist of emotions, pixel values and usages based on which it is possible to classify the images among different groups. The initial step is to divide the dataset into training and testing categories. The proposed model successfully classifies the dataset in X_train, X-test which contains pixel values. Y_train, Y_test consists of emotions. Upon execution of encoding and reshaping data will be ready for training purposes. As discussed earlier, CNN based model consists of 'n' convolution layers, 'm' fully connected layers and ReLU. The next phase is to generate the batches with the desired size i.e. 64 in this approach. CNN consists of a few more steps after this batch normalization as follows-

- Batch-normalization
- Max-pooling
- Dropout
- Flattening

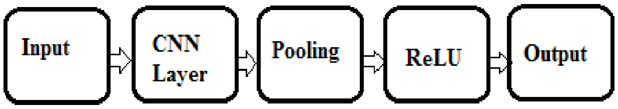

Fig. 1. Working of CNN.

Given data can be processed in 'n' epochs i.e. 100 in the proposed approach. It is nothing but training the neural network with all data from the given dataset. Epochs decide the accuracy after training the data and as the epoch increases output curve moves from underfitting to optimal and then moves to overfit. The steps included in this process can be decided with the help of the following equation-

$$\text{steps\_in\_epoch} = \text{Total\_TrainingSamples}/\text{Training\_BatchSize} \quad (1)$$

### B. BiLSTM

Deep learning algorithms are very useful in facial expression recognition. It consists of 02 LSTMs to process the input in the forward direction and others to process in the backward direction. It is proved that BiLSTM gives better prediction accuracy than LSTM. Once the input is processed in both directions (i.e. forward and backward), the model executes encoding to concatenate the inputs. The proposed approach model consists of CNN and BiLSTM methods for better accuracy. The advantage of BiLSTM is given input can be fully utilized to gain better accuracy. One can say using BiLSTM it is possible to preserve the information from future to past and past to future.

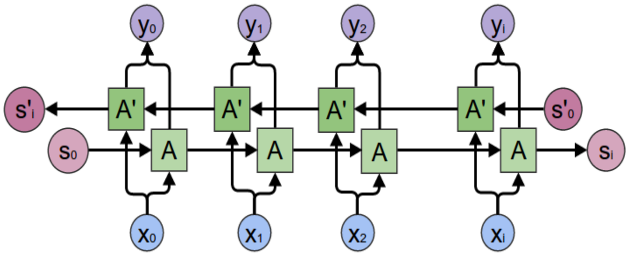

Fig. 2. BiLSTM.

BiLSTM learns (see Fig. 2) from a sequence of data i.e. processing the input forward and backward and works on the principle of maximum utilization of the available information. There is a Hidden layer to remembering the information between these steps. More the hidden layers, the model become overfits the training data. BiLSTM also consists of a learning rate parameter for input weights and depends on the following –

1) Input gate (Forward)
2) Forget gate (Forward)
3) Cell candidate (Forward)
4) Output gate (Forward)
5) Input gate (Backward)
6) Forget gate (Backward)
7) Cell candidate (Backward)
8) Output gate (Backward)

The proposed approach consists of a pre-training layer where a given set of images or input video will be processed and then passed to the next phase. The next subsequent layers of the proposed model are the attention layer and mapping of the extracted feature layer. One can integrate the HAAR cascade classifier to detect the face or specific region of the face from the given image to extract the features.

### C. Advantages of Proposed Approach

The advantage of the integrated CNN-BiLSTM approach is that CNN is known for maximum feature extraction from the given set of images or video using a max-pooling layer. As discussed earlier, BiLSTM preserves the information in the memory cells to process it in both directions. BiLSTM also consists of hidden layers (states) to retain the information. To utilize the strengths of these models, an integrated approach is proposed. The output of the CNN model is given as an input to the BiLSTM. Output of this integrated approach is discussed in the result and discussion section of this paper with the application of quality parameters such as F1 score, precision and recall.

## IV. RESULTS AND DISCUSSION

As discussed earlier the given dataset consists of images with different emotions. Those images are grouped under a separate label as shown in Table I.

TABLE I. ANALYSIS OF THE DATASET

| | Emotion | Number |
|---|---|---|
| 0 | Angry | 4953 |
| 1 | Disgust | 547 |
| 2 | Fear | 5121 |
| 3 | Happy | 8989 |
| 4 | Sad | 6077 |
| 5 | Surprise | 4002 |
| 6 | Neutral | 6198 |

Different emotions like anger, sadness, disgust, fear, happiness, surprise and neutral are detected from the given set of images. Table I is the count of images with different emotions.

TABLE II. SHAPE OF THE DATA

| | |
|---|---|
| train shape | (28709, 3) |
| validation shape | (3589, 3) |
| test shape | (3589, 3) |
| train _X shape | {} |
| train _Y shape | (28709, 48, 48, 1) |
| val _X shape | {} |
| val _Y shape | (3589, 48, 48, 1) |

Above Table II is the analysis of the given dataset. The proposed integrated approach initially divides the values in terms of training and testing data. Along with these values model also validates the dataset.

Table III elaborates the pixel values of the images available in the dataset that is used for training purposes. These pixel values plays important role in the analysis, classification and final prediction of the accuracy.

TABLE III. PIXEL VALUES

| Emotion | Pixel values | Use pixel Values for |
|---|---|---|
| 0 | 0 70 80 82 72 58 58 60 63 54 58 60 48 89 115 121... | Training |
| 1 | 0 151 150 147 155 148 133 111 140 170 174 182 15... | Training |
| 2 | 2 231 212 156 164 174 138 161 173 182 200 106 38... | Training |
| 3 | 4 24 32 36 30 32 23 19 20 30 41 21 22 32 34 21 1... | Training |
| 4 | 6 4 0 0 0 0 0 0 0 0 0 0 0 3 15 23 28 48 50 58 84... | Training |
| 5 | 2 55 55 55 55 55 54 60 68 54 85 151 163 170 179 ... | Training |
| 6 | 4 20 17 19 21 25 38 42 42 46 54 56 62 63 66 82 1... | Training |
| 7 | 3 77 78 79 79 78 75 60 55 47 48 58 73 77 79 57 5... | Training |
| 8 | 3 85 84 90 121 101 102 133 153 153 169 177 189 1... | Training |
| 9 | 2 255 254 255 254 254 179 122 107 95 124 149 150... | Training |

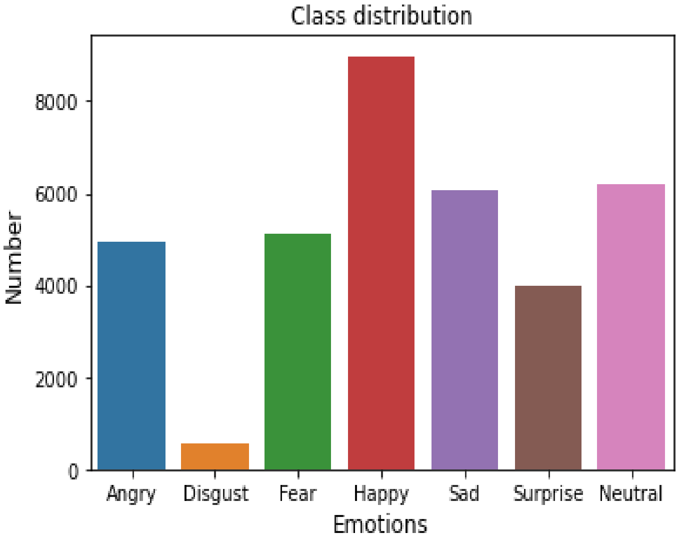

Fig. 3. Distribution of emotions.

Successful categorization of images into different emotions shows there are maximum images under the "happy" category. Fig. 3 shows the distribution of emotions.

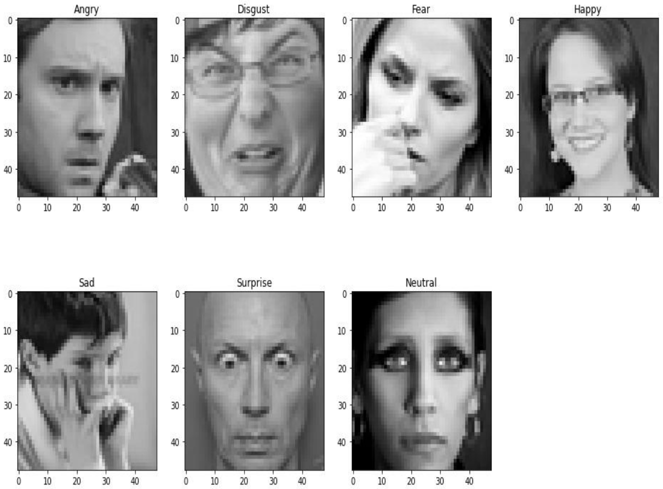

Fig. 4. Analysis of images.

Model based on *testing, training and validated data* labels individual image with its "emotion category" as shown in Fig. 4 and Fig. 5. Results showed integration of the CNN with BiLSTM gave good accuracy. BiLSTM is useful where the analysis of sequences or series of sequences is required. Fig. 5 shows classification of data into training, testing and validating data.

Fig. 6 elaborates on the application of quality parameters like precision, recall and F1-score on different emotion categories. Precision helps in determining the prediction accuracy of the model. In the previous step, model evaluates the given dataset values into training data and testing data. Upon successful classification model validates the remaining data.

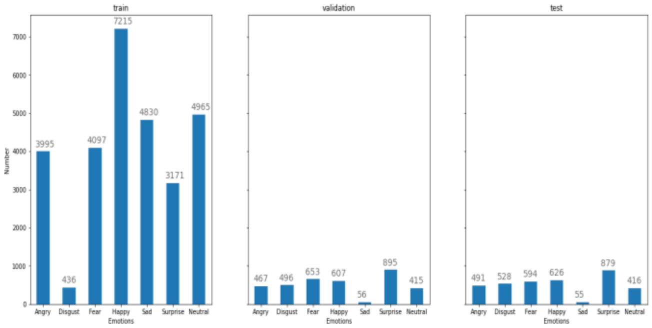

Fig. 5. Train-Test-Validate the dataset.

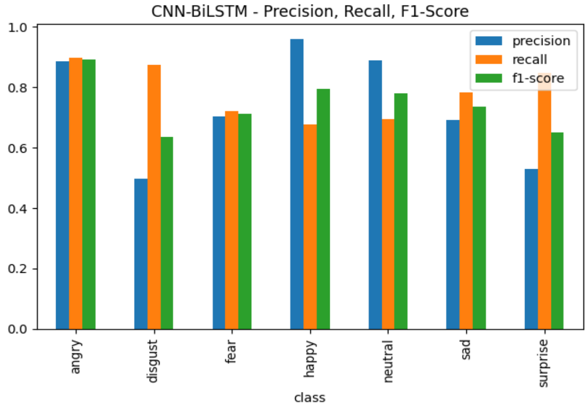

Fig. 6. Applying quality parameters - Precision, Recall and F1-Score.

Recall helps in error minimization and also helps in studying the model with different memory performance for different emotions.

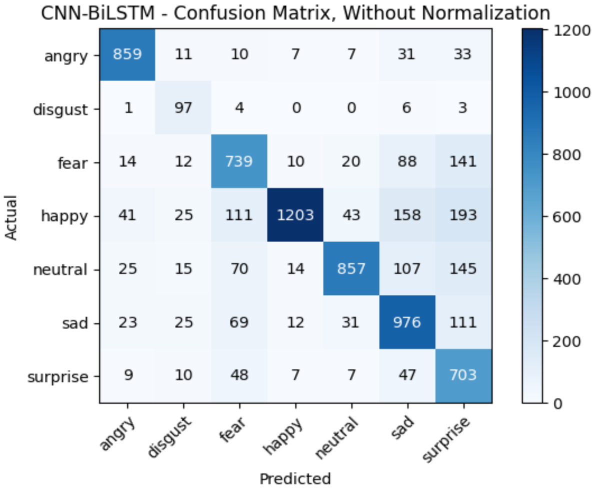

Fig. 7. Confusion Matrix for CNN-BiLSTM without Normalization.

It is good to consider F1-score for the proposed model as it includes both precision and recall. Precision, Recall and F1-score parameters were evaluated on different emotion categories available in the given dataset. Presentation of confusion matrix is shown in Fig. 7 (without normalization) for the proposed CNN-BiLSTM model and Fig. 8 is the confusion matrix for existing HERO approach.

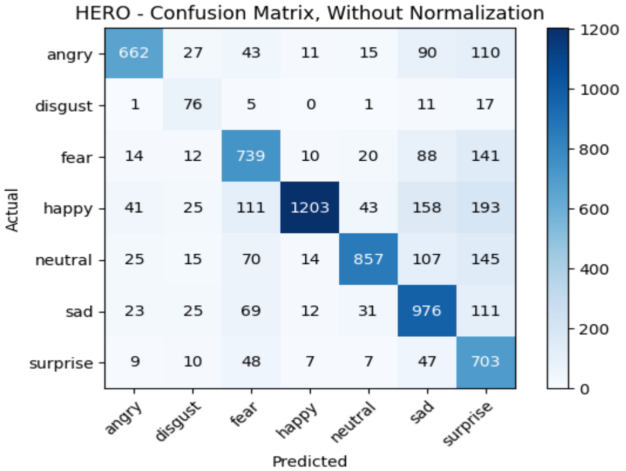

Fig. 8. Confusion Matrix for HERO (existing approach) without Normalization.

## V. Conclusion

The proposed model gives best results using the CNN-BiLSTM approach for facial expression recognition. The proposed model evaluated the performance of both the approaches i.e. CNN, BiLSTM and the existing HERO approach. Results discussed demonstrated that, individual CNN and BiLSTM can give good results with improved accuracy in recognizing the facial expressions. Comparison of the existing and CNN-BiLSTM integrated approach presented with the help of different parameters like F1-score, precision and recall. Evaluating these parameters it is proved that proposed integrated CNN-BiLSTM approach is very effective.

## Acknowledgment

This work is supervised by Dr. A. B. Nandgaokar, Department of Electronics and Telecommunications, Dr. Babasaheb Ambedkar University, Lonere. Author thanks him for the continuous help and guidance provided to complete this research work. The author also thanks the Director of the Institution, the Head of Department and other technical staff of the University for the help and for providing necessary infrastructure.

***Abstract*—The caravan industry in China is facing significant challenges, primarily because the mode of caravan travel is relatively niche within the country and the industry as a whole has had a slow start. This has ultimately resulted in a mismatch between the design aesthetics of caravans and the preferences of Chinese consumers. Based on the foundation of understanding user preferences, this study proposes a new design methodology that integrates the Kano model, the Analytic Hierarchy Process (AHP), and TRIZ theory to align with the preferences of Chinese users. Initially, a Kano model is constructed based on the suggestions from experts and users to categorize user needs. Subsequently, the AHP method is employed to reclassify the key needs identified in the Kano model, establish judgment matrices, and develop a scoring system to provide a scientific basis for design decisions. Finally, TRIZ theory is applied to address potential physical and technical contradictions encountered during the design process, thereby developing practical and aesthetically pleasing caravan design solutions.**

***Keywords*—*Kano model; towed caravans; exterior design; Analytic Hierarchy Process (AHP); TRIZ theory***

## I. Introduction

Today, with the development of globalization, the recreational vehicle (RV) industry has seen widespread proliferation in both developed and developing countries [1]. RV products are primarily categorized into two types: self-propelled RVs and towable caravans, distinguished by their mode of propulsion. Towable caravans are towed behind a vehicle, relying on the towing vehicle for power, while self-propelled RVs possess their own propulsion systems. Nonetheless, the design approach of towable recreational vehicles (RVs) in the Chinese market is characterized by its conservatism, markedly lacking in uniqueness and innovation. This prevalent design philosophy, primarily focused on replicating foreign models, does not effectively accommodate China's unique national conditions and the behavioral patterns of its users. Consequently, there is a paramount need for dedicated research and development efforts aimed at producing indigenous RVs, specifically engineered to fulfill the distinct needs of local consumers [2].This is primarily due to a lack of comprehensive qualitative analysis of consumer preferences during the design process, resulting in a failure to meet consumer needs. In the gathering of Chinese literature, research on the development of RV products primarily revolves around consumer demands, with keywords such as humanization, aesthetics, and innovation featuring prominently in the Chinese literature [3-5]. Therefore, it is necessary to strengthen the design process and prioritize the product characteristics so that the user needs are correctly weighted [6].User characteristic analysis emerges as a pivotal step within the realms of product design and enhancement, facilitating a profound comprehension of user necessities and fostering an augmentation in product contentment. At present, the Kano model, AHP (Analytic Hierarchy Process) analysis method, and TRIZ (Theory of Inventive Problem Solving) theory stand as efficacious instruments for user analysis and the application of engineering technologies, having been substantively implemented across a diversity of domains.

Kano model was proposed by the Japanese scholar Noriaki Kano in 1984 [7], the model is utilized to assess the impact of product or service attributes on customer satisfaction, It categorizes user needs into distinct classifications to better meet customer expectations, encompassing the following five product attributes:(1) Must-be,(2) One-dimensional,(3) Attractive,(4) Indifferent, and (5) Reverse. By constructing specific product quality elements, the quantification analysis of user needs in the product design and development process is addressed. It captures the nonlinear relationship between product performance and customer satisfaction [8]. In their study on ceramic souvenirs, Tama [9] employed a combination of Kansei Engineering for extracting design-related words and the Kano Model for statistical analysis. The study's findings highlighted the significant role of visual characteristics in consumer satisfaction. Jin [10] et al. combined the Kano model with Kansei Engineering to enhance product emotional design, using customer reviews to identify and prioritize key features. Their approach, applied to smartphone design, provides insights for aligning product development with customer emotional needs.

The Analytic Hierarchy Process (AHP) is a multi-level decision-making method established by American operations researcher T.L.Saaty [11].According to their respective objectives, the problem is decomposed into different levels, and factors are weighed at each level to ensure the independence and scientific rigor of the final outcome. The purpose is to assist decision-makers in systematically balancing and making decisions in complex decision environments. They decomposed the elements determining user requirements into levels such as objectives, criteria, and solutions, conducting both qualitative and quantitative analyses to derive high-quality solutions. In product development and design, the Analytic Hierarchy Process (AHP) can assist in precisely selecting the final design factors. These design factors are typically critical elements affecting product performance, cost, quality, and other aspects, playing a decisive role in the overall performance and competitiveness of the product.

Varolgüneş [12] et al. utilized QFD and AHP in their research, focusing on customer-driven design for thermal hotel structures. Their approach, validated through stakeholder participation, effectively translated complex customer requirements into specific design elements. Han [13] et al. used a survey to delineate design elements for medical products in elderly households, applying an AHP model for systematic prioritization. This research enhances medical product design evaluation for elderly usage. Zhang [14] et al. derived cultural genes from Southern Dynasties' stone carvings using memetics. They created a design element genetic map, applied AHP for factor weighting, and analyzed user needs to develop cultural and creative product designs. Liu [15] et al. used AHP to improve medical product design for rhinitis, prioritizing design elements and reducing decision risks. Their approach, combining expert input and indicator ranking, streamlines development for rhinitis medical products.

The Kano Model enables a multi-dimensional assessment of product features, complementing the AHP model, which lacks a clear analysis of the urgency in improving a single evaluation factor. The AHP model determined the relative importance of customers’ demands. It is helpful in improving the design efficiency and enriching the product types [16].However, the results derived from integrating the Kano model with the Analytic Hierarchy Process do not address how to conduct design practices, thus necessitating the introduction of TRIZ theory. TRIZ, a theory of inventive problem-solving, was developed by Altshuler and his team after analyzing 2.5 million patents worldwide. It provides a logical approach to developing creativity for innovation and inventive problem solving [17]. Altshuller identified 39 technical parameters and 40 inventive principles that can be used to eliminate technical contradictions [18]. Any technological conflict can be described by a pair of parameters, and for every such described technological conflict, there exists an innovative solution. The methods for solving these are summarized and distilled into 40 inventive principles, Caligiana [19] et al. integrated QFD and TRIZ theories to develop a design method for direct open moulds. This approach included six-question analysis, assessment matrices, and morphological matrix analysis. The QFD analysis results defined product requirements and architecture, which were then used in TRIZ analysis to complete the design process. Gao[20] et al. applied the TRIZ theory, incorporating techniques like the Conflict Matrix, Substance Field Analysis, Standard Solutions, and Effects, to analyze and redesign infusion systems. Their work illustrates the broad utility of TRIZ theory in medical device development.

In previous literature studies, the Kano model, AHP (Analytic Hierarchy Process) analysis method, and TRIZ theory have been successfully applied by scholars to address a variety of practical problems, demonstrating their substantial utility and efficacy. To date, no literature has employed this integrated approach in the development of towable caravans, hence, this research carries a unique innovative value in its methodological application. In the process of the study, through the Kano model, user requirements are meticulously categorized, and then optimized through the Analytic Hierarchy Process to ensure that the design solutions comprehensively meet the diverse needs of users. In the face of engineering technical contradictions, TRIZ theory is applied for resolution. Three design proposals are developed using computer models and evaluated to determine a final design solution. We collaborated with Chinese RV companies and conducted a six-month exploratory study within the Chinese RV industry, recording real-time data in the engineering development of towed RVs. This data provided a valuable basis for further optimizing the design solutions.

The contributions of this paper are as follows:

A towed caravans evaluation model based on Kano-AHP and TRIZ theories is proposed.

A novel evaluation system for the design field of Chinese towed caravans is provided, integrating methods for addressing engineering technical problems and offering strong support for product development.

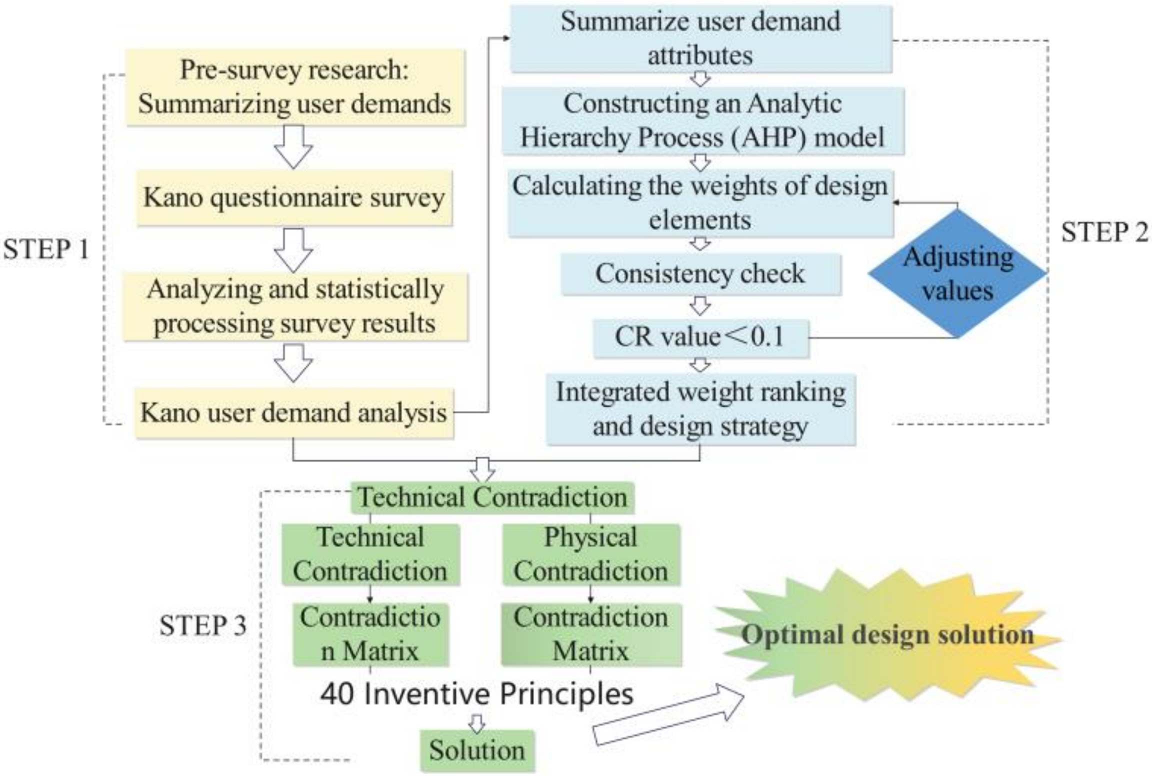
Through computer modeling techniques, three towed caravans design proposals are developed. Based on the actual requirements of RV enterprises, these three designs were evaluated and one design that best meets market demands and production realities was selected.

The structure of the remainder of this paper is as follows: Section
II will provide a detailed description of the preliminary work a nd experimental process of the paper and explain the process of handling and categorizing user requirements through the Kano model. Section III will optimize the comprehensive evaluation of towed recreational vehicles according to the results of the Kano model using the Analytic Hierarchy Process. Section IV will employ TRIZ theory for technical analysis based on the results of the needs and propose the final design solution. Section V will analyze and discuss the final design solution, identifying the optimal solution by comparing the strengths and weaknesses of different proposals and discussing its feasibility in production and market prospects. Section VI will summarize the research content and outcomes of the paper, extracting the innovative points and contributions of the study, and looking forward to future research directions and application prospects, providing a beneficial reference for the sustained development of the Chinese RV market.

## II. User Demand Analysis Based on the Kano Model

### A. Research Process

Thorough discussions and careful analysis by the design team, we defined a research direction focused on serving Chinese users and developing trailer campers. Following this, we established a complete and targeted research framework. The entire experimental design process is illustrated in Fig. 1.



Pre-survey research: Summarizing user demands
Kano questionnaire survey
Analyzing and statistically processing survey results
Kano user demand analysis
STEP 1
Summarize user demand attributes
Constructing an Analytic Hierarchy Process (AHP) model
Calculating the weights of design elements
Consistency check
CR value＜0.1
Integrated weight ranking and design strategy
Adjusting values
STEP 2
Technical Contradiction
Technical Contradiction
Physical Contradiction
Contradictio n Matrix

40 Inventive Principles
Solution
STEP 3
Optimal design solution

Fig. 1. Experimental design flowchart.

## B. *User Demand Segmentation*

More and more working-class people are joining this travelling [21], the focus of user demands should not be on the elite class. Wu [22] et al. found that Chinese RV users are characterized by their deep love of travel, pursuit of freedom, comfort, personalization, and a passion for nature. Under the guidance of seasoned professionals, the design team defined the target audience for towable RVs as middle-aged and older adults aged between 50 and 60 years. This demographic has significant purchasing power and places particular emphasis on the safety and comfort of RVs, as well as the desire to enjoy RV travels with their families. After identifying the target users, it was necessary to further refine their needs. After identifying the target user groups, it is necessary to further refine their needs. Cost-effectiveness and family-centric considerations have become the guiding principles for our questionnaire data collection. The primary concerns of users are centered on the qualifications of towing vehicles and the conditions for driving. Thus, it is advisable to focus research on medium and small-sized trailers. Additionally, our design team conducted thorough discussions with five RV owners, among whom two own towable RVs, to collect insights. These owners shared their principal considerations when purchasing RVs, complemented by the recommendations of a design professor. Based on the basic functions of towable RVs, user needs were categorized into primary needs: functionality, aesthetics, and materials. These primary needs laid the foundation for further work, facilitating the breakdown and refinement into specific secondary needs, which were organized and summarized in Table I.

TABLE I. USER DEMAND SEGMENTATION

| Primary Needs | Secondary Needs |
|---|---|
| Functional Layer | Ventilation<br>Smart Lock<br>Safety Alarm<br>Off-road Capability<br>Space Expansion<br>Sunshade<br>Easy Operation<br>Viewing Space<br>Vehicle Monitoring |
| Aesthetic Layer | Decals<br>Minimalist Design<br>Light-colored Body<br>Streamlined Appearance<br>Biomimetic Form<br>Decorative Lights<br>Rugged Structure<br>Rounded Feel |
| Material Layer | High Load-bearing Chassis<br>Additional Screen Door<br>Lightweight Materials<br>Integrated Windows<br>Eco-friendly Materials<br>Clean Energy<br>Customized Materials |

### C. Questionnaire Design and Analysis

In Tables II and III, the design team conducted a Kano questionnaire survey comprising 85 responses. To ensure the accuracy and reliability of the survey outcomes, we distributed 41 paper questionnaires individually at the Trailer Camping Exhibition. Additionally, we collected 44 questionnaires through an online platform. This combined online and offline approach allowed us to comprehensively cover the target user group and gather diverse data. To evaluate the reliability and effectiveness of the questionnaire, the SPSS 27 software was employed to conduct a reliability test on the online survey [23]. The results indicated a Cronbach’s Alpha coefficient of 0.817 for the online questionnaire, demonstrating a high level of reliability and validity for our questionnaire.

If the appearance design of the trailer has the following characteristics, what is your attitude?

TABLE II. KANO POSITIVE QUESTIONNAIRE ON TRAILER DESIGN

| Characteristics | Like | Must-Be | Neutral | Live-with | Dislike |
|---|---|---|---|---|---|
| Ventilation | 5 | 4 | 3 | 2 | 1 |
| Decals | 5 | 4 | 3 | 2 | 1 |
| Lightweight Materials | 5 | 4 | 3 | 2 | 1 |

If the appearance design of the trailer does not have the following characteristics, what is your attitude?

TABLE III. KANO REVERSE QUESTIONNAIRE ON TRAILER DESIGN

| Characteristics | Like | Must-Be | Neutral | Live-with | Dislike |
|---|---|---|---|---|---|
| Ventilation | 5 | 4 | 3 | 2 | 1 |
| Decals | 5 | 4 | 3 | 2 | 1 |
| Lightweight Materials | 5 | 4 | 3 | 2 | 1 |

### D. User Satisfaction Analysis

After eliminating invalid questionnaires, a significant number of valid questionnaires were successfully recovered. Based on these questionnaires' results, we recorded the frequency of positive and negative outcomes into the Kano result evaluation form, the evaluation table and results were tabulated for each attribute [24], as presented in Table V. The user’s feedback on different requirements is classified, and these requirements are divided into different attribute types accordingly. Attractive (A) means that when the product or service does not provide this function, there is no negative impact on consumer satisfaction; however, when this feature is provided, consumer satisfaction increases significantly. One-dimensional (O) means that when the product or service provides this function, consumer satisfaction will increase ; when this function is not provided, consumer satisfaction will show a downward trend. Indifferent (I) means that no matter whether the product or service provides this function, it has little effect on consumer satisfaction. Must-be (M) means that when the product or service provides this function, it has no effect on user satisfaction; however, when this function is not provided, user satisfaction will show a downward trend. Reverse(R) means that when a product or service provides this function, it will cause user dissatisfaction; when this function is not provided, the user’s satisfaction will be improved, and the quality Q represents the result is questionable. Kano model requirement analysis is presented in Table IV.

TABLE IV. KANO MODEL DEMAND MATRIX

| User Attitude | | Inverse Problem | | | | |
|---|---|---|---|---|---|---|
| | | Like | Must-Be | Neutral | Live-with | Dislike |
| Forward Problem | Like | Q | A | A | A | O |
| | Must-Be | R | I | I | I | M |
| | Neutral | R | I | I | I | M |
| | Live-with | R | I | I | I | M |
| | Dislike | R | I | R | R | Q |

We use the Better-Worse coefficient analysis method to calculate the satisfaction coefficient of each demand. The Better-Worse coefficient analysis method is used to obtain each functional requirement index in t Kano model, and calculate the user's satisfaction and dissatisfaction, see Formula (1) (2).The calculation result of the Better coefficient is 0 ~ 1, and the closer the Better coefficient is to 1, it means that providing this function is sensitive to the user 's satisfaction. The calculation result of the Worse coefficient is -1 ~ 0, and the closer it is to -1, the more sensitive it is to the user 's dissatisfaction [25].According to the results obtained, the Kano model results are analyzed, see Table V, and the quadrant diagram is drawn (see Fig. 2).

$$Better = \frac{A+O}{A+O+M+I} \tag{1}$$

$$Worse = (-1)*\frac{O+M}{A+O+M+I} \tag{2}$$

TABLE V. ANALYSIS OF KANO MODEL RESULTS

| Demand items | M | O | A | I | R | Q | Attribute | Better | Worse |
|---|---|---|---|---|---|---|---|---|---|
| Ventilation | 18 | 46 | 12 | 9 | 0 | 0 | O | 0.682 | -0.753 |
| Off-road Capability | 9 | 41 | 20 | 15 | 0 | 0 | O | 0.718 | -0.588 |
| Easy Operation | 7 | 44 | 16 | 18 | 0 | 0 | O | 0.75 | -0.6 |
| Minimalist Design | 14 | 57 | 8 | 6 | 0 | 0 | O | 0.765 | -0.835 |
| Light-colored Body | 9 | 38 | 16 | 17 | 5 | 0 | O | 0.675 | -0.588 |
| Rugged Structure | 9 | 40 | 7 | 23 | 6 | 0 | O | 0.595 | -0.620 |
| High Load-bearing Chassis | 6 | 48 | 23 | 8 | 0 | 0 | O | 0.835 | -0.635 |

| | | | | | | | | |
|---|---|---|---|---|---|---|---|---|
| Clean Energy | 11 | 39 | 15 | 17 | 3 | 0 | O | 0.659 | -0.61 |
| Safety Alarm | 47 | 13 | 9 | 16 | 0 | 0 | M | 0.259 | -0.706 |
| Biomimetic Form | 36 | 15 | 14 | 19 | 0 | 1 | M | 0.345 | -0.607 |

## III. Build user Demand Hierarchy Analysis Model

Incorporating the experimental outcomes from the Kano model, the inclusion of 'Attractive (A)' demands within the AHP framework contributes significantly to refining the prioritization and comprehensive evaluation processes of identified user needs. Quantifying the expertise of professionals and conducting comprehensive assessments of various indicators from diverse perspectives and levels further facilitates a more thorough and comprehensive understanding of their relative significance.

### *A. Constructing a User Needs Hierarchy Analysis Model*

Filling the comparison matrix involves comparing every element from the set of criteria to itself through a pairwise comparison [26], thereby assisting the decision maker in setting preferences to make the best selection possible [27]. The model is divided into the target layer, criterion layer [13], and Sub-criterion layer. Finally, the user demand hierarchy model is constructed, as shown in Fig. 3.

- Target layer: Design Concept of a Towable Trailer Camper (X).
- Criteria layer: Space Expansion(A),Sunshade(B), Decals(C),Lightweight Materials(D),Vehicle Monitoring(E) and Viewing Space(F).
- Sub-criterion layer: Side retractable expansion compartment for vehicles ($A_1$) , Rear retractable

expansion compartment for vehicles ($A_2$), Roof lift-expandable compartment for vehicles ($A_3$), Hybrid Expansion Module Mode ($A_4$), Portable Assembly ($B_1$), Integrated ($B_2$), Retractable ($B_3$), PVC color decal ($C_1$), Paint spray art ($C_2$), Aluminum plate ($D_1$), Fiber reinforced plastics ($D_2$), Carbon fiber ($D_3$), Covert RV surveillance ($E_1$), Overt RV surveillance ($E_2$), Rooftop Terrace ($F_1$), Indoor Viewing ($F_2$), Viewing Tent ($F_3$).

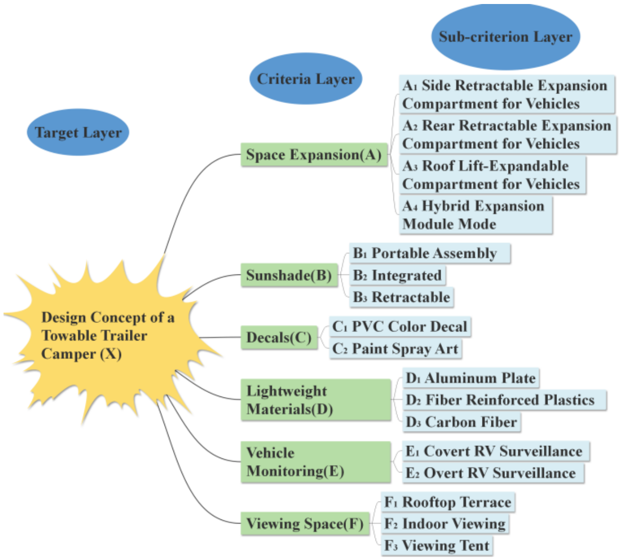

Fig. 3. User needs hierarchy analysis model.

## B. *Calculate the Weights of Design Elements*

In the Analytic Hierarchy Process (AHP), to avoid a singular qualitative outcome, elements are typically compared pairwise to determine the relative importance between them. The judgment matrix reflects the importance of each variable in the hierarchical structure and forms the core component of this method. The judgment matrix was set up with the adoption of the ‘ninth level method’ [28].The definition of the 1-9 ratio scale is outlined in the Table VI.

TABLE VI. SCALE OF JUDGMENT MATRIX IMPORTANCE INDICATORS

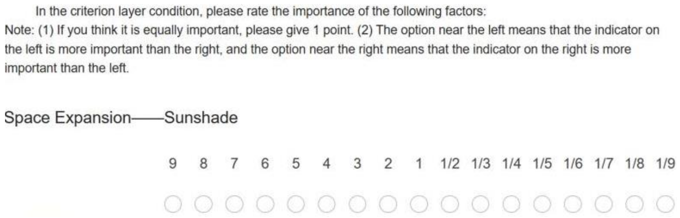
| Scale | Level of importance | Implication |
|---|---|---|
| 1 | Equally important | Indicator a and indicator b are equally important |
| 3 | Slightly important | Indicator a is marginally more important than indicator b |
| 5 | Significantly important | Indicator a is significantly more important than indicator b |
| 7 | Very important | Indicator a is very important compared to indicator b |
| 9 | Absolutely important | Indicator a is more important than indicator b |
| 2,4,6,8 | Inversion comparison | Take the middle part |

To ensure the objectivity and rigor of the evaluation process, this experiment involved 4 RV styling development engineers and 2 product design professors in the decision-making process. Based on the ratio scale in Table VI, this study conducted pairwise comparisons of various parameters to precisely assess their relative importance. Each judgment matrix is presented in an n×n dimension, where n represents the number of parameters. The element bij in the matrix indicates the importance of parameter bi relative to parameter bj, as seen in Formula (3).

The judgment matrix Y is presented in Equation (3):

$$Y = \begin{bmatrix} b_{11} & b_{12} & \dots & b_{1n} \\ b_{21} & b_{22} & \dots & b_{2n} \\ \dots & \dots & \dots & \dots \\ b_{n1} & b_{n2} & \dots & b_{nn} \end{bmatrix} \tag{3}$$

During the decision-making process, six experts were organized to discuss in meetings and fill out questionnaires anonymously. The results of the collected questionnaires were then fed back to the experts for result analysis, and based on the results of the previous round, questionnaires were distributed again. This cycle was repeated until the final consensus of the experts was reached [29-31]. Some of the questionnaires are shown in Fig. 4, and the consolidated matrix is seen in Formula (4).



In the criterion layer condition, please rate the importance of the following factors:

Note: (1) If you think it is equally important, please give 1 point. (2) The option near the left means that the indicator on the left is more important than the right, and the option near the right means that the indicator on the right is more important than the left.

Space Expansion——Sunshade

| 9 | 8 | 7 | 6 | 5 | 4 | 3 | 2 | 1 | 1/2 | 1/3 | 1/4 | 1/5 | 1/6 | 1/7 | 1/8 | 1/9 |
|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|---|
| ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ | ○ |

Fig. 4. Expert questionnaire (part).

The final judgment matrix X is given in the Formula (4):

$$X = \begin{bmatrix} 1 & 2 & \dots & 1/3 \\ 1/2 & 1 & \dots & 1/5 \\ \dots & \dots & \dots & \dots \\ 3 & 5 & \dots & 1 \end{bmatrix} \tag{4}$$

Normalize the judgment matrix according to Formula (5):

$$\overline{b_{ij}} = \frac{b_{ij}}{\sum_{k=1}^{n} b_{ki}}, i, j = 1, 2, \dots, n \tag{5}$$

Calculate the average value of each parameter's normalized row in the judgment matrix according to Formula (6):

$$W_i = \sum_{j=1}^{n} \frac{\overline{b_{ij}}}{n}, i = 1, 2, \dots, n \tag{6}$$

Tables VII display the assessment results for each proposal:

TABLE VII. TARGET-LEVEL JUDGMENT MATRIX AND WEIGHTS

| Target layer | Criteria layer | Weight | Rank | Sub-criterion layer | Weight | Rank |
|---|---|---|---|---|---|---|
| X | A | 0.142 | 3 | $A_1$ | 0.345 | 2 |
| | | | | $A_2$ | 0.062 | 4 |
| | | | | $A_3$ | 0.146 | 3 |
| | | | | $A_4$ | 0.447 | 1 |
| | B | 0.118 | 4 | $B_1$ | 0.110 | 3 |
| | | | | $B_2$ | 0.309 | 2 |
| | | | | $B_3$ | 0.581 | 1 |
| | C | 0.049 | 6 | $C_1$ | 0.750 | 1 |
| | | | | $C_2$ | 0.250 | 2 |
| | D | 0.253 | 2 | $D_1$ | 0.083 | 3 |
| | | | | $D_2$ | 0.724 | 1 |
| | | | | $D_3$ | 0.193 | 2 |
| | E | 0.055 | 5 | $E_1$ | 0.667 | 1 |
| | | | | $E_2$ | 0.333 | 2 |
| | F | 0.383 | 1 | $F_1$ | 0.655 | 1 |
| | | | | $F_2$ | 0.265 | 2 |
| | | | | $F_3$ | 0.080 | 3 |

### *C. Consistency Check*

In order to ensure consistency in evaluators' relative judgment logic throughout the evaluation process, it's necessary to conduct a consistency check on the judgment matrix. Calculate the consistency ratio based on the order of 'n' in the judgment matrix. In the consistency check, λ max is used as a significant validation parameter for the consistency ratio. Saaty validated that for a positive reciprocal matrix, λ max is always greater than or equal to 'n'.If the CR < 0.10, the matrix is considered consistent, and the derived weights are then reliable for supporting decision-making [6].If the CR value exceeds 0.1, it requires experts to recompare various parameters in the judgment matrix until the CR value falls within an acceptable range. Generally, a smaller CR value indicates better consistency in the judgment matrix.

The calculation process is as follows:

$$\lambda_{\max} = \sum_{i=1}^{n} \frac{(AW)i}{nWi} \tag{7}$$

λ max represents the maximum eigenvalue, and 'n' stands for the order of the judgment matrix.

$$CI = \frac{\lambda_{\max} - n}{n - 1} \tag{8}$$

CI represents the Consistency Index of the judgment matrix.

$$CR = \frac{CI}{RI} \tag{9}$$

RI represents the Random Index for Average Random Consistency, and CR stands for Consistency Ratio. The values for the Average Random Consistency Index are provided in Table VIII.

The calculated CR values from Table VII were subjected to a consistency check, indicating that all the judging matrices passed the consistency check and that the sum of the weights satisfying the condition should be equal to one [32].The experimental results are feasible, as shown in Table IX.

### *D. Comprehensive Weight Ranking*

Based on the weight values from Table VII, the determination of the sub-criteria layer's respective indicator weights towards the combined weight vector of the target layer is established, as detailed in Table X. Within the criteria layer, the ranking of weight values is as follows: F > D > A＞B＞E＞C. Based on the prioritization of weights, the design of innovative scenic viewing spaces requires special attention. Next, the inclusion of multifunctional vehicle monitoring devices should be considered. At the same time, the creation of visual appeal and first impressions should not be overlooked, as people often focus their attention on objects they encounter for the first time. The vehicle's decal decorations and the style of the model also impact consumers' purchasing decisions, thus their roles need to be considered in the design process. At the level of sub-criteria, the ranking of comprehensive weight values is as follows: $F_1$＞$D_2$＞$F_2$＞$B_3$＞$A_4$＞$A_1$＞$D_3$＞$C_1$＞$E_1$＞$B_2$＞$F_3$＞$D_1$＞$A_3$＞$E_2$＞$B_1$＞$C_2$＞$A_2$, Experimental results indicate that in the Chinese consumer market, sensitivity and awareness of unique design elements, such as rooftop terraces, are relatively high.

TABLE VIII. AVERAGE RANDOM CONSISTENCY INDEX

| Matrix rank | 1 | 2 | 3 | 4 | 5 | 6 | 7 | 8 | 9 | 10 |
|---|---|---|---|---|---|---|---|---|---|---|
| RI | 0 | 0 | 0.52 | 0.89 | 1.12 | 1.26 | 1.36 | 1.41 | 1.46 | 1.49 |

TABLE IX. CONSISTENCY TEST RESULTS

| F | X | A | B | C | D | E | F |
|---|---|---|---|---|---|---|---|
| λ max | 6.475 | 4.124 | 3.004 | 2 | 3.066 | 2 | 3.033 |
| CI | 0.095 | 0.041 | 0.002 | 0 | 0.033 | 0 | 0.016 |
| RI | 1.260 | 0.890 | 0.520 | 0 | 0.520 | 0 | 0.520 |

## IV. Application of Exterior Design in Towed Caravans

Before conducting the TRIZ theoretical analysis, we conducted an in-depth examination of the legal restrictions stipulated in the "Road Traffic Safety Law of the People's Republic of China" regarding towable caravan, to gain a comprehensive understanding of the operational rules and limitations for such vehicles within the legal framework of our country. Based on the "Better-Worse" ranking of the Kano model and the weight ranking of the Analytic Hierarchy Process (AHP), caravan development engineers have identified the main contradictions faced in practical applications. By analyzing the types of contradictions according to TRIZ theory and consulting the corresponding contradiction matrix for recommended inventive principles, the conflict analysis and resolution principles are presented in the Table XI-XII.

TABLE XI. Physical Contradiction

| Conflict Number | Conflict | Type of Contradiction | Separation Mode | Inventive Principle |
|---|---|---|---|---|
| 01 | Clean Energy (solar panels)-Rooftop Terrace | Physical Contradiction | Space | 1，2，3，4，7，13，17，24，26，30 |

Clean energy is supplied through solar energy storage to reduce energy consumption and achieve sustainability and environmental protection. However, the presence of solar energy storage systems limits the available area of the rooftop leisure area. To address the physical contradiction between clean energy (solar panels) and rooftop terraces, the principle of spatial separation is applied to resolve the conflict between solar panels and rooftop terraces in physical space. This conflict arises from two different properties exhibited by the same material under the same conditions. Methods such as segmentation (Principle 1) and multi-dimensional operation (Principle 17) are used for problem-solving. Specifically, the rooftop is divided into two independent areas: one area for solar energy storage and another area as a rest area for users. Through this division, an innovative application of rooftop space is achieved.

TABLE XII. Technical Contradiction

| Conflict Number | Conflict | Type of Contradiction | Improved Parameters | Deteriorating Parameter | Inventive Principle |
|---|---|---|---|---|---|
| 01 | Lightweight Materials-Side retractable expansion compartmet for vehicles | Technical Contradiction | No.7 Volume of moving object | No.1 Weight of moving object | 2,26, 29,40 |
| 02 | Easy Operation-Retractable |  | NO.35 Adaptability | NO.33 Weight of moving object | 15,34, 1,16 |
| 03 | Easy Operation-Overt RV surveillance |  |  |  |  |

To address the technical contradiction between lightweight materials and the vehicle's side expansion chamber, the extraction principle (Principle 2) and the composite material principle (Principle 40) are primarily employed for resolution. The use of retractable vehicle side expansion compartments effectively increases the usability of space while also enhancing user experience. The expansion chamber is made of aluminum alloy to increase its stability. For the common technical contradiction between simplicity of operation and intelligent retractable awnings, overt RV surveillance, the principles of elimination and recovery (Principle 34) and the dynamic principle (Principle 15) are mainly used for resolution. Discarding the superfluous functions and parts simplifies operations under a variety of functionalities, dividing user operations into one-button start and mobile phone operations, categorizing the use functions accordingly.

## V. Results and Discussion

### *A. Design Outcomes of Styling*

The design team analyzed the results of the evaluation of various indicators. In terms of space expansion, expanding from the sides was found to be more in line with user needs and corporate development objectives. It is necessary to consider the strength, durability, and load-bearing capacity of materials. Using fiberglass for the outer shell enhances robustness. For the expansion cabin, an internal framework made of aluminum alloy is employed to reinforce, improving the trailer's stability and durability, thus ensuring the safety of users. A simple and easy-to-deploy square awning tent is used for the sunshade, operated in a roll-up fashion for user convenience. Camping sites are generally chosen in the wild, so the design of vehicle monitoring must ensure no blind spots in the field of view, considering the synchronous viewing of sound and image to help users directly obtain external information and ensure their safety. The development of the rooftop terrace received the highest weight value in the AHP evaluation, with the vehicle's top development based on the segmentation principle of TRIZ theory. Similarly, the rooftop needs to have load-bearing capacity to withstand impacts and knocks. In the course of in-depth communication with enterprises, it was understood that Chinese users have a relatively conservative preference for the appearance of trailers. Therefore, we will take the style of trailers popular in the Chinese market as a reference for research and innovative design. Additionally, Chinese laws have strict management requirements for the modification of trailer vehicle models, considering the safety of pedestrians and drivers. In terms of material selection, we must adhere to international standards to ensure product compliance and avoid potential risks associated with vehicle launch. For example, in the choice of vehicle lights, we referred to the lamp models provided by suppliers to RV enterprises, and the design of the lamp assembly layout was based on China's traffic management legislation. Although aesthetics is an element of interesting value that provides value to the product [33], it is necessary to consider that large-scale car body decals would incur high costs. In the decal design, we fully considered the three elements of fashion, beauty, and simplicity, and determined the final decal style.

The first design proposal was the original plan developed by the team, see Fig. 5. Simultaneously, based on the preliminary concept, the overall dimensions of the vehicle were annotated, and a layout design of the interior space was drawn up based on these dimensions. This serves as an important reference for our exterior design, as seen in Fig. 6. Anti-roll frames were equipped on both sides to prevent the danger of users rolling off while resting (see Fig. 7).

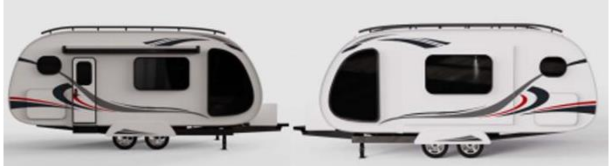

Fig. 5. The first design scheme.

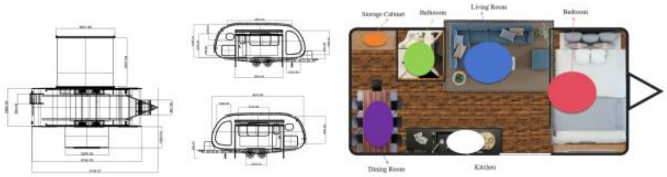

Fig. 6. Internal structure and dimensioning diagram.

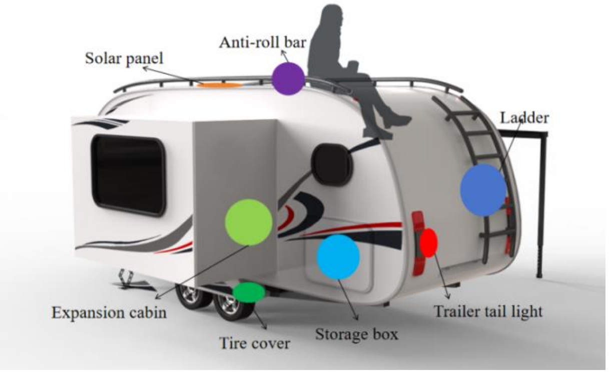

Fig. 7. The first design scheme function display diagram.

The second design proposal (see Fig. 8 and 9). The roof adopts a folding structure, utilizing the principle of segmentation. The position of the solar panels can be leaned against after the top of the towable caravans is folded. This design has a smaller area of solar panels, prioritizing services for user leisure. Based on the first proposal, slight adjustments were made to the exterior design; the body's curvature was reduced to expand the area of the windows, facilitating users in enjoying the scenery, surveillance cameras with no dead spots can play a deterrent role.

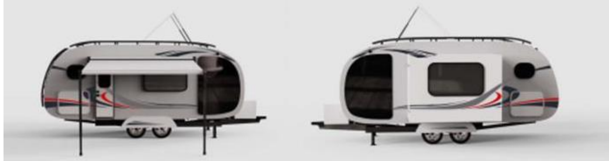

Fig. 8. The second scheme design.

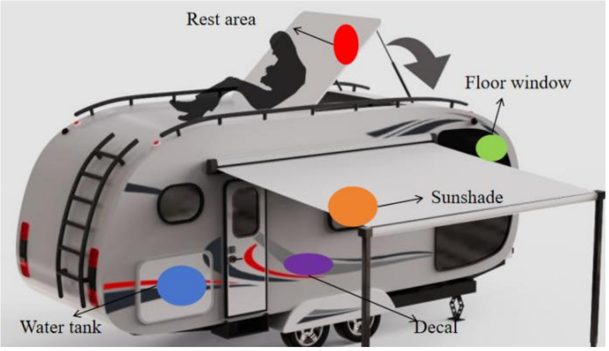

Fig. 9. The Second design scheme function display diagram.

The third design proposal (see Fig. 10), places the solar panels on an elevatable roof, dividing the roof space into two parts. When the ceiling is raised, it can be used as a terrace, providing users with more activity space. As seen in Fig. 11, the solar panels can continue to absorb energy.

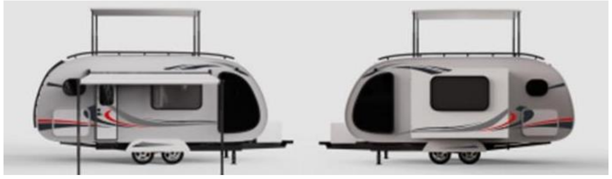

Fig. 10. The third scheme design.

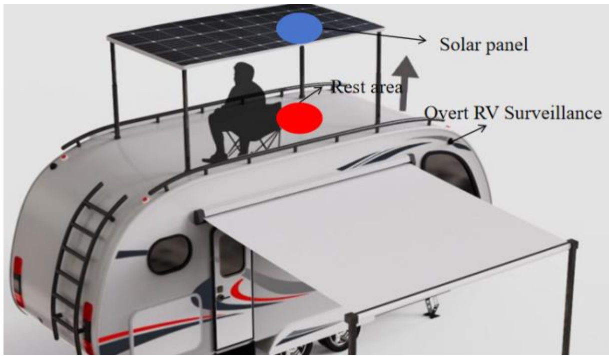

Fig. 11. The Third design scheme function display diagram.

## B. *Discussion of Practical Development Issues*

During the finalization phase of the design proposals, an in-depth discussion was conducted within the group. The first design proposal had clear shortcomings in terms of user experience, with its activity space being limited to half, obviously failing to meet the practical needs of actual users. This proposal also lacked innovation, making it difficult to stand out in the market, and was considered as a basis for subsequent improvements. Although the folding structure and floor-to-ceiling window design of the second proposal were creative, offering more space for user activities compared to the first proposal, the space for the rooftop solar panels was too small to be practically operational. The third proposal, with its elevatable terrace design, provided users with a much broader activity space, enhancing the user experience. The simple terrace design effectively resolved the issue of potential decreases in user willingness to use due to high appearance costs. Considering its practicality, innovation, and cost-effectiveness, the third proposal holds significant market potential and user appeal, warranting further investment in the production phase.

To ensure driving safety, the manufacturing process of the towable caravans needs to rigorously integrate multiple intelligent systems, including real-time display of braking status, driving balance control, tire pressure monitoring, reversing image, intelligent alarm, and smart lock systems. The integration of these systems aims to provide users with real-time information and services, necessitating the development of a dedicated mobile interaction system for intelligent management and control. However, it is noteworthy that the actual production process of the towable caravans is exceedingly complex, involving numerous technical details and process requirements. Therefore, decisions made in the preliminary phase will directly impact the smooth progression of the subsequent production process and the quality and performance of the final product.

## VI. Conclusions

This study, based on the capture of user data, optimizes the Analytic Hierarchy Process (AHP) through the Kano model, scientifically calculates the weight values of each element, and thus makes an accurate assessment of the importance of each element. This not only provides solid theoretical support for the design of towable caravans but also ensures the high specificity and practicality of the design scheme. During the research process, we actively cooperated with caravan companies, fully drawing on their rich market experience, conducted in-depth analyses of contradictions that arose during the design process with the aid of TRIZ theory, and proposed viable solutions. On this basis, three trailer caravan schemes were designed, and through thorough discussion by team members, a design scheme that fits the principles of practical development was selected.

However, there are some shortcomings in this study. First, the development cycle of towable caravans is long and involves many factors. Although a towable caravan shape that meets the needs of Chinese consumers has been designed, it still needs to be continuously adjusted and optimized according to actual production situations. Second, the finalization of the scheme is still limited by the decision-making of the R&D team and does not fully consider the preference differences of consumers towards the design scheme. Lastly, the caravan industry in China started later, and the trailer caravan market is relatively niche. Enterprises are relatively conservative in innovation, which also limits our bold attempts in scheme design.

In the future, we will continue to focus on the development process of towable caravans in China, recording and solving problems encountered during development. At the same time, we plan to further apply this theoretical framework to explore the interior design of trailer caravans, with the aim of meeting user needs while enhancing the economic benefits of enterprises. By continuously optimizing design schemes and exploring new design ideas, we will vigorously promote the sustained and healthy development of China's caravan industry.

***Abstract*—Human resource management (HRM) plays a crucial role in the effective functioning of modern businesses. However, as the volume of data continues to increase, HR professionals are facing growing challenges in objectively gathering, measuring, and interpreting human resources data. The research problem addressed in this study is the need to improve methods for the objective classification of teams based on the most relevant performance factors considering the subjectivity of current tools. To tackle this issue, the research questions focus on the possibility of developing an efficient model for team classification using supervised machine learning algorithms. This study consists of developing and validating three team classification models using the support vector machine (SVM), the K-nearest neighbor (KNN) algorithm, and the multiple linear regression algorithm (MLR) after using PCA for data reduction. Following extensive validation, the module based on MLR was identified as the most effective, achieving an accuracy of 87.5% in Predicting employee performance, which makes it possible to anticipate and fill employee skills gaps and optimize recruiting efforts. This work provides human resources professionals with a data-driven decision support to enhance Human Resources Management using Machine Learning.**

***Keywords*—HRM; HR analytics; Employee Performance Prediction; Support Vector Machine (SVM) Algorithm; K-Nearest Neighbor (KNN) Algorithm; Multiple Linear Regression (MLR) algorithm; Principal Component Analysis (PCA)***

## I. Introduction

Human resources management (HRM) is considered one of the most strategic functions of a company as it plays a vital role in boosting productivity and competitiveness. People are at the center of overall performance improvement, and companies must use the heterogeneity of their resources to create a competitive advantage. The development of skills such as Valuable, Rare, Inimitable and Non-substitutable (VRIN) is crucial for companies to align their resources with the overall business strategy [1].

With the era of digital transformation, managing team performance has become a complex and complicated task. Traditional IT tools are unable to collect and analyze the mass of data available through several new sources. However, companies that invest in big data software to understand and improve the performance of employees are likely to achieve organizational goals gain a competitive edge [2], including competitive advantages, identifying talents, and retaining high performers, better understanding of low performers, simulating the performance of candidates during recruitments, playing a strategic role in the structure of teams, and prioritizing HR investments to achieve greater work performance.

The deployment of HR analytics in HRM is no longer an option, and companies that ignore the revolution of digital technology risk being left behind. By deploying machine learning algorithms, companies can avoid significant costs if these mines of information are not exploited, namely, the costs associated with replacing employees especially when key skills are lost, the cost of hiring new staff, and the cost of training for replacements are important [3].

However, despite long-standing efforts to objectively assess performance to demonstrate factors that impact the performance of employees and quantify its impact on business outcomes, namely the effectiveness of training [4], but to this day, none of this work has been able to identify more than two factors and subsequently predict the performance results of a team using machine learning algorithms, identifying the specific factors that predict team performance remains a challenge.

To fill this gap, considering this context which makes increased competition, this study aims to respond to the need to improve performance management using machine learning algorithms, the results make possible the prediction of the performance of employees. the study consists of developing methods to objectively classify teams according to the most relevant performance factors, unlike the subjectivity of evaluation based primarily on interviews. three team classification models are developed and validated using support vector machine (SVM), K-nearest neighbor (KNN), and multiple linear regression (MLR) algorithm after using the principal component analysis (PCA) for the reduction of a dataset published by HRM professors at the New England College of Business, including 36 variables linked to 311 employees used to train and test the models. After evaluating the results, the MLR-based model appears to be the most effective, with an accuracy of 87.5% in predicting employee performance, making it possible to anticipate skills gaps and optimize recruitment efforts. This research provides a data-driven decision support tool to improve human resource management through machine learning.

In this paper, a structured approach to present our research is used. Firstly, in Section II, the relevant literature will be reviewed. Then, in Section III, the proposed approach and the dataset will be defined, and the steps involved in constructing the model will be outlined. The results obtained from the approach will also be presented. Next, in Section IV, the results obtained from the models will be evaluated. Finally, in Section V, the paper will be concluded.

## II. Related Work

The review of the relevant literature is structured as follows: firstly, the evolution of human resource management and its technologies, with a particular focus on HR analysis, is examined. Next, the Performance appraisal process and its factors are delved into. Finally, the existing works that have employed machine learning algorithms in evaluating employee performances are explored.

### A. Human Resource Management and HR Analytics

As per the literature, human resources management is a collection of practices that are employed to administer, mobilize, and develop human resources involved in the organization's activities to align them with the overall business strategy. In today's modern organizations, human resources have become the key to success, making the practices of human resources management crucial for the company's overall performance, especially in an era characterized by intense competition, globalization, and internationalization of markets.

The explosive growth of data in various fields of industry has made gathering, measuring, and interpreting HR data a complex and challenging task. As a result, new advanced practices and technologies have emerged, leading to the rise of human resources analytics (also known as people analytics) as a separate sub-field of business analytics [5].

According to the literature, HR analytics is defined as the collection and application of talent data to improve critical talent and business outcomes. HR analytics leaders enable HR leaders to develop data-driven insights that inform talent decisions, improve workforce processes, and promote a positive employee experience [6].

According to the information provided, Gardner's model, depicted in Fig. 1, highlights various aspects of HR Analytics, which include:

- Descriptive analytics: This dimension involves examining HR data to answer the question of "What happened?
- Diagnostic analytics: Diagnostics reveal the underlying causes of the events presented by descriptive data and answer the question of "Why did it happen?"
- Predictive analytics: The most important dimension of HR Analytics, which focuses on what might happen in the future based on the details of past events using statistical modeling (Machine learning).
- Prescriptive analytics: This dimension suggests data-driven options or actions to take based on the predictions. Unlike classic human decisions that are often subject to the process of gut feeling and illogical biases, it guides what to do in a particular situation based on given HR data.

As HR analytics emerged as a new trend, it has garnered significant attention and budget allocation. Numerous studies have been conducted to investigate its role, potential opportunities, and challenges associated with its implementation. [7], [8], [9], [10].

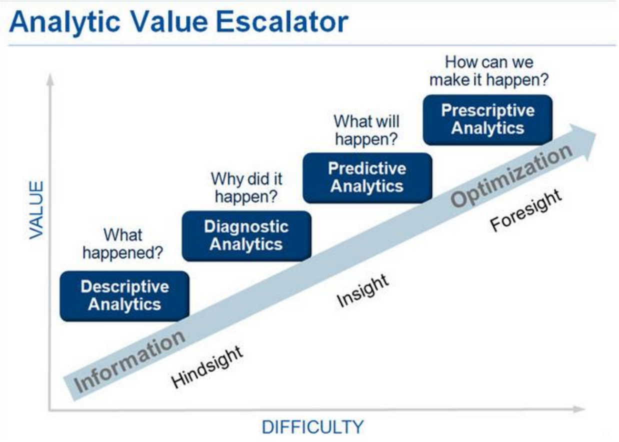

Fig. 1. Analytic value escalator (gardner's model).

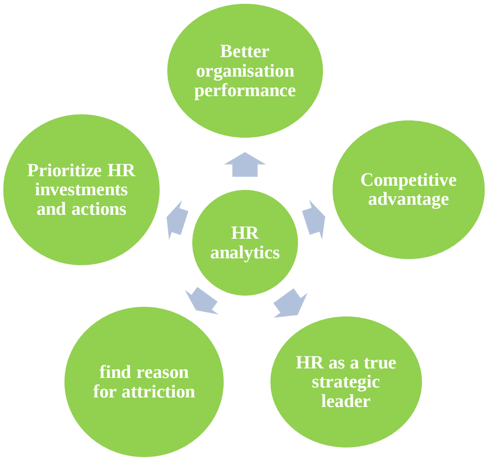
Regarding potential opportunities, HR analytics can offer valuable insights into various issues such as attrition, strategic decisions related to performance management, and investments in training programs, as depicted in Fig. 2.



Better organisation performance
Competitive advantage
HR as a true strategic leader
find reason for attrition
Prioritize HR investments and actions
HR analytics

Fig. 2. Opportunities of HR analytics.

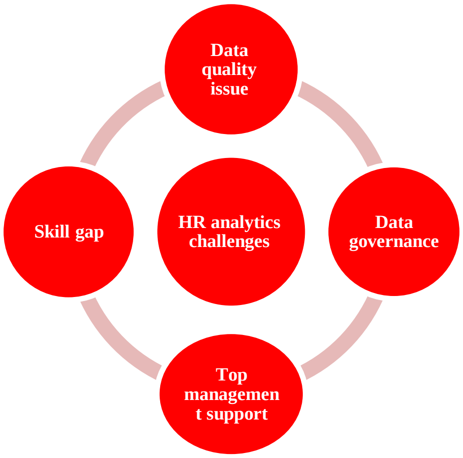


Fig. 3. Challenges of using HR analytics.

Despite the increasing attention that HR analytics has received, it is still in its early stages, and only a limited number of models have been developed so far, as noted in study [11]. Many studies have attempted to identify the challenges that organizations face when implementing HR analytics, as illustrated in Fig. 3.

### B. Performance Management

After conducting a literature review, it was found that performance is a complex and multifaceted concept that is difficult to define, as noted in study [12]. However, in an industrial organizational context, performance is typically associated with excellence and is defined as an official report that records a result achieved at a specific moment in time, in a particular setting, based on objectives and expected outcomes measured using various indicators. This definition is closely tied to the company's vision, strategy, and objectives, as highlighted in study in [13] and [14]. It is therefore essential to develop an instrument for assessing job performance, as performance appraisal and management of employees and teams can be subject to perception and subjectivity if not based on data.

As such, performance management is a continuous process that aims to make informed decisions to achieve optimal outcomes by identifying and addressing problems and utilizing appropriate tools for measurement, as depicted in Fig. 4, and noted in study [15].

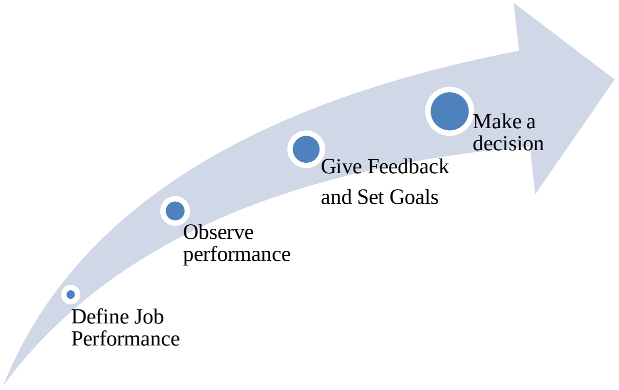

Fig. 4. Performance appraisal process.

### C. Performance Assessment

Numerous research studies have investigated the factors that influence job performance. Training is one such factor, and the study conducted by Joshua S. Bendickson and Timothy D. Chandler in 2019 [16] served as the inspiration for our own research. Additionally, other studies have explored the impact of factors such as workforce diversity [17], leadership style [18], determinants of employee engagement [19], the role of employee satisfaction as a mediator of compensation and career development [20], and the effect of organizational communication and culture [21] on job performance.

Despite extensive research, the exact factors that influence job performance have not been pinpointed. In 2013, a study called "The Analytics Era" examined more than 200 indicators and concluded that the most appropriate indicators vary depending on the company and activity. Therefore, HR must prioritize aligning HR analytics with the business priorities of the company to select the appropriate indicators.

Several studies have proposed models based on machine learning algorithms that predict employee performance based on HR data. For example, Iwamoto et al. [22] proposed a model based on multiple regression that evaluates individual performance based on the financial outcomes of employees that influence the performance of the organization. This represents a significant step towards an objective assessment of individual performance. Later, Abdullah et al. [23] established a model that assesses individual performance against knowledge and skills through a case study in Malaysia, wherein the analytical hierarchy process is used to integrate the multifaceted preferences of the five criteria of human capital to determine the importance of the four identified indicators.

Furthermore, Chen and Chen [24] and QA Al-Radaideh, E Al Nagi [25], applied a data mining algorithm based on decision trees and association rules to employee characteristics and performance. In a recent study by JM Kirimi and CA Moturi [26], data mining classification was used to predict employee performance. They compared the results of three different machine learning algorithms, namely ID3, C4.5, and Naïve Bayes. This study found that the C4.5 algorithm had the highest accuracy due to several factors that had a significant impact on employee performance. For instance, the experience attribute had the maximum gain ratio. This study serves as a starting point for the research.

## III. Methodology

### A. Research Design

Comparing several processes for executing machine learning projects, such as KDD, Scrum, Kanban, SEMMA, or TDSP, the Cross Industry Standard Process for Data Mining (CRISP-DM) model has been chosen. This model is the most widely used industry-independent form of data mining since 2017, owing to its various advantages that have resolved existing problems. The CRISP-DM methodology provides a uniform framework for guidelines, planning, and managing a project [27].

The CRISP-DM model is a six-phase process model that encompasses the entire data mining project, from business understanding to deployment, as depicted in Fig. 5. The six phases are as follows:

- Business Understanding: This phase involves identifying the problem, defining the project objectives, and determining the data mining goals. It also includes assessing the resources required for the project.
- Data Understanding: This phase involves collecting and exploring the data to understand its characteristics, quality, and relationships. This provides a foundation for the subsequent phases.
- Data Preparation: This phase involves cleaning, transforming, and integrating the data to prepare it for

modeling. It also includes selecting the appropriate data to use for modeling.

- Modeling: This phase involves selecting and applying appropriate modeling techniques to the prepared data. It includes creating and evaluating multiple models to determine the optimal model for the project.
- Evaluation: This phase involves assessing the performance of the model and determining its effectiveness. It also includes determining if the model meets the project objectives.
- Deployment: This phase involves deploying the model in the production environment and monitoring its performance. It also includes preparing documentation and training materials for stakeholders.

By following the CRISP-DM model, it can be ensured that the machine learning [28] project is well-structured, well-documented, and well-executed, resulting in high-quality and actionable insights.

### B. Dataset Description

Considering the factors that affect job performance, as identified in the literature review, a database published by HRM professors at New England College of Business has been selected. This database comprises 311 employee profiles and includes 36 variables that offer insights into employee performance. Utilizing this database, a comprehensive analysis of the factors that impact employee performance can be conducted, enabling informed decisions based on the results. This will facilitate gaining a deeper understanding of the factors influencing job performance and developing effective strategies to enhance employee performance.

The variables in the database cover various aspects such as income, engagement, satisfaction, projects, number of days an employee was late in the last 30 days, absences, and other HR-related data. The complete list of variables is summarized in Table I.

TABLE I. DESCRIPTION OF THE VARIABLES

| **Dataset** | **Variables** | |
|---|---|---|
| | ***Description*** | ***Data type*** |
| Employee Name | Employee’s full name | Text |
| EmpID | Employee ID is unique to each employee | Text |
| MarriedID | Is the person married (1 or 0 for yes or no) | Binary |
| MaritalStatusID | Marital status code that matches the text field MaritalDesc | Integer |
| EmpStatusID | Employment status code that matches text field EmploymentStatus | Integer |
| DeptID | Department ID code that matches the department the employee works in | Integer |
| PerfScoreID | Performance Score code that matches the employee’s most recent performance score | Integer |
| FromDiversityJobFairID | Was the employee sourced from the Diversity job fair? 1 or 0 for yes or no | Binary |
| PayRate | The person’s hourly pay rate. All salaries are converted to hourly pay rate | Float |
| Termd | Has this employee been terminated - 1 or 0 | Binary |
| PositionID | An integer indicating the person’s position | Integer |
| Position | The text name/title of the position the person has | Text |
| State | The state that the person lives in | Text |
| Zip | The zip code for the employee | Text |
| DOB | Date of Birth for the employee | Date |
| Sex | Sex - M or F | Text |
| MaritalDesc | The marital status of the person (divorced, single, widowed, separated, etc) | Text |
| CitizenDesc | Label for whether the person is a Citizen or Eligible NonCitizen | Text |
| HispanicLatino | Yes or No field for whether the employee is Hispanic/Latino | Text |
| RaceDesc | Description/text of the race the person identifies with | Text |
| DateofHire | Date the person was hired | Date |
| DateofTermination | Date the person was terminated, only populated if, in fact, Termd = 1 | Date |
| TermReason | A text reason / description for why the person was terminated | Text |
| EmploymentStatus | A description/category of the person’s employment status. Anyone currently working full time = Active | Text |
| Department | Name of the department that the person works in | Text |
| ManagerName | The name of the person’s immediate manager | Text |
| ManagerID | A unique identifier for each manager. | Integer |
| RecruitmentSource | The name of the recruitment source where the employee was recruited from | Text |
| PerformanceScore | Performance Score text/category (Fully Meets, Partially Meets, PIP, Exceeds) | Text |
| EngagementSurvey | Results from the last engagement survey, managed by our external partner | Float |
| EmpSatisfaction | A basic satisfaction score between 1 and 5, as reported on a recent employee satisfaction survey | Integer |
| SpecialProjectsCount | The number of special projects that the employee worked on during the last 6 months | Integer |
| LastPerformanceReviewDate | The most recent date of the person’s last performance review. | Date |
| DaysLateLast30 | The number of times that the employee was late to work during the last 30 days | Integer |

According to the literature review, nine significant variables were identified for building the model: "MarriedID," "GenderID," "Salary," "EngagementSurvey," "EmpSatisfaction," "SpecialProjectsCount," "DaysLateLast30," and "Absences" as dependent variables, and "PerfScoreID" as the independent variable. The data was then split into two datasets, with 248 records used for training the model and 63 records for testing and validating it. By focusing on the most significant variables, a model that accurately predicts employee performance can be developed. Data processing and model building were conducted using the R software, with the HR dataset transformed into a data frame consisting of 311 rows and 36 columns. Data cleaning and checking for missing values were performed to ensure accuracy and completeness, improving the reliability of the model's predictions. With the cleaned data, the model was built using R software, leveraging its powerful data analysis, and modeling capabilities to develop an accurate prediction model for employee performance.

### *C. Model Building*

*1) Steps of model construction:* To predict employee performance based on their profile, the steps outlined in Fig. 6 were followed. Firstly, the most relevant factors impacting employee performance were identified based on the literature review. Next, the database was prepared by cleaning the data and checking for missing values. To improve result visualization, the data was compressed using PCA, which can synthesize a large dataset compared to other compression techniques, aiding in better data visualization and model accuracy. Three models using the SVM, MLR, and KNN algorithms were established to predict employee performance, each trained using the compressed training set. Finally, the results of each model on the test set were evaluated to determine the most efficient model. By following these steps, an accurate and reliable model for predicting employee performance based on their profile can be developed, facilitating informed decisions and effective strategies to enhance employee performance and achieve organizational goals.

*2) Data compression using Principal component analysis:* PCA is a dimensionality reduction algorithm that involves transforming interrelated variables, also known as "correlated" variables in statistics, into new variables that are decorrelated from each other. These new variables are known as "principal components" or "principal axes" [29].

By utilizing PCA, the number of variables in the dataset can be reduced and the visualization of the data improved. This is particularly useful when dealing with large datasets that are difficult to visualize or analyze. The principal components generated by PCA can be used to represent the data in a lower-dimensional space, making it easier to analyze and interpret.

Overall, PCA is a powerful technique that can be used to improve the accuracy and efficiency of machine learning models by reducing the number of variables and improving the visualization of the data. By incorporating PCA into the model, A more accurate and reliable model can be developed to effectively predict employee performance based on their profile.

To apply the Principal Component Analysis (PCA) algorithm to the training set, the "FactoMineR" package in R software was utilized. By analyzing the distribution of variables in each factor generated by PCA, factor 1 was interpreted as the "behavior factor," which accounts for 41.42% of the variance, and factor 2 was interpreted as the "achievement factor," which accounts for 35.97% of the variance, as summarized in Table II and Fig. 7.

The behavior factor, factor 1, is the most significant in terms of variance and includes variables that assess days of late and engagement. The achievement factor, factor 2, comprises variables that assess salary and special projects done for the society. Factors with an absolute value greater than 0.40 were considered significant and retained, while those with an absolute value less than 0.40 were deleted for the clarity of the table.

TABLE II. COORDINATES FOR THE VARIABLES

| **Variables** | **Factors** | | | |
|---|---|---|---|---|
| | ***Factor 1*** | ***Factor 2*** | ***Factor 3*** | ***Factor 4*** |
| Salary | 0.57 | 0.65 | 0.47 | |
| EngagementSurvey | 0.69 | -0.55 | | 0.44 |
| SpecialProjectsCount | 0.57 | 0.66 | -0.46 | |
| DaysLateLast30 | -0.72 | 0.52 | | 0.43 |

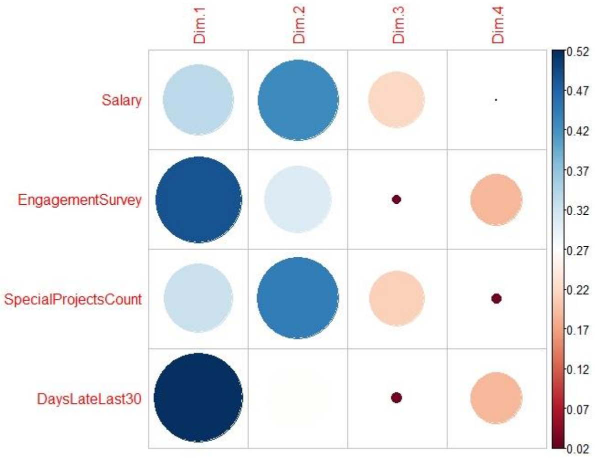

Fig. 7. The variables's contributions.

By utilizing PCA and analyzing the factors generated, better understanding of the underlying variables that impact employee performance can be achieved. This will facilitate the development of more effective strategies to enhance employee performance and achieve organizational goals.

The figure labeled as Fig. 8 provides a visual representation of the distribution of individuals based on the first two factors of the Principal Component Analysis of the chosen data set. The analysis has been performed to identify and understand the variables that have the most significant impact on the data set. The figure helps to illustrate how different employee are distributed based on the two factors and provides insights into how is performing in relation to performance score ID of each one.

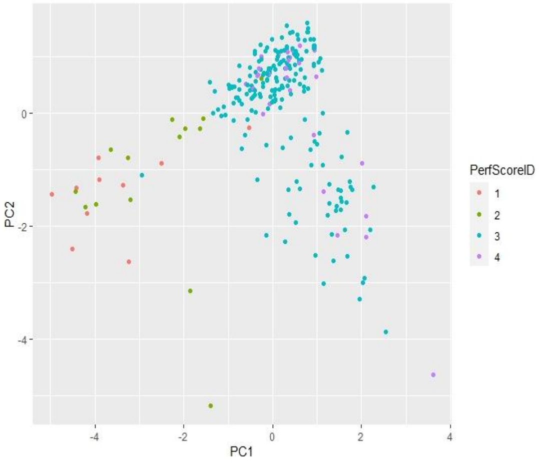

Fig. 8. Individual's graph (PCA).

*3) SVM :* As the first model, the support vector machine (SVM) algorithm is performed on the compressed database using Principal Component Analysis (PCA). SVMs are a powerful machine learning algorithm applicable for classification, regression, and outlier detection purposes. The basic model of the SVM classifier is a linear classifier processing a set of linearly separable data points with two class labels. It devises an optimal separating surface based on support vectors that maximizes the distance to the nearest training-data point of any class, also known as the functional margin. The optimal separating surface is referred to as a hyperplane or a set of hyperplanes in a higher-dimensional space [30].

Let, $s_a = \{(x_1, y_1), (x_2, y_2), \dots, (x_N, y_N)\}$ be a training set for two classes, where $x_i \in \mathbb{R}^n$ denotes the input vectors,

$y_i \in \{-1,1\}$ stands for their class label, and N is the number of the observations (samples).

In sum, SVM algorithm help to find computationally the "maximum-margin hyperplane" that divides the group of points $x_i$ for which $y_i = 1$ from the group of points for which $y_i = -1$.

The following diagram in Fig. 9, illustrates these concepts visually:

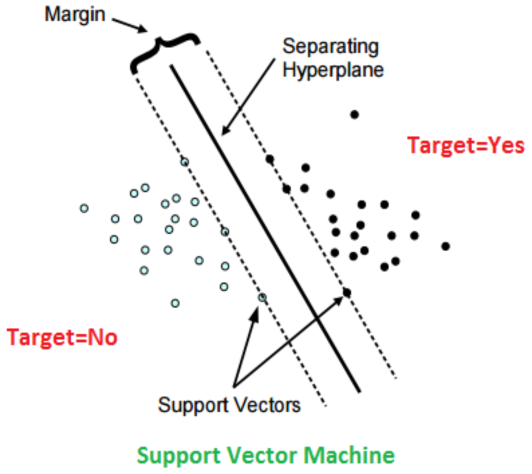

Fig. 9. Linear SVM concept.

To solve nonlinear problems, SVMs can perform a non-linear classification using kernel functions such as polynomial, sigmoid, Gaussian radial basis function (also called RBF or Gaussian kernel) or sigmoid kernel, that converts non-linear separable problems to linear separable problems by adding more dimensions to it, that implicitly mapping their inputs into high-dimensional feature spaces where the problems may be solved linearly. The discriminant function with kernel $K(x, x_i)$ is defined in Eq. (1).

$$f(x) = sgn\{\sum_{i=1}^{N} \alpha_i y_i k(x, x_i) + b\} \qquad (1)$$

where, sgn(u) is the sign function where:

if $u > 0$ then $sgn\ (u) = 1$ , $if\ u < 0\ then\ sgn\ (u) = -1$ ;

x is the sample to be recognized; b is called the bias or threshold and $\alpha_i$ is the Lagrange multiplier.

The "e1071" package on the R software was utilized to apply the SVM algorithm to the training set. Upon examining the graph of individuals, it was observed that the data was not linearly separable. Therefore, the decision was made to apply Kernel SVM. For the rest of the study, the Gaussian radial basis function (GRBF) was chosen as the kernel function in the model. This function is defined in Eq. (2) and has shown excellent performance [31]:

$$K(x, x_i) = exp(-\gamma \|x - x_i\|^2) \tag{2}$$

The figure labeled as Fig. 10 illustrates the results obtained from the model using the GRBF kernel to classify the training dataset based on the first two factors of the Principal Component Analysis. The graph shows how well the model has been able to classify the training data based on the chosen factors and provides valuable insights into its performance.

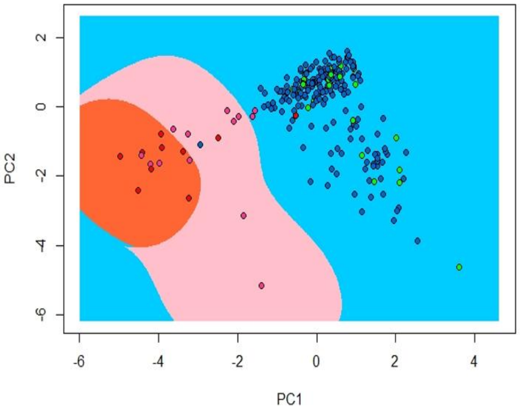

Fig. 10. GRBF SVM results on the training set.

To evaluate the effectiveness of the model, it was applied to the test database and achieved an accuracy rate of 87%. A graphical representation of the results obtained from the model using the Gaussian radial basis function (GRBF) kernel to classify the test dataset based on the first two factors of the Principal Component Analysis has been provided in the figure labeled as Fig. 11. The graph illustrates how well the model has been able to classify the test data based on the chosen factors and provides valuable insights into its performance.

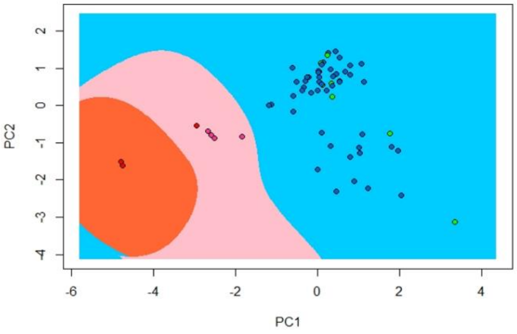

Fig. 11. GRBF SVM results on the test set.

Although the model achieved a high level of precision, it was observed that it was not able to accurately predict the most efficient employees (class 4). However, it was able to accurately predict the other classes. This indicates that the model may not be suitable for identifying the most efficient employees, and there may be other factors that are contributing to their performance that are not accounted for in the model. Further analysis and investigation may be required to identify these factors and improve the accuracy of the model.

*4) Multinomial logistic regression:* In the second employee performance classification model, multinomial logistic regression (MLR) was employed on the compressed database using Principal Component Analysis (PCA). MLR is a statistical method utilized to model and analyze categorical outcomes with more than two categories. It extends binary logistic regression, enabling the prediction and estimation of probabilities for multiple categories simultaneously.

While linear regression is suited for continuous outcome variables, aiming to find a linear relationship between predictors and the outcome, multinomial logistic regression is designed for categorical outcomes with multiple categories. It estimates probabilities for each category based on predictor variables. Linear regression assumes a linear relationship and normality of residuals, while multinomial logistic regression assumes independence of observations and the absence of multicollinearity. Understanding the nature of the outcome variable and the research question is crucial in choosing between these two methods.

Logistic regression is the most common form of classification algorithm employed, especially in industry. Its range is bounded between 0 and 1, and when the target is categorical, the outcome represents the probability that the output is true [32]. Intuitively, it is a process of modeling the probability of an outcome given an input variable that can be extended into multiple classes.

Multinomial logistic regression involves estimating the coefficients for each independent variable in the model. The estimation is typically performed using maximum likelihood estimation, which aims to find the values of the parameter from the training set that maximize the likelihood of observing the given set of outcomes. Once the coefficients are estimated, they can be used to predict the probabilities of each outcome category for new observations.

The mathematics of the classifier relies on the outcome to distribution P(Y|X) where Y is a dependent variable and X={x_1,…,x_n } is independent variable. Due to applying a nonlinear log transformation using the logistic function called also sigmoid function [33], the parametric model of Logistic Regression can be written as in Eq. (3):

$$P(Y = 1|X, W) = \frac{1}{1+e^{(w_0+\sum_{i=1}^{n} w_i x_i)}} \tag{3}$$

When there are more than two categories, as is the case in the study, multinomial logistic regression is utilized, which is a powerful statistical classification algorithm that generalizes logistic regression to multiclass problems.

Intuitively, since y = {0,1...n}, the problem is divided into n+1 binary classification problems, where in each one, the probability that y is a member of one of the classes is predicted. This process is repeated, applying logistic regression to each case, and then using the hypothesis that returned the highest value as the prediction.

The output obtained is a probability vector Y, containing probabilities {y,…,y_k } for the k target classes, since the total probability of all the possible events in a system is always 1. Finally, the outcome with the highest probability will be the predicted outcome for the given feature set [34], as shown in Eq. (4) and Eq. (5).

$$y_i = P(y = i|x, w) \tag{4}$$

$$Y = max(y_i) \tag{5}$$

The figure labeled as Fig. 12 illustrates the results obtained from the model using MLR based on the first two factors (PC1 and PC2) of the training set. The graph depicts how well the model has been able to classify the training data based on the chosen factors and provides valuable insights into its performance.

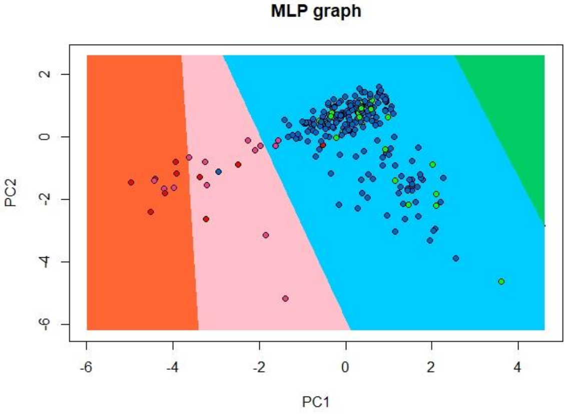

Fig. 12. Multinomial logistic regression on the compressed training set.

Based on the outcomes, the model can differentiate between low performers (indicated by the red region), employees with potential to improve (represented by the pink region), individuals who perform well (denoted by the blue region), but it cannot predict high performers (depicted by the green region). Finally, assessing the model's performance on the test set, the graph depicted in Fig. 13 illustrates the results of the model using MLR in relation to PC1 and PC2 of the test data set.

The classifier has achieved an accuracy of 87.3%, which indicates that it is capable of accurately identifying the performance level of employees.

However, It has been observed that the model is unable to predict high-performing employees (class 4), despite its satisfactory accuracy in predicting the other classes. It is worth mentioning that the time taken to find the nearest neighbors is also relatively short, indicating good efficiency.

*5) K-nearest neighbors algorithm:* Utilizing the K-nearest neighbors (KNN) algorithm as the third model for employee performance classification, the compressed database with PCA was employed. KNN is an intuitive and widely used machine learning algorithm for classification and regression tasks [35]. It is particularly useful when the decision boundaries are non-linear, as is the case with the data. The KNN algorithm is non-parametric and relies on the concept of similarity to make predictions. One of its advantages is its simplicity and ease of implementation. It does not make any assumptions about the underlying data distribution, making it applicable to a wide range of problems. KNN can also handle both numerical and categorical data.

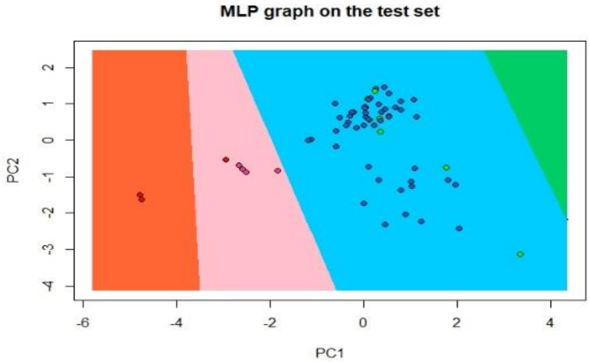

Fig. 13. Multinomial logistic regression results on the test set.

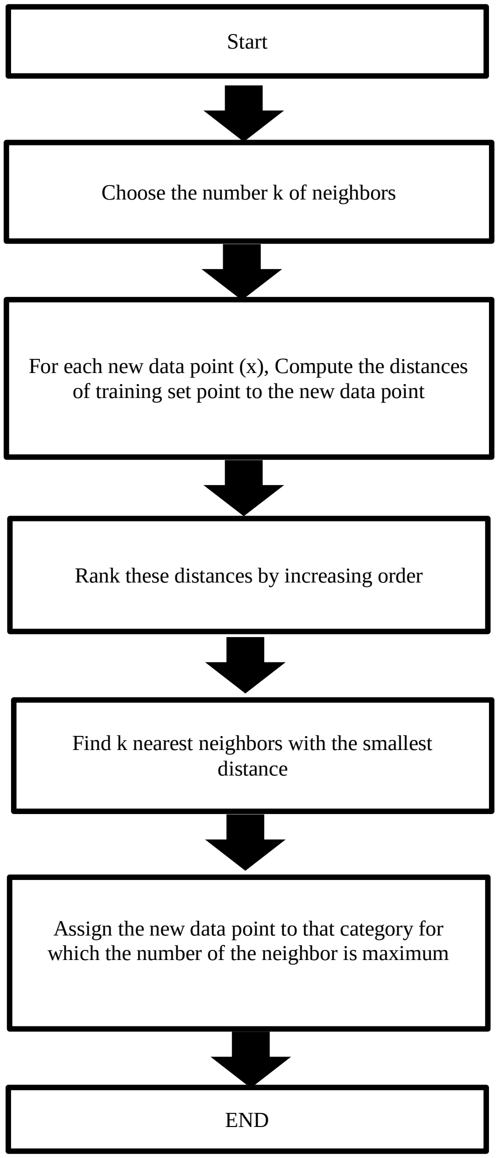
In KNN, the training data consists of labeled instances with known classes or values. When a new instance is to be classified or predicted, the algorithm looks for the k closest instances in the training set based on a distance metric, typically Euclidean distance. The predicted class or value of the new instance is determined by majority voting (for classification) or averaging (for regression) the labels or values of its k nearest neighbors. This means that the category Y of the new data is assigned by calculating the distance to each point in the training set and assigning it to the majority class of the k nearest neighboring data. The only parameter to be fixed is k, the number of neighbors to consider.

However, the KNN algorithm has some limitations. It can be computationally expensive, especially for large datasets, as it requires calculating distances between the new instance and all training instances. Furthermore, KNN is sensitive to the choice of k and the distance metric. Selecting an appropriate value for k and determining the most suitable distance metric can significantly impact the algorithm's performance. The steps of the algorithm are illustrated in Fig. 14.

The "class" library in R was used to generate a graph depicting the performance of the KNN model, based on the first two factors (PC1 and PC2) of the training dataset. The graph is shown in Fig. 15.

In order to test and validate the model, it was applied to the test database, resulting in an accuracy of 85.71%. The results are illustrated in Fig. 16.

Despite the high precision achieved, it is noted that the model is unable to predict the most efficient employees (class 4), although it performs well in predicting the other classes.



Start
Choose the number k of neighbors
For each new data point (x), Compute the distances of training set point to the new data point
Rank these distances by increasing order
Find k nearest neighbors with the smallest distance
Assign the new data point to that category for which the number of the neighbor is maximum
END

Fig. 14. KNN steps.

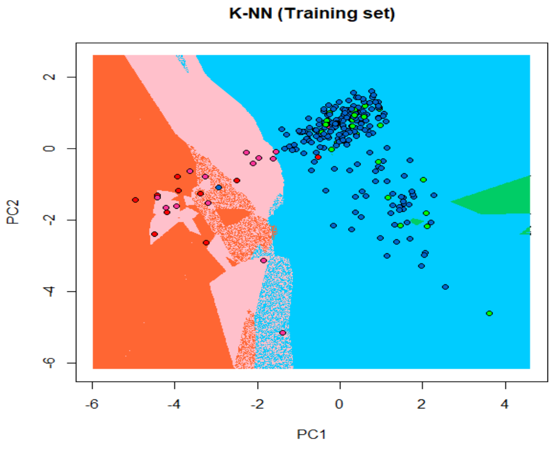


Fig. 15. KNN results on the training set.

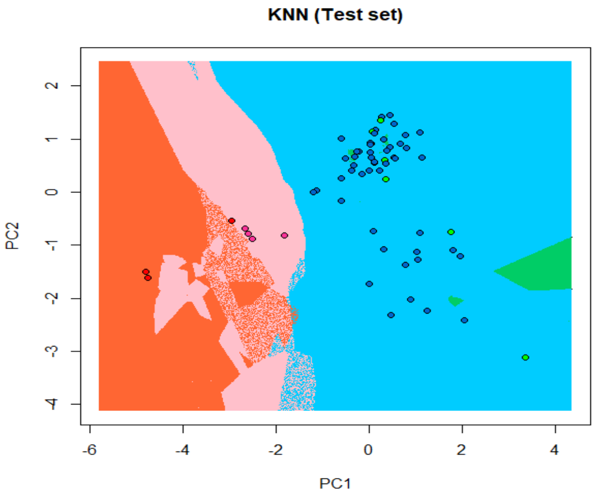

Fig. 16. KNN results on the test set.

Additionally, it is worth mentioning that the KNN algorithm has some limitations. Firstly, it can be computationally expensive, particularly for larger datasets, as it requires the calculation of distances between the new instance and all training instances. Secondly, the performance of KNN is highly dependent on the choice of k and the distance metric used. Selecting an appropriate value for k and determining the most suitable distance metric can significantly impact the algorithm's performance.

## IV. Results and Discussion

Upon testing the three constructed models, it was observed that each model achieved varying levels of accuracy on the test set. The SVM, MLR, and KNN models achieved accuracy scores of 87%, 87.5%, and 85.7% respectively. The results indicated that the MLR model performed the best, with an accuracy score of 87.5%.

In the study, despite the challenges of acquiring HR data, a model was established to address this challenge. Firstly, the opportunities and limitations of applying machine learning techniques in the field of human resource management, particularly performance management, were identified. This allowed the research efforts to focus on leveraging the opportunities and mitigating the associated risks.

Secondly, a literature review was conducted to identify the most relevant factors and classify them into fields of performance evaluation based on related works.

Thirdly, after identifying the most relevant performance factors and selecting the most appropriate database, the PCA algorithm was used to compress the selected factors into two factors - the "behavior factor" with 41.42% of the variance and the "achievement factor" with 35.97%.

Finally, three classification algorithms (SVM, MLR, and KNN) were applied separately to the compressed database, and their accuracy was tested. Based on the results, it was determined that the MLR model achieved the highest accuracy score of 87.5%.

Therefore, the conclusion is drawn that the second model, which uses MLR as a classifier, is the most efficient model to adopt for the objective classification of employees based on the most relevant performance factors.

## V. Conclusions

In today's world, it is becoming increasingly challenging for human resources managers to objectively and quantifiably classify employees based on relevant performance factors, especially in a highly competitive environment where data continues to grow exponentially, making the task more difficult. However, it is possible to classify the performance of human resources based on data, including salary, commitment, productivity (reflected by the number of projects carried out), absence, and the number of days in arrears.

The model enables the prediction of the performance class, allowing for the identification of low performers (red region), employees with potential to improve (pink region), individuals who perform well (blue region), and high performers who cannot be predicted by any of the three models (green region).

The quantified results obtained through the model provide human resources managers with a powerful classifier, enabling them to:

*1)* Identify talented employees with a good level of performance (blue region) and retain them.

*2)* Boost the performance of employees with an average score (pink region).

*3)* Plan for better organizational performance by understanding low performers (red region).

*4)* Achieve other economic benefits, such as optimizing time and recruitment results, which are no longer subject to subjective decisions. Additionally, the training strategy can be adapted to the specific needs of each performance region, thereby reducing the cost of training.

As a perspective of the research, the model needs to be tested on a larger database in a real industrial context, using questionnaires targeted around the chosen performance factors.

In summary, the results confirm that performance management can shift from being curative to predictive, and the model combining PCA and GRBF is a promising tool for predicting performance based on HR data and making data-based decisions for the three performance classes.

## Acknowledgment

I would like to express my sincere gratitude to all those who have given me the opportunity to complete this paper. I would like to extend a special thanks to Pr. AKNIN Noura and Pr. CHRAYAH Mohamed, whose valuable contributions through stimulating suggestions and encouragement were instrumental in helping me finalize this work.

# Advancing Strawberry Disease Detection in Agriculture: A Transfer Learning Approach with YOLOv5 Algorithm

Chunmao LIU
Henan Polytechnic Institute, Nanyang Henan 473000, China

***Abstract*—Strawberry Disease Detection in the Agricultural Sector is of paramount importance, as it directly impacts crop yield and quality. A multitude of methods have been explored in the literature to address this challenge, but deep learning techniques have consistently demonstrated superior accuracy in disease detection. Nevertheless, the current research challenge in deep learning-based strawberry disease detection remains the demand for consistently high accuracy rates. In this study, we propose a deep learning model based on the Yolov5 architecture to address the aforementioned research challenge effectively. Our approach involves the generation of a custom dataset tailored to strawberry disease detection and the execution of comprehensive training, validation, and testing processes to fine-tune the model. Experimental results and performance evaluations were conducted to validate our proposed method, demonstrating its ability to achieve accurate results consistently. This research contributes to the ongoing efforts to enhance strawberry disease detection methods within the agricultural sector, ultimately aiding in the early identification and mitigation of diseases to preserve crop yield and quality.**

***Keywords—Strawberry disease detection; deep learning; agricultural; YOLOv5 model; training***

## I. Introduction

Strawberries are one of the most beloved and economically significant crops in the agricultural industry [1], [2]. However, the cultivation of these delicate fruits is often hindered by various factors, including diseases that can drastically reduce yield and quality [3]. The early detection of strawberry diseases is crucial to prevent the spread of infections and minimize crop losses [4]. This paper focuses on the application of advanced technologies, particularly deep learning methods, for the purpose of strawberry disease detection in agriculture.

The importance of strawberry disease detection in agriculture cannot be overstated. Strawberry plants are susceptible to a range of diseases, including powdery mildew, gray mold, and anthracnose, among others [5], [6]. These diseases can lead to significant reductions in crop yield, rendering them a major concern for strawberry growers. The ability to detect these diseases early and accurately is essential for timely intervention, reduced pesticide usage, and improved crop management, thereby ensuring the economic viability of strawberry production [7].

Historically, the detection of strawberry diseases in agriculture has relied on visual inspection by experts and the use of traditional diagnostic tools [8]. However, recent advancements in technology have revolutionized disease detection in agriculture. Researchers and practitioners have increasingly turned to automated methods, including computer vision and machine learning 9], to enhance the accuracy and efficiency of disease detection in strawberries. In this context, the paper reviews the latest advances in strawberry disease detection methods, particularly focusing on the emergence of deep learning approaches as a promising solution [10], [11].

Deep learning-based approaches have gained substantial attention in recent years for strawberry disease detection. Compared to other methods, deep learning techniques offer the advantage of automatically learning relevant features from large datasets, thereby enabling accurate and efficient disease identification. The use of deep learning in agriculture, including strawberry disease detection, has become a subject of intense research due to its potential to outperform traditional methods and address the limitations associated with human expertise.

Despite the promise of deep learning-based approaches, several challenges and limitations persist. Achieving high accuracy in disease detection is demanding, and these models often struggle with issues such as data scarcity, class imbalance, and robustness in real-world agricultural settings. Addressing these challenges and improving the robustness and accuracy of deep learning models is a critical area for further research.

The research problem centers on the inefficiency and limitations of current disease detection methods, particularly in the face of increasing challenges such as disease spread and crop loss [19]. Our research objectives encompass the development of an advanced deep learning model tailored for strawberry disease detection, leveraging the advantages of CNNs to enhance accuracy and efficiency. Additionally, we aim to provide a comprehensive evaluation of our proposed method through rigorous experimentation and performance analysis.

In this study, we propose a deep learning method using the CNN to address the demanding requirements of strawberry disease detection. We leverage the advantages of deep learning in automatically extracting relevant features from strawberry images, ultimately enhancing the accuracy and efficiency of disease detection. To validate our approach, we generate a custom dataset and conduct rigorous training, validation, and testing processes.

This paper makes three significant contributions as,

*1)* The paper develops a tailored dataset to address the challenges of strawberry disease detection, filling a critical gap in the field's available resources.

*2)* It introduces an efficient deep learning methodology utilizing CNNs to enhance the accuracy of strawberry disease detection, representing a notable advancement in agricultural disease identification techniques.

*3)* Through comprehensive experimentation and evaluation, the paper validates the effectiveness of its proposed method while offering insights and solutions to address current limitations in strawberry disease detection research.

This rest of this paper is as follows; Section II presents related works. The research methodology discusses in Section III. Results and discussion present in Section IV. Finally, this paper concludes in Section V.

## II. Related Work

The field of agriculture has witnessed remarkable advancements, largely driven by the significant contributions of machine learning and deep learning techniques. These cutting-edge technologies have played a pivotal role in transforming disease prediction, classification, and identification in plants. Their adoption offers numerous advantages, including non-invasiveness, cost-efficiency, speed, and reliability in plant disease detection. This transformative potential has spurred a multitude of research efforts aimed at advancing plant disease diagnosis and detection. Among the pioneering researchers who have made substantial contributions in this domain, notable figures include:

The paper in [12] introduced YOLOv5-ASFF, a multistage strawberry detection algorithm that refines the YOLOv5 model. This approach utilizes an Adaptive Spatial Feature Fusion (ASFF) module to enhance strawberry detection accuracy. It combines features from different stages of the YOLOv5 network, thereby improving detection performance. While the method shows promise in strawberry detection, it lacks a comprehensive discussion of limitations and does not propose specific avenues for addressing potential challenges or improving the model's practical applicability. Further research should focus on addressing these limitations and evaluating the model's performance in real-world agricultural settings.

The authors in [13] presented a method for strawberry defect identification utilizing deep learning and infrared-visible image fusion. The approach aims to enhance detection accuracy by fusing infrared and visible images, leveraging the complementary information they provide. However, the study lacks an extensive discussion of the limitations of the proposed method, hindering a comprehensive understanding of potential challenges. Future work should focus on addressing these limitations and assessing the model's performance under various environmental conditions to enhance its practical utility in strawberry quality control.

The authors in [14] presented a method for strawberry defect identification utilizing deep learning and infrared-visible image fusion. The approach aims to enhance detection accuracy by fusing infrared and visible images, leveraging the complementary information they provide. However, the study lacks an extensive discussion of the limitations of the proposed method, hindering a comprehensive understanding of potential challenges. Future work should focus on addressing these limitations and assessing the model's performance under various environmental conditions to enhance its practical utility in strawberry quality control.

The paper in [15] introduced a method for strawberry flower and fruit detection using an autonomous imaging robot and deep learning techniques. The robot captures images of strawberry plants in agricultural fields and employs deep learning algorithms to identify and distinguish between flowers and fruits. The system shows promise in automating this labor-intensive task. However, the study does not thoroughly discuss the limitations, particularly regarding challenges in diverse environmental conditions or varying plant growth stages. Future research should address these limitations to ensure the model's robustness and reliability in real-world, dynamic agricultural settings.

The authors in [16] presented a method for detecting two-spotted spider mites and predatory mites in strawberry crops employing deep learning technology. The approach involves training a deep learning model on image data to distinguish between these mite species. However, the study lacks a comprehensive discussion of the model's limitations, such as the potential for misclassification in complex real-world conditions or its scalability to large-scale agricultural applications. Future research should focus on addressing these limitations and refining the model's practical applicability for effective pest management in strawberry cultivation.

The paper in [17] presented a deep-learning model for identifying diseases in strawberry plants. The method utilizes convolutional neural networks (CNNs) to analyze images of strawberry plants and classify them into disease categories. However, the paper does not explicitly address the limitations of the model or potential challenges, such as variations in lighting and image quality in real-world agricultural settings. Future work should focus on enhancing the model's robustness and its adaptability to diverse conditions for practical disease management in strawberry cultivation.

The papers in question collectively illustrate the significant role that deep learning and augmented reality play in the context of strawberry farming. The study in [14] and [13] both focus on enhancing strawberry quality. The former emphasizes real-time ripeness detection using augmented reality and deep learning, enabling timely harvesting, while the latter employs deep learning for defect identification, ensuring high-quality strawberry production. The study in [15] introduces the concept of an autonomous imaging robot in strawberry farming. This robot employs deep learning to detect both strawberry flowers and fruits, aiding in monitoring growth stages and optimizing farm management. In the realm of pest management, the study in [16] showcases deep learning's utility in identifying spider mites and predatory mites on strawberry plants, which is crucial for pest control strategies. Lastly, the study in [17] emphasizes the importance of disease detection in strawberry farming. This paper employs deep learning techniques to detect various diseases afflicting strawberry plants, facilitating early diagnosis and prompt intervention. Collectively, these papers emphasize the versatility and transformative potential of deep learning and augmented reality in strawberry farming, addressing issues such as ripeness, quality, growth stage monitoring, pest control, and disease management.

In comparing these papers, it's evident that deep learning, combined with innovative technologies like augmented reality and autonomous imaging robots, offers significant advantages to the strawberry agriculture sector. These technologies enable real-time decision-making, quality control, efficient growth stage monitoring, pest detection, and disease management. However, the specific applications highlight different aspects of strawberry farming, such as quality control, growth stage monitoring, and pest and disease management, showcasing the breadth of issues that deep learning can address in the agricultural domain. Ultimately, these papers collectively underscore the potential for technology-driven advancements in modern strawberry farming practices.

## III. Methodology

### A. Data Collection

In our research, we harnessed the power of diverse resources to construct a comprehensive dataset for strawberry disease image analysis. We gathered a significant portion of our dataset from various internet resources, which offered a wide range of strawberry disease images captured under different environmental conditions. Additionally, we leveraged Roboflow, a robust platform that provides curated and labeled datasets for machine learning tasks. The classes of our dataset involve Angular Leaf Spot, Anthracnose Fruit Rot, Blossom Blight, Gray Mold, Leaf Spot, Powdery Mildew Fruit, and Powdery Mildew Leaf. By combining these resources, we were able to create a rich and diverse collection of strawberry disease images that represented the real-world variability encountered in agricultural settings.

The dataset was carefully assembled to reflect the variability encountered in real-world agricultural conditions. Images were captured under different environmental settings, encompassing variations in lighting, background, and disease severity. This diverse representation ensures that the trained model is capable of recognizing and accurately classifying strawberry diseases across a spectrum of scenarios.

To ensure that our deep learning model could effectively handle the intricate nuances of strawberry disease detection, we employed data augmentation techniques to augment our dataset. These techniques played a vital role in generating more images and improving the model's robustness. Common data augmentation methods we applied included rotation, which introduced variations in orientation, and flipping, both horizontally and vertically, to enable the model to recognize diseases from multiple perspectives. Additionally, we incorporated scaling, which mimics the effects of different camera distances and zoom levels. Contrast and brightness adjustments were also applied to account for variations in lighting conditions. These augmentation techniques collectively created a dataset with a wide range of variations, closely mirroring the complexities of real-world agricultural conditions. This diverse dataset became instrumental in training a deep learning model capable of accurately and robustly detecting strawberry diseases, even in challenging environments.

By meticulously curating and augmenting our dataset, we ensured that our deep learning model is trained on a diverse and representative collection of strawberry disease images. This rich dataset forms the foundation for robust and accurate disease detection, enabling the model to effectively handle the intricate nuances of real-world agricultural conditions.

The study utilizes a dataset sourced from Robloflow, comprising a total of 6394 images. This dataset is split into three subsets for training, validation, and testing purposes. The training set consists of 5901 images, accounting for approximately 92% of the total dataset, while the validation and test sets contain 247 and 246 images, respectively, and making up 4% each. Notably, no preprocessing steps were applied to the images before training. However, augmentations were implemented during training, with each training example producing three outputs. These augmentations include rotations of 90° clockwise, counterclockwise, and upside down, as well as rotations within a range of -15° to +15°, adjustments to brightness and exposure between -25% and +25%, and the application of cutout with three boxes, each at 10% size. These augmentation techniques aim to enhance the robustness and generalization capabilities of the trained model when faced with variations and complexities in real-world strawberry disease images.

### B. Feature Extraction using Convolutional Neural Network

Convolutional Neural Network-based Object Detectors are mainly suitable for a wide range of applications, not just recommendation systems. You Only Look Once (YOLO) models excel in the field of object detection due to their high performance. YOLO divides an image into a grid system, where each grid is responsible for detecting objects within its boundaries [20]. These models are particularly well-suited for real-time object detection using data streams, and they are known for their efficiency, requiring minimal computational resources. Ultralytics YOLOv5 represents the latest advancement in the the YOLO series, setting new standards in the field of computer vision. This state-of-the-art (SOTA) model not only inherits the accomplishments of its YOLO predecessors but also introduces innovative features and enhancements to enhance its performance and versatility significantly. As shown in Fig. 1, the YOLOv5 is engineered with a strong emphasis on speed, precision, and user-friendliness, making it a superior option for an extensive array of applications, including object detection, instance segmentation, and image classification tasks [18].

### C. The Proposed Yolov5 Model

In this study, the generation of YOLOv5 models for strawberry disease detection follows a systematic process involving several key steps, including model initialization, model configuration, and hyperparameter tuning. Here is a step-by-step guide outlining how the YOLOv5 models are generated:

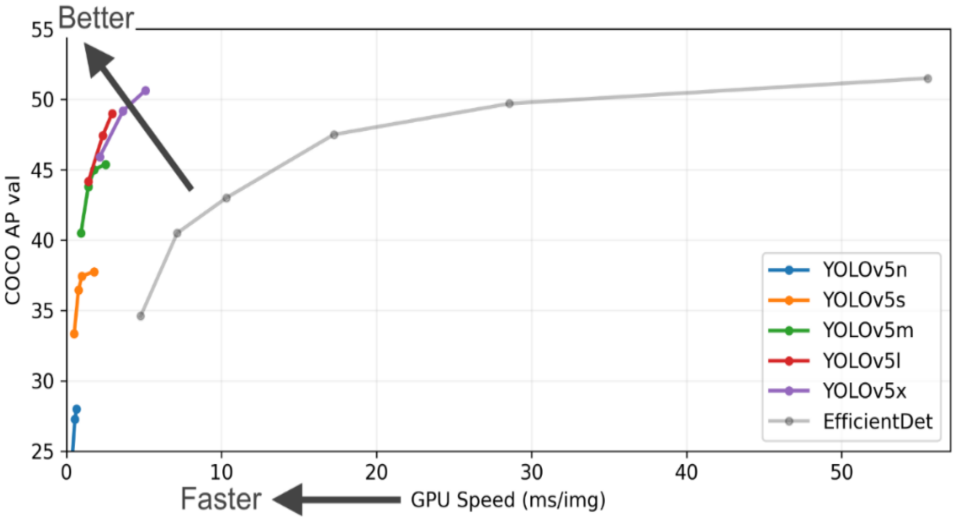

Fig. 1. YOLOv5 versions: COCO AP val denotes mAP@0.5:0.95 metric measured on the 5000-image COCO val2017 dataset over various inference sizes from 256 to 1536. GPU Speed measures the average inference time per image on the COCO val2017 dataset using an AWSp3.2xlarge V100 instance at batch-size 32. EfficientDet data from Google/automl at batch size 8.

*1) Model initialization:*

*a)* The process begins with initializing the YOLOv5 model architecture. YOLOv5 is a deep learning-based object detection model that uses the CNN backbone for feature extraction and prediction.

*b)* The model is initialized with pre-trained weights, typically obtained from training on a large-scale dataset from COCO, which helps accelerate the training process and improve model performance.

*c)* The pre-trained weights provide a good starting point for feature extraction, enabling the model to capture generic patterns relevant to object detection tasks.

*2) Model configuration:*

*a)* Once initialized, the YOLOv5 model architecture needs to be configured for the specific task of strawberry disease detection.

*b)* This involves adjusting the input size of the images, as well as the number of classes to be detected. In this case, the model is configured to detect various classes of strawberry diseases, such as Angular Leaf Spot, Anthracnose Fruit Rot, Blossom Blight, Gray Mold, Leaf Spot, Powdery Mildew Fruit, and Powdery Mildew Leaf.

*3) Hyperparameter setting for model generation:*

*a)* Hyperparameters play a crucial role in determining the performance and behavior of the model during training. Setting appropriate hyperparameters is essential for achieving optimal performance.

*b)* Key hyperparameters include learning rate, batch size, optimizer choice, weight decay, and the number of training epochs.

*c)* Hyperparameters are typically set through experimentation and validation on a separate validation dataset. Techniques such as grid search or random search may be employed to explore the hyperparameter space and identify the optimal configuration.

*4) Model training and evaluation:*

*a)* Once the model architecture is initialized, configured, and hyperparameters are set, the model is trained on the annotated dataset of strawberry disease images.

*b)* During training, the model iteratively learns to predict the presence and location of different disease classes in the input images.

*c)* After training, the model's performance is evaluated using metrics such as mean Average Precision (mAP), precision, recall, and F1-score, to assess its effectiveness in detecting strawberry diseases.

### *D. Model Evaluation Techniques*

Precision, recall, F1 score, and mean Average Precision (mAP) stand as common metrics used to evaluate the performance of object detection models. In the context of tomato leaf disease detection using YOLOv8 and YOLOv5, these metrics serve the following purposes:

*1) Precision:* This metric assesses the accuracy of the model's positive predictions in disease detection. It quantifies the ratio of true positive predictions (correctly identified diseases) to the total number of positive predictions, which encompasses both true positives and false positives. High precision indicates that the model is typically correct when predicting diseases, though it does not account for instances missed by the model.

*2) Recall*: Also known as sensitivity, recall evaluates the model's capability to identify all instances of a specific class (disease) within the dataset. It's determined by dividing the number of true positive predictions by the total number of actual positive instances. High recall suggests that the model can capture most positive instances, but it doesn't consider false positives.

*3) F1 Score*: The F1 score strikes a balance between precision and recall, as it is the harmonic mean of these two metrics. It offers a well-rounded evaluation of the model's performance by considering both false positives and false negatives. A higher F1 score indicates a favorable equilibrium between precision and recall, offering a single metric for assessing the overall effectiveness of the model.

*4) mAP (mean Average Precision*): mAP emerges as a comprehensive metric for object detection models. It takes precision and recall into account across different confidence thresholds for predicted bounding boxes. mAP is calculated by averaging the Average Precision (AP) values across various classes. AP is computed by generating a precision-recall curve for each class and determining the area under the curve. Consequently, mAP delivers a global assessment of model performance that considers multiple classes and confidence levels.

### *E. Model Evaluation and Discussion*

Fig. 2 presents data on the impact of the number of training epochs on the performance of a YOLOv5s-based strawberry disease detection model. The results show a clear trend of improvement as the number of epochs increases. Precision, which measures the accuracy of positive predictions, rises from 0.49218 at epoch 1 to 0.87756 at epoch 17. Recall, reflecting the model's ability to capture all relevant instances, increases from 0.44742 to 0.90167 over the same epochs. Moreover, the mean Average Precision at an IoU threshold of 0.5 (mAP_0.5) also sees consistent growth, going from 0.42374 to 0.93036. These findings suggest that extended training enhances the model's capacity to accurately detect strawberry diseases, with all three metrics showing notable improvement.

In summary, the data underscores the importance of training duration in enhancing the YOLOv5s-based strawberry disease detection model's performance. More epochs lead to increased precision, recall, and mAP_0.5, signifying improved accuracy and disease identification capabilities. However, it is essential to strike a balance between training and overfitting to achieve optimal results, and the data illustrates the benefits of extended training in this context.

Fig. 3 presents data on the performance metrics of a YOLOv5n-based strawberry disease detection model at different epochs during training. As we observe the data, several trends emerge with respect to the impact of epochs on the model's performance. In the early epochs (e.g., epochs 0-3), both precision and recall metrics exhibit some degree of variation, with precision generally increasing and recall showing fluctuations. The mAP_0.5 values also experience gradual improvements. However, as training progresses (e.g., epochs 4-12), precision, recall, and mAP_0.5 consistently increase. This indicates that the model is becoming more accurate in detecting strawberry diseases and improving its ability to classify true positives (precision) and identify all actual positive cases (recall). Towards the later epochs (e.g., epochs 13-19), we observe a plateau effect. Precision, recall, and mAP_0.5 metrics stabilize, showing that the model's performance has reached a certain level of maturity. These metrics do not increase significantly beyond this point. This suggests that further training may not yield substantial improvements, and the model has reached a state of diminishing returns.

Overall, the data in the table reflects the progression of the YOLOv5n-based strawberry disease detection model's performance as training epochs increase. It demonstrates how the model evolves in terms of precision, recall, and mAP_0.5, ultimately reaching a point of stability where additional training epochs do not lead to significant performance gains.

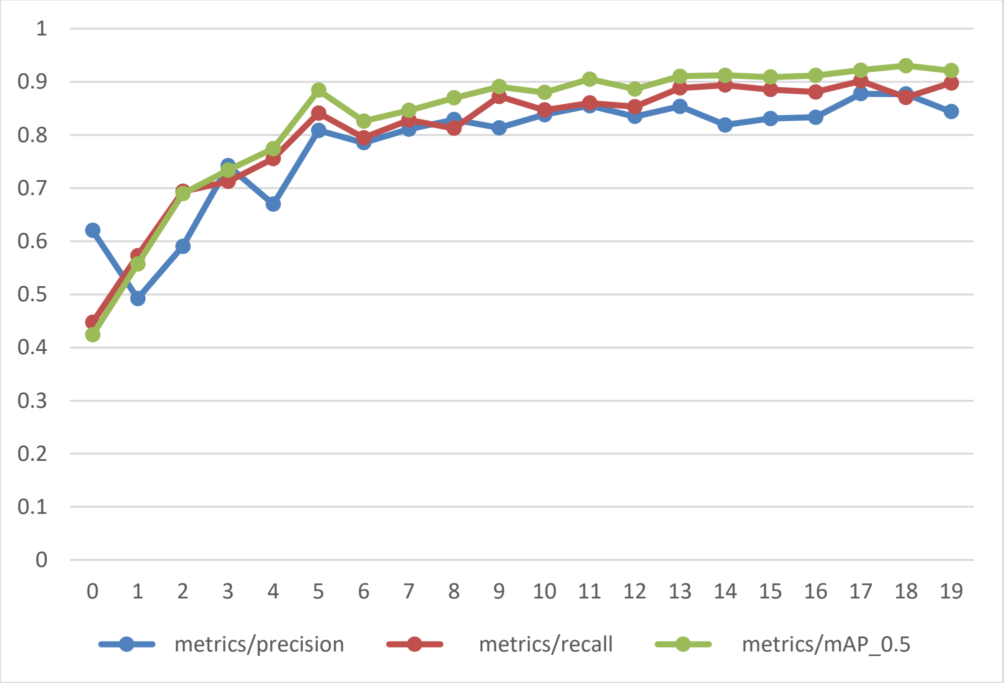

Fig. 2. Result of Yolov5s.

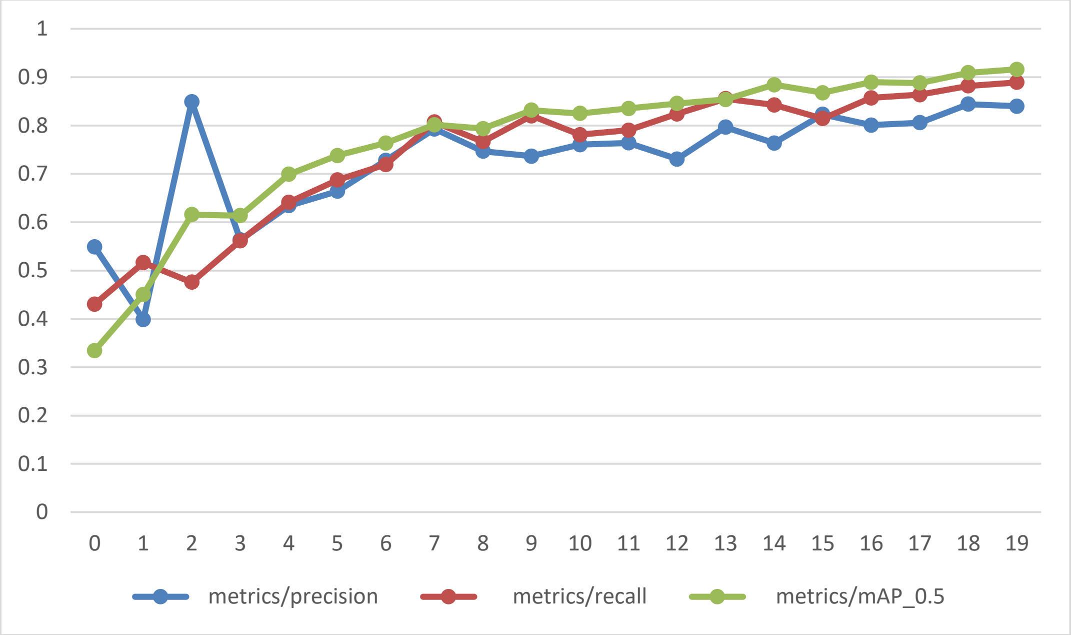

Fig. 3. Result of Yolov5n.

Fig. 4 provides data on the performance metrics of a YOLOv5m-based strawberry disease detection model at various epochs during training. As we examine the data, several trends become apparent regarding the impact of epochs on the model's performance. In the initial epochs (e.g., epochs 0-4), precision and recall exhibit varying trends. Precision starts relatively high but drops slightly, while recall steadily increases. This suggests that, in the early stages, the model becomes more adept at identifying actual positive cases but may include some false positives. Subsequently (e.g., epochs 5-10), there is a marked improvement in both precision and recall, with a significant increase in mAP_0.5. This signifies that the model is enhancing its ability to both accurately classify positive cases and detect a higher proportion of actual positive cases. In the later epochs (e.g., epochs 11-19), the metrics continue to improve, although there are diminishing returns. Precision remains high, and recall shows steady progress, ultimately stabilizing at a relatively high value. The mAP_0.5 reaches its peak, indicating the model's ability to achieve accurate and consistent strawberry disease detection.

Overall, the data in the table reflects the evolution of the YOLOv5m-based strawberry disease detection model's performance across different training epochs. It illustrates how the model refines its precision and recall, achieving a balance that leads to high mAP_0.5 values, ultimately plateauing after a certain number of epochs.

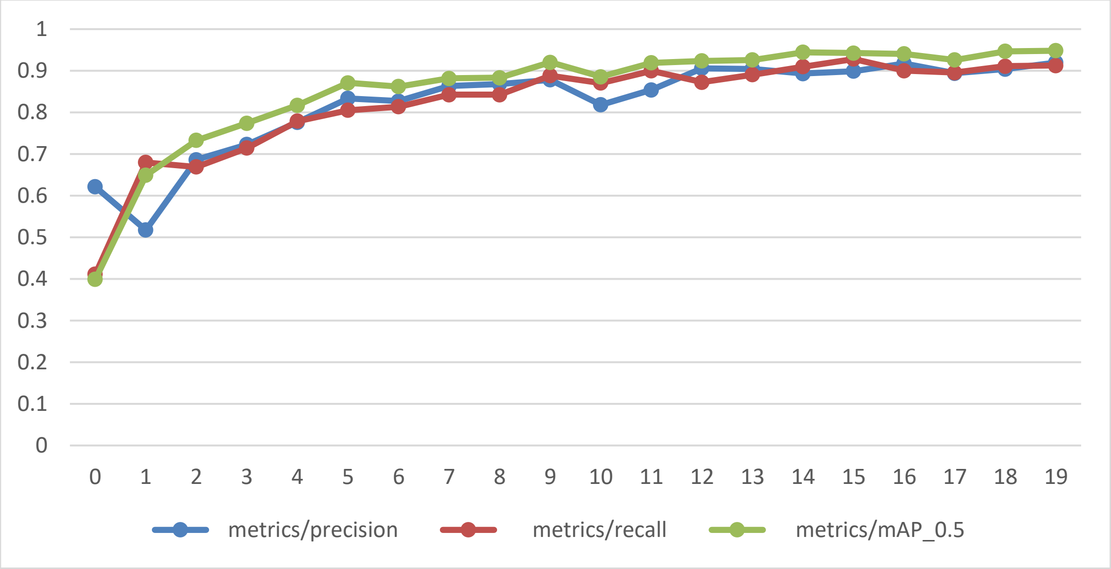

Fig. 4. Result of Yolov5m.

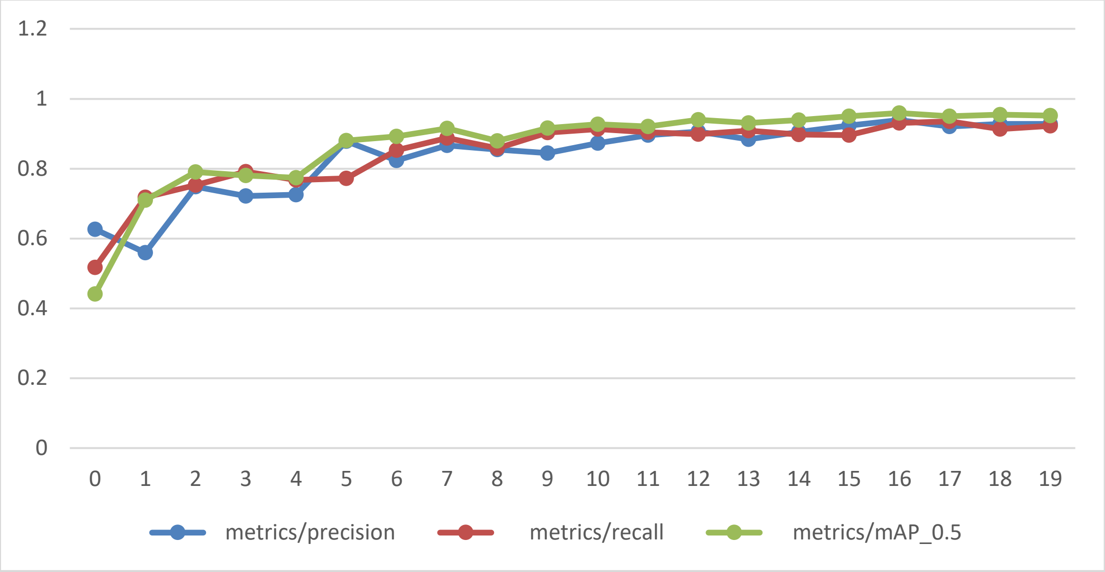

Fig. 5. Result of Yolov5l.

Fig. 5 provides data on the performance metrics of a YOLOv5l-based strawberry disease detection model at different epochs during training. Analyzing the data reveals how epochs affect the model's performance. In the early epochs (e.g., epochs 0-4), the model's precision, recall, and mAP_0.5 exhibit an upward trajectory, with both precision and recall increasing. This suggests that the model gradually becomes more precise in identifying strawberry diseases and also starts to recall a higher proportion of actual cases. As training progresses (e.g., epochs 5-10), there is a substantial improvement in precision, recall, and mAP_0.5. Precision remains consistently high, and recall steadily increases. These improvements are indicative of the model's growing ability to both accurately classify positive cases and detect a higher proportion of true positive cases, leading to a significant boost in mAP_0.5. In the later epochs (e.g., epochs 11-19), the performance metrics continue to rise, although the rate of improvement becomes less pronounced. Precision remains high, while recall shows steady progress, eventually stabilizing at a relatively high value. The mAP_0.5 reaches its peak, indicating the model's proficiency in achieving accurate and consistent strawberry disease detection.

Overall, the data in the table demonstrates how the YOLOv5l-based strawberry disease detection model evolves over training epochs, refining its precision and recall and ultimately achieving a state of high and stable performance as reflected in the mAP_0.5 values.

## IV. Results and Discussion

In our research, we conducted an extensive series of experiments to evaluate and compare the performance of various YOLOv5 models, namely YOLOv5s, YOLOv5n, YOLOv5m, and YOLOv5l, in the context of strawberry disease detection. Table I shows the comparison of different versions of YOLOv5.

The primary aim of these experiments was to identify the most accurate and effective model for this specific task. Each of the models was rigorously trained and tested using a diverse dataset encompassing different disease classes, and the performance results were collected and analyzed.

Upon careful examination of the table of results, it is evident that the YOLOv5l model achieved the highest mean Average Precision (mAP) at an Intersection over the Union (IoU) threshold of 0.5, with a score of 0.95. Furthermore, the YOLOv5l model displayed the highest precision of 0.97, which indicates that it had the lowest rate of false positives, making it highly reliable in correctly classifying disease instances. Additionally, the YOLOv5l model exhibited the highest recall (0.98), signifying its ability to detect a substantial proportion of actual disease cases within the dataset. Consequently, the YOLOv5l model outperformed the other models in terms of F1-score, achieving a value of 0.92, indicating a harmonious balance between precision and recall. Fig. 6 shows the graph of the comparison of different versions of YOLOv5.

TABLE I. The Comparison of Different Version of YOLOv5

| Model | mAP 0.5 | precision | recall | F1-score |
|---|---|---|---|---|
| YOLOv5s | 0.92 | 0.94 | 0.97 | 0.87 |
| YOLOv5n | 0.91 | 0.98 | 0.94 | 0.86 |
| YOLOv5m | 0.94 | 0.93 | 0.97 | 0.91 |
| YOLOv5l | 0.95 | 0.97 | 0.98 | 0.92 |

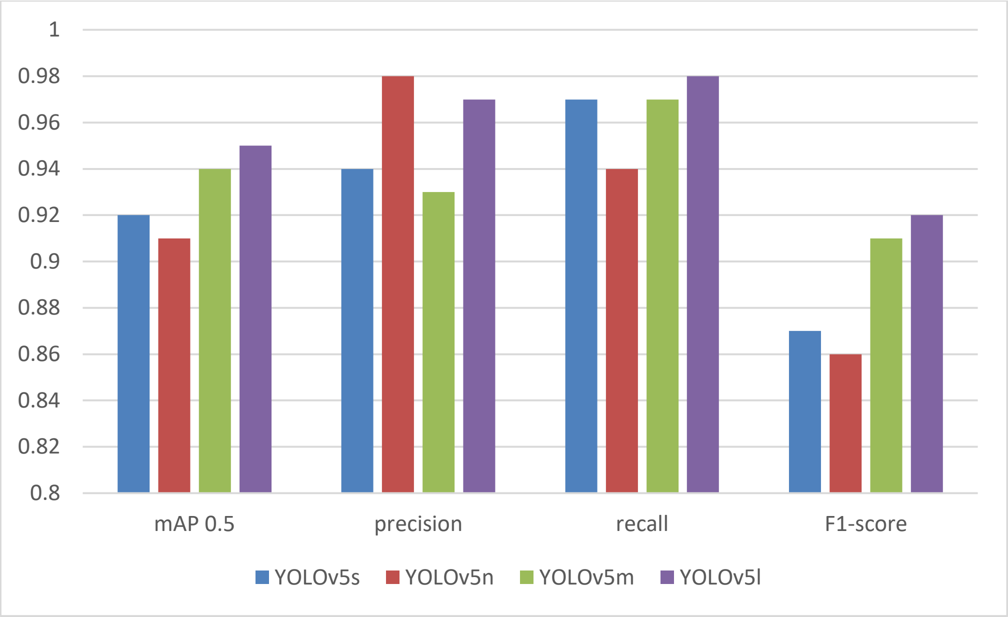

Fig. 6. The graph of the comparison of different versions of YOLOv5.

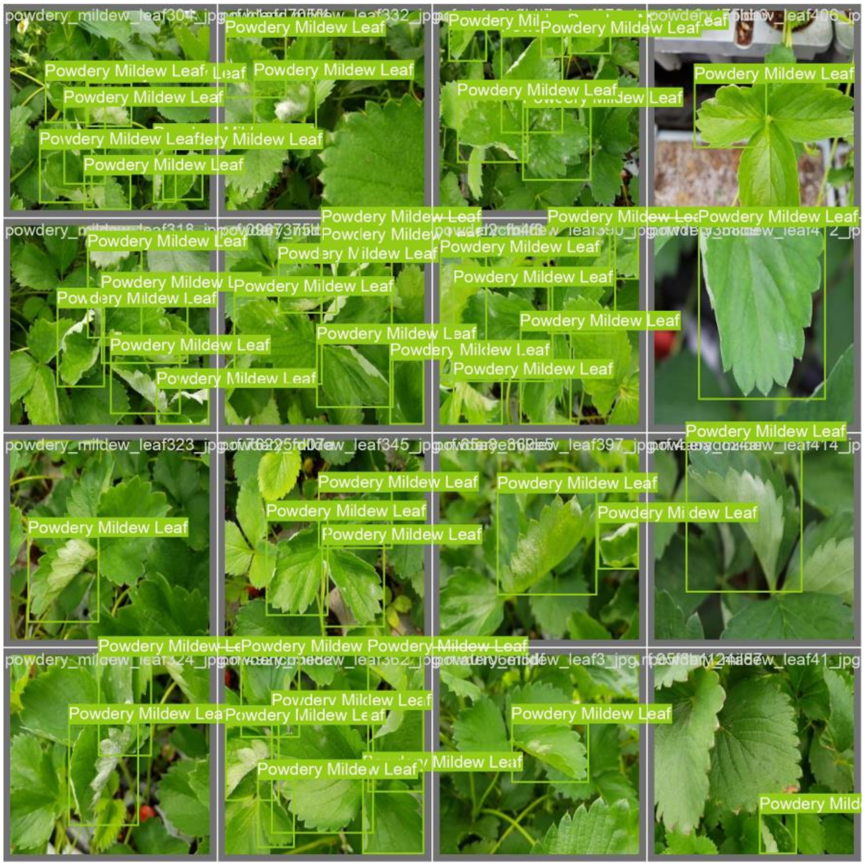

Fig. 7. The result of the YOLOv5l model.

These results suggest that the YOLOv5l model is the most effective and accurate model for strawberry disease detection among the ones tested. The superior performance of YOLOv5l can be attributed to its larger architecture and capacity to capture more detailed features, allowing it to make highly precise predictions while maintaining a high recall rate. In conclusion, based on the extensive experiments conducted, we have successfully identified and validated the YOLOv5l model as the most accurate and effective choice for strawberry disease detection, ensuring reliable and robust disease diagnosis in agricultural settings. Fig. 7 shows the result of the YOLOv5 model.

These results underscore the pivotal role of YOLOv5 models, particularly YOLOv5l, in enhancing disease diagnosis and contributing to more robust and reliable agricultural practices. Fig. 7 shows the result of the YOLOv5l model.

As result, the research addresses this need by proposing a deep learning-based solution using CNNs, which are renowned for their ability to extract relevant features from large datasets. A key aspect of the study is the creation of a custom dataset comprising diverse strawberry disease images sourced from various internet resources and augmented using techniques like rotation, flipping, scaling, and contrast adjustments. These augmentations aim to simulate real-world agricultural conditions, thereby enhancing the robustness of the trained model. The proposed method undergoes extensive experimentation and evaluation, culminating in promising results that underscore its effectiveness in accurately detecting strawberry diseases.

The effectiveness of the proposed method is evident from the reported results, showcasing high precision, recall, and F1-scores across different YOLOv5 models. Notably, the YOLOv5l model emerges as the top performer, demonstrating exceptional accuracy in detecting strawberry diseases. The robustness of the method is attributed to several factors, including the utilization of deep learning techniques, the creation of a diverse and representative dataset, and the application of data augmentation strategies to enhance model generalization. By leveraging the power of CNNs and innovative dataset construction, the proposed method offers a promising solution to the challenges of strawberry disease detection in agriculture, ultimately contributing to improved crop management and yield optimization in the industry.

The scalability of the proposed work in utilizing deep learning for strawberry disease detection in agriculture is evident through its adaptability to diverse agricultural settings and potential for broader applications. By employing the Yolo based approach and leveraging advancements in computer vision and machine learning, the proposed method offers a scalable solution that can be tailored to address disease detection challenges across different crops and agricultural environments. The methodology's reliance on automated techniques allows for efficient processing of large-scale datasets, facilitating the detection of various diseases with high accuracy and precision. Moreover, the creation of a custom dataset tailored to strawberry diseases exemplifies the scalability of the approach, as similar datasets can be curated for other crops, enabling the extension of the method to different agricultural contexts. Additionally, the proposed method's performance across different YOLOv5 models demonstrates its scalability in accommodating varying computational resources and model complexities, making it adaptable to different infrastructure constraints. Overall, the scalability of the proposed work lies in its ability to be applied across diverse agricultural scenarios, offering a scalable and effective solution to disease detection challenges in the agricultural industry.

## V. Conclusion and Future Work

In the agricultural sector, the accurate detection of strawberry diseases holds paramount importance for crop management and yield optimization. Various methodologies have been explored in the literature for this purpose, with deep learning-based approaches consistently demonstrating superior accuracy compared to alternative methods. However, the existing research landscape reveals a pressing challenge in achieving the high accuracy rates necessary for practical implementation. To address this challenge, this study introduces a novel deep-learning model based on the Yolov5 architecture. We present a comprehensive approach involving the creation of a custom dataset and the execution of rigorous training, validation, and testing processes. For the performance evaluation and results comparison purpose, various YOLOv5 models are experimentally evaluated to determine their effectiveness in strawberry disease detection, with the aim of identifying the superior-performing model. Through systematic experimentation and rigorous evaluation, the results collected from different YOLOv5 variants are compared to ascertain their respective performances in accurately identifying and localizing strawberry diseases within agricultural images. By analyzing the standard metrics across the different YOLOv5 models, insights are gained into their capabilities and limitations in addressing the complexities of disease detection in strawberries. Ultimately, the findings highlight the superior-performing YOLOv5 model, which demonstrates the highest levels of accuracy and efficiency in detecting strawberry diseases. Additionally, it is noted that previous studies have similarly shown the effectiveness of YOLOv5 models compared to other detection algorithms, reaffirming the robustness and reliability of the YOLOv5 framework for agricultural applications. Two notable limitations in strawberry disease detection using deep learning methods are the need for larger and more diverse datasets to enhance model generalization and the necessity for real-time deployment solutions in field conditions, which current models may not fully support. To address these limitations, future work could focus on, first, the acquisition and curation of extensive datasets containing a wider range of strawberry disease instances and environmental conditions further to improve the robustness and generalization of deep learning models. Second, researchers can explore the development of edge computing solutions that enable real-time disease detection in the field, reducing the reliance on centralized computing resources and facilitating immediate, on-site interventions for improved crop management and disease control. These advancements would contribute significantly to the practicality and effectiveness of strawberry disease detection systems in agriculture.

# Profiling and Classification of Users Through a Customer Feedback-based Machine Learning Model

Jihane LARIOUI, Abdeltif EL BYED
Laboratory of Computer Science and Systems, HASSAN 2 University Faculty of Science.
Ain Chock Casablanca, Morocco

***Abstract*—The systems aimed at predicting user preferences and providing recommendations are now commonly used in many systems such as online shops, social websites, and tourist guide websites. These systems typically rely on collecting user data and learning from it in order to improve their performance. In the context of urban mobility, user Profiling and Classification represent a crucial step in the continuous enhancement of services provided by our multi-agent system for multimodal transportation. In this paper, our goal is to implement and compare some machine learning (ML) algorithms. We will address the technical aspect of this implementation, demonstrating this model leverages customer feedback to develop a thorough understanding of individual preferences and travel behaviors. Through this approach, we can categorize users into distinct groups, enabling a finer personalization of route recommendations and transportation preferences. The ML model analyzes customer feedback, identifies recurring patterns, and continuously adjusts user profiles based on their evolution. This innovative approach aims to optimize the user experience by offering more precise and tailored recommendations, while fostering dynamic adaptation of the system to the changing needs of urban users.**

***Keywords*—Machine learning; urban mobility; multimodal transportation; multi-agent systems**

## I. Introduction

The expansion of urban mobility, driven by population growth and rapid urbanization, has introduced new complex challenges in transportation management. In densely populated urban areas, transportation systems must cope with increasing demand, often resulting in issues such as traffic congestion, longer travel times, and heightened pressure on existing infrastructure.

The data challenge in this context stems from the need to collect, process, and interpret massive and diverse amounts of information related to urban mobility. Data comes from various sources, including traffic sensors, navigation apps, public transportation, connected vehicles, and other Internet of Things (IoT) devices. Managing this variety of often unstructured data poses challenges in terms of collection, real-time processing, and analysis to derive actionable insights [7].

In response to this challenge, the application of machine learning (ML) techniques is becoming increasingly crucial. ML enables the processing of complex data and the discovery of hidden patterns, thereby providing insights to improve planning, operational efficiency, and user satisfaction in the field of urban mobility. In summary, effective urban mobility management requires an innovative and technological approach to overcome the challenges related to the quantity and diversity of data generated by urban travel.

The machine learning algorithms we intend to implement play a crucial role within our multi-agent system [16, 17, 18], acting in complement to significantly improve overall performance and decision-making. These algorithms seamlessly integrate into our approach, leveraging the rich data collected on user history, transportation choices, and preferences. By enhancing the decision-making capabilities of our system, machine learning algorithms enable increased customization of the services offered [8]. By analyzing emerging patterns from this data, the algorithms can anticipate user needs, dynamically adjust route recommendations, and optimize interactions within the multi-agent system. Thus, this synergy between agent intelligence and the adaptive capabilities of machine learning algorithms aims to provide a more responsive, efficient, and perfectly aligned urban mobility experience tailored to each user's individual preferences.

The establishment of a user data collection procedure represents a crucial step in the evolution of our multi-agent system for multimodal information. This initiative aims to establish closer interaction with users by gathering information about their preferences, behaviors, and experiences during multimodal travel.

The first objective of our work is to exploit this data to enhance the system's capabilities through learning process. By analyzing users' choices and habits over time, the system will be able to adjust its recommendations and responses based on individual preferences. This increased personalization will not only improve user satisfaction but also optimize the overall system performance by making it more responsive and adaptive.

The application of machine learning (ML) in the field of urban mobility is of major interest due to several factors. Firstly, the variety of available datasets covers a wide range of aspects related to urban travel, such as location data, user preferences, traffic conditions, and more. ML offers the opportunity to extract complex patterns from this diverse data, enabling a thorough understanding of travel patterns [9].

Furthermore, the use of ML can contribute to smarter and more proactive decision-making in urban mobility management. Machine learning models can analyze emerging trends in real-time, anticipate congestion, and provide personalized recommendations to users. This paves the way for more efficient optimization of transportation systems, thereby reducing travel times, greenhouse gas emissions, and traffic congestion.

User data collection will also refine the preference criteria used in the decision-making process, ensuring a more precise match between generated recommendations and specific traveler expectations. Therefore, this step represents a strategic advancement toward an intelligent multimodal transportation system capable of dynamically adjusting to evolving user needs and preferences, ultimately optimizing the urban mobility experience.

In summary, the variety of available datasets in the context of urban mobility presents a unique opportunity to harness the potential of machine learning to significantly improve urban transportation management, promoting smoother, sustainable, and adaptive mobility.

In this article, our goal is to implement the integration and implementation part of machine learning (ML) algorithms. We will address the technical aspect of this implementation, demonstrating how the ML algorithm is applied to process and enhance urban mobility data. This practical application will be a crucial step in realizing our theoretical approach in a functional system that is adaptive to the challenges of contemporary urban mobility.

The next section will be dedicated to the state of the art, followed by a presentation of the methodology for designing our multi-agent system for multimodal transportation, detailing the ML part and its relevance in our system while highlighting the essential contribution of the ML agent to our architecture. Then, we will explore the implementation part of these algorithms in our system. The results from these implementations will be examined in detail in the next section, demonstrating the concrete impact of integrating machine learning algorithms on the evolution of our architecture.

## II. Literature Review

In recent academic literature, there has been significant interest in the realm of urban mobility, particularly regarding the integration of machine learning algorithms into intelligent transportation systems (ITS). The aim is to enhance the efficiency, effectiveness, and overall quality of transportation services within urban environments [2]. This interdisciplinary field brings together expertise from transportation engineering, computer science, data analytics, and urban planning to address the complex challenges inherent in urban transportation. Researchers have delved into various aspects of urban mobility, leveraging machine learning techniques to tackle diverse problems. One key area of focus involves predicting transportation demand patterns, such as the need for taxis, ride-sharing services, or public transit, with the goal of optimizing resource allocation and service provision. By harnessing historical travel data, demographic information, and other relevant factors, predictive models can anticipate fluctuations in demand and facilitate proactive decision-making by transportation authorities and service providers.

Another critical application of machine learning in intelligent transportation systems is route optimization and trip planning. By analyzing real-time traffic data, weather conditions, and user preferences, algorithms can generate optimal routes for vehicles, minimizing travel times, fuel consumption, and environmental impact. This not only benefits individual commuters but also contributes to overall traffic management and congestion mitigation efforts in urban areas.

Furthermore, machine learning algorithms play a crucial role in detecting and predicting traffic congestion. By analyzing sensor data from traffic cameras, GPS-enabled vehicles, and infrastructure sensors, these algorithms can identify congested areas in real-time and forecast potential bottlenecks [3]. This information enables traffic management authorities to implement timely interventions, such as adjusting signal timings, rerouting traffic, or deploying additional resources to alleviate congestion and improve traffic flow.

Overall, the integration of machine learning into intelligent transportation systems holds immense promise for revolutionizing urban mobility. Through innovative research and practical implementation, researchers and practitioners aim to create safer, more efficient, and sustainable transportation networks that cater to the evolving needs of urban populations.

In research [1], the author investigates the prediction of passenger flow within urban areas, focusing on the city of Oslo, Norway. Traditional macro models for traffic flow simulation face limitations in capturing the complexity of real traffic patterns. In contrast, machine learning (ML) models offer promising alternatives. The study compares the effectiveness of a traditional Spatial Interaction model (SIM) with a selective ML model for traffic flow prediction. Results reveal that while the SIM is interpretable and requires fewer parameters, it struggles to accurately represent real flow dynamics compared to the ML model. Statistical analyses support these findings, highlighting the potential of ML models in discerning passenger movement trends and simulating traffic scenarios. The research provides a decision support system for urban planners and policymakers to forecast traffic flow accurately, contributing to the ongoing discussion on the role of machine learning in transportation modeling.

In the other hand, in study [4] the author focuses on human mobility as an interdisciplinary field encompassing physics and computer science. While various models and prediction methods have been proposed for understanding and forecasting human mobility, the emergence of multi-source heterogeneous data from handheld terminals, GPS, and social media has opened new avenues for exploring urban mobility patterns in detail. Such studies are crucial for applications spanning urban planning, epidemic control, location-based services, and intelligent transportation management. This survey focuses on human-centric perspectives within a data-driven context, examining mobility patterns at individual, collective, and hybrid levels. It also reviews prediction methods across four aspects and discusses recent developments while addressing open issues to guide future research. This comprehensive review serves as a valuable resource for newcomers seeking an overview of human mobility and provides insights for researchers aiming to develop unified mobility models.

The author in [5] in her thesis, delves into predicting user mobility using deep learning algorithms, with the aim of enhancing service quality for users and reducing paging costs for telecom carriers. Through a comprehensive literature review, RNN, LSTM, and variants of LSTM are identified as suitable deep learning algorithms for the task. Subsequently, an experiment is conducted to evaluate the performance of these algorithms, both as a global model and individual models. The results reveal that individual models demonstrate superior performance in predicting user mobility compared to the global model. Hence, it is concluded that individual models represent the preferred technique for this purpose, offering valuable insights for optimizing mobility prediction strategies.

The author in study [6] on his paper tried to investigate the integration of AI, machine learning, and data analytics in smart transportation planning to enhance urban mobility sustainability. It tackles two core questions: how these technologies can optimize urban transportation systems and the potential benefits they offer. The methodology involves collecting transportation data, applying statistical analysis, and developing a simulation model calibrated with real-world data to evaluate various scenarios. Performance metrics like travel time and congestion levels are used to assess strategy effectiveness. The findings demonstrate improved transportation efficiency and sustainability in New York City but acknowledge limitations such as data availability and modeling assumptions. Overall, this research contributes to evidence-based decision-making in civil engineering, providing insights for stakeholders and urban planners striving for sustainable urban mobility.

Based on this research and several others, we observe the significant contribution that machine learning provides to urban mobility.

## III. Presentation of the ML Methodology Design Approach

### A. *Contribution of Machine Learning to Urban Mobility*

Machine Learning, as an essential component of artificial intelligence, offers promising perspectives for transforming the way we perceive and manage mobility in dynamic urban environments. This enlightened introduction by machine learning brings a new and adaptive dimension to multimodal information systems dedicated to mobility, providing substantial benefits for both users and urban mobility managers.

This section will explore the multiple contributions of ML, highlighting how these advanced techniques can be deployed to improve service personalization, optimize routes, predict demand, manage traffic, provide intelligent recommendations, and foster continuous evolution through feedback collection. The goal is to demonstrate how the integration of ML transforms urban mobility systems into intelligent entities capable of dynamically adapting to user needs and the complex challenges of urban life.

The contribution of Machine Learning (ML) in the field of urban mobility is significant and offers substantial benefits to improve efficiency, service personalization, and overall user experience quality. Indeed, Machine Learning can contribute to enhancing urban mobility management on several levels.

*1) Personalization of services:* ML algorithms enable understanding users' individual preferences by analyzing their travel habits, previous choices, and other relevant data. This personalization offers the opportunity to provide tailor-made route recommendations, considering each user's specific preferences.

*2) Route optimization:* ML techniques, such as decision trees, can be used to analyze historical travel data, real-time traffic conditions, and other relevant variables. By using this information, the system can recommend optimized routes that minimize travel time, costs, or other specific criteria.

*3) Transport demand prediction:* ML models can be employed to predict fluctuations in transport demand based on various factors, such as time of day, days of the week, and special events. These predictions enable better resource management and more efficient transport service planning.

*4) Feedback collection and continuous improvement:* ML algorithms can be applied to analyze user feedback, assess customer satisfaction, and identify potential areas for improvement in the mobility system. This allows for continuous adaptation to changing user needs.

In our context, we pay particular attention to the aspects of Feedback Collection and Continuous Improvement. This approach promotes continuous adaptation to changing user needs, thus constantly optimizing the services offered. By leveraging the collected data, these algorithms contribute to a thorough understanding of individual preferences, facilitating targeted adjustments to improve the overall urban mobility experience.

The integration of ML into multimodal information systems thus offers an intelligent approach to solving complex issues related to urban mobility, contributing to a smoother, personalized, and efficient user experience.

### B. *Proposed Approach*

The design methodology we have adopted for the Machine Learning (ML) part of our system revolves around a systematic and iterative approach. We have implemented a process that integrates robust design principles while considering the specific features and particular requirements of urban mobility data.

The first step of our methodology involves clearly defining the objectives of ML modeling in our system. We identify specific aspects of urban mobility that we wish to address, such as predicting optimal routes, traffic management, or improving the user experience. This phase guides the whole design process.

In the second step, we proceed with data collection and preparation. This crucial step involves selecting relevant data sources, cleaning the data to remove inconsistencies and outliers, and preparing the data to make it usable by ML models. Data quality plays a central role in the overall system performance, hence the interest in the semantic layer which will be used to unify the data and solve the interoperability problem [13].

The third step refers to the model selection. Depending on the defined objectives and the characteristics of the data, we choose the most suitable ML algorithms. This selection may vary depending on specific requirements, such as route classification, travel time prediction, or other aspects related to urban mobility.

Model training and evaluation represent an iterative phase, where we adjust the model parameters based on observed performance. This involves using techniques such as cross-validation to ensure model generalization to new data. The design methodology for the Machine Learning (ML) part of our system is not limited only to prediction and optimization but also extends to user experience personalization through user profiling and feedback collection [10].

The implementation of Machine Learning (ML) in our urban mobility system relies on the use of several algorithms, each tailored to specific aspects of personalization, prediction, and optimization. The Machine Learning algorithms presented in this section are classified into three main categories as shown in the Fig. 1 below: supervised learning, unsupervised learning, and reinforcement learning. This classification organizes these approaches based on their methodologies and respective objectives, thus providing a structured foundation for understanding how these algorithms contribute to the design and improvement of our multimodal information system based on agents.

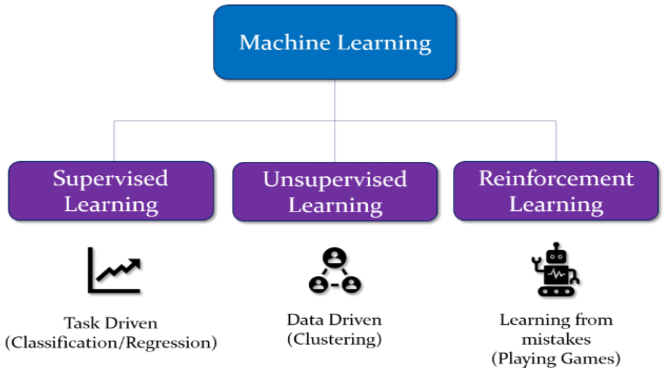

Fig. 1. Machine learning algorithms.

Among the Supervised Learning algorithms, we find:

- Decision Trees: Decision trees are used to model users' choices based on various characteristics. For example, a decision tree could determine what type of transportation a user prefers based on factors such as duration, cost, and safety. These models can be used, in our context, to understand user decision patterns and guide route recommendations accordingly.

Among the Unsupervised Learning algorithms, we find:

- K-Means: The K-Means algorithm is applied to group users into homogeneous clusters, thus identifying similar travel profiles. For instance, this algorithm could help us segment users into clusters to personalize route recommendations based on shared preferences within each group.

Among the Reinforcement Learning algorithms, we find:

- Reinforcement Learning: Reinforcement learning is used to improve the system over time by adjusting recommendations based on user feedback. In our case, considering the rewards and penalties of past route choices, the system adapts to provide more personalized suggestions.

This diversity of approaches allows our system to adapt to the various nuances and complexities of user preferences regarding urban mobility. Thus, in our approach to implementation, we will opt for the k-means algorithm for user classification and segmentation. The Decision Trees algorithm will be used for data learning, thus guiding route recommendations based on user preferences. Concurrently, the reinforcement learning algorithm will be implemented to adapt the system, offering personalized suggestions to each user.

User feedback collection is integrated into the process proactively. Mechanisms are put in place to solicit user feedback on their travel experiences. This feedback is then analyzed using ML models, allowing us to understand changing preferences, anticipate user needs, and continuously improve the service. This entire methodology of profiling and feedback collection using ML aims to create a personalized user experience while providing valuable data for decision-making in our multi-agent system dedicated to urban mobility. The process of profiling and feedback collection using machine learning (ML) is essential for creating a personalized user experience within our multi-agent system dedicated to urban mobility. This process combines the use of user profiling techniques and feedback data collection to optimize interaction between the system and users, while providing valuable insights for decision-making.

- User Profiling: The system collects data on user behavior, such as route preferences, preferred modes of transport, preferred schedules, and other relevant data.

- Feedback Collection: Interactive feedback mechanisms are integrated into the system, allowing users to express their preferences, provide feedback on routes, and rate their overall experience.

- Personalization of User Experience: Using user profiles and feedback information, the system adapts its route recommendations, thus offering a more personalized user experience in line with individual preferences.

- Enhanced Decision-Making: Data from profiling and feedback collection provide crucial information for decision-making in the multi-agent system. This information can be used to adjust recommendation policies, optimize routes, and overall improve service quality.

By integrating profiling and feedback collection through machine learning, our system aims to create a more intuitive and personalized interaction with users, while fueling a virtuous cycle of continuous improvement based on user feedback.

Finally, the implementation of the model in our multi-agent system is carried out in a way that ensures smooth integration with other components, especially the semantic layer and the agents responsible for decision-making. Our ML design methodology is centered on rigor, adaptability, and continuous optimization to ensure high performance in solving urban mobility-related problems.

### C. Evolution of the Multi-agent System Architecture for Multimodal Transport

Our previous work [14, 15] has already presented the overall architecture of our multi-agent system for multimodal transport. However, this proposed architecture does not include the integration of the ML component, hence the interest in setting up an evolution of this architecture to include all the components of our system.

A major evolution of our architecture will be the subject of this section and will consist of integrating a dedicated Machine Learning agent, responsible for providing personalized recommendations to each user. This ML agent, now an integral part of our multi-agent system, will play a central role in refining travel needs. By leveraging extensive data on user history, this new agent will be able to analyze trends and individual preferences. Its ability to identify complex behavioral patterns will allow it to suggest alternative routes, thus refining the initial proposal based on each user's specific preferences. This fusion of agent intelligence and the expertise of the new ML agent aims to offer an even more precise, responsive, and tailored urban mobility experience to the evolving needs of each user.

By integrating a dedicated Machine Learning agent, our goal is to go beyond mere feedback collection by establishing a dynamic process of analysis and adaptation. This ML agent, by examining user feedback, will be able to assess customer satisfaction more thoroughly and discern subtle trends in their preferences.

The introduction of our new ML agent marks a significant advancement in our architecture, promising a more sophisticated interaction with the multi-agent system. By leveraging emerging patterns from user history, this ML agent will be able to suggest alternative and tailored routes, thus refining decision-making based on each user's specific preferences. The quality and quantity of the collected data will play a crucial role in the ML agent's ability to develop insightful and relevant travel suggestions. Thus, the establishment of a robust data collection procedure becomes a strategic element, allowing our ML agent to fully leverage available information to offer highly personalized and relevant travel suggestions.

From the PTA agent, we retrieve the initial parameters set by the user, namely the choice of modes of transportation, preferences in terms of time, cost, safety, and number of connections, as well as navigation data, including details of the routes taken. These data are then stored in a MongoDB collection. The ML agent then processes this data and performs its learning model in order to provide new route recommendations and classify each user according to their profile. This process is illustrated in Fig. 2.

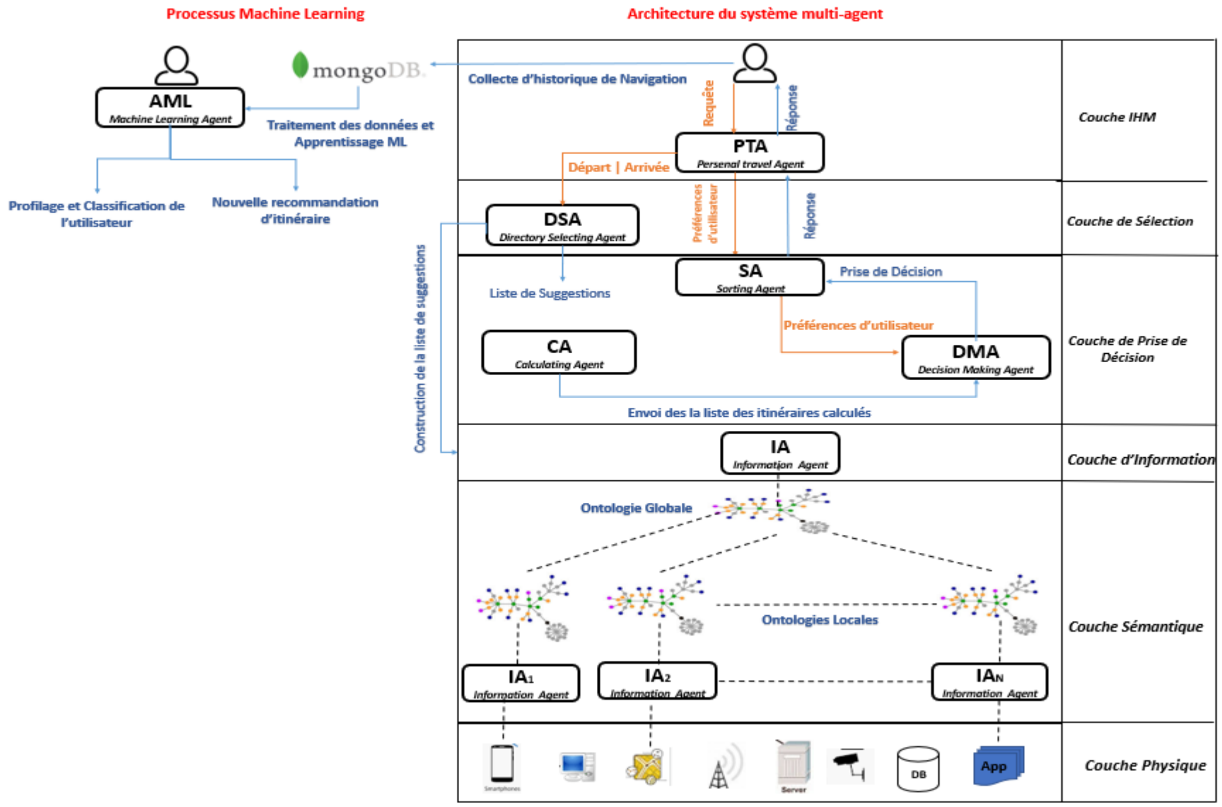

Fig. 2. New Multi-agent System Architecture including ML agent for urban mobility.

## IV. ML Algorithms Implementation in the Multimodal Information System

In this section dedicated to the implementation of our solution in the multimodal information system, we will specifically focus on the integration of Machine Learning (ML) techniques to enhance our approach. We will delve into detail on how these algorithms are applied to improve service personalization, user profiling, feedback collection, and ultimately, how they contribute to informed decision-making in the field of urban mobility. The goal is to demonstrate how ML methods can be valuable assets in optimizing the user experience and providing smarter route recommendations in our multimodal information system.

We reiterate that our methodological approach relies on the integration of three Machine Learning (ML) algorithms within our multimodal information system. We will begin our implementation with the reinforcement learning algorithm, focused on analyzing user history to enhance route recommendations [11]. Indeed, the reinforcement learning algorithm is used to train an agent to make decisions in an environment to optimize performance. In parallel, utilizing the Decision Tree algorithm will allow us to gain deep insights into user behavior in the context of urban mobility. Lastly, we will implement the K-means algorithm on a representative sample of 500 users to segment the population into distinct clusters, thus fostering a more personalized approach in our route recommendations. This progressive approach aims to leverage the advantages of each algorithm to optimize the user experience in our system.

### A. *Data Collection Process*

The comprehensive approach used in the data collection process aims to understand user behavior by analyzing their browsing history. User preferences in terms of time, cost, security, and connections are also considered. This approach enables the creation of detailed profiles for each user, thereby contributing to service personalization.

Data collection also includes an analysis of the routes chosen by users, including any modifications made along the way. These diverse data are consolidated to create a solid foundation for the development of an intelligent and adaptive urban mobility system.

The collected data, stored in MongoDB collections, are organized flexibly to allow for precise retrieval. Once captured, these data are used as a crucial resource for machine learning algorithms. The goal is to provide a personalized, responsive, and efficient urban mobility experience by optimizing recommendations and dynamically adjusting the system according to evolving user preferences.

Information regarding each user's past route choices has been collected and recorded in a structured manner. This includes details such as the routes taken, transport preferences, starting and ending points, schedules, etc. These data are stored in MongoDB collections that allow retrieval of the following information for each user: below is an example of a MongoDB collection structure for storing user navigation history and preferences. This collection is created in JSON format, encompassing all user journey information.

In the example illustrated in Fig. 3, we have:

- Each user is identified by a "userID."
- Navigation history is stored as an array "history," where each journey is represented by a document with details such as the departure location, arrival location, time, mode of transport, cost, duration, number of connections, security, and frequented zone.
- User preferences are stored in a "preferences" document, assigning weights to each criterion (time, cost, connections, security).
- Frequented zones are listed in a "frequentZones" array.
- The user's activity time is recorded with start and end times to have an idea of the busiest hours.

This organization allows for efficient retrieval of user-specific information. These rich data will serve as raw material for the future machine learning algorithms that we plan to implement.

### B. *Application of the Reinforcement Learning Algorithm*

The reinforcement learning algorithm constitutes a central pillar of our approach, focusing particularly on the in-depth analysis of user history to refine route recommendations. By utilizing the data stored in MongoDB collections, the algorithm explores users' past choices, examining previously taken routes, preferred modes of transportation, as well as adjustments made based on individual preferences [12].

This analysis process enables the reinforcement learning algorithm to discern significant behavioral patterns. By learning from past experiences, the algorithm can assign rewards or penalties to certain actions or routes, thus contributing to the refinement of future recommendations. For example, if a user prefers shorter routes with fewer transfers, the algorithm will adjust its recommendations accordingly, favoring routes that meet these specific criteria.

A thorough analysis of historical data is conducted to identify behavioral patterns, recurring preferences, and individual user trends. This step allows for insights into past choices. To accomplish this modeling, it is important to define an agent, states, actions, the environment, as well as the reward for each action maintained, as illustrated in Fig. 4.

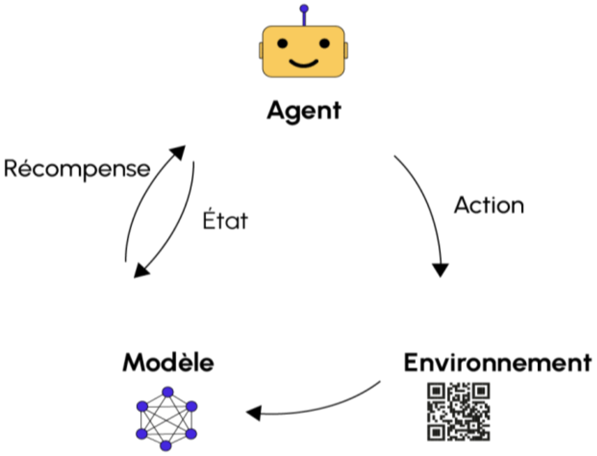

Fig. 4. Reinforcement algorithm modeling.

Based on the identified behavior models, the reinforcement algorithm has been developed. It utilizes historical data to dynamically adjust the weights of criteria in route recommendations, giving more importance to aspects preferred by each user. The development of the reinforcement algorithm involves the practical implementation of agent logic and interactions with its environment. In our urban mobility context, the reinforcement algorithm aims to recommend personalized routes based on the user's past actions and the evolution of the environment. The approach aims to leverage these histories to dynamically adjust route recommendations, paying particular attention to recurring choices and emerging user preferences. In essence, this approach is based on the idea that users' past decisions can provide valuable insights into their future preferences. Thus, by understanding and modeling these behaviors, the reinforcement algorithm contributes to further personalizing route suggestions, thereby enhancing the overall user experience of the multimodal system.

### C. Application of the Decision Tree Algorithm

In this section, we will delve into the application of the Decision Tree algorithm within our multimodal transportation information system dedicated to urban mobility. The main objective is to better understand the decision-making patterns of users when they choose their routes by identifying the key factors that influence these choices.

The Decision Tree algorithm is a supervised learning method that is well-suited for analyzing complex decisions. By successively dividing the data into subsets based on specific features, this algorithm allows for easy visualization and interpretation of decision-making processes. The Decision Tree algorithm, or decision tree, is a supervised learning method used in the field of artificial intelligence. Its main objective is to model decision-making by creating a tree-like structure based on specific criteria. This decision tree allows for a clear and hierarchical visualization of the different possible decision paths based on the data characteristics. The main concepts associated with the Decision Tree algorithm are illustrated in Fig. 5.

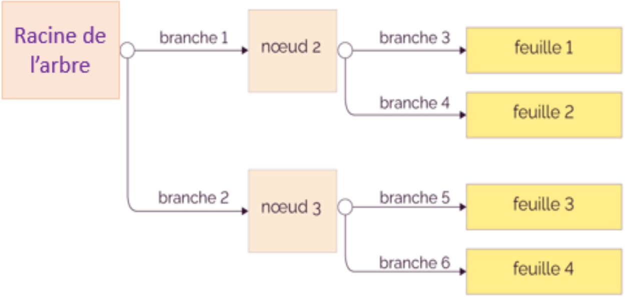

Fig. 5. Representation of the modeling of the decision tree algorithm.

Root Node: The initial division of data based on the criterion that maximizes the separation of classes.

Internal Nodes: Decision points in the tree that determine the next feature to evaluate.

Leaves: Terminal nodes of the tree representing classes or predicted values.

Branches: Paths between nodes, indicating how the data is segmented.

Splitting Criteria: Features guiding the division of data at each node.

Building the decision tree is a key step in applying the Decision Tree algorithm to model user behavior in urban mobility. Here's how this step was carried out:

Selection of Root Node: The algorithm begins by selecting the feature, at the root node, that divides the dataset into the most homogeneous subsets in terms of user behavior. The chosen feature at this stage is the one that provides the most information for decision-making. In our case, we set the feature as the choice of transportation method (bus, tram, etc.), with criteria such as availability, frequency, cost, security, travel duration, and number of transfers for each mode of transport.

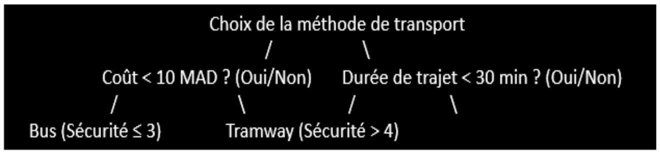
Data Set Division: Once the feature is selected, the dataset is divided into subsets based on the possible values of this feature. Each subset is associated with a branch from the root node. In our case, we separated the data into subgroups for each mode of transport based on the following splitting criteria: Frequency of use, availability, security, pricing, travel duration, and number of transfers.

Process Repetition: The division process is repeated for each child node, selecting the most informative feature each time to split the current subset. This process continues until a stopping condition is met, such as a maximum number of levels in the tree or sufficient purity of the subsets. In our case, the features for Child Nodes are the specific line choices for each mode of transport, and for criteria, we have average travel time, serviced stations, security, cost, and number of transfers.

Class Assignment: Each leaf of the tree represents a class or final decision. The examples in each leaf share similar characteristics and are grouped based on these similarities. These classes can be interpreted as user behavior segments. In our case, the defined classes depend on different user segments based on transportation preferences. Examples of Classes: “Users preferring tram for safety and speed”, “Users opting for express bus due to lower cost”.

Validation and Adjustment: Once the tree is built, it is typically validated using separate data to assess its generalization ability. If necessary, adjustments can be made to optimize the model's performance. To validate the model in our case, we used a separate dataset to evaluate the predictive performance of the tree. Following this evaluation, we adjusted the model by adapting some parameters, such as the depth of the tree, to optimize generalization.

The diagram in Fig. 6 below provides a simplified example of a decision tree schema for modeling user behavior in the context of urban mobility. We consider criteria such as security, cost, travel time, and number of transfers. Note that this is an abstract representation, and the criterion values may vary depending on the data.



Choix de la méthode de transport
Coût < 10 MAD ? (Oui/Non)
Durée de trajet < 30 min ? (Oui/Non)
Bus (Sécurité ≤ 3)
Tramway (Sécurité > 4)

Fig. 6. Representation of the decision tree algorithm.

In this representation, if the trip cost is less than 10 MAD and the travel duration is less than 30 minutes, the user may choose the bus if security is moderate (security rating ⩽ 3) or the tram if security is high (security rating > 4). In this context, we identify two types of users: "*Users preferring the tram for safety and speed*" and *"Users opting for the bus due to lower cost."*

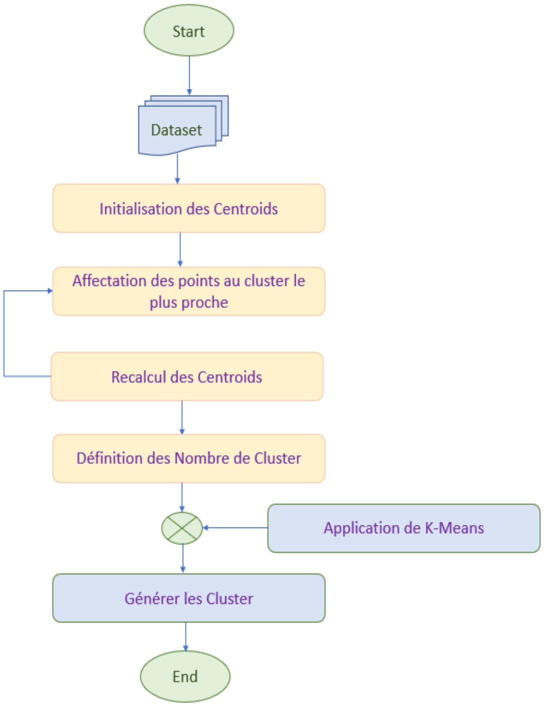
In conclusion of the Decision Tree algorithm application, we have successfully modeled user preferences in urban mobility. By understanding the criteria influencing their choices, such as safety, speed, and cost, we are better equipped to personalize route recommendations and enhance the experience of each user.

### *D. Application of the K-Means Algorithm*

The K-means, also known as the centroid-based clustering algorithm, is a method of unsupervised machine learning. Its main objective is to divide a dataset into several clusters, where each cluster is represented by a central point called a centroid. The algorithm assigns each data point to the cluster whose centroid is closest to it, minimizing the sum of squared distances between the data points and their respective centroids.

In the context of urban mobility, applying K-means to our user data will allow us to group travelers with similar behaviors. These behaviors may include specific preferences such as preferred mode of transportation, frequent travel times, visited geographical areas, etc. By segmenting users meaningfully, we can better understand the different profiles within our system.

The K-means algorithm is a clustering algorithm that aims to partition a dataset into K clusters, where each cluster is characterized by its center of gravity, called a centroid. The number of clusters K is a parameter that the user must specify before applying the algorithm. The principle of the K-means algorithm can be summarized in several steps as illustrated in Fig. 7.



Start
Dataset
Initialisation des Centroids
Affectation des points au cluster le plus proche
Recalcul des Centroids
Définition des Nombre de Cluster
Application de K-Means
Générer les Cluster
End

Fig. 7. K-Means algorithm steps.

In the context of our analysis, we utilized the elbow method to determine the optimal number of clusters (k) in the context of multimodal transportation and urban mobility. The results indicate that the elbow of the inertia cost graph was identified around k=3. This suggests that three clusters appear to be the optimal number to segment user data based on their preferences, behaviors, or characteristics related to urban mobility. Each cluster could represent a distinct group of users sharing similarities in their choices of transportation modes, preferred routes, or other relevant criteria. Thus, with k=3, we are able to better understand the diversity of user behaviors in the context of multimodal transportation, which can then guide the customization of services and recommendations to more accurately meet the specific needs of each identified group. Therefore, the implementation of the K-means algorithm in our context resulted in three different clusters. In the following chapter, we will examine the results of this experimentation in detail, including the types of clusters and the characteristics identified for each profile type.

## V. Experimentation and Results

This section is dedicated to analyzing the results obtained from the application of key algorithms in our system, while providing an in-depth insight into trends, behaviors, and user preferences regarding urban mobility. These results not only strategically group users but also shed light on how this information can be leveraged to improve system efficiency and respond more personally to the needs of each user.

### *A. Result of Applying the Reinforcement Learning Algorithm*

The reinforcement learning algorithm, based on each user's navigation history, provides the system with deep insights into the preferences and travel behavior of each individual. This thorough understanding of the user serves as a solid foundation for subsequent steps, including the application of k-means and the decision tree algorithm. Using a sample of 500 users, the reinforcement learning algorithm was able to categorize the types of navigation histories as follows:

*1) Fast profile:* This type of user prioritizes the fastest routes and prefers express modes of transportation and direct routes. From these results, we observed that this type is less sensitive to costs and transfers.

*2) Economic profile:* This type of user prioritizes the most economical routes and favors routes with reduced costs, even if they involve longer travel times. They may also opt for cheaper modes of transportation.

*3) Balanced profile:* This type of user seeks a balance between cost, duration, and comfort. They accept moderate travel times for balanced routes and also have moderate sensitivity to costs and travel times.

*4) Cautious profile:* This type of user places great importance on safety by avoiding risky areas, even if it means taking detours. They may choose safer modes of transportation, even if they are slightly more expensive.

These profiled pieces of information will then be used in the classification process with k-means and the decision tree, allowing for a more tailored customization of route recommendations for each user.

### *B. Result of Applying the Decision Tree Algorithm*

The results interpreted in this section are based on the data collected from 500 users in an urban mobility system, including information on estimated travel time, associated cost, and route choices. To explore the results, we will first follow the modeling process of the decision tree algorithm according to the following steps:

*1) Data collection:* We have a dataset with examples of users. We remind that data collection is done through a JSON file from the MongoDB collection. MongoDB is used as a database to store user information, including their navigation history, preferences, activity hours, frequented zones, etc. The data stored in this MongoDB database is then used for training the decision tree model and other machine learning algorithms. In the example below, we present only (see Table I) a sample proposal made by the system to represent the results:

TABLE I. Sample Data for Decision Tree Application

| Travel Duration | Cost | Safety on a scale of 1 to 5 | Route Choice |
|---|---|---|---|
| 20Min | 5 | 1 | A |
| 30Min | 8 | 2 | A |
| 25min | 6 | 1 | B |
| 35min | 10 | 3 | B |

*2) Creation of the decision tree:* Root of the Tree: Division based on the estimated travel duration.

- Internal Node 1: Division of trips under 30 minutes.
- Internal Node 2: Division of trips with a perceived safety of 4 or more.
  - Leaf 1: Prediction "A" for the route.
  - Leaf 2: Prediction "B" for the route.
- Internal Node 3: Division of trips with a perceived safety of less than 4.
  - Leaf 3: Prediction "B" for the route.
- Internal Node 4: Division of trips of 30 minutes or more.
  - Leaf 4: Prediction "B" for the route.
  - Leaf 5: Prediction "A" for the route.

*3) Detailed interpretation:* We added a division based on the number of transfers at each internal node. The second internal node divides trips with a perceived safety of 4 or more based on the number of transfers. The third internal node divides trips with a perceived safety of less than 4 based on the number of transfers. According to the results obtained on the types of decisions made by users "Users preferring the tramway for safety and speed," "Users opting for the express bus due to lower cost," here is the interpretation:

Users preferring the tramway for safety and speed: We identified a group of users through the application of the Decision Tree algorithm who attach great importance to safety and speed when choosing their mode of transportation.

Users opting for the express bus due to lower cost: We identified a segment of users through the application of the Decision Tree algorithm for whom cost is a determining factor in the choice of mode of transportation. The model's decisions indicate that these users are directed towards the bus, which is probably associated with lower costs compared to other modes of transportation.

In summary, these interpretations highlight the specific preferences of certain user groups regarding criteria such as safety, speed, and cost. This information is crucial for customizing route recommendations and improving the user experience in the urban mobility system.

*4) Model evaluation:* Evaluating a decision tree model typically involves using a separate dataset called a test set.

This test set consists of data that the model has not seen during its training. Here's how it could be done:

Test Set: A separate dataset from the training set, usually around 20 to 30% of the total data, is reserved for evaluation.

Prediction on the Test Set: The decision tree model is used to predict route choices on this test set.

Comparison with True Values: The model's predictions are compared to the actual route choices of the test set.

Evaluation Metrics: Different metrics can be used, such as accuracy (the percentage of correct predictions), confusion matrix, recall, precision, etc.

This allows the model trained on a sample to make predictions on new cases, thus contributing to customizing route recommendations based on user preferences and characteristics. This approach would take into account the number of transfers in addition to travel duration, cost, and perceived safety to understand user route choices in an urban mobility context.

### C. Result of Applying the K-Means Algorithm

The application of the K-Means algorithm in the context of urban mobility has generated significant results that help to better understand user behaviors and preferences regarding transportation. The clusters obtained represent distinct groupings of users based on their criteria for route selection, such as travel time, cost, number of transfers, safety, etc. These results play a crucial role in personalizing route recommendations, thereby contributing to an optimized user experience tailored to each profile.

Using a sample of 500 users with various characteristics associated with their travels and navigation history, we applied the K-Means algorithm to group these users into clusters based on these characteristics. On the same dataset presented previously, we present a proposal made by the system to represent the results with the following features:

TABLE II. SAMPLE DATA FOR K-MEANS APPLICATION

| Users | Cost | Safety on a scale of 1 to 5 | Number of transfers |
|---|---|---|---|
| User 1 | 5 | 1 | 1 |
| User 2 | 8 | 2 | 0 |
| ⋮ | ⋮ | ⋮ | ⋮ |
| User 500 | 10 | 3 | 2 |

These data will be used for applying the k-means algorithm to group these users into three clusters as shown in Table II. We start by initializing the centroids by randomly selecting three users from the database to represent the initial centroids. Each user is described by attributes such as travel time, cost, number of transfers, security, etc. According to the elbow method applied, we obtained k=3 clusters as the optimal number of clusters for our context. The results obtained with k=3 provide a balanced representation of the different user behaviors. Then we apply our K-means algorithm, the implementation results in three distinct clusters. These clusters help understand users' travel preferences and can be used to personalize route recommendations. These clusters also classify users into three different profiles: Economic, Standard, and Premium.

Cluster 1 Economic Profile: the chosen criterion among cluster users is the lowest possible cost. These users are very cost-sensitive and are willing to sacrifice travel time, security, or the number of transfers to minimize their expenses. They prefer economical options even if it means compromising on other aspects. Generally, these users prefer to use the bus as a means of transportation.

Cluster 2 Standard Profile: These users choose criteria such as acceptable security, minimal number of transfers, flexibility in terms of time and cost. These users are moderate and flexible, seeking a balance between cost, security, and travel time. They are willing to accept acceptable security and a minimal number of transfers, while maintaining some flexibility in terms of time and cost.

Cluster 3 Premium Profile: the predominant criteria in this cluster are: minimal travel time, high security. These users are willing to pay a premium price for an optimal travel experience. They seek routes with minimal travel time and maximum security. Cost is a secondary consideration as long as the other criteria are met.

Each cluster represents a specific segment of travelers with distinct preferences, which allows for adapting route recommendations and services to meet their specific needs. These differentiated profiles will serve as a solid foundation for further personalizing route recommendations, thereby contributing to a more tailored and efficient user experience. The combination of these results reinforces the relevance of our multi-agent approach, where each agent can dynamically adapt to the specific characteristics of each user cluster, thus improving the overall management of urban mobility. The next step will be to further explore these profiles to refine recommendations and offer an even more personalized user experience.

### D. Discussion and Results Evaluation

The algorithms implemented in our system were chosen to address specific objectives, thus contributing complementarily to the overall decision-making process in urban mobility.

The primary objective of the Reinforcement Algorithm is to learn from users' past behaviors to recommend personalized routes. The Decision Tree Algorithm was implemented to understand the factors influencing users' route choices. The aim is to gain clear insights into the specific motivations guiding users' choices and to better understand and analyze the decisions made by users. The purpose behind implementing the K-Means Algorithm is the classification and segmentation of users based on their general profiles. This approach aims to simplify personalization by grouping users with similar preferences, thereby facilitating the recommendation of routes tailored to each segment.

In the same context, each algorithm has made a unique contribution to our understanding of user preferences and behaviors in the complex context of urban mobility.

- Reinforcement Algorithm: By identifying four distinct clusters, this algorithm offers detailed granularity to understand the various nuances in users' preferences. The "Prudent," "Economic," "Fast," and "Balanced" clusters enable route recommendations to be adapted according to these specific profiles.

- Decision Tree Algorithm: With two well-defined clusters, this algorithm highlights specific characteristics influencing route choices. The categories "Users preferring the tramway for safety and speed" and "Users opting for the bus due to lower cost" offer clear insights into users' motivations.

- K-Means Algorithm: By classifying users into three clusters – "Economic," "Standard," and "Premium" - K-Means offers segmentation based on criteria such as cost, speed, and safety. This approach simplifies personalization by grouping users with similar preferences.

Indeed, without the Reinforcement Algorithm, we would not benefit from a robust user navigation history. It provides an essential foundation by learning from past behaviors and creating relevant clusters, thus enabling fine personalization.

Likewise, in the absence of the Decision Tree Algorithm, our ability to understand how decisions were made by users would be limited. This algorithm offers valuable insights by identifying clusters based on specific patterns, thereby contributing to the transparency of the decision-making process.

Lastly, the integration and implementation of the K-Means Algorithm have been highly successful in classifying users into well-defined profiles. K-Means not only simplifies user segmentation by grouping those with similar preferences but also facilitates the recommendation of routes tailored to each profile.

This variety of algorithms has been carefully integrated to leverage their respective strengths, thus creating a robust system capable of adapting to individual user needs while optimizing overall urban mobility management.

By combining these approaches, our system aspires to offer a comprehensive solution that integrates fine-grained behavior-based personalization, understanding of influential factors, and global classification of user preferences. The ultimate goal is to provide route recommendations that are both effective for individual users and beneficial for overall urban mobility management.

## VI. Conclusion

The introduction of a machine learning (ML) approach represents a significant evolution. This work has constituted a deep dive into the implementation and results of machine learning algorithms, in which we have addressed the outcomes and evaluation of these different ML algorithms integrated into our system. Each of the three algorithms, namely Reinforcement, Decision Tree, and K-Means, has been meticulously applied to address specific objectives within the system.

This combination of approaches has enriched the system's ability to provide smarter and more personalized urban mobility solutions. By integrating these algorithms complementarily, we have succeeded in understanding the complexity of user preferences and dynamically adapting to their needs. As part of the system's continuous improvement, this approach enables adaptation to changing user needs and ensures efficient urban mobility management.

In conclusion, this technical achievement harmoniously blends the domains of semantics, decision-making, and machine learning to give rise to an innovative agent-based information system dedicated to the constant optimization of urban mobility.

## Acknowledgment

Jihane Larioui is a PhD student in the Laboratory of computer science and systems at Hassan II University, Faculty of Science in Casablanca, Morocco. She currently works as a Technical Business Intelligence Lead in wellknown companies. Her main current research interests concern multi-agent systems and decision-making in the context of urban mobility.

***Abstract*—Harassment is an offensive behavior, intimidating and could cause discomfort to the victims. In some cases, the harassments could lead to a traumatic experience to the vulnerable victims. Currently, the harassments towards women in social media have become more daring and are rising. The increasing number of the social media users since the Covid-19 pandemic in 2020 might be one of the factor. Due to the problem, this research aims to assist in detecting the harassment sentiments toward women in Twitter. The sentiment analysis is based on a machine learning approach and Support Vector Machine (SVM) has been chosen due its acceptable performance in sentiment classification. The objective of the research is to explore the capability of SVM in the detection of harassments toward women in Twitter. The research methodology covers the data collection using Tweepy, data preprocessing, data labelling using TextBlob, feature extraction using TF-IDF vectorizer and dataset splitting using the Hold-Out method. The algorithm was evaluated using the Confusion Matrix and the ROC analysis. The algorithm was integrated with the Graphical User Interface (GUI) using Streamlit for ease of use. The implementation of the SVM algorithm in detecting the harassments toward women was successful and reliable as it achieved good performance, with 81% accuracy. The recommendations for the SVM model improvement is to train the dataset of other languages and to collect the Twitter data regularly. The performance of SVM would also be compared with other machine learning algorithms for further validations.**

***Keywords*—Harassment; women; detection; twitter; SVM**

## I. Introduction

Sentiment analysis is a computational process of identifying and categorizing opinions from a text to extract a particular attitude or belief toward a specific topic. It works by depending on Natural Language Processing (NLP) and implementing a machine-learning algorithm that aims to classify an opinion expressing a positive or negative opinion or sentiment [1]. NLP is a design and implementation of models, systems, and algorithms used for understanding human-like language to solve problems [2]. In the rapid development of social media communities, sentiment analysis has become a hot research topic in NLP [3]. It is crucial to gain deeper insight from public opinion, especially on social media. Many people use the internet to express opinions, thus this situation enables the monitoring of public sentiment for many purposes such as analyzing customers' preferences in businesses and predicting people views or actions on certain important matters. The usage of social media has been increased since the Covid-19 pandemic due to the world wide lock down. People have been more engaged to the internet and the social media has also become the platform for distributing information, besides expressing thoughts.

Harassment covers behaviours of an offensive nature, referring to behaviours that appear to be disturbing, upsetting or threatening. Day by day, cyber harassment toward women is becoming more prevalent and needs to be taken more seriously as it could leave a traumatic impact on an individual. In order to alleviate this problem, many sentiment analysis research have been done to detect the sexual or harassment sentiment on text. The reason sentiment analysis is widely used in analyzing cyber harassment towards women is that it is a reliable and most effective method for analyzing text content. Many harassers become more active anonymously in social media, posting sexist comments and sexist jokes. During the pandemic, these kind of comments could be worst and become increasing since everybody could only meet or socialize over the internet. Sexual harassment can be found in many forms, whether verbally, psychologically, physically, gestural and visually. Exposure to sexual harassment is highly gendered, such that girls are equally or more likely to experience cross-gender harassment, while boys are more likely to experience same-gender harassment [4]. One of the barriers in reporting sexual harassment is victim-blaming, where someone places the responsibility on the victim instead of the person who harmed them. This situation causes difficulties for the victim to come forward and report the problem. This can cause negative impacts on mental health, such as inability to focus, fear, career seatback, and else.

The UN Women has reported a global rise in online harassment of women and girls since the onset of the corona virus [5]. The problem is that any people can communicate anonymously and instantaneously in the virtual world, providing the optimal climate for harassment to transpire [6]. The situations become uncontrollable over time, leading to an uncomfortable and dangerous environment especially to the vulnerable victims. Since cyber harassment towards women, especially sexual harassment cases, is proliferating due to a lack of oversight by the authorities, action needs to be taken to exterminate this behavior. Using sentiment analysis is extremely useful in social media monitoring as it allows gaining an overview of the wider public opinion behind particular topics. Hence, the sentiment analysis to detect harassment on women in social media needs to be initiated to identify harassed and hated messages sent towards women. Sentiment analysis is an ideal technique for analyzing Twitter's tweets to detect the harassment word. As the data in Twitter continues to grow over time, it becomes a suitable platform for sentiment analysis. The factor that makes Twitter a suitable platform for sentiment analysis is that it has varied from regular people, celebrities, politicians, and even companies.

This study is proposing the machine learning based sentiment classification to detect harassments toward women based on Support Vector Machines (SVM). This research is intended to classify tweets into categories, whether the tweet is “Harassment” or “Not Harassment”. SVM has been chosen for this research as the algorithm could produce results with excellent accuracy in most studies [7]. The performance of SVM has been promising in the sentiment classification problems. The main objective of this research is to explore the performance of SVM in the sentiment classification of harassments toward women based on Twitter data. The ability of sentiment analysis to distinguish positive and negative sentiments is expected to help the community and also authorities in detecting harassments toward women. Through sentiment analysis, the harassment in social media can be detected and help the authorities monitor people more closely so that harassment cases can be reduced. Thus, it brings a safer community around the world, especially to a woman.

This paper is organized into five main sections which are the Introduction in Section I, Literature Review which contains brief explanation on SVM and the similar works in Section II, Materials and Methods in Section III, Results and Discussion in Section IV and finally Section V concludes the paper.

## II. Literature Review

### A. Support Vector Machine

Support Vector Machine (SVM) is a supervised machine learning algorithm that builds a model by learning from a known class (labelled training data) [8]. SVM is mighty at recognizing a subtle pattern in a complex dataset [9]. SVM works by creating a decision between two classes to predict labels from one or more feature vectors. A boundary separates it called a hyperplane [9]. The hyperplane is oriented so that it is as far away from the closest data points from each class as possible. Support vector refers to the closest point from each of the classes. The key for the SVM algorithm is finding the correct hyperplane position to classify the class [8]. SVM can generate a model based on a small training set while ensuring lower error levels in the test. In a linearly separable class, SVM seeks a hyperplane that separates the two-class vectors, which is a positive and negative class with the greatest margin in linearly separable cases [10]. Then for more complex problems, SVM solves the problem by using additional features such as kernel trick [8]. The techniques purposely convert low dimensional input space into higher dimensional space to solve not separable problems. The data can easily be classified into different classes by using a hyperplane. SVM has many different types of kernel functions; the popular kernel functions are the linear kernel, polynomial kernel, and Radial basis function (RBF) kernel [11]. This research has been implementing the linear kernel due to its suitability with this sentiment classification problem. Support Vector Machine (SVM) is one of the most efficient machine learning algorithms [12]. A study of mobile network prediction by [13] proven that SVM does provide high accuracy in prediction.

### B. Similar Works

There are several similar works that studies harassment towards women in social media platforms. The research contains a similar objective and problem but uses a different algorithm. Table I shows similar projects comprising title, project objectives, year, the problem faced, research result and references.

Based on Table I, the first similar work is Understanding the silence of sexual harassment victims through the #WhyIDidntReport movement by [14], where the project aims to identify tweets that disclose a reason for remaining silent after sexual violence. Sexual violence has become more severe across the globe, and many women have been through this experience, urge to the need for research to support and identify the factor of sexual violence. This project used a few algorithms, and SVM outperformed with 92% precision compared to the linear kernel, Random Forest, Naïve Bayes, and Gradient Boosting.

The following project analyses #MeToo hashtagged posts on Twitter by [15]. This project objective is to analyze tweets that reveal patterns and attributes such as emotion and reaction to the hashtag #MeToo. This project is initiated to explore the topics and patterns that lead to sexual harassment. This project uses the approach of modeling aggregate words and generating issues from the particular text.

Analysis of sexual harassment tweet sentiment on Twitter in Indonesia using Naïve Bayes by [16] is the third equivalent work. This research objective is to identify positive and negative sentiment in tweets that lead to sexual harassment within social media. This study is an effort to control and monitor sexual harassment that occurs in social media since the situation leads to a severe impact such as psychological trauma and negatively affects the victims. This project used the Naïve Bayes algorithm and recorded an accuracy of 83 %.

A similar works also study the field of harassment that occurs in social media, which is a study initiated by [17]. The objective is to develop a detection system to detect sexual harassment in text. The problem that arises causes this project's need is the seriousness of the negative and traumatic impacts of cyberbullying. For this project, they used a few different algorithms for the detection. The algorithm that gives the highest accuracy is SGD. Classifier outperformed other algorithms, which are SVC, Multinomial NB, Linear SVC, Decision tree, Random Forest and KNN.

Another research aims to detect hate speech on text data and audio data. This research has implemented SVM, Random Forest (RF), Naive Bayes (NB) and Logistic Regression (LR) to identify bullying and online harassment in the cyberspace. The results have shown that SVM has outperformed other algorithms with the best accuracy of 92.3% [18].

Finally, a research in Bangladesh aims to detect sexual harassments from Bangla texts [19]. The research is motivated by the increasing improper usage of the social media. In this research, CNN-LSTM has outperformed other algorithms. However, SVM has outperformed other machine learning algorithms such as NB, RF, Decision Tree (DT), AdaBoost, SGD, LR and K-Nearest Neighbour.

Based on these similar works, SVM has shown good performance in the research by [14] and [18] with the accuracies of more than 90%. This research has chosen SVM due to its capability and also good performance in solving various other classification problems [20-22]. It is expected that SVM could also produce good results in this sentiment classification problem.

TABLE I. SIMILAR WORKS

| No | Title | Objective | Problem | Result | Ref. |
|---|---|---|---|---|---|
| 1 | Understanding the silence of sexual harassment victims through the #WhyIDidntReport movement | To identify tweets that disclose a reason for remaining silent after sexual violence. | Sexual violence has become more severe globally since many women have to go through this experience. | SVM outperform with 92% precision compared to the linear kernel, Random Forest, Naïve Bayes, and Gradient Boosting. | [14] |
| 2 | Can women break the glass ceiling?: An analysis of #MeToo hashtagged posts on Twitter | To analyze tweets that reveal patterns and attributes such as emotion and reaction relating to the hashtag #MeToo. | An uprising of online movements on social media (#MeToo) by women worldwide who started to reveal their stories of being sexually harassed along with the #MeToo. | Generates topic form tweets by directly modelling aggregate word co-occurrence. | [15] |
| 3 | Analysis of sexual harassment tweet sentiment on Twitter in Indonesia using Naïve Bayes | To identify positive and negative sentiment leading to sexual harassment | The act of sexual harassment has occurred a lot in social media nowadays. This situation causes psychological trauma and negatively affect the victims. | Reaches accuracy of 83%. | [16] |
| 4 | Sentiment Analysis-Based Sexual Harassment Detection Using Machine Learning Techniques | To propose an approach that could be utilized towards developing a detection system to detect sexual harassment in text. | The negative and traumatic impacts of cyberbullying can be severe for society and even lead to absenteeism and suicide. | SGD. Classifier gives the highest accuracy (81%) than SVC, Multinomial NB, Linear SVC, Decision tree, Random Forest, and KNN. | [17] |
| 5 | Online Harassment Detection using Machine Learning | To identify bullying and online harassment in cyberspace | Cyberbully causes mental consequences | SVM outperformed RF, NB, LR with 92.3% accuracy | [18] |
| 6 | Sexual Harassment Detection using Machine Learning and Deep Learning Techniques for Bangla Text | To detect sexual harassment from Bangla text | Increasing amount of offensive Bangla text in different social media platforms | Deep learning algorithms achieved higher accuracies. However SVM outperform other machine learning algorithms. | [19] |

## III. MATERIALS AND METHODS

The research was carried out based on six main phases, which were the data collection, data preprocessing, data labelling, feature extraction, classification based on SVM and classifier's performance evaluation. After the performance evaluation, the classifier model was integrated with the graphical user interface to be used by users. The flowchart which briefly demonstrates the system development process is given in Fig. 1.

Based on Fig. 1, the first step is the data collection which involves the scraping of data from Twitter using Tweepy. In this research, a total of 2522 data had been collected and processed. The scraped data or the raw dataset is saved in the CSV file. The raw data is then imported into Google Colaboratory to be preprocessed and transformed into the appropriate form. There are a few steps in the data preprocessing phase which are the duplicate data removal, case conversion, URL removal, punctuation removal, hashtag removal, short word removal, tokenization, stop word removal, POS tag labeling and finally the lemmatization. The following phase is data labeling by using TextBlob. Data will be labelled as positive or negative in this phase.

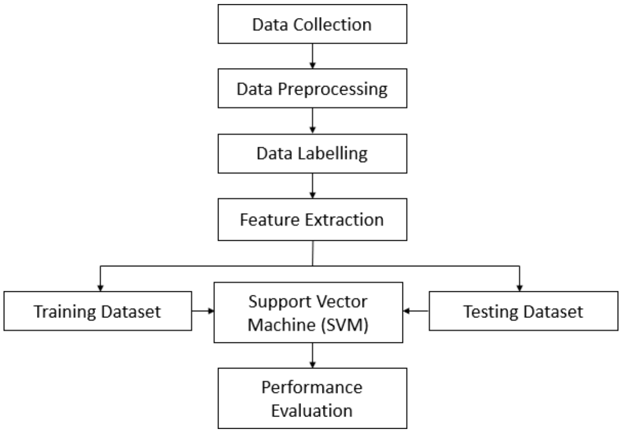

Fig. 1. Flowchart of system development process.

In the feature extraction phase, the dataset will undergo vectorization using TF-IDF. This process enables the dataset to be converted to the format readable by SVM. Then, the dataset will be split into the training and testing dataset using the hold-out method. The dataset will be split into three ratio splits and the best results will be recorded. The performance evaluation phase measures the performance of SVM based on the Confusion Matrix accuracy, recall, precision, F1-Score and also the AUC (Area under the Curve) value. Parameter tuning is to be done in this phase in order to obtain the best SVM model. Fig. 2 shows the system's architecture which demonstrates the system's overall process starting from the data collection until the SVM model usage by the user. The sentiment classification system will produce the output of “Harassment” or “Not Harassment” based on the user input.

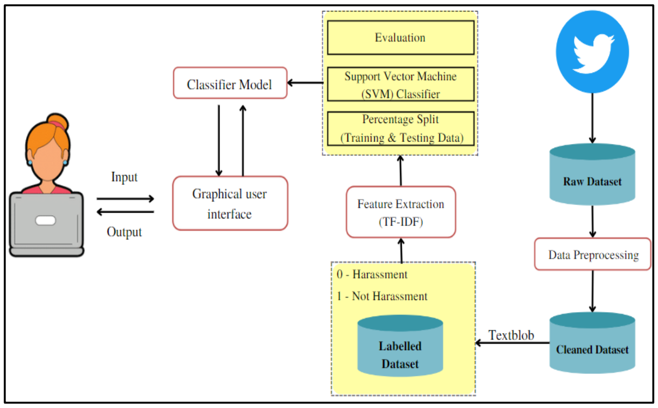

Fig. 2. System architecture design.

## A. *Data Collection*

The data in this research was scrapped using the Twitter Application Programming Interface (API) during the month of March to August 2022. During this time, the world was still in the Covid-19 pandemic. A total of 2522 rows of tweets were scrapped using the Tweepy package. Tweepy is a python library that allows users to access Twitter API. Data collection was done by using eight different keywords, which were #isthisok, #metoo, slut, stupid women, women abuse, women bad, women weak and women whore. These harassment-related keywords were used to get the harassment sentiments as much as possible to train the prototype.

## B. *Data Pre-processing*

The data extracted from Twitter API are unstructured and not uniform. This process is important to ensure reliable and accurate results can be obtained. Reference [23] stated that Pre-processing techniques are used on the target data set to minimize data size and hence boost the system's efficiency. Fig. 3 shows the steps of data preprocessing which include seven stages.

Based on Fig. 3, the first phase is to remove the duplicated data in order to avoid the inconsistent in the prototype developed. Then, the data will undergo the lowercase conversion so that it would be easier to be process. It aids in the maintenance of the consistent flow during NLP activities nd text mining [24]. Afterwards, any URL and links from the dataset will be removed since it is not needed, besides its existence will disturb the efficiency of the prototype developed. This is followed by removing the Twitter handles (@) and punctuation to minimize the data size and increase efficiency.

The next phase is the tokenization and stop word removal. Tokenization is the process of breaking down a raw string into meaningful tokens. The string will be split by referring to non-letter characters such as space, commas, full-stop and other punctuation [25]. The next process is the stop word removal, in which this process eliminates irrelevant words from the dataset in order to provide intelligent patterns or information [25]. After the text is tokenized into words, the word is analyzed one by one using a loop. If that particular word is detected as a stop word, it is removed to save computing time. Natural Language Toolkit (NLTK) can be used to implement the process of stop word removal. NLTK has a pre-built collection of stop words for about 22 languages [26]. The word that matches the word from the NLTK corpus will be removed during the loop. Then, the tokenized word undergoes POS-Tag labelling to label each word to the appropriate part of speech (POS). Part of speech includes nouns, verbs, adverbs, adjectives, pronouns and conjunction. This step differentiates the meaning and weight of every word context. This phase is important because sometimes the same word holds a different importance in different sentences.

The last phase of data preprocessing is the lemmatization. Lemmatization is a process of text normalization in order to maintain uniformity. There are two options for text normalization which are stemming and lemmatization. Stemming is a process that stems the words to its roots by removing the suffixes within the word [26]. While lemmatization is the process of removing inflectional ends from a word and returning the base or dictionary form without changing its meaning [27]. However, lemmatization produces more relevant results compared to stemming [28]. The result generated by lemmatization is a real term in English because it uses corpus to match root forms, which makes it more accurate. Hence, lemmatization is used for text normalization in this research for a better result in classification. Fig. 4 shows the example of the cleaned dataset. During preprocessing phase, the number of data was reduced from 2522 to 1558 after the preprocessing.

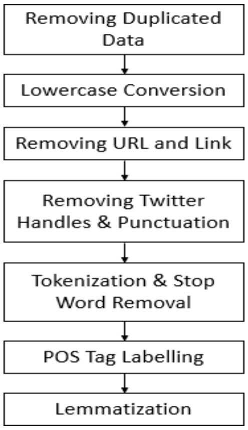

Fig. 3. Pre-processing steps.

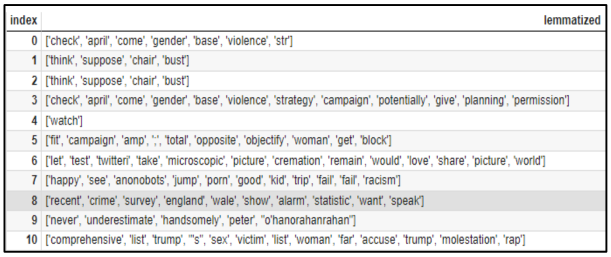

| index | lemmatized |
|---|---|
| 0 | ['check', 'april', 'come', 'gender', 'base', 'violence', 'str'] |
| 1 | ['think', 'suppose', 'chair', 'bust'] |
| 2 | ['think', 'suppose', 'chair', 'bust'] |
| 3 | ['check', 'april', 'come', 'gender', 'base', 'violence', 'strategy', 'campaign', 'potentially', 'give', 'planning', 'permission'] |
| 4 | ['watch'] |
| 5 | ['fit', 'campaign', 'amp', ':', 'total', 'opposite', 'objectify', 'woman', 'get', 'block'] |
| 6 | ['let', 'test', 'twitteri', 'take', 'microscopic', 'picture', 'cremation', 'remain', 'would', 'love', 'share', 'picture', 'world'] |

| 8 | ['recent', 'crime', 'survey', 'england', 'wale', 'show', 'alarm', 'statistic', 'want', 'speak'] |
| 9 | ['never', 'underestimate', 'handsomely', 'peter', "o'hanorahanrahan"] |
| 10 | ['comprehensive', 'list', 'trump', "'s", 'sex', 'victim', 'list', 'woman', 'far', 'accuse', 'trump', 'molestation', 'rap'] |

Fig. 4. Example of cleaned dataset.

### C. *Data Labelling*

The tweets that were extracted from the Twitter do not have corresponding labels [28]. Therefore, the data or tweets need to be labelled before they can be used for training and testing. The APIs that has been used for data labelling was Textblob. Textblob is a Python package for text processing and provides a straightforward API for exploring NLP tasks. Textblob uses Parts-of-Speech (POS) for sentiment labelling [29]. Support Vector Machine (SVM) model performs better when using labels provided by Textblob than other APIs, which are Vivekn, Meaning Cloud and Pattern [30]. Therefore, Textblob was used for data labelling for this research project. The polarity score is as shown in Table II.

This project aims to develop a binary classifier model that only classifies two possible outcomes, whether “Harassment” or “Not Harassment”. Therefore, only two class labels are needed to train the classifier model. Due to the reason, sentiment detected as neutral will be removed from the dataset to avoid misdetection. After the neutral sentiment text has been removed, the original number of data has been reduced from 1557 to 1192.

TABLE II. RANGE OF POLARITY

| ***Polarity*** | ***Sentiment Class*** |
|---|---|
| More than 0 | Not Harassment (positive) |
| Less than 0 | Harassment (negative) |
| 0 | Neutral |

### D. *Feature Extraction*

Before the model development, text or word must be converted into the numerical representation which could be understood by SVM to be processed. In this phase, the text words will be converted into numerical vectors. The feature extraction technique that will be implemented is the TF-IDF (Term Frequency-Inverse Document Frequency). TF-IDF is a numerical measure meant to indicate the importance of a word to a document in a certain corpus [31]. A study by [22] shows SVM that uses TF-IDF as a feature extraction technique generates a good and reliable classification result. There are 3 calculations in order to get the numerical presentation of each word which are Term Frequency (TF), Inverse Document Frequency (IDF) and TF-IDF score. Firstly, the Term Frequency (TF) value is calculated using (1). TF represents the frequency of a word in a tweet. The number “n” indicates the number of times that phrase appears in the document.

$$\text{TF} = n \,/\, \text{Number of term in the document} \tag{1}$$

Then, Inverse Document Frequency (IDF) reflects the frequency on which a term appears in a corpus of tweets. Eq. (2) is used to calculate the IDF value.

$$\text{IDF} = \text{No. of documents} \,/\, \text{No. of document with term ‘t’} \tag{2}$$

The last one is to calculate the number TF-IDF score for each word using Eq. (3). Words with a higher score are considered more significant, whereas those with a lower score are considered less essential.

$$\text{TFIDF} = TF\ x\ IDF \tag{3}$$

For each new word inserted to the corpus, it will loop to find the word variable in the corpus and calculate their vector value. If the word variable is not found, the TF-IDF vectorizer will recalculate the corpus to find the value of vector for that word. This process continues until all line of data in that dataset is vectorized. The number of column or word variables produces in this phase was 3982.

### E. *Dataset Splitting*

After the data has been vectorized using the TF-IDF, the dataset has been split into two datasets which are the training and the testing dataset. The training dataset was used to train the SVM classifier model, while the testing dataset was used to evaluate the performance of the classifier. The method used to split the dataset was the hold-out method. The hold out method is a method that permanently splits the data into certain percentages. This approach was chosen because it was efficient and easier to implement. In this research, the split ratio was set to 3 splits, which were 90:10, 80:20 and 70:30. 10.

### F. *SVM Implementation*

In this research, after the dataset has been trained and tested, the codes has been deployed as the SVM classifier model. Fig. 5 shows the phases of the SVM implementation in this research. The following sections will explain the process of implementation of SVM.

*1) Applying SMOTE to training dataset:* SMOTE (Synthetic Minority Oversampling Technique) is a process of handling imbalance dataset by duplicating the minimum data. The labelled data used for training were not balanced, where the dataset contains 498 negative data and 455 positive data. In this case, the positive data was duplicated until it reaches the same value as negative data which was 498. If the imbalanced data is not handled, it can cause bias situation where the classifier always go to the origin, which means the classifier cannot perform the classification efficiently.

Creating Kernel Matrix: Kernel matrix is a set of mathematical functions that is used in SVM. It takes the dataset as training dataset and transforms the data into required form to be learnedby SVM algorithm.

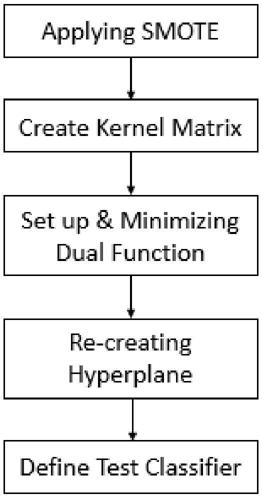

Fig. 5. SVM implementation phases.

*2) Set up and minimizing dual function:* Setting up and minimizing dual function are done by applying cvxpy package. This is to express complex optimization problem from previous stage into a readable form, so that the solver is able to translate the problem into support vector. In this phase, the value support vector is calculated, higher value indicates the point is more important as a support vector. Support vector is a point used to represent the data. Then it is classified to positive or negative using default hyperplane. This model development used linear SVM and utilized Eq. (4) to classify the weight of support vector.

$$k( X1, X2 ) = X1 \text{ x } X2 \qquad (4)$$

*3) Re-creating hyperplane:* This section is used to recreate the hyperplane or boundaries to effectively classify the support vector. If this phase is ignored, the default hyperplane that has been created in previous phase will be used for classification which is not effective.

*4) Define test classifier:* In this phase, the classifier will classify each data in the dataset and the results of classification are compared with the original labels from Textblob. The accuracy of the system is determined by comparing the total of correct calculation.

### *G. Performance Evaluation*

Performance evaluation is necessary to see whether the system is fulfilling the objectives and shows an effective classification. The performance metrics used in this research are the Classification Report, Confusion Matrix and the ROC curves. Classification report and Confusion Matrix show the value of accuracy, recall, precision and F1-score. Eq. (5) is used to calculate the classifier's accuracy, Eq. (6) calculates the precision and Eq. (7) calculates the recall value. TP represents the True Positive, TN is the True Negative, FP represents the False Positive and FN is the False Negative.

$$\text{Accuracy} = (TP + TN) / (TP + TN + FP + FN) \qquad (5)$$

$$\text{Precision} = TP / ( TP + FP ) \qquad (6)$$

$$\text{Recall} = TP / ( TP + FN ) \qquad (7)$$

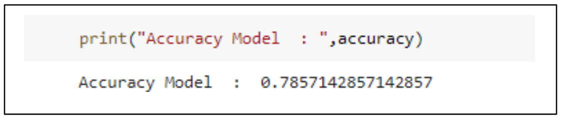
Eq. (8) calculates the F1-score, which is the value of the weighted average of precision and recall and it is almost the same as accuracy.

$$\text{F1-Score} = 2(( \text{Recall x Precision} )/( \text{Recall} + \text{Precision})) \qquad (8)$$

ROC curves is use to illustrate and evaluate the effectiveness of a classification algorithm. Rather than providing only values, it provides graphical representation of the classifier's performance [32]. The performance of classifier is measured by observing the value of AUC (area under ROC curve). The greater the AUC number, the better the classifier's performance (between 0.5-1.0).

## IV. Results and Discussion

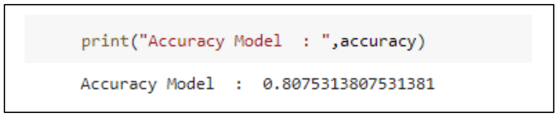
This section reports the evaluation results which are the Classification Report, Confusion Matrix and the ROC curve. Before the training and testing phase, the data had been balanced using the SMOTE techique. Fig. 6 shows the accuracy before applying SMOTE, while Fig. 7 shows the accuracy of the model after applying SMOTE on the dataset. Based on the figures, there is quite a significant difference in the accuracy values between the model that uses SMOTE and the one which does not. The model that used SMOTE has a higher accuracy and could produce more reliable classification



```
print("Accuracy Model  : ",accuracy)

Accuracy Model  :  0.7857142857142857
```

Fig. 6. Accuracy before SMOTE implementation.



```
print("Accuracy Model  : ",accuracy)

Accuracy Model  :  0.8075313807531381
```

Fig. 7. Accuracy after SMOTE implementation.

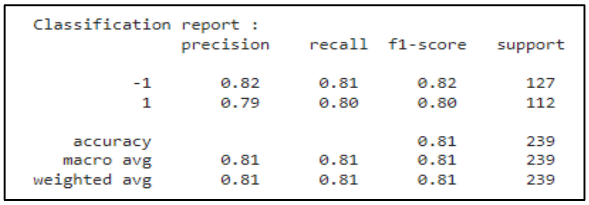
In the training and testing phase, there were three split ratios that had been used. The accuracy results from the different percentage splits are shown in the Table III. From the table, the dataset of 80:20 split produces the highest accuracy of 80.75%. Therefore, the percentage split of 80:20 is applied throughout the model development. For splitting of the 1192 data using the 80:20 ratio, 950 data is used to train the classifier while the other 224 data is used to evaluate the model performance.

TABLE III. Split Ratio Results

| Percentagesplit | Accuracy | Precision | Recall | F1-Score |
|---|---|---|---|---|
| 90:10 | 78.33% | 77.36% | 74.55% | 75.93% |
| 80:20 | 80.75% | 78.94% | 80.36% | 79.64% |
| 70:30 | 79.05% | 78.48% | 78.03% | 78.26% |

### *A. Classification Report*

The Classsification Report was used to report the accuracy, recall, precision and F1-score. The classification was calculated using the Scikit Learn module available on Python. Fig. 8 shows the output of classification report of the model constructed. The accuracy achieved by the classifier is 81%, which is considered as good and acceptable. The precision measures the exactness of the classifier and the value is 79%. This value denotes less false positive obtained by the module. The recall value measured is 80%, which represents less false negative in the classification. Less false negative and the less false positive denote that the system can accurately classify the input given by the user. The value of F1-Score obtained by user is 80%, which indicates the harmonic balance between the recall and precision values. These values can be concluded as good, reliable and had achieved the classifier's objective in solving the sentiment classification problem.



```
Classification report :
               precision    recall  f1-score   support

          -1       0.82      0.81      0.82       127
           1       0.79      0.80      0.80       112

    accuracy                           0.81       239
   macro avg       0.81      0.81      0.81       239
weighted avg       0.81      0.81      0.81       239
```

Fig. 8. Classification report.

### B. *Confusion Matrix*

Fig. 9 shows the Confusion Matrix which represents the value of True Positive (TP), False Negative (FN), False Positive (FP) and True Negative (TN) predicted by the classifier. Confusion matrix is the calculation of the number of right and wrong predictions, which are then summarized with the count values and divided by class. By looking at the confusion matrix plot, it gives an insight of the error made by the classifier model and the type of error being made. Based on Fig. 9, 90 is the value of TP, which indicates the number of not harassing tweets which is predicted correctly, while value 22 represents FP, which is supposedly to be non-harassment tweet but incorrectly predicted as the harassment tweet. The value of 24 represents FN which is the number of harassment tweets that are incorrectly labelled as non-harassment. Lastly, the TN value indicates 103 harassment tweets which are predicted correctly by the classifier. From the results, it can be observed that the classifier has made 46 incorrect predictions out of the 239 predictions made. The classifier only made incorrect predictions for about 19%. Hence, the model still can be concluded as good and reliable as the false prediction percentage is still small.

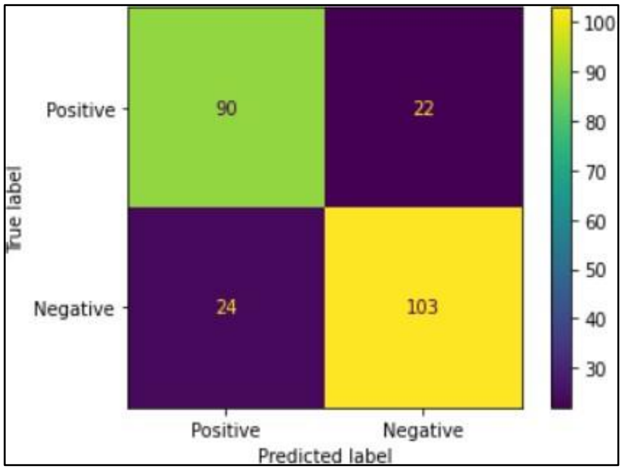


Fig. 9. Confusion matrix.

### C. *ROC Curve*

Fig. 10 shows the ROC curve for the detection of the harassment tweets. The AUC value obtained for this classifier is 0.81, which is near to 1. As the AUC value is approaching value 1, it is proven that the SVM classifier model obtained is reliable and could classify the data correctly. Thus, the 0.81 AUC value demonstrates that the classifier model obtained is capable in distinguishing the classes of “Harassment” and “Not Harassment” in this research.

### D. *Discussion*

Based on the evaluation results obtain in the evaluation phase, the SVM classifier has been able to detect the harassment tweets towards women in this research with good and reliable performance. The finding during the labelling of data has shown that there were more negative (Harassment) tweets than the positive ones. This shows that something has to be done to curb more harassments toward women over the Twitter. Perhaps Twitter itself could block any contents that has bad sentiments towards women. This is crucial as more people are using Twitter nowadays since the pandemic. Fig. 11 shows the word cloud for the negative words that have been analyzed. The word cloud is the visual presentation of the words used in the tweets. The bigger words such as ‘stupid’ and ‘woman’ show that the words were the most frequently used in the tweets.

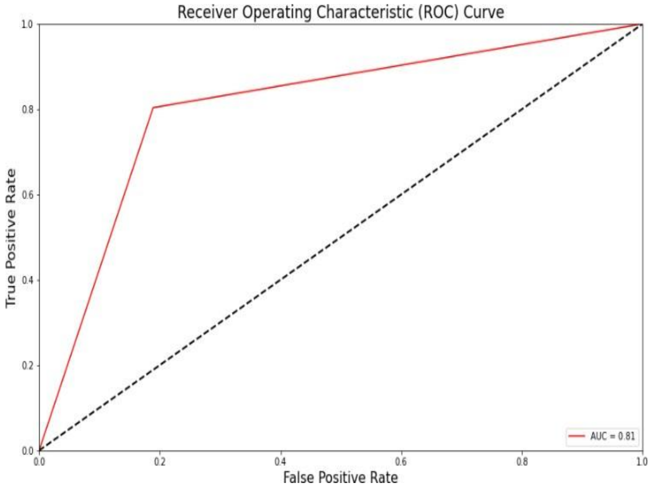

Fig. 10. ROC curve.

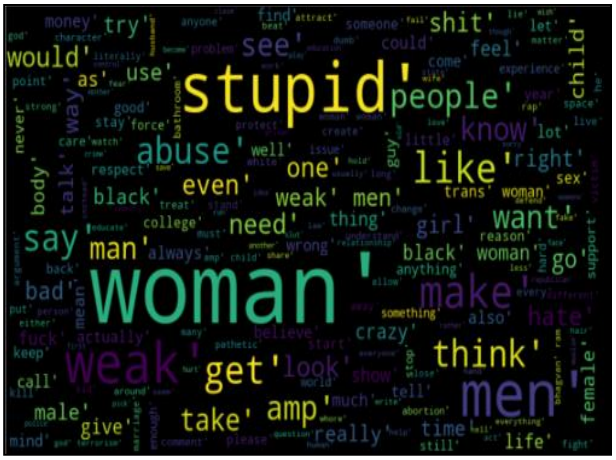

Fig. 11. Word cloud for negative words.

## V. Conclusion

This research has explored the capability of SVM in the sentiment classification of harrassments toward women based on Twitter data. The accuracy achieved by the SVM classifier was 81%, which indicates the good and acceptable performance of the model. This research could contribute to the community as it help to detect harassments toward women through Twitter. By detecting harassments that occurs within the social media, law enforcement could be made and actions could be taken against the harassers. Apart from legal action, this classifier would also help in detecting and taking down the harassment posts. This could increase the quality of the social media content and make a safer space for women on social media. The limitation associated with this classifier is that it can only analyze English Tweets. It would be better if the classifier could also detect harassments in other languages as harassments occur in various languages in the world. In future works, besides collecting and training dataset with other languages such the Malay language, data should also be scraped regularly. This is to collect more relevant and latest data in order to produce a better performance machine learning model. The results of SVM classifier model could also later be compared with other machine learning techniques such as the Naive Bayes and the deep learning algorithms.

## ACKNOWLEDGMENT

Special gratitude goes to Universiti Teknologi MARA Cawangan Terengganu for the continuous support given towards the advancement of research in the university.

Department of ECE, Sasi Institute of Technology and Engineering, Tadepalligudem, Andhra Pradesh, India[3]

*Abstract*—**Dietary pattern assessments, essential for chronic illness management and well-being, involve time-consuming manual data input and food intake remembering. A more dependable and automated approach is needed since such procedures may create mistakes and inconsistencies. This study solves a long-standing problem by automating nutritional assessment using deep learning and image analysis. CNNs, deep learning models for image processing, were employed in our study. Food category algorithms are trained with thousands of pictures. Even with numerous food items, these models can distinguish them in digital photographs. Our method calculates food portions after identification. Photometric food measurements are obtained using reference objects like plates and forks. Yet another deep learning model predicts portions. The method evaluates food calories last. Select food types and portions are matched to nutritional databases. These findings might automate, enhance, and user-centrically assess food intake in health informatics. Our first experiments are encouraging, but we must understand the approach's limits and need for refinement. The findings underpin future research and development. This approach envisions a future where patients can monitor their nutrition and doctors can get accurate data. This may prevent and treat lifestyle problems.**

***Keywords—Deep learning; convolutional neural networks; food calorie estimation; dietary assessment; computer vision; health informatics***

## I. Introduction

The impact of dietary habits on human health and well-being is indisputable. The increasing incidence of lifestyle-related ailments, such as obesity, diabetes, and cardiovascular disease, has underscored the imperative for proficient evaluation and surveillance of dietary patterns. Conventional approaches to dietary assessment encompass self-reporting by individuals or guidance from a healthcare provider. The utilization of these methodologies necessitates individuals to accurately recollect their dietary intake within a designated timeframe, which may introduce potential inaccuracies stemming from memory bias, misconceptions regarding portion sizes, or deliberate underreporting influenced by social desirability. Therefore, it is evident that the current manual, labor-intensive, and frequently unreliable techniques emphasize the necessity for a system that is more efficient, dependable, and automated. This research presents an innovative methodology to address a persistent problem by utilizing artificial intelligence, specifically deep learning and image analysis methodologies. Deep learning, which falls under the umbrella of machine learning, has demonstrated substantial progress in various domains of study, such as computer vision, speech recognition, and natural language processing. Convolutional Neural Networks (CNNs) have garnered considerable interest in the realm of image analysis, due to their diverse architectural designs. Convolutional Neural Networks (CNNs) have demonstrated exceptional performance in various tasks, including object detection and image classification. Consequently, they are highly suitable for the purpose of identifying food items in dietary assessment.

This study utilizes Convolutional Neural Networks (CNNs) that have been trained on a large dataset consisting of thousands of images representing a wide range of food categories. This functionality allows our system to effectively and precisely recognize food items depicted in digital images, presenting a potentially advantageous substitute for the labor-intensive process of manually recording food consumption. After the process of identifying food items, our approach utilizes size references and deep learning models to estimate the portion size of each individual food item. The calorie content of the meal is subsequently estimated through the process of cross-referencing the identified food items and their corresponding portion sizes with established nutritional databases. The purpose of this process is to streamline the dietary assessment process, offering a more accessible, dependable, and effective approach in comparison to conventional methods.

This paper aims to present a comprehensive examination of our methodology, encompassing the utilization of deep learning techniques for the purpose of food identification and estimation of portion sizes. Additionally, this paper will analyze the experimental findings and provide a comparative analysis with established methodologies. Notwithstanding the potential obstacles and constraints, this study makes a substantial contribution to the domain of health informatics and presents a novel approach in addressing the management of lifestyle diseases. This study contributes to a larger initiative aimed at promoting healthier dietary habits and improving health outcomes by offering individuals a convenient and effective means of monitoring their dietary intake.

## II. Literature Survey

The breadth of deep learning applications has expanded remarkably in recent years, encompassing various fields of study and novel methodologies. One such method is the Deep Belief Network (DBN)-Deep Neural Network (DNN), proposed in study [1], which extracts artificial feature vectors from oscillometric waves to discern complex non-linear relationships with reference nurse blood pressures. This DBN-DNN-based regression model illuminates an intriguing intersection of machine learning and healthcare. Meanwhile, in the realm of smart grids, the study in [2] delves into deep learning-based interval state estimation. The study introduces scenario-based two-stage sparse cyber-attack models for smart grids, accounting for both complete and incomplete network information. Similarly, in the perception estimation field, [3] offers a visual-tactile cross modal retrieval framework to correlate tactile information with visual material surface details. Expanding the scope of facial recognition, [4-5] propose the Multitask Manifold Deep Learning ($M^2DL$), a novel face-pose estimation framework. The framework integrates a visual transformation Convolutional Neural Network (CNN) to enhance traditional feature extraction methods. In the dietary assessment domain, a novel vision-based method [6-7] relies on real-time three-dimensional (3D) reconstruction and deep learning view synthesis to estimate food portion sizes accurately. Concurrently, in the field of travel time estimation (TTE), [6-7] presents the Nei-TTE method, a deep learning approach leveraging neighboring data.

Tackling challenges in solar cell defect detection, [8-9] introduce a complementary attention network (CAN). The CAN connects a channel-wise attention subnetwork with a spatial attention subnetwork, emphasizing defect features while concurrently suppressing background noise. In the arena of image compression, [8-9] propose an innovative approach to enhance transformation-based compression standards like JPEG, significantly reducing data transmission requirements. Meanwhile, [10] presents an intelligent anomaly detection method based on prediction intervals (PIs), aiming to identify malicious attacks of varying severity during secure operations .Medical data security receives a novel approach in [11] with the development of a multiobjective convolutional interval type-2 fuzzy rough FL model. The model, based on NAS (CIT2FR-FL-NAS), employs an improved multiobjective evolutionary algorithm. The study in [12-13] offers a lightweight model based on attention-inception CNN and Long-Short Term Memory (LSTM) to solve significant energy cost problems in resource allocation, typically ignored by programming and heuristic methods. In biometric security, [14] proposes a low-cost palm vein recognition system for smart phones, using RGB images. Meanwhile, the study in [15] focuses on intelligent fault diagnosis through a deep adversarial sub domain adaptation network, addressing the limitations of global domain adaptation methods, which often overlook fine-grained information and discriminative features. The study in [16] introduces Mask2Defect, a new data augmentation algorithm for metal surface defect inspection that enhances traditional data augmentation methods. On the other hand, [17] develops a Convolutional Neural Network (CNN) based method to learn non-stationary and complex features from raw wind farm reactive power time series, offering a predictive controller for voltage flicker mitigation. A distinct methodology to evaluate time-sensitive collaborative robotics applications enabled by Wireless Time Sensitive Networking (WTSN) is described in [18]. Following this, [19] presents a deep interpolation ConvNet (DICN) architecture comprising multiple sub-ConvNet units, a weight unit, and a fusion unit. Lastly, in the context of industrial IoT network traffic prediction, the study in [20] proposes the Flow2graph method, demonstrating the impressive versatility and applicability of deep learning methods across varied fields.

## III. Methodology

The proposed method operates in two main stages: (i) food identification and (ii) portion size estimation and calorie computation. The following sections provide an in-depth description of each stage.

### A. Food Identification

The first stage involves identifying the food items present in a given image. This is achieved by employing Convolutional Neural Networks (CNNs), a type of deep learning model particularly suitable for image analysis tasks. The input to the CNN is a 3-channel RGB image of size $n \times n$ pixels. The CNN architecture we use consists of several convolutional layers followed by pooling layers, fully connected layers, and a final softmax layer. Each convolutional layer in the network applies several convolutional filters to the input. These filters can be represented as a $m \times m \times d$ matrix where $m$ is the filter size and $d$ is the depth of the input image or feature map. Each filter is convolved across the width and height of the input, computing the dot product between the entries of the filter and the input, producing a 2-dimensional activation map. The outputs of all filters are then stacked along the depth dimension, forming the final output feature map. Pooling layers are then used to reduce the spatial size of the representation, helping to control over fitting. Fully connected layers then perform high-level reasoning from the features extracted by the previous layers. The softmax layer at the end outputs the probability distribution over the food categories. In our experiments, we utilize transfer learning by starting with pre-trained models (such as VGG16, InceptionV3, and ResNet50) and fine-tuning these models on food specific image datasets, including Food-101 and UECFOOD256.

### B. Portion Size Estimation and Calorie Computation

Once the food items in an image are identified, the next stage involves estimating the portion size of each item. To do this, we first compute the dimensions of the food items. We use known objects present in the image, such as a plate or a fork, as size references. This is done by comparing the area in pixels of the known object to its actual size, thus obtaining a scale for the image. The area in pixels of the food item is then converted into actual area using this scale. The volume of the food item is estimated assuming that the food item is of a regular shape like a cylinder or cuboids, whose volume can be computed using basic geometric formulas. Next, we use a deep learning model to estimate the portion sizes from the computed volumes. The model is trained on a dataset where the inputs are the computed volumes and the outputs are the actual portion sizes, obtained using a kitchen scale. Finally, the estimated portion size of each food item is used to compute the calorie content. This is done by cross-referencing the identified food item and its portion size with a standard nutritional database. In mathematical terms, let $f_i$ be a food item identified by the CNN, $p_i$ the estimated portion size for $f_i$, and $c(f)$ the calorie content per unit portion size for a food item $f$. The total calorie content $C$ of a meal consisting of $N$ food items can be computed as:

$$C = \sum_{i=1}^{N} p_i \cdot c(f_i) \tag{1}$$

This formula sums the product of the estimated portion size and the calorie content per unit portion size for each food item, giving the total calorie content of the meal.

## IV. Problem Formulation

In our proposed model, we aim to estimate the total caloric content $C$ of a meal consisting of $N$ food items identified in a given image. Each food item $f_i$ in the image is identified using a Convolutional Neural Network (CNN). For each identified food item $f_i$, we compute a portion size $p_i$ using a deep learning model that uses the estimated volume of the food item. The calorie content $c(f)$ for a food item $f$ per unit portion size is obtained from a standard nutritional database. Therefore, the total caloric content $C$ can be formulated as:

$$C = \sum_{i=1}^{N} p_i \cdot c(f_i) \tag{2}$$

Here, the main problem is to estimate the portion size $p_i$ for each food item $f_i$. Assuming the food item is of a regular shape like a cylinder or a cuboid, we first estimate the volume $V_{real}$ of the food item using its real-world area $A_{real}$, which is obtained from the area $A_{pixel}$ in the image using the scale of the image $\rho$:

$$\rho = \frac{S_{real}}{S_{pixel}} \tag{3}$$

$$A_{real} = A_{pixel} \times \rho^2 \tag{4}$$

$V_{real}$ = Volume calculation from $A_{real}$geometric Formulas (5)

Finally, the portion size $p_i$ is estimated from $V_{real}$ using a deep learning model. This model is trained on a dataset where the inputs are the computed volumes and the outputs are the actual portion sizes, obtained using a kitchen scale. Our goal is to minimize the difference between the estimated portion sizes and the actual portion sizes. This can be formulated as the following optimization problem: Finally, the portion size $p_i$ is estimated from $V_{real}$ using a deep learning model. This model is trained on a dataset where the inputs are the computed volumes and the outputs are the actual portion sizes, obtained using a kitchen scale. Our goal is to minimize the difference between the estimated portion sizes and the actual portion sizes. This can be formulated as the following optimization problem:

$$\min_{p_i} \sum_{i=1}^{N} \left(p_i - p_{actual,i}\right)^2 \tag{6}$$

where, $p_{actual,i}$ is the actual portion size for food item $f_i$.

## V. Proposed Model

The proposed methodology revolves around two core stages: (i) Food Identification and (ii) Portion Size Estimation and Calorie Computation. Let's delve into these in greater detail.

### A. Food Identification

The primary phase involves identifying food items within a provided image. This recognition is facilitated through the use of Convolutional Neural Networks (CNNs), a form of deep learning model well-suited for image analysis tasks. Let's represent the input to the CNN as an RGB image $I_{RGB}$ of dimensions $n \times n \times 3$.The structure of the CNN incorporates several convolutional layers (*conv*), pooling layers (*pool*), fully connected layers (*FC*), and a softmax layer at the end. A convolutional layer can be mathematically expressed as follows:

$$Conv_{out} = f(Conv_{in} * K + b) \tag{7}$$

Where $Conv_{in}$ is the input to the convolutional layer, which could be an input image or the output from a previous layer. $K$ is the convolutional kernel of size $m \times m \times d$, with $m$ being the filter size and $d$ is the depth of the input image or feature map. $*$ represents the convolution operation. $b$ is the bias term. $f$ is the activation function, which introduces non-linearity to the model (usually ReLU). $Conv_{out}$ is the output feature map. Following convolutional layers, pooling layers are utilized to reduce the spatial dimensions of the representation and control over fitting. The operation in a pooling layer can be described as:

$$Pool_{out} = f_{pool}(Pool_{in}) \tag{8}$$

Where $Pool_{in}$ is the input to the pooling layer, usually the output of a convolutional layer. $f_{pool}$ is the pooling function, such as max pooling or average pooling. $Pool_{out}$ is the output of the pooling layer. The fully connected layers take the output of the last pooling layer and flatten it into a 1-D vector:

$$FC_{out} = f(FC_{in}W + b) \tag{9}$$

Where $FC_{in}$ is the input to the fully connected layer. $W$ and $b$ are the weight matrix and bias vector. $f$ is the activation function, often a sigmoid or a tanh function. $FC_{out}$ is the output of the fully connected layer. The softmax layer at the end generates a probability distribution over the food categories:

$$Softmax_{out} = \frac{e^{FC_{out}}}{\sum_{j=1}^{C} e^{FC_{out_j}}} \tag{10}$$

Where $C$ is the number of food categories. We employ transfer learning by initiating our system with pre-trained models (VGG16, InceptionV3, ResNet50), further fine-tuned on food-specific image datasets (Food101, UEC-FOOD256).

### B. Portion Size Estimation and Calorie Computation

Once the food items in the image are successfully identified, the subsequent stage entails estimating the portion size for each item. To achieve this, we first compute the dimensions of the food items in terms of pixels. By utilizing known objects present in the image (such as a plate or a fork) as size references, we can estimate the actual size of each food item in the image. Given that a reference object with a known real-world size $S_{real}$ appears in the image with a size of $S_{pixel}$, the scale of the image $\rho$ can be obtained as:

$$\rho = \frac{S_{real}}{S_{pixel}} \tag{11}$$

$$A_{real} = A_{pixel} \times \rho^2 \tag{12}$$

Where $A_{pixel}$ is the area of the food item in the image. Assuming that the food item is of a regular shape like a cylinder or a cuboid, the volume $V_{real}$ of the food item can be computed using basic geometric formulas. A deep learning model then estimates the portion sizes from these computed volumes .Lastly, the calorie content is computed by cross-referencing the identified food item and its portion size with a standard nutritional database. In mathematical terms, let $f_i$ be a food item identified by the CNN, $p_i$ the estimated portion size for $f_i$, and $c(f)$ the calorie content per unit portion size for a food item $f$. The total calorie content $C$ of a meal consisting of $N$ food items can be computed as:

$$C = \sum_{i=1}^{N} p_i \cdot c(f_i) \tag{13}$$

This formula sums the product of the estimated portion size and the calorie content per unit portion size for each food item, yielding the total calorie content of the meal.

**Algorithm 1** Food Calorie Estimation Algorithm

```
**Input:** Image $I$
**Output:** Total calorie content $C$
**Initialization:** Load pre-trained model for food identification
**Food Identification:**
Apply pre-processing to $I$
Feed $I$ to CNN
Get food item $f_i$ identified by CNN
**Portion Size Estimation:**
Detect known objects in $I$ for scale estimation
Estimate the area of $f_i$ in pixels, $A_{pixel}$
Calculate real-world area $A_{real}$ using image scale
Estimate volume $V_{real}$ of $f_i$ assuming regular geometric shapes
Train deep learning model to get portion size $p_i$ from$Vreal$
**Calorie Computation:**
Cross-reference $f_i$ with nutritional database to get calorie content
    per unit portion size $c(f_i)$
calorie content$C$ =0$C$ of meal as $C = \sum_{i=1}^{N} p_i \cdot c(f_i)$
: **Return**Compute
```

## VI. Evaluation Metrics

In order to assess the effectiveness and accuracy of the proposed model, several evaluation metrics can be employed. We can measure the performance at each stage: food identification, portion size estimation, and overall calorie estimation.

- Food Identification: The accuracy of food identification can be evaluated using common classification metrics, such as:
    - Accuracy: This is the most straightforward metric, which measures the proportion of correctly identified food items over all items.

$$Accuracy = \frac{Number\ f\ orrect\ redictions}{Total\ umber\ f\ redictions} \tag{14}$$

- Precision, Recall, and F1-score: These are useful when dealing with imbalanced datasets. Precision measures the proportion of true positive predictions among all positive predictions, recall measures the proportion of true positive predictions among all actual positive instances, and the F1score is the harmonic mean of precision and recall.

$$Precision = \frac{True\ ositives}{True\ ositives + False\ ositives}) \tag{15}$$

$$Recall = \frac{True\ ositives}{True\ ositives + False\ egatives} \tag{16}$$

$$F1\ core = 2 \times \frac{Precision \times Recall}{Precision + Recall} \tag{17}$$

Portion Size Estimation: This is essentially a regression problem, and thus we can use metrics such as:

- Mean Absolute Error (MAE): This metric calculates the average of absolute differences between the target value and the value predicted by the model.

$$MAE = \frac{1}{N} \sum_{i=1}^{N} \left| p_i - p_{actual,i} \right| \tag{18}$$

Root Mean Squared Error (RMSE): RMSE is the square root of the average of squared differences between the target value and the value predicted by the model. This metric gives a higher weight to large errors.

$$RMSE = \sqrt{\frac{1}{N} \sum_{i=1}^{N} \left(p_i - p_{actual,i}\right)^2} \tag{19}$$

- Overall Calorie Estimation: Similar to portion size estimation, we can use regression metrics to evaluate the accuracy of the calorie computation, including MAE and RMSE. Additionally, we can calculate the percentage error relative to the actual calorie content.
    - Mean Percentage Error (MPE): This metric calculates the average of percentage differences between the target value and the value predicted by the model.

$$MPE = \frac{100\backslash\%}{N} \sum_{i=1}^{N} \left( \frac{C_i - C_{actual,i}}{C_{actual,i}} \right) \tag{20}$$

## VII. Expected Outcomes

The graph in Fig. 2 produced is a bar chart that represents the probability distribution over different food categories predicted by the deep learning model for a given image. The model identifies the food item present in the image and assigns a probability to each possible category. The probabilities are plotted against each category to visually represent the model's confidence in identifying the given food item as belonging to each specific category.

Food Categories: This axis lists the food categories that the model can identify. In this case, we have five categories: 'Apple', 'Banana', 'Pizza', 'Burger', and ‘Salad’. Each of these is a potential classification that the model can assign to the image it's analyzing.

Probability: This axis represents the probability that the food item in the image belongs to each category. The model assigns these probabilities based on the features it has learned during training. A high probability suggests that the model is confident that the food item in the image belongs to a specific category. Fig. 1 shows the food sample image.

Fig. 1. Food sample image.

TABLE I. FOOD IDENTIFICATION

| Food Categories | Probability |
|---|---|
| Apple | 0.20 |
| Banana | 0.15 |
| Pizza | 0.25 |
| Burger | 0.22 |
| Salad | 0.18 |

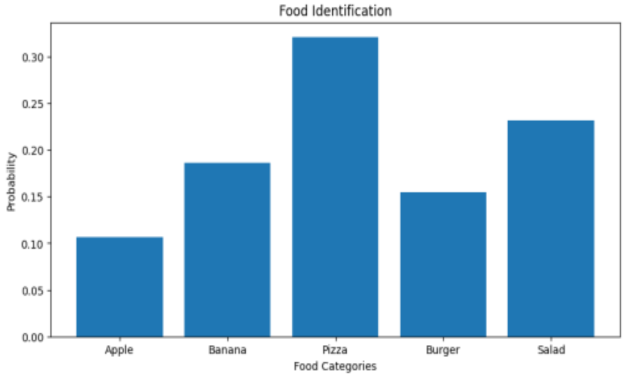

Fig. 2. Food identification probabilities.

Bars: Each bar corresponds to a food category, and its height indicates the model's confidence (probability) that the food item in the image belongs to that category. Table I shows the probability of food categories. Analyzing the graph, you can identify which category has the highest probability, and thus, which food item the model most confidently identifies in the image. For example, if the 'Pizza' bar is the tallest, it suggests that the model is most confident that the food item in the image is a pizza. We have to note that these probabilities are softmax outputs from a deep learning model, which can be interpreted as confidence scores assigned by the model. They sum up to 1 across all categories, but a high score in one category doesn't mean there's a high statistical likelihood that the image is indeed of that category; it's just the category that the model thinks is the most likely based on its training. The true accuracy of the model's predictions depends on factors such as the quality and variety of its training data, how well its architecture captures the relevant features, and so on.

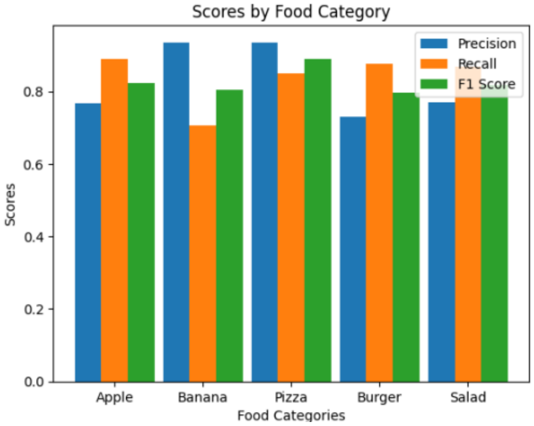

Fig. 3. Scores by food category.

The grouped bar plot from Fig. 3 shows the performance metrics of the hypothetical deep learning model for each food category - 'Apple', 'Banana', 'Pizza', 'Burger', 'Salad'. Each bar represents a performance metric score (between 0 and 1) for a specific food category.

Food Categories: The categories on the X-axis represent the different food classes that our model is trained to recognize. These are the categories against which the precision, recall, and F1 scores are evaluated. The Y-axis represents the values of precision, recall, and F1 scores. Each of these metrics provides different information about the model's performance: Precision measures the accuracy of positive predictions. In this context, it asks the question: "Of all the times the model predicted a specific food category, how often was it correct?" A high precision score indicates that when the model identifies an image as a certain food category, it is highly likely to be correct. Recall (or sensitivity) measures the true positive rate. It asks: "Of all the images that were truly a certain food category, how often did the model correctly identify it?" A high recall score means the model is good at detecting a specific food category but may also have a high rate of false positives.F1 Score is the harmonic mean of precision and recall. It tries to balance the two and is particularly useful when the distribution of classes is uneven.

It provides a single metric that encapsulates both precision and recall. Bars: Each group of bars corresponds to a food category, with individual bars representing precision, recall, and F1 score for that category. This graph allows us to easily compare these metrics across different categories. For example, you can compare precision for 'Apple' with 'Pizza' and check which food category the model is better at predicting accurately. High scores in these metrics indicate that your model is performing well in both correctly identifying the food categories (high precision) and not missing any food categories (high recall).

- X-Axis (Food Categories): The categories on the Xaxis represent the different food classes that our model is trained to recognize. These are the categories against which the precision, recall, and F1 scores are evaluated.

- Y-Axis (Scores): The Y-axis represents the values of precision, recall, and F1 scores. Each of these metrics provides different information about the model's performance:

- Precision Precision measures the accuracy of positive predictions. In this context, it asks the question: "Of all the times the model predicted a specific food category, how often was it correct?" A high precision score indicates that when the model identifies an image as a certain food category, it is highly likely to be correct.

- Recall Recall (or sensitivity) measures the true positive rate. It asks: "Of all the images that were truly a certain food category, how often did the model correctly identify it?" A high recall score means the model is good at detecting a specific food category but may also have a high rate of false positives.

- 1 F1 Score is the harmonic mean of precision and recall. It tries to balance the two and is particularly useful when the distribution of classes is uneven. It provides a single metric that encapsulates both precision and recall.

- Bars: Each group of bars corresponds to a food category, with individual bars representing precision, recall, and F1 score for that category.

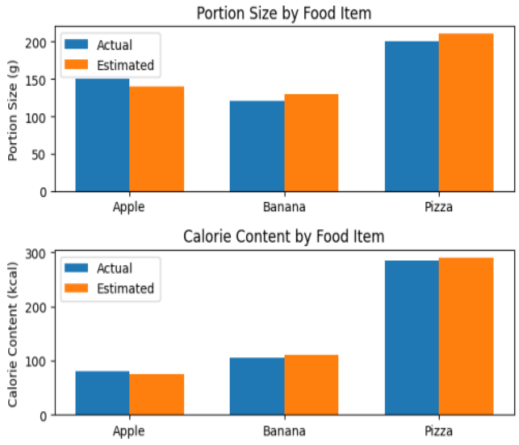

Fig. 4. Portion and calorie estimation.

This graph in Fig. 4 allows us to easily compare these metrics across different categories. For example, you can compare precision for 'Apple' with 'Pizza' and check which food category the model is better at predicting accurately. High scores in these metrics indicate that your model is performing well in both correctly identifying the food categories (high precision) and not missing any food categories (high recall). The two bar graphs form Fig 4 generated provides a comparative view of the estimated and actual values for portion sizes and calorie content of food items. Portion Size by Food Item: The first graph compares the actual portion size (in grams) with the estimated portion size of the three food items – 'Apple', 'Banana', and 'Pizza'. The X-axis represents the food items and the Y-axis denotes the portion size in grams. Each food item has two bars - one representing the actual portion size (blue) and the other depicting the estimated portion size (orange). If the model's estimations are perfect, the orange bar (Estimated) would coincide completely with the blue bar (Actual) for each food item. However, any difference between these bars indicates the discrepancy between the model's estimations and the actual values. Calorie Content by Food Item: The second graph performs a similar comparison but for the calorie content of the food items.

The X-axis represents the food items and the Y-axis denotes the calorie content in kilocalories (kcal). Similar to the first graph, each food item has two bars - one representing the actual calorie content (blue) and the other depicting the estimated calorie content (orange). Again, a perfect estimation would result in the complete coincidence of the blue and orange bars for each food item. Any deviation between these bars indicates an error in the model's calorie estimation. These plots can serve as a valuable tool for visually assessing the performance of your model. If the estimated bars closely match the actual bars, it indicates that your model is performing well in estimating the portion sizes and calorie content of food items. Conversely, a significant deviation might suggest that further improvements are needed.

## VIII. Conclusion

This paper introduces a deep learning-based food calorie estimation method for dietary assessment. Transfer learning from pre-trained models like VGG16, InceptionV3, and ResNet50 is used to leverage the robustness of convolutional neural networks (CNNs) for food identification from images. These models, trained on food-specific image datasets, can recognize many food items. The model also estimates portion sizes creatively. The model could calculate food item dimensions from pixel area by using common objects in the image, such as a plate or fork. After computing volumes, a second deep learning model estimated portion sizes. A nutritional database was used to calculate the meal's calories. This method calculated a meal's total calories, improving dietary assessment. The proposed model is promising, but the problem is complex. Food preparation, presentation, and serving sizes affect the model's accuracy. For more accurate estimations in diverse real-world settings, the model must be refined and adapted. This paper proposes a promising deep learning approach for automated, accurate dietary assessment. By giving users an easy way to track their caloric intake, this work could impact healthcare, fitness, and diet planning. It could also open up new research in dietary assessment and health informatics.

# Multi-Objective Reinforcement Learning for Virtual Machines Placement in Cloud Computing

Chayan Bhatt, Sunita Singhal
Department of Computer Science and Engineering, Manipal University Jaipur, Jaipur, Rajasthan, India

***Abstract*—The rapid demand for cloud services has provoked cloud providers to efficiently resolve the problem of Virtual Machines Placement in the cloud. This paper presents a VM Placement using Reinforcement Learning that aims to provide optimal resource and energy management for cloud data centers. Reinforcement Learning provides better decision-making as it solves the complexity of VM Placement problem caused due to tradeoff among the objectives and hence is useful for mapping requested VM on the minimum number of Physical Machines. An enhanced Tournament-based selection strategy along with Roulette Wheel sampling has been applied to ensure that the optimization goes through balanced exploration and exploitation, thereby giving better solution quality. Two heuristics have been used for the ordering of VM, considering the impact of CPU and memory utilizations over the VM placement. Moreover, the concept of the Pareto approximate set has been considered to ensure that both objectives are prioritized according to the perspective of the users. The proposed technique has been implemented on MATLAB 2020b. Simulation analysis showed that the VMRL performed preferably well and has shown improvement of 17%, 20% and 18% in terms of energy consumption, resource utilization and fragmentation respectively in comparison to other multi-objective algorithms.**

***Keywords*—Virtual machines placement; cloud computing; reinforcement learning; energy consumption; resource utilization**

## I. Introduction

In the world of digitalization, Cloud Computing has become one of the popular platforms to render an immense pool of services to its customers [1]. Cloud providers such as Amazon EC2, Google app engine, Azure, etc. provide users with different applications and platforms to run their businesses efficiently and promote Quality of Service (QoS) simultaneously [2].

Virtualization forms an essential technology of the cloud, based on which it creates Virtual Machines (VM) over the active servers to perform tasks as requested by different clients [3, 4]. The number of cloud clients has been rapidly growing to avail the wide range of day-to-day cloud services due to which there has been a drastic need for more VM to fulfill the demands of its customers. This caused the activation of more Physical Machines (PM) and spiked up the power consumption of the cloud data center. As a result, it has become a challenge for cloud providers as it causes additional operational costs that hinder the overall progress and profit of the system.

Proper placement of VM plays an important role in curbing the effect of power consumption. If VM are allocated strategically and resources of PM are optimally used, it leads to turning up less PM and minimizes overall energy consumption and carbon emissions simultaneously [5].

An efficient VM placement approach is a powerful tool for maintaining cost reduction, performance upgradation and consistent reliability of cloud data centers. However, designing an effective VM placement solution is not trivial due to large-scale cloud data centers, PM heterogeneity and use of multidimensional resources [6].

Hence, to solve the problem of VM Placement, many heuristics and meta-heuristics algorithms have been proposed to build an optimal solution for VM Placement. Differential Evolution (DE) [7], Simulated Annealing (SA) [8], Genetic Algorithms (GA) [9], Ant Colony Optimization (ACO) [10] and Particle Swarm Optimization (PSO) [11] have been continuously used to design and develop efficient solutions for placing VM on the cloud. Many hybrid algorithms have also been designed to bring an effective version placement considering different objectives.

Researchers are now focusing on multi-objective problems where different parameters such as energy usage, system performance, operational cost, completion time and QoS standards are being considered simultaneously to examine the effectiveness of VM placement solutions.

In [12], a multi-objective Mayfly Strategy has been designed for large-scale cloud data centers. It involves the collection of five dependent objective functions and converting them into minimum matrix reduction with the help of principal component analysis. This matrix serves as input to the Mayfly optimization metaheuristic and finds the optimal solution for VM placement. The comparative analysis showed that the above approach has a faster and higher convergence rate. It minimizes the power consumption, resource wastage, traffic and Service Level Agreement (SLA) violation of different configurations but involves greater computation time and cost.

Furthermore, a framework involving Deep Reinforcement Learning (RL) to solve VM placement, has been proposed by Luca et al in [13]. It works on three main objectives-minimization of software/hardware outages, co-location interference and power consumption. Six different VM placement heuristics have been used. Three of them were novel and the rest of the three were the enhancement of existing algorithms. However, the proposal required to take traffic and SLA violations into account. Similarly, Yao et al. [14] used Chebyshev scalarization in multi-objective RL to solve the problem of VM placement. The concept of the Pareto set has been used to lower energy consumption and resource wastage simultaneously. It solves the weight selection problem. However, it required enhancement in scalability and completion time.

In study [15], a multi-objective RL algorithm has been designed to minimize power consumption and SLA violations. In the proposed technique, a single objective function was used by summing up the two objectives without considering the weights. As a result, only one solution was obtained at a time by the above algorithm.

It has been observed that energy consumption has been one of the main factors that has affected the progress of the cloud as it not only increases the operational costs of the data centers but also causes high carbon emissions in the environment [16]. Similarly, many other factors such as SLA violations, resource wastage, QoS, network traffic, etc. have shown notable impact on the performance of cloud data centers and hence, became a prime focus for many researchers to work on and come up with reliable and efficient solutions [17].

Thus, to deal with the significant issue of energy consumption, this paper presents a VM Placement that minimizes the number of active servers and promotes optimal resource utilization.

The main contributions of this paper include:

- An RL-based VM placement has been proposed that deals with the minimization of the number of active servers to host the requested VM and maintain optimal resource utilization.
- An enhanced selection policy has been applied that selects actions of choosing an appropriate PM for a respective VM. It ensures that the algorithm goes through proper exploration and exploitation.
- Two heuristics have been used for the ordering of VM. The sequence of the VM in which it is processed has been manipulated to bring a desirable and efficient VM solution.
- Pareto approximate set has been used to obtain solutions according to the objectives and have weightage as per the perspective of the users.

The rest of the paper is organized as follows: Section II demonstrates the system model and problem formulation of VM placement. It also covers a detailed description of VMRL. Section III depicts the simulation analysis of the proposed work and its comparison with other existing techniques. The conclusion of the paper has been presented in Section IV.

## II. Methodology

### A. Reinforcement Learning

Reinforcement learning is a decision-making approach that explores the environment and takes suitable action to gain maximum reward for a specific situation. It is a self-teaching process that uses a trial-and-error method to discover the best solution for a non-deterministic problem. It has been implemented in many automated systems that perform a lot of small decisions without human guidance. It consists of an agent that perceives the unknown environment and performs actions to reach its goal. The agent starts from the initial state and by applying actions, it moves towards its final goal by traversing through different states [18]. Based on applied action, a reward is given to the agent for that state. The reward expresses the goodness of the state and is stored in the form of a Q value along with the next state, in a Q-table. The Q - table gets updated iteratively. The Q-values of the current state can be updated using Eq. (1).

$$Q(s,a) = Q(s,a) + \alpha * (r + \gamma * Max\, Q(s',a') - Q(s,a) \quad (1)$$

Q (s, a) denotes action-value estimates of the current state, Q (s', a') denotes action-value estimates of the next state, r refers to the achieved reward, alpha is the learning rate and gamma is the discount factor. After traversing all the states, the path that accommodates maximum reward is the optimal solution.

### B. Pareto Approximate Set

Most of the researchers have followed the concept of Pareto dominance [19] to solve the problem of multi-objective. By using the Pareto set, multi-objective algorithms solve large-scale complex problems and rather than giving a single best solution, it provides a set of same quality solutions based on different objectives.

### C. Energy Consumption

Energy consumption has become a critical issue for cloud providers as they need to invest the maximum in curbing its overall effect on cloud data centers. It has been observed that PM consume the maximum amount of power and causes high carbon emissions. Past studies have shown that energy consumption has a linear relationship with the CPU utilization of PM [20]. Moreover, it has been proven that idle PM are primarily responsible for wasting energy and are required to be shut down when not in use. The energy model has been formulated as per Eq. (2).

$$Ei = (Emax - Eidle) * UiCPU + Eidle \quad (2)$$

Emax denotes energy consumption when PM is fully utilized and Eidle denotes energy consumption of an idle PM. UiCPU represents the CPU utilization of the particular PM. In the proposed work, the energy consumption of fully loaded PM is fixed at 185 w and for idle PM, it is 120 w.

### D. Resource Utilization

Proper Resource utilization brings a positive outcome for a better VM placement approach. Optimal use of resources leads to less resource wastage and activation of servers. If the resources are not used wisely, it may cause resource fragmentation and degradation in system performance [21]. In this paper, we have considered only two resources: CPU and memory. Resource wastage of PM can be evaluated using the following Eq. (3).

$$Rwastage = \frac{|Lcpu - Lram| + e}{Ucpu + Uram} \quad (3)$$

Lcpu and Lram denote normalized residual resources of CPU and memory. Ucpu and Uram denote normalized utilization of CPU and memory.

### *E. Problem Statement*

Cloud computing consists of different configured data centers that hold numerous PM, having different attributes and configurations [22]. It involves memory, processor, and network bandwidth. To perform the execution of tasks requested by the customers, VM are created and deployed on these PM under specific constraints as mentioned below [23].

$$i \sum mi \ (Vid) \ <= \ Pid \qquad (4)$$

$$i \sum m(Vm) < \ Pm \ \ (5) \ i \sum mi \ (Vcpu) \ <= \ Pcpu \qquad (6)$$

$$i \sum mi \ (Vbw) \ <= \ Pbw \qquad (7)$$

Constraint in Eq. (4) denotes that each VM should be deployed on only a single PM. Constraints in Eq. (5), (6) and (7) verify that the required resources of a VM should not exceed the resource capacities of the PM. Like PM, VM also have specific configurations and attributes, concerning memory, bandwidth, and processing power.

*1) VM Ordering:* The proposed approach selects the best method to map the requested VM to the available PM. The order in which VM are processed has been changed to achieve better solutions for VM placement problems. We have considered two simple heuristics for the deployment of VM.

*a) Heuristic I-VMRL I:* In this approach, the dot product of requested resources of VM and the sum of utilizations of PM are evaluated using Eq. (8) and based on results, VM are arranged in non-ascending order. RL is applied to the new ordering of VM.

$$(VMcpu\ .Nj\ PMcpu) + \ (VMmem.Nj\ PMmem) \qquad (8)$$

Here, VMcpu and VMmem are the requested resources of the VM. $\sum_{Nj=1} PMcpu$ is the sum of CPU utilization and $\sum_{Nj}$ $=1\ PMmem$ is the sum of memory utilization of all available PM.

*b) Heuristic II- VMRL II:* This approach obtains the difference between the resource utilization of all PM and the resources required by the current VM as mentioned in Eq. (9) based on the results, VM are sorted in non-descending order.

$$(VMcpu - \ Nj\ PMcpu)2 \ + \ (VMmem - \ Nj\ PMmem)2 \ \ (9)$$

*2) VM placement based on Reinforcement Learning (VMRL):* A VM placement based on Reinforcement Learning (VMRL) has been presented in this paper. RL provides better decision-making and hence is adopted to design an effective VM Placement solution [24]. A learning agent is established to perceive the resource requirements and capacities of the VM and PM and take suitable actions to accomplish the goal of reducing the number of active PM by properly conserving the resources.

The agent works in the state space $S_t$ = {s1, s2……….sn} where n is equal to the number of requested VM. St represents the set of normalized resource utilization in two – dimensions i.e., for CPU and memory utilization. A graphical representation of VMRL is depicted in Fig. 1.

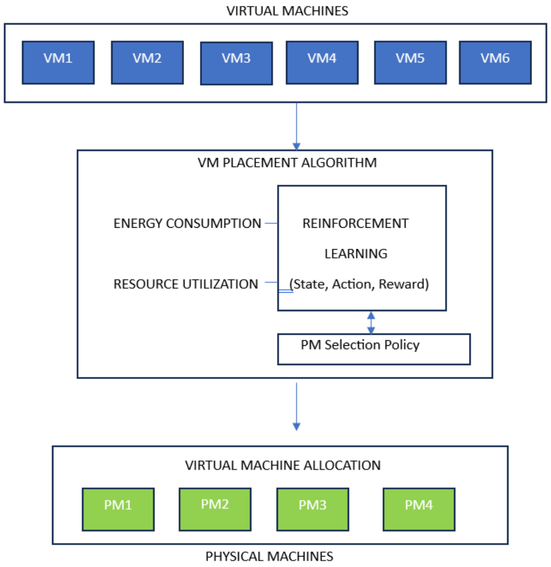

Fig. 1. Graphical representation of working of VMRL algorithm.

*a) Selection:* The agent performs actions to select a particular PM for the corresponding VM and ensures that the PM satisfies all the constraints defined in the VM policy [25]. The action space denotes all the PM that can accommodate a particular VM at time step t. The period between two iterations is considered as time step t. The selection of action is to be performed in two phases. In phase I, selection probabilities are assigned to the favorable PM by applying an enhanced Tournament-based selection method. All the feasible PM are divided into sub-groups and are provided with respective selection probabilities based on their Q-value by using Eq. (10).

$$Pi = \frac{2(i-1)}{K(K-1)}\ q \ + \frac{2(k-i)}{K(K-1)}(1-q);\ \text{i} \in \{1,2,3\ldots.\ \text{K}\} \quad (10)$$

Here Pi is the selection probability of a favorable PM that can host a specific VM and K is the population size. The PM with a higher Q-value is assigned a higher selection probability whereas the PM with a low Q-value is assigned a smaller selection probability.

*b) Sampling:* In Phase II, a sampling algorithm called the Roulette Wheel is applied to generate the fittest PM. In this approach, each possible action is appointed a portion on roulette according to selection probabilities assigned in phase I and the roulette wheel is spun K times to select suitable PM successively. This procedure helps to maintain a balance between exploration and exploitation processes and ensures that past experiences lead to fast convergence toward optimal VM placement solutions.

*c) Rewards:* Rewards are awarded as per the action performed by the agent in every state and are stored in the form of Q- value in the Q- table. They are calculated based on the two objectives. Let r = {r1, r2} where r1 denotes the reward for the first objective and r2 denotes the reward for the second objective as defined in Eq. (10) and Eq. (11). Better rewards are given for the actions that give favorable outcomes as per the defined objectives.

$$r1 = \frac{E}{E' t{+}1{+}\,\eta} \tag{11}$$

Et depicts the total energy consumed by all PM at time step t, and E t+1 depicts the total energy consumed by all PM after the current VM gets allocated to PM.

$$r2 = \frac{R}{R' t{+}1{+}\,\eta} \tag{12}$$

Rt depicts the resources wasted by all PM at time step t, and Rt+1 depicts the resource wasted by all PM after the current VM gets allocated to PM. By traversing from one state to another and by collecting the rewards, the agent achieves its goal in the form of an optimal VM solution. The path that obtains maximum cumulative rewards is the best VM solution.

The algorithm begins with the initialization of parameters and Q-table. Let us assume that there are three PM as {PM1, PM2, PM3} and six VM as {VM1, VM2, VM3, VM4, VM5, VM6}. Hence, there will be a Q-table of 3x6 columns as depicted in Fig. 2. Initially, all the values of the Q-table are initialized with zero.

Now, the VM will be arranged as per the heuristic I and II respectively. After the VM ordering, for state S1, the VM will be selected from the VM list and the PM that can accommodate the current VM will be searched. Action will be performed using an enhanced Tournament based selection policy. The respective reward will be calculated using Eq. (11) and Eq. (12). After the evaluation of the reward, the Q-table will be updated based on the reward and next state using Eq. (1) as depicted in Fig. 3.

Similarly, all the states will be accessed and their Q-values will be updated. After several iterations, the Q-table will get populated with the values. Let us assume that the Q-table has been updated with the values as depicted in Fig. 4.

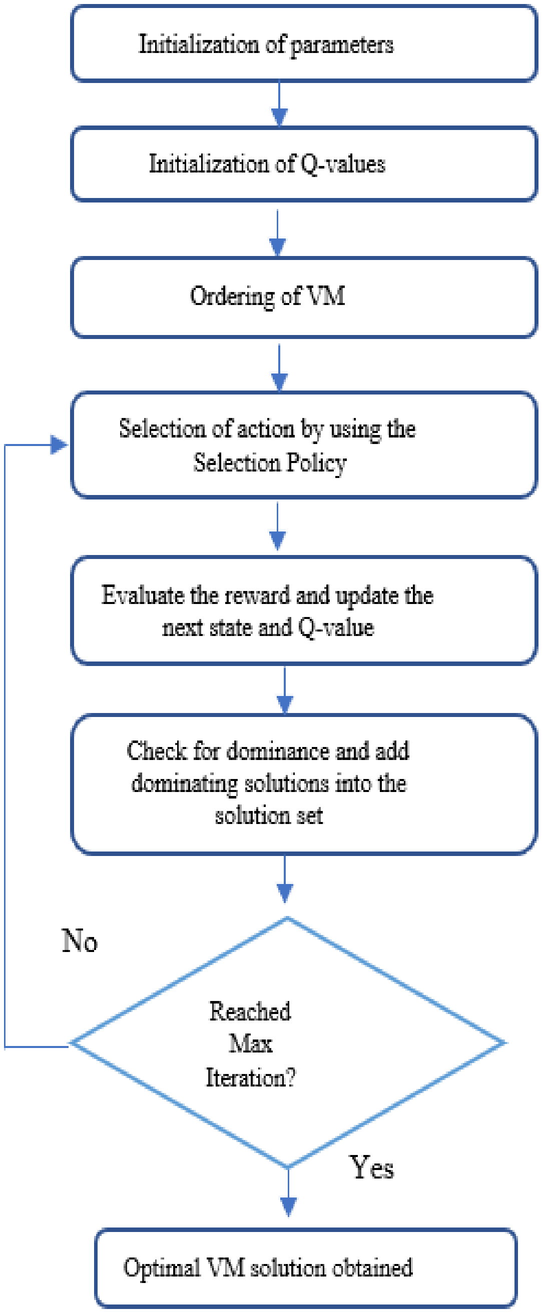
Q (s, a) = Q (s, a) + α * (r + γ * Max Q (s,’ a’) – Q (s, a))
Q (1,3) =Q (1,3) + α (4 + γ (Q (2,2)-Q (1,3))) =6+3=9

Fig. 4. Updated Q-Table after few iterations.

In this time step, exploitation is performed and the state-action pair having the highest q-value is selected. This procedure continues to execute till the algorithm reaches maximum iteration and provides optimal VM placement solution.

The flowchart and the pseudocode for the proposed algorithm have been shown below in Fig. 5 and Algorithm 1.



Initialization of parameters
Initialization of Q-values
Ordering of VM
Selection of action by using the Selection Policy
Evaluate the reward and update the next state and Q-value
Check for dominance and add dominating solutions into the solution set
No
Reached Max Iteration?
Yes
Optimal VM solution obtained

Fig. 5. Flowchart of proposed framework: VMRL.

Algorithm I: VM Placement using Reinforcement Learning (VMRL)

```
1. Create a set S and initialize it to null.
2. Create a Q-table and initialize all its values with zero
3. For i = 1 to M (no. of VM)
4. Initialize the current state.
5. Generate the ordering of VM. Select a VM from the VM set V
6. Select the action based on the selection policy. The action provides the mapping of the selected VM to an available PM that satisfies all the constraints.
7. Generate the reward for the action.
8. Update the q-value and the next state in the Q-table.
9. Check for the Pareto dominance. If the solution is not dominated by the solutions in set S then add it to set S otherwise discard the solution.
10. Discard all the solutions inside set S that are dominated by the current solution.
11. Repeat steps 3 to 8 till maximum iteration. Return the optimal solution in set S.
```

## III. Results and Discussion

The performance metrics and experiment setup have been described to evaluate the verification and validation of VMRL. The experiments have been performed on MATLAB 2020b. The hardware configuration used for implementing the proposed work has a 3.2GHz CPU, 1 TB HDD and 8GB RAM. To find the effectiveness of VMRL, our proposed framework has been compared with three different multi-objective algorithms i.e., MOPSO (Multi-Objective Particle Swarm Optimization), MOACO (Multi-Objective Ant Colony Optimization) and VMPORL (VM Placement based on multi-objective RL) respectively, in term of resource utilization, number of active PM, energy consumption and resource fragmentation. The specifications of the servers used are mentioned in Table I.

TABLE I. Specifications of PM

| Server Type | MIPS | Storage (GB) | Memory (GB) |
|---|---|---|---|
| HP ProLiantG4 | 1860 | 4 | 1000 |
| HP ProliantG5 | 2660 | 4 | 1000 |

### A. Quality Indicators

Quality indicators are required for multi-objective algorithms to examine the quality of Pareto approximate set [26]. For the proposed VMRL, three quality indicators have been used: Overall Non-dominated Vector Generation (ONVG), Chi-Square and Hypervolume. The comparison results with other three algorithms in terms of these quality indicators have been provided in Table II. It is seen that the weight selection holds a significant role in multi-objective optimization and its quite challenging to find out an appropriate weight which will provide good Pareto Front. For proposed VMRL, 10 randomly generated weight tuples have been used and an average of 10 trials has been considered. It is observed that as per statistical analysis of all three indicator values, VMRL has performed well as compared to other multi-objective algorithms.

TABLE II. QUALITY INDICATORS FOR ALGORITHMS

| Algorithm | ONVG | Chi-square | Hypervolume |
|---|---|---|---|
| MOPSO | 23.54 | 22.87 | 165.59 |
| MOACO | 25.37 | 23.54 | 174.34 |
| VMPORL | 33.01 | 32.42 | 315.67 |
| VMRL(I) | 39.23 | 40.58 | 345.23 |
| VMRL(II) | 37.45 | 41.22 | 355.17 |

### B. *Comparison with other Algorithms*

The comparison among the algorithms has been evaluated on the dataset, having VM into a batch of 200, 400, 600 and 800. The dataset is the real-time workload trace GWA-T-12 Bitbrains [27] that stores performance metrics of VM from distributed data centers of Bitbrains.

*1) Scenario I:* Fig. 6 depicts the experimental results of VMRL by using heuristic – I. It is observed that the performance metrics are strongly affected by the data center workload. The dot product provides control over the trade-off between the power consumed and Quality of Experience (QoE). Fig. 6(a) shows the performance of VMRL for activating the number of servers to deal with the requested VM. It is seen that the VMRL outperforms the other multi-objective algorithms i.e., MOACO, MOPSO and VMPORL. This indicates that VMRL can host a greater number of VM on lesser PM as compared to other algorithms thereby contributing to energy and resource savings. This can be seen in Fig. 6 (b), Fig. 6 (c) and Fig. 6(d) where VMRL has shown a considerable improvement of 17 % in energy consumption, 20% in resource utilization and 18% in resource fragmentation respectively in comparison to other approaches.

*2) Scenario 2:* Fig. 7 depicts the simulation analysis of VMRL by using heuristic II. Fig. 7(a) depicts that the VMRL can give optimal solutions by hosting different batches of VM on lesser PM. In Fig. 7(b), it is seen that the proposed technique was successful in bringing down the overall energy consumption without having outcomes of past experiences. Fig. 7(c) and Fig. 7(d) represent the resource utilization and fragmentation of VMRL in comparison to other algorithms. It is seen that VMRL gives the best results in all instances, proving it to be efficient and robust. VMPORL also came up with good outcomes on the performance metrics. The enhanced selection policy used for the selection of appropriate PM has brought a desirable change in the simulation results and upgraded the performance of VMRL in comparison to other existing techniques.

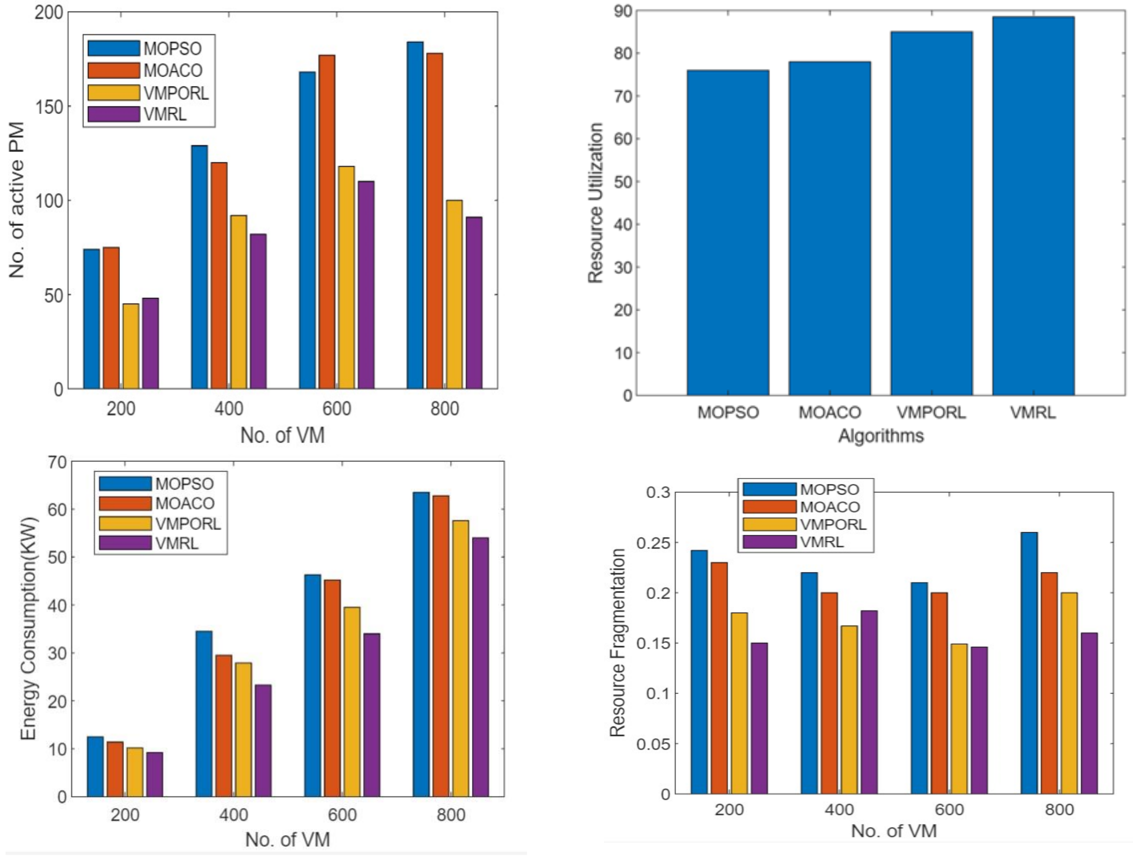


Fig. 6. Comparisons of algorithms using Heuristic I in terms of (a) Number of active servers (b) Resource Utilization of PM (c) Energy Consumption (d) Resource Fragmentation of PM.

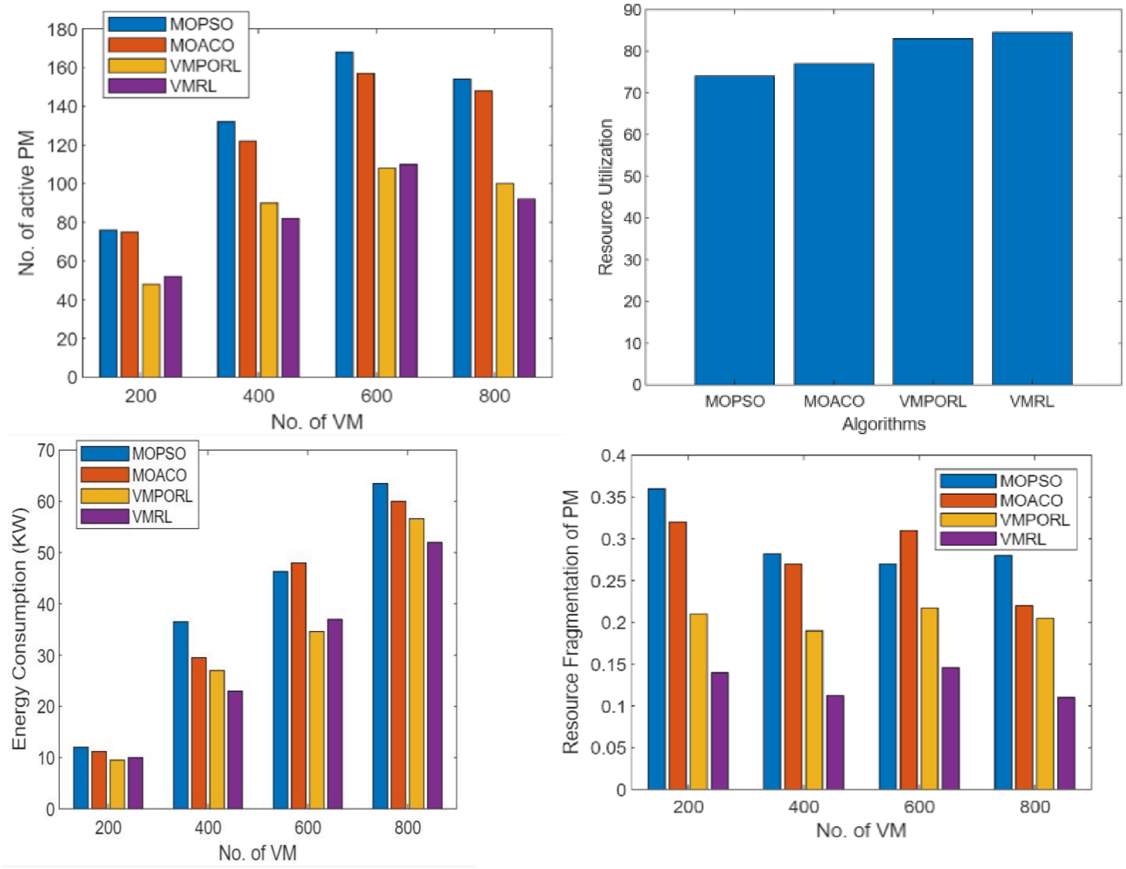

Fig. 7. Comparisons of algorithms using Heuristic II in terms of (a) Number of active servers (b) Resource Utilization of PM (c) Energy Consumption (d) Resource Fragmentation of PM.

## IV. Conclusion

VM placement holds a significant role in cloud computing. An effective placement of VM on an appropriate PM can lead to minimum resource wastage and energy consumption [28]. In this paper, a multi-objective VM Placement approach has been presented that works on the principle of Reinforcement Learning. An enhanced selection strategy has been applied to select the actions suitable for mapping VM with PM. Two resource-managing heuristics have been used for ordering VM, considering the target objectives. Pareto approximate set has been built to provide optimal VM solution. The proposed technique has been implemented on MATLAB 2020b. It has been compared with other multi-objective algorithms. The simulation analysis showed that the VMRL has performed considerably well in comparison to other existing algorithms. In future studies, VM migrations and cost minimization could be taken into account to deal with the wider perspective of cloud platform.

# A New Aerial Image Segmentation Approach with Statistical Multimodal Markov Fields

Jamal Bouchti[1], Ahmed Bendahmane[2], Adel Asselman[3]
Optique and Photonic Team-Faculty of Sciences, Abdelmalek Essaadi University, Tetuan 93002, Morocco[1, 3]
Department of Computer Science-ENS, Abdelmalek Essaadi University, Tetuan 93002, Morocco[2]

**Abstract—Aerial images, captured by drones, satellites, or aircraft, are omnipresent in diverse fields, from mapping and surveillance to precision agriculture. The efficacy of image analysis in these domains hinges on the quality of segmentation, and the precise delineation of objects and regions of interest. In this context, leveraging Markov fields for aerial image segmentation emerges as a promising avenue. The segmentation of aerial images presents a formidable challenge due to the variability in capture conditions, lighting, vegetation, and environmental factors. To meet this challenge, the work proposes an innovative method harnessing the power of Markov fields by integrating a multimodal energy function. This energy function amalgamates key attributes, including color difference measured by the CIEDE2000 metric, texture features, and detected edge information. The CIEDE2000 metric, derived from the CIELab color space, is renowned for its ability to measure color difference more consistently with human perception than conventional metrics. By incorporating this metric into the energy function, the approach enhances sensitivity to subtle color variations crucial for aerial image segmentation. Texture, a vital attribute characterizing regions in aerial images, offers crucial insights into terrain or objects. The method incorporates texture features to refine the separation of homogeneous regions. Contours, playing a fundamental role in segmentation, are identified using an edge detector to pinpoint boundaries between regions of interest. This information is integrated into the energy function, elevating contour consistency and segmentation accuracy. This article comprehensively presents the methodological approach, the conducted experiments, obtained results, and a thorough discussion of the method's advantages and limitations.**

***Keywords—Image segmentation; multimodal markov fields statistical integration; CIEDE2000 color difference; texture features; edge information***

## I. Introduction

Aerial image segmentation is identified as a critical area within the domain of image processing, indispensable for a breadth of applications from environmental monitoring to precision agriculture. The objective of segmenting an image into meaningful regions presents notable challenges due to the diversity and complexity of landscapes captured, variable lighting conditions, and the occurrence of atmospheric phenomena [1]. Therefore, segmentation techniques need to be robust and precise to identify objects and areas of interest effectively [2].

Traditional segmentation approaches, including thresholding methods [3] [4], region growing [5], contour-based techniques [6], and pixel classification [7], are fundamental but exhibit limitations when confronted with the complexity of aerial imagery. For example, thresholding is simple to implement but struggles with intensity variations across images, and region growing demands substantial computational resources and can be compromised by noise. Conversely, deep learning techniques such as convolutional neural networks (CNNs) have advanced the field significantly by facilitating nuanced and precise semantic segmentation, capitalizing on their ability to learn complex features from extensive datasets [8] . Despite the efficiency of these deep learning methods, challenges persist, including the requirement for vast amounts of annotated data for training and a considerable demand for computational power.

Additionally, the selection of an appropriate color space for segmentation remains an unresolved issue, as each space has its own set of benefits and drawbacks. The RGB space, for instance, despite being widely used for display, proves less efficient for segmentation due to the high correlation among its components [9].

In response to these challenges, a novel method based on multimodal Markov fields has been introduced, representing a promising alternative adept at handling the intrinsic diversity and complexity of aerial images. By leveraging the strength of multimodal Markov fields [10], this approach aims to surpass the limitations of both traditional methods and deep learning by integrating multimodal information for more accurate and robust segmentation. This integration enables the capture of spatial dependencies between pixels and subtle variations in texture and color, facilitating detailed segmentation that is finely tuned to the unique challenges of aerial imagery.

The multimodal strategy not only facilitates a clearer distinction between objects and areas of interest but also provides the adaptability required to manage different lighting conditions and atmospheric variances without the need for extensive annotated data sets for training. This approach introduces a sophisticated technique that utilizes the potential of Markov fields through a multimodal energy function. This function integrates several critical attributes, such as color differences measured by the CIEDE2000 metric, texture features, and information from edge detection.

The CIEDE2000 metric, based on CIE Lab color spaces, is recognized for its ability to measure color differences in a manner that aligns more closely with human visual perception compared to traditional metrics. By incorporating this metric, the method can better account for subtle color variations, which are crucial for the segmentation of aerial images.

Texture, an important characteristic for defining regions in aerial images, provides essential information about the nature of the terrain or objects. Texture features derived from the HSV (Hue, Saturation, Value) color space, known for its reduced sensitivity to lighting variations compared to the RGB space [11], are utilized to improve the separation of homogeneous regions.

Moreover, considering the fundamental role of contours in segmentation, an edge detector is used to identify the boundaries between regions of interest0. This information is incorporated into the energy function to improve the consistency of contours and the accuracy of segmentation.

The paper thoroughly presents the methodological approach, the experiments conducted, the results achieved, and a detailed discussion on the advantages and limitations of the method, opening up new perspectives for the analysis of aerial images (see Fig. 1) in various application domains.

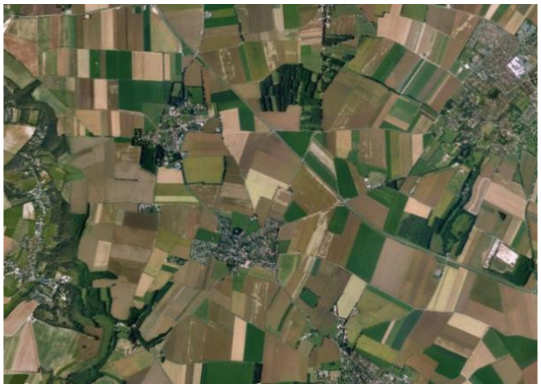

Fig. 1. Aerial image.

## II. Theoretical Foundations

Successful segmentation of aerial imagery relies on a solid theoretical foundation, integrating a variety of techniques and measurements. In this section, the essential theoretical underpinnings of the multimodal segmentation approach are explored. Segmenting an image Y involves dividing all the pixels S into homogeneous regions: $S = S_1 \cup S_2 \cup ... \cup S_K$.

The label map (Xs, s∈S) is introduced to represent a partition: pixel $s \in S_j \Leftrightarrow X_s = j$.

The probabilistic modelling approach to the segmentation problem consists of:

- Consider the image $Y = (Y_s)$ and the label map $X = (X_s)$ (to be constructed) as random variables governed by a statistical law π;
- propose a modelling ≡ define such a law π;
- With X and Y linked by the law π, and Y given, reconstruct or estimate X using π and Y.

Note that if the law of image formation F:

$$X = (X_s) \text{ a } Y = (Y_s) = F(X)$$

If it were completely known, the only task would be to invert F! However, such a deterministic function F is unrealistic, because the mechanism of image formation is complex, to say the least, and is marred by noise, i.e. the randomness or handling errors that occur. The probabilistic model approach defines passages by conditional statistical laws. Markov fields are some of the most widely used examples of such laws.

### A. Markov Fields in Image Segmentation

Markov fields are a powerful mathematical framework widely used in computer vision [12], particularly for image segmentation [13]. They provide a structured way of modeling the spatial dependencies between pixels in an image. In a segmentation context, Markov fields are used to capture the spatial regularity of regions of interest. More specifically, they model the neighborhood relationships between pixels and facilitate the propagation of information about whether pixels belong to a particular class. The notion of neighborhood is then defined [14], which designates a set of pixels located around a central pixel. Consider a pixel S whose position in the image is given by the coordinates (m, n). Its affix is therefore s = (m, n). A neighborhood of S, denoted V(S), is defined as a set of connected pixels P' defined by:

$$N(i,j)=\left\{ (k,l) \mid 0<(k-i)^2+(l-j)^2<constant \right\}$$

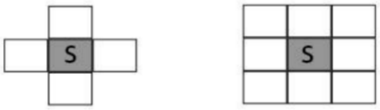

Fig. 2. 4 and 8 neighborhoods.

A clique is any subset A of sites that are mutual neighbors Fig. 2.

Examples of cliques are shown in Fig. 3:

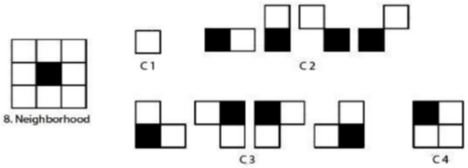

Fig. 3. Cliques for 8 neighborhoods.

1) *Gibbs distribution:* Gibbs fields are commonly used to model thermodynamic systems in statistical physics. The Gibbs distribution is a central concept in MRFs. This equivalence means that the interaction potential between random variables follows a Gibbs distribution [15]. This makes it possible to describe the interactions between the variables in a coherent way, while maintaining the notion of spatial dependence [16].

2) *Hammersley-Clifford theorem:* The Hammersley-Clifford theorem is a result in probability theory, mathematical statistics and statistical mechanics that gives the necessary and sufficient conditions under which a strictly positive probability distribution (of events in a probability space) can be represented as events generated by a Markov random field [17].This is the fundamental theorem of random

fields, which states that a probability distribution with strictly positive mass or density satisfies one of the Markov properties with respect to an undirected graph G if and only if it is a Gibbs random field, i.e. its density can be factored over the cliques (or complete subgraphs) of the graph. In other words, this theory states that the probability of a configuration of states depends mainly on the local relationships between the random variables in the field [18].

### B. CIEDE2000 Color Difference

The CIEDE2000 metric, derived from CIE Lab color spaces, plays a central role as a color attribute in the approach. Designed to measure color difference more accurately[19], CIEDE2000 takes into account the non-linearities of human perception of color. It subtly captures variations in hue, saturation and luminosity, offering a more robust measurement of color difference than its predecessors [20].

The individual components of this formula are as follows:

$$\Delta E_{00} = \sqrt{(\Delta L'/K_L S_L)^2 + (\Delta C'/K_C S_C)^2 + (\Delta H'/K_H S_H)^2 + RT(\Delta C'/K_C S_C)(\Delta H'/K_H S_H)}$$

Where:

ΔL': Difference in luminance between Lab_1 and Lab_2.

ΔC': Difference in chroma (color intensity) between Lab_1 and Lab_2.

ΔH': Hue difference (hue of the color) between Lab_1 and Lab_2.

The $S_L$, $S_C$ and $S_H$ components are adjustment factors to take account of non-linearities in the perception of color by the human eye:

$S_L$: Adjustment factor for luminance.

$S_C$: Chromaticity adjustment factor.

$S_H$: Tint adjustment factor.

The $k_{L,}$ $k_C$ and $k_H$ values are parameters that depend on the luminance of the sample and the color of the average sample.

RT is an additional correction factor.

Integrating the CIEDE2000 metric into the energy function enables more accurate segmentation by considering the subtle nuances of color present in aerial images.

### C. Texture as a Segmentation Attribute

Texture is an essential element for characterizing regions of interest in aerial images. It represents the repetition of patterns or structures and can provide crucial information about the nature of the terrain or objects.

*1) Co-occurrence matrix in the HSV Space:* The co-occurrence matrix, also known as the correlation matrix, is a powerful image processing technique that quantifies the spatial relationships of grey levels or pixel values in an image. The co-occurrence matrices contain a very large amount of information and are therefore difficult to manipulate. For this reason, fourteen indices (defined by Haralick) [21] which correspond to descriptive characteristics of textures can be calculated from these matrices. In the context of the study, An innovative approach is taken using the HSV (Hue, Saturation, Value) color space. Specifically, The focus is on the hue (Hue) and intensity (Value) components. Hue represents color tone, while intensity captures luminance. The aim is to exploit these two components to assess the homogeneity and correlation of textures in aerial images.

*a) Homogeneity:* The more frequently the same pair of pixels is found, the higher this index becomes, for example in a uniform image, or a texture that is periodic in the direction of translation Fig. 4.

$$Homogeneity = \sum_{i=1}^{q-1}\sum_{j=1}^{q-1}\frac{P(i,j)}{1+|i-j|}$$

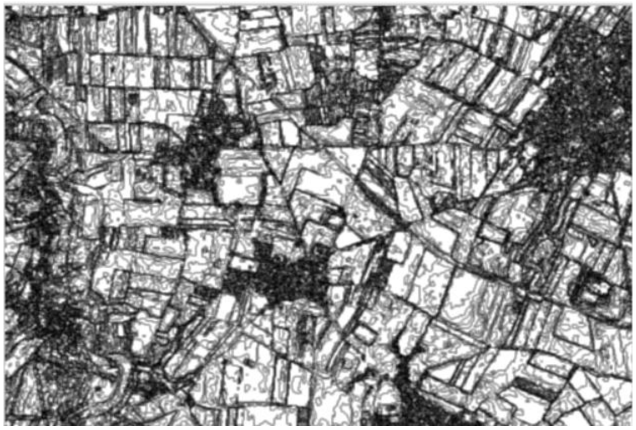

Fig. 4. Homogeneity result.

*b) Correlation:* describes the correlations between the rows and columns of the cooccurrence matrix Fig. 5.

$$Correlation = \sum_{i=1}^{q-1}\sum_{j=1}^{q-1}\frac{ijP(i,j)-u_i u_j}{\sigma_i \sigma_j}$$

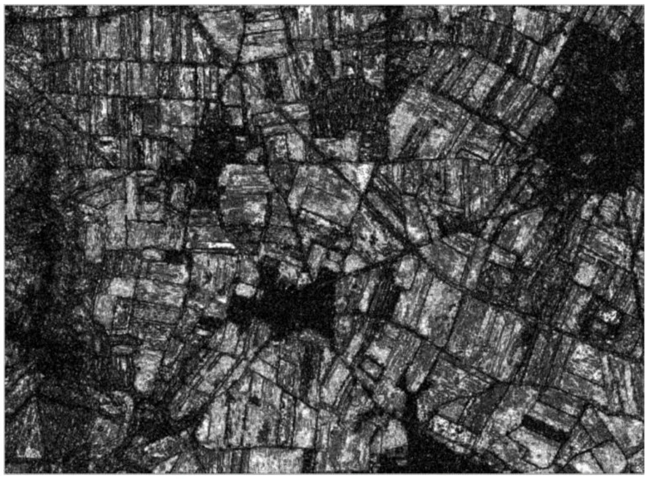

Fig. 5. Correlation result.

The co-occurrence matrix in HSV space allows us to analyze how hue and intensity values co-vary within a local image window. This approach is essential for detecting regions with similar textures based on variations in hue and intensity. More formally, the co-occurrence matrix tells us the joint probability of observing a pair of hue and intensity levels in each neighborhood. This information is then used to calculate texture measures such as homogeneity and correlation, which are incorporated into the Markov field model to improve aerial image segmentation. These characteristics make it easier to distinguish homogeneous regions, enhancing the quality of the segmentation.

### D. Role of Contour Detectors

Contours play a fundamental role in the segmentation of aerial images. Precise delineation of regions of interest depends largely on edge detection.

Several methods have been developed to accomplish this task [22], each with its own advantages and disadvantages as shown in Table I.

TABLE I. SEVERAL METHODS FOR EDGE DETECTION, ADVANTAGES, AND DISADVANTAGES

| Method | Advantages | Disadvantages |
|---|---|---|
| Directional Derivatives[23] | -Simple implementation;<br>-Effective for sharp contours | -Sensitive to noise;<br>-Reaction to varying brightness |
| Edge Detection Filters | -Flexibility in adjusting filters;<br>-Easily extendable to color image | -Sensitive to noise;<br>-Limited response to diagonal contours;<br>-Excessive smoothing on curved contours |
| Laplacian Operators[24] | -Sharp edge detection;<br>-Robust to variable lighting;<br>-Capable of detecting fine contours | -Sensitive to noise;<br>-Computationally intensive;<br>-Limited response to subtle details |
| Hough Transform[25] | -Robust to noise presence;<br>-Can detect non-linear contours | -High computational cost;<br>-Sensitive to discontinuities;<br>-Parameter tuning required |
| Canny Edge Detector[26] | -Good detection of sharp contours;<br>-Effective noise suppression;<br>-Accurate localization | -Sensitive to parameter settings;<br>-Computationally intensive;<br>-May be sensitive to weak contours |

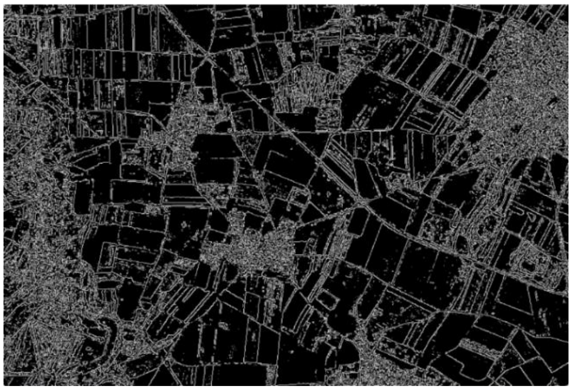

Fig. 6. Edge detection result.

A single edge detector may be limited in its ability to capture the diversity of existing edges.

This is why a combination of detectors is used in the approach, each bringing its own specific expertise to highlight certain types of contours to identify the boundaries between objects and structures present in the image.

The information extracted by these edge detectors Fig. 6 is incorporated into the Markov field energy function, which promotes edge coherence between pixels and, as a result, more robust and accurate segmentation.

## III. METHODOLOGY

In this section, the methodology developed for the segmentation of aerial images using Markov fields with a multimodal energy function is described in detail.

### A. Multimodal Approach to the Energy Function

The segmentation approach is based on a multimodal energy function, designed to capture various key features of aerial imagery simultaneously. This energy function integrates color difference based on the CIEDE2000 metric, texture features, and detected edge information.

The aim of this approach is to improve the consistency and accuracy of segmentation by taking advantage of several key attributes.

### B. Combining Attributes in the Energy Function

*1) CIEDE2000 color difference:* The CIEDE2000 metric is integrated into the energy function as a measure of pixel similarity. It encourages the grouping of pixels that share similar color characteristics, while taking subtle color nuances into account.

*2) Texture:* Texture characteristics are extracted from aerial images and used to assess the textural coherence of regions. This component of the energy function distinguishes homogeneous regions from textured areas, contributing to more accurate segmentation.

*3) Contour detector:* Detected contour information is incorporated to encourage contour consistency in segmentation. This component aims to ensure that the boundaries of the regions of interest are well defined.

### C. Comparative Analysis of Models

In the quest for the most effective method for segmenting aerial images, a range of models was evaluated, each possessing unique characteristics and capabilities Table II. Central to this analysis were Markov Random Fields (MRF), known for their robust modeling of spatial interactions, alongside Conditional Random Fields (CRF), Deep Learning techniques, Graph Cut optimizations, and the Watershed algorithm. The choice of model significantly impacts the quality of segmentation, particularly in complex scenarios such as aerial imagery, where accuracy, detail, and computational efficiency are paramount. A comprehensive comparison is provided below, highlighting the strengths and weaknesses of these models:

After thorough consideration of the advantages and limitations of each model, the decision to utilize Markov Random Fields (MRF) for the segmentation of aerial images was driven by the model's exceptional ability to handle spatial complexities and the rich textural and contour information inherent in aerial imagery. Despite the computational demands, the flexibility and robustness of MRFs, particularly when combined with an efficient optimization algorithm like Iterated Conditional Modes (ICM), offer a sophisticated balance between detail accuracy and processing efficiency. This makes MRF an ideal choice for studies aiming at high-quality segmentation of aerial images where precision and reliability are crucial.

TABLE II. VARIOUS IMAGE SEGMENTATION METHODS, ADVANTAGES, AND DISADVANTAGES

| Model | Characteristic | Advantages | Disadvantages |
|---|---|---|---|
| MRF | Generative model emphasizing spatial interactions among pixels. | - Models spatial dependencies effectively.<br>- Robust to local variations.<br>- Suited for images with complex textures and structures. | - Computationally intensive.<br>- Energy function definition demands precision. |
| CRF | Conditional model focusing on pixel label dependency on observed data. | - Integrates global and local information.<br>- Modelling of conditional dependencies is flexible. | - High computational complexity for inference.<br>- Feature and parameter selection is critical. |
| Deep Learning | Data-driven approach using neural networks for feature extraction and segmentation. | - Capable of learning from large data sets.<br>- Demonstrates excellent performance across diverse tasks. | - Requires extensively annotated data sets.<br>- Interpretability and control over decisions are limited. |
| Graph Cut | Optimization model based on graph theory, aiming to minimize a cost function for segmentation. | - Captures global image properties effectively.<br>- Yields precise and clean segmentations. | - Initialization sensitivity.<br>- May over-segment highly textured images. |
| Watershed | Morphological model that segments images based on gradient analysis, treating images as topological surfaces. | - Intuitive and straightforward to implement.<br>- Effective at outlining object boundaries in high-contrast images. | - Prone to over-segmentation in noisy contexts.<br>- Frequently necessitates post-processing for optimal segmentation. |

### D. Markov Field Model

The Markov field model is the underlying structure of the segmentation method. It is used to model the spatial relationships between pixels and to propagate information about whether pixels belong to a particular class. The MRF model is employed to describe the spatial dependency of pixels and attributes within the image. This allows us to efficiently exploit the multimodal information embedded in the energy function.

The Energy function incorporates color difference, texture and contour detector attributes, enabling a comprehensive approach to aerial image segmentation that is sensitive to subtle variations in color, texture, and shape:

The energy function E is defined as the sum of three terms:

$$E(I,S)=\alpha\ E_{color}(I,S) + \beta\ E_{texture}(I,S) + \lambda\ E_{contour}(I,S)$$

Where:

α, β, λ are weighting coefficients to control the influence of each term of the function.

I represent the input image.

S is the map of segmentation labels, where each pixel is associated with a class (object or background).

Each term in the energy function is defined as follows:

*1) CIEDE2000 Color Difference Term:* Ecolor (I,S) measures the color difference between pixels in the same region (class) in the segmented image $I_S$ using the CIEDE2000 metric. It encourages color consistency within each region:

$$E_{\text{Color}}(\text{I}, \text{S}) = \sum_{r} \sum_{p \in r} \Delta\text{E00}(\text{I}_\text{p}, \mu_\text{r})$$

The average μr essentially represents the average color of region r in CIELab space. It is calculated by traversing all the pixels that belong to the region reconverting its color components (L, a, b) in CIELab space, summing them to obtain three sums: ΣL, Σa and Σb, then devising each sum by the number of pixels N in the region r to obtain the average components μr of the region r.

To optimize processing, a region graph is constructed with the number of pixels N and the mean μr, which is updated each time a pixel is added to a region.

$\Delta E00\ (I_p, \mu_r)$ is the CIEDE2000 color difference between pixel Ip and the average color of region r ($\mu_r$ ). The lower ΔE00 is, the more similar the color of pixel Ip is to the average color μr of region r.

*2) Texture term:* $E_{texture}(I, S)$ evaluates the texture in each segmented region. Texture measurements will be used based on the co-occurrence matrix calculated from the variation of the Hue and intensity attributes of the pixel color in HSV space with respect to the average of the region and neighborhood to which it belongs, to promote the homogeneity of textures within each class:

$$E_{\text{texture}}(\text{I}, \text{S}) = \sum_{r} \sum_{p \in r} 1 - \text{H}(\text{I}_\text{p}, \mu_\text{r})$$

$H(I_p, \mu_r)$ is a measure of the homogeneity of the texture of pixel Ip with respect to the region $\mu_r$ to which it belongs, The higher H is, the more homogeneous the texture.

The homogeneity measure from the co-occurrence matrix is already a normalized value between 0 and 1, where 0 represents minimum homogeneity (maximum variability) and 1 represents maximum homogeneity (no variability). This is the reason the homogeneity value is subtracted from 1, to minimize the energy function the more homogeneous the region becomes.

The steps below will be followed to calculate H ($I_p$ , $\mu_r$ ):

*1) Calculate the co-occurrence matrix for the region r:* For each pixel Ip in region r, examine the Hue and intensity attributes of the neighboring pixels (we'll use neighborhood 8) in region r. Create the co-occurrence matrix, which records the frequency of pairs for each attribute and is generally symmetrical.

*2) Normalize the co-occurrence matrix:* Each element of the co-occurrence matrix is divided by the sum of all the elements of the matrix to normalize the values in the range 0 to 1. This step produces a co-occurrence probability matrix.

*3) Calculate homogeneity:* The standardized matrix is used to calculate homogeneity, which is a measure of the inverse of the variation in the attributes used.

The formula used to calculate the homogeneity $H(I_p,\mu_r)$ is as follows:

$$H(I_p,\mu_r)=\sum_{i,j} 1+|i-j|2P(i,j)$$

P(i,j) is the probability of co-occurrence of chromaticity's i and j in the normalized matrix.

|i-j| is the difference between chromaticity i and j.

*4) Average homogeneity:* Once the homogeneity has been calculated for each pixel Ip in region r, these values can be averaged to obtain an overall measure of the homogeneity of the texture in region r.

This measure will be used as a component of the energy function to encourage texture consistency within each segmented region. The higher the homogeneity, the more uniform the texture is, and vice versa.

*3) Contour term:* $E_{\text{contour}}$(I, S) encourages contour consistency, Firstly, Edge detectors will be used to identify the edge locations in the image, and then an edge map will be built where the marked pixels or regions correspond to the edge locations. This map will contain binary values (edge or non-edge).

The following function is defined:

$$E_{\text{Contour}}(\mathrm{I},\mathrm{S}) \;=\; \sum_{r}\sum_{pq\in r} D_{pq}.\left|\mathrm{S_p}\,,\mathrm{S_q}\right|$$

$D_{pq}$ is a factor based on contour detection between pixels Ip and Iq. It is calculated by comparing the contour values of neighboring pixels p and q in the contour map. If pixels p and q are neighbors and one is on the contour while the other is not, this indicates a label discontinuity along the contour:

If pixel p is on the contour (high contour value) and pixel q is not on the contour (low contour value), or vice versa, then $D_{pq}$ is defined as a high penalty factor, $D_{pq}$ = 1 (to strongly penalize label discontinuity).

If the two pixels p and q are both on the contour (or both outside the contour), it is defined as a low penalty factor, $D_{pq}$ = 0 (so as not to penalize label consistency).

The expression "$|S_p - S_q|$" is a term which measures in absolute value the difference in labels ($S_p$ and $S_q$) of pixels p and q within the same region of the segmentation and which penalizes label discontinuities to encourage their coherence within each region.

If "$S_p$" and "Sq" are the same (i.e. neighboring pixels have the same label), then "$|S_p - S_q|$" is zero. This means that there is no penalty for label consistency, as the labels are already the same.

On the other hand, if "$S_p$" and "Sq" are different (i.e. neighboring pixels have different labels), then "$|S_p$ - Sq|" is greater than zero. This means that there is a penalty for label discontinuity within the same region. This penalty encourages the model to assign similar labels to neighboring pixels in the same region, thereby promoting the consistency of the segmentation.

This energy model integrates the three attributes (color difference, texture, and contours) to promote the coherence of the segmentation regions by taking into account the visual and structural characteristics of the pixels. Segmentation is achieved by minimizing this energy function using the Iterated Conditional Modes (ICM) optimization algorithm.

*4) ICM algorithm for segmentation optimization:* The segmentation is optimized using the Iterated Conditional Modes (ICM) algorithm. This is an efficient iterative algorithm that iterates through the set of pixels taking into account spatial dependencies and the multimodal energy function and seeks to find the best pixel label configuration that minimizes the energy function E(I,S) and corresponds to the most accurate segmentation [27].

However, an iterative algorithm without a stopping condition could continue to iterate indefinitely. Introducing this stopping condition saves computation time and resources by stopping the algorithm once convergence criteria are satisfied.

Here Table III shows some common stopping conditions for ICM:

TABLE III. COMMON STOPPING CONDITIONS, ADVANTAGES, AND DISADVANTAGES

| Stopping Criterion | Brief Description | Advantages | Disadvantages |
|---|---|---|---|
| Energy Convergence | Stops the algorithm when the energy converges, i.e., it ceases to decrease significantly. | - Can lead to rapid convergence. | - Sensitive to local energy minima. |
| Maximum Number of Iterations | Halts the algorithm after a fixed number of iterations. | - Precise control over execution time. | - May not converge if the number is too low. |
| Label Stagnation | Stops the algorithm when labels no longer change between successive iterations. | - Saves computation time. | - May lead to suboptimal segmentation. |
| Local Convergence | Halts the algorithm if labels locally converge around certain pixels. | - Accelerates local convergence. | - Risk of premature convergence. |
| Cross-Validation | Uses cross-validation to estimate model performance and stops when performance stabilizes. | - Suitable for avoiding overfitting. | - Can be computationally expensive. |
| Maximum Execution Time | Stops the algorithm after a predefined execution time. | - Controls overall execution time. | - May lead to suboptimal convergence. |
| Segmentation Quality Criterion | Stops the algorithm based on a specific measure of segmentation quality achieved. | - Directly optimizes segmentation quality. | - Depends on a subjective measure of quality. |

In the method, a combination of several of these conditions will be used to ensure that the algorithm stops appropriately. More specifically, the global energy convergence criterion combined with the execution time will be applied to prevent the algorithm from running in an infinite loop.

**Algorithm 1:**

```
Input
  S: Source image
  α, β, λ: Ponderation parameters
  ε: Convergence threshold
  τ: Maximum execution time
//Initialization
Read the source image S
Convert S to HSV space $S_{HSV}$
Convert S to Lab space $S_{Lab}$
Calculate the contour map
Compute Homogeneity and correlation for each pixel $x \in S$
Initialize the LabelMap with Labels {1,2,......,SHighxSWidth}
// Label Propagation
For each pixel (x in S):
    If (P1 and P2 are Neighborhood Pixels And
     $P1_{indH} = P2_{indH} = 1$) then
     $P1_{Label} = P2_{Label} = \min(P2_{Label}, P2_{Label})$
    End
 End
// Energy Minimization
For each pixel (x in S):
    // Compute Energy Function
    Calculate $E(I, S) = \alpha E_{Color}(I, S) + \beta E_{texture}(I, S) + \lambda E_{contour}(I, S)$
    //Update Label
    Evaluate E(I, S)
    Update the label $X_{Label}$
//Convergence Check
While ( $\|E(I, S)_{New} - E(I, S)_{Old}\| \geqslant \varepsilon$ And Execution time $< \tau$ ) do
    For each pixel (x in S):
     //Update label based on energy minimization
     $X_{Label}$ = argmin_Label E (I, S) for all possible labels
     $E(I, S)_{Old} = E(I, S)_{New}$
    End
 End
//Output
 Display the final segmented image
```

## IV. RESULT

In this phase, the algorithm begins by reading the source image S Fig. 2. Subsequently, the conversion of the image S to the HSV and Lab color spaces is performed, providing a suitable representation for color and brightness analysis. The contour map is calculated to capture significant variations in the image. Simultaneously, measures of homogeneity and correlation are computed for each pixel, laying the foundation for the initial label assignment Fig. 7.

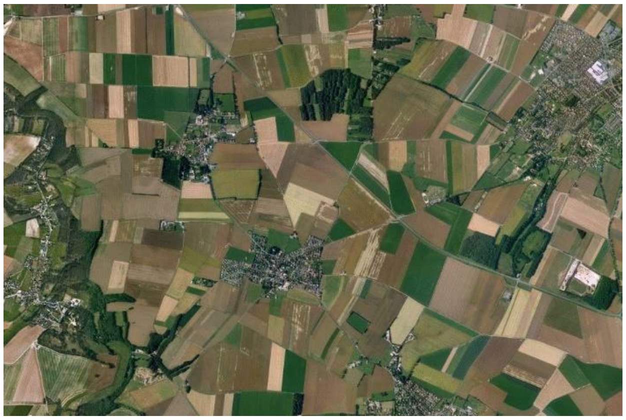

Fig. 7. Original Image used in the experimental test.

The label propagation phase is initiated to establish initial relationships between neighboring pixels. For each pixel x in the source image S, a neighborhood analysis is conducted to examine adjacent pixels, namely P1 and P2. If both exhibit homogeneity ($P1_{indH} = P2_{indH} = 1$), their labels are adjusted to ensure coherence. This step aims to create an initial label assignment that considers the homogeneity characteristics within local pixel neighborhoods, setting the groundwork for subsequent energy minimization and label refinement Fig. 8.

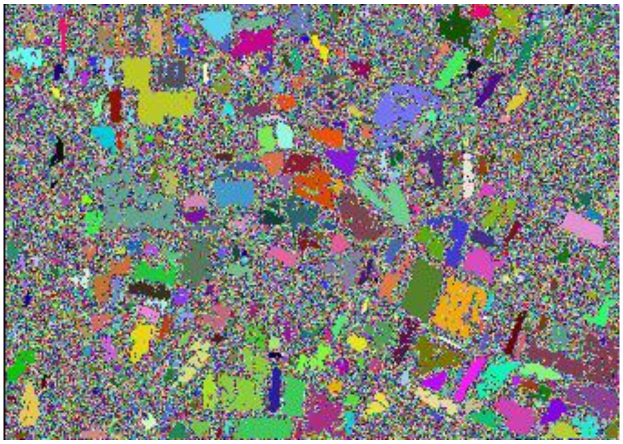

Fig. 8. Class and label assignment after neighborhood label update.

In this phase, the system's energy is minimized for each pixel x. The energy function E (I,S) is calculated by combining contributions from CIEDE2000 color difference, texture, and contours. This energy is used to update labels, promoting pixel coherence within the context of the entire image.

The convergence check loop is introduced to iterate through label updates until satisfactory convergence is achieved or the specified maximum execution time (τ) is exceeded. In each iteration, labels are updated using the ICM approach, where each pixel adjusts its label to minimize local energy. This step continues until the energy difference between consecutive iterations falls below a threshold ε, indicating satisfactory convergence Fig. 9.

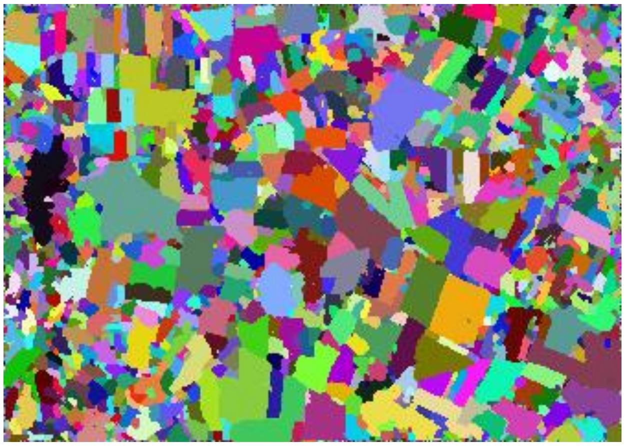

Fig. 9. Final labeling result.

Finally, the algorithm leads to the presentation of the final labeling result, displaying the segmented image. The optimized labels obtained (see Fig. 10) after the algorithm's convergence reflect the successful segmentation of the original image based on color, texture, and contour criteria.

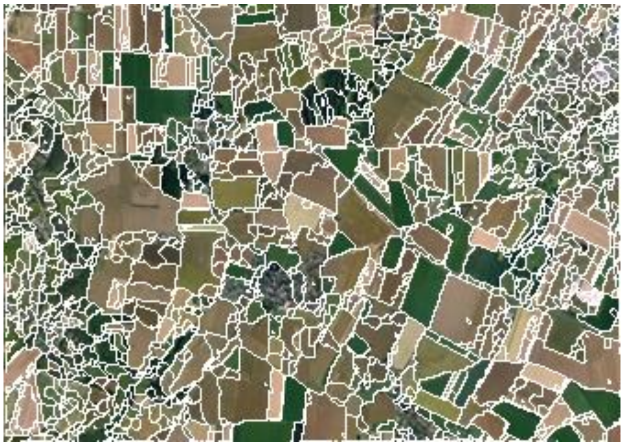

Fig. 10. Segmented image.

## V. Conclusion

The image segmentation approach based on Markov field methodology (MRF) and exploiting the attributes of color difference, texture and edge detection was subjected to an exhaustive evaluation. The results obtained demonstrate the robustness of the method in accurately delineating the contours of complex objects within images.

The CIEDE2000 color difference measurement was particularly effective at capturing subtle variations in color, ensuring accurate segmentation even under changing lighting conditions. The incorporation of texture information has enhanced the method's ability to discriminate between homogeneous but textured regions, improving segment consistency.

At the same time, the use of edge detectors, such as the Canny operator, has made it possible to highlight the boundaries between objects, improving the sharpness and overall accuracy of the segmentation.

To quantitatively evaluate the performance of the approach, commonly used metrics such as precision were utilized, recall and F-measure. The results demonstrated competitive performance.

With existing methods, highlighting the ability of the model to produce segmentations faithful to the real contours of objects in a variety of images.

In addition, in-depth visual analyses have been carried out, highlighting the ability of the method to handle complex cases such as the presence of fine structures, objects with blurred edges, and significant texture variations. These qualitative observations confirm the relevance of the approach in various applications, from computer vision to medical image analysis.

In conclusion, the results obtained support the validity and effectiveness of the Markov field-based image segmentation approach, demonstrating its potential for a variety of applications requiring accurate and robust segmentation. Ongoing improvements and future extensions to this methodology promise to further enhance its versatility and applicability in a variety of contexts.

# Path Planning and Control of Intelligent Delivery UAV Based on Internet of Things and Edge Computing

Xiuzhu Zhang
School of Economics and Management, Jiaozuo University, Jiaozuo China

***Abstract*—This paper investigates the intelligent delivery UAV path planning and control problem based on the Internet of Things and edge computing, and proposes a novel model and algorithm to realize the collaborative optimization of the path planning and control of the UAV, which improves the intelligence level and flight efficiency of the UAV. In this paper, the mathematical model of UAV path planning and control is firstly established, the relationship and influencing factors among the elements of UAV, edge server, delivery task, path planning and control are analyzed, and the optimization objectives and constraints are proposed. Then, this paper designs an algorithmic framework for UAV path planning and control, using the support and guidance of edge computing to achieve the cooperative optimization of path planning and control of UAVs, taking into account the constraints and objectives of the UAVs themselves, as well as the synergy and competition between UAVs. Then, this paper proposes specific algorithms for UAV path planning and control, adopting methods such as meta-heuristics, to solve the optimization problem of UAV path planning and control, and improve the intelligent level and flight performance of UAVs.**

## I. INTRODUCTION

With the development of IoT technology, more and more smart devices are connected to the Internet, forming a huge data source. This data is characterized by massive, diverse, real-time, dynamic, etc., which pose great challenges to traditional cloud computing platforms, such as high latency, low bandwidth, low reliability, and high energy consumption. To address these issues, edge computing, as an emerging computing paradigm, shifts computing resources from cloud centers to servers on the edge side of the network to provide computing support for connected end devices. Edge computing enables local processing and analysis of data, reduces data transmission and latency, and improves the quality of service and user experience while protecting data security and privacy [1].

The computing power and battery capacity of UAVs are very limited, which cannot meet the demands of complex data processing and long flight times. Therefore, combining edge computing and UAVs to build a mobile edge computing network based on UAVs is an effective solution. In this kind of network, UAVs can transmit data to the edge side for fast processing and analysis through the communication connection with edge servers, and at the same time obtain guidance and support from the edge side to improve the intelligence level and flight efficiency of UAVs. The generalized UAV path planning framework is shown in Fig. 1 [2], [3].

Path planning and control of UAVs is one of the core technologies of UAVs, which determines the flight trajectory and maneuvers of UAVs and directly affects the performance and safety of UAVs. In the UAV-based mobile edge computing network, the path planning and control of UAVs should not only consider the UAVs' own constraints and objectives, such as flight time, energy consumption, load, and task completion, but also consider the influencing factors of edge computing, such as the location and number of edge servers, computational capacity, and communication link quality. In addition, when multiple UAVs perform delivery tasks in the same area at the same time, the synergy and competition between UAVs, such as path conflict, resource allocation, and task coordination, are also considered. Therefore, the study of intelligent delivery UAV path planning and control based on IoT and edge computing is a topic of great theoretical significance and practical value [4].

Current research has mainly focused on the enhancement of quality of service and user experience of IoT applications by edge computing, while less consideration has been given to the enhancement of intelligence and efficiency of IoT devices by edge computing. As a typical IoT device, the improvement of intelligence and efficiency of UAVs can not only enhance the function and performance of UAVs, but also reduce the operation cost and risk of UAVs [5]. Therefore, it is a meaningful work to study how to optimize the path planning and control of UAVs using edge computing.

Under the cooperative operation environment, the edge computing-based intelligent delivery UAV system can better balance the load of each UAV and ensure the fairness of task allocation and the effectiveness of resource use by dynamically adjusting the path planning strategy. In addition, this approach can also achieve dynamic optimization of UAV paths, avoid flight conflicts, and adapt to changing environmental conditions and task priorities, thus significantly improving the operational efficiency and task completion quality of the entire UAV cluster.

Against the background of the current rapid development of the Internet of Things (IoT) and drone technology, intelligent distribution drones have shown broad application prospects in the field of logistics and distribution due to their unique advantages of high efficiency, convenience and flexibility. However, in the process of executing distribution tasks, UAVs are limited by their own limited computing power, short battery life and instability of wireless communication, especially in the face of large data volume, real-time response requirements of high scenarios, the traditional centralized cloud computing architecture is difficult to meet the needs of efficient and accurate path planning and control. In addition, when multiple UAVs work together, it is also necessary to take into account the fairness of task allocation, path conflict avoidance, and overall task completion efficiency and many other issues [6], [7]. Therefore, this paper proposes a research method for intelligent distribution UAV path planning and control based on IoT and edge computing, which can make up for the shortcomings of traditional methods in processing large-scale data, real-time decision-making, and responding to changes in the local environment of the UAV, and by integrating the advantages of IoT and edge computing, it can effectively solve the computational bottlenecks and communication delays faced by UAVs when they perform their tasks. IoT technology enables UAVs to acquire and transmit rich environmental information in real time, while edge computing can provide instant computing resources and services near the data source, greatly reducing the delay of data transmission and improving the data processing speed, which in turn supports UAVs to make more accurate and real-time path planning and control decisions.

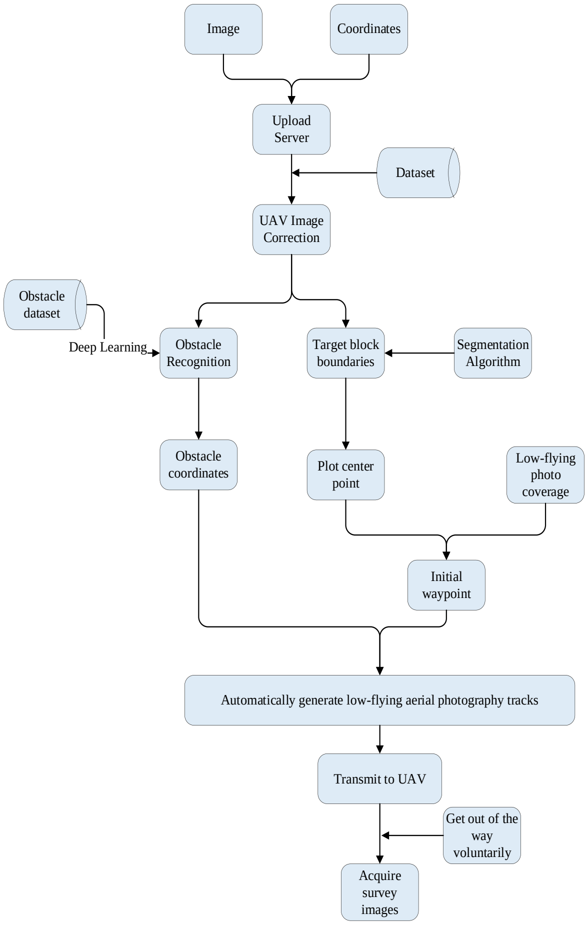

Fig. 1. Drone path planning model.

The research contributions of this paper mainly include the following aspects: (1) Constructed a mathematical model for intelligent delivery UAV path planning and control based on IoT and edge computing environment, deeply analyzed the interaction mechanism among core elements such as UAVs, edge servers, and delivery tasks, and clarified the objective function and necessary constraints for optimizing the path planning and control of UAVs. (2) Designed a set of new Algorithmic framework, which takes into account the individual performance constraints and target requirements of a single UAV when performing a task, as well as the fair scheduling, path conflict avoidance, and overall task efficiency optimization of multiple UAVs when performing tasks together. (3) A specific path planning and control algorithm for intelligent delivery UAVs is proposed, which combines the heuristic, meta-heuristic, and machine learning methods to solve the problems of UAVs in actual operation. The path optimization problem of UAVs in actual operation improves the intelligence level and flight execution efficiency of the UAV system.

The main content is divided into five sections. Section I introduces the research background. Section II analyzes the current research status. Section III explains the research methods. Section IV analyzes and discusses the research results. Finally, Section V concludes the paper..

## II. Literature Review

Cui et al. [8] studied a cooperative path planning algorithm for UAV clusters based on edge computing, which uses the location information and movement laws of the edge server to guide the path planning of the UAVs, while taking into account the synergy and competition between the UAVs, to optimize the UAVs' task completion and flight efficiency. Cui et al. [9] investigated a collaborative task allocation method for UAV clusters based on edge computing, which utilizes the edge server's computational capability and data analysis advantages to provide decision support for task allocation for UAV clusters, while optimizing the UAVs' task execution effectiveness by considering the UAVs' energy consumption, flight time, and task priority. Dec et al. [10] utilized the communication resources and link quality of the edge server to provide communication optimization for UAV clusters, while factors such as communication demand, communication interference and communication cost of UAVs are considered to optimize the communication performance and communication efficiency of UAVs. Ding et al. [11] investigated a cooperative security assurance method for UAV clusters based on edge computing, which utilizes the security technology and security policy of edge servers to provide services for UAV clusters to provide security assurance, while considering factors such as the security demand, security threat and security cost of UAVs, to optimize the level of security and the security benefit of UAVs.

In summary, the research related to UAV path planning and control has been relatively mature, and the number of its results is shown in Fig. 2. Although the above series of studies have made significant progress in edge computing-based UAV cluster path planning, task assignment, autonomous navigation, communication optimization, and security, there are still some important limitations and knowledge gaps to be addressed in this area. First, most current research focuses on single or partial optimization objectives, such as information update speed, energy consumption, flight time, and mission completion, while it remains a challenge to maximize the overall effectiveness of UAV clusters in the context of multi-objective optimization. Second, although edge computing enhances the real-time computation and decision-making capabilities of UAVs, in practical applications, the computational resources of edge servers are not unlimited, and how to effectively schedule and utilize them under resource-constrained conditions to cope with large-scale and high-density UAV cluster operations is an issue that needs to be explored in depth. Furthermore, the reliable communication, obstacle avoidance and adaptive flight capabilities of UAVs in complex and dynamic environments need to be further strengthened, especially in extreme or unexpected situations, how to utilize edge computing technology to improve the UAV's anti-interference capability and fault recovery speed, and to safeguard the flight safety and service continuity needs more research. In addition, current research has not paid enough attention to and explored in-depth the compliance issues of edge computing in UAV applications, which involve user privacy, data security, and regulatory compliance. In summary, although edge computing-based UAV clustering research has achieved a series of results, limitations in multi-objective optimization, efficient scheduling in resource-constrained environments, adaptation to complex environments, and legal and ethical issues reveal the large research space and development potential that remain in this area.

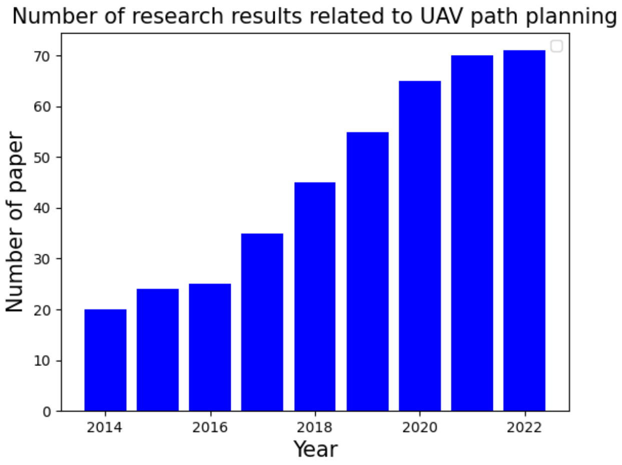

Fig. 2. Number of research results related to UAV path planning.

## III. Research Methodology

### A. UAV Path Planning Model

Suppose there are $N$ drones, $M$ edge servers, and $K$ delivery tasks. Each UAV $i$ has an initial position $p_i^0$ and a target position $p_i^f$, as well as some constraints, such as maximum speed $v_{imax}$, maximum acceleration $a_{imax}$, maximum turning angle $\theta_{imax}$, maximum flight time $t_{imax}$, maximum payload $w_{imax}$ etc. [12]. Each edge server $j$ has a fixed location $q_j$, as well as some resource parameters such as computing power $c_j$, storage capacity $s_j$, communication bandwidth $b_j$, etc. [13], [14]. Each delivery task $k$ has a weight of the demanded item $w_k$, a location of the demanded item $r_{ks}$, a location of the delivery destination $r_{kd}$, and a delivery time window $[t_{kmin}, t_{kmax}]$. The distance between the UAV, the edge server, and the delivery task can be measured in terms of the Euclidean distance, i.e., $d(x,y)=(x-y)^T(x-y)$, where *x* and *y* are any two position vectors [15], [16].

The purpose of path planning and control of UAVs is to find a set of optimal control inputs $u_i(t)$ that enable the UAV to complete the delivery task while satisfying constraints and minimizing some optimization objective function. The optimization objective function can be the UAVs' total flight time, total flight distance, total energy consumption, total delay, etc., or it can be a weighted function that integrates several factors. For example, if the optimization objective is to minimize the total flight time of the UAV, then the optimization objective function is specifically shown in Eq. (1). where, $t_i^f$ is the time for the UAV $i$ to reach the target position [17], [18].

$$\min \sum_{i=1}^{N} \int_0^{t_i^f} dt \tag{1}$$

The constraints for path planning and control of UAVs include kinematics and dynamics constraints of UAVs, collision avoidance constraints between UAVs, communication connectivity constraints between UAVs and edge servers, matching constraints between UAVs and delivery tasks, and time window constraints for delivery tasks. Each delivery task can only be executed by one UAV, as shown in Eq. (2). Where $y_{ik}$ indicates whether the UAV $i$ executes the delivery task $k$, which takes the value of 0 or 1. The load capacity of the UAV cannot exceed the maximum limit, i.e., Eq. (3) [19].

$$x_k = \sum_{i=1}^{N} y_{ik}, \quad k = 1, \ldots, K \tag{2}$$

$$\sum_{k=1}^{K} w_{ik} y_{ik} \le w_{imax}, \quad i = 1, \ldots, N \tag{3}$$

where, $w_{ik}$ denotes the weight of the item for the delivery mission $k$ and $w_{imax}$ denotes the maximum load capacity of the drone $i$.

The drone cannot fly beyond the maximum limit, as shown in Eq. (4) [20].

$$\sum_{k=1}^{K}\sum_{j=1}^{M}(d(s_k,t_k)y_{ik}+d(p_i^0,q_j)z_{ij}$$
$$+d(q_j,p_i^t)z_{ij})\le d_{imax},\quad i=1,\ldots,N \tag{4}$$

where, $d(\cdot,\cdot)$ denotes the distance between two locations, $s_k$ denotes the location of the demanded item of the delivery task $k$, $t_k$ denotes the location of the delivery destination of the delivery task $k$, $p_i^0$ denotes the initial location of the drone $i$, $q_j$ denotes the location of the edge server $j$, $p_i^t$ denotes the location of the drone $i$, $d_{imax}$ denotes the maximum flight distance of the drone $i$, and $z_{ij}$. Indicates whether the drone $i$ is connected to the edge server $j$, which takes the value of 0 or 1. The drone must complete the delivery within the time window of the delivery task, as shown in Eq. (5) [21], [22].

$$t_k=\max\{y_{ik}=1\}\left(\sum_{j=1}^{M}\frac{d(p_i^0,q_j)}{v_i z_{ij}+L_i z_{ij}}+d(s_k,t_k)\right),$$
$$k=1,\ldots,K \tag{5}$$

### B. Algorithmic Framework

The path planning and control algorithm framework for smart delivery UAVs based on IoT and edge computing builds a complete set of decision-making processes, as shown in Fig. 3. The framework covers six key steps from information interaction to real-time control:

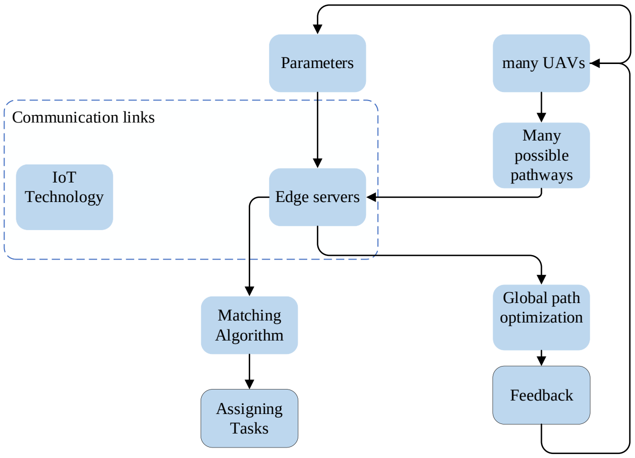

Fig. 3. Path planning and control algorithm framework based on IoT and edge computing.

Step I: In the initialization phase of the system, the UAV establishes a stable communication link with the edge server through IoT technology, and sends its real-time status data as well as the specific demand parameters of the delivery task it is carrying to the edge server. The server receives and stores this information and analyzes and preprocesses it in depth [23].

Step II: The edge server uses matching algorithms to assign optimal or sub-optimal delivery tasks to each UAV based on the received UAV status and task demand information, aiming to achieve an optimal balance of several key performance indicators, such as total flight time, distance, energy consumption, and latency. Subsequently, the server will send the allocation results back to the relevant drones in real time [24].

Step III: Immediately after getting the task assignment, the UAV uses the path planning algorithm to autonomously design an efficient flight path from its current location to the target location based on the matching scheme provided by the edge server. In this process, the kinematics and dynamics constraints of the UAV itself are fully considered to ensure safe flight while avoiding collisions with other UAVs and the time window requirements of the delivery task are strictly followed. After the planning is completed, the UAV sends the finalized path information to the edge server again [25].

Step IV: Based on the path planning results submitted by all UAVs, the edge server performs global path optimization using a cooperative optimization algorithm to promote effective collaboration and competition among multiple UAVs, so as to achieve the overall optimal or near-optimal path layout of the entire distribution network. The optimized path planning scheme is then fed back to the participating drones.

Step V: The UAV applies the appropriate control algorithm to generate a set of best-fit control input commands based on the co-optimization path returned by the server. The UAV performs precise flight operations accordingly and is able to adjust its control strategy in real time to respond to changing environmental factors. This set of control inputs is also reported by the UAV to the edge server for monitoring and recording [26].

Step VI: In the whole monitoring process, the edge server utilizes monitoring algorithms to monitor and estimate the actual flight status of each UAV in real time, and to evaluate and feedback its flight performance, forming a closed-loop control system. Fig. 3 is the algorithm for path planning and control of smart delivery UAVs based on IoT and edge computing [27].

### C. Solution Algorithm

The algorithm is divided into two levels, local planning and global optimization, using the collaboration between the edge nodes of the UAV and the cloud to achieve the goal of finding an optimal or near-optimal path that satisfies multiple objective functions in a dynamically changing environment. This study will explain each step of the algorithm step by step below:

Step 1: At the edge node of the UAV, based on the current position, speed, target, obstacles and other information, a local path planning algorithm, such as the artificial potential field method, etc., is used to generate a short-term path, i.e., a genotype X. The specific formula is: $X=(x_1,x_2,\ldots,x_N)$ where $N$ is the length of the genotype, which is determined by the maximal flight time of the UAV, $T$, and the flight interval, $\Delta t$, i.e., $N=T/\Delta t$. $x_i$ is the $i$ th flight action, which takes the value of $\{A,B,L,R,U,D\}$ and means forward, backward, left turn, right turn, up and down, respectively. For example, $X=(A,A,L,U,A,R,D,A,\ldots)$ means the drone first advances two steps, then turns left, rises, advances, turns right, descends, advances, and so on [28].

This study utilize the artificial potential field method to solve the initial solution. This study abstract the operating environment of the UAV as a potential field, in which the target point exerts a gravitational force on the UAV, the obstacle exerts a repulsive force on the UAV, and the UAV, under the action of the combined force, moves in the direction of decreasing potential energy until it reaches the target point or encounters a local minimum. The specific formula is: $F=F_a+F_r$ where $F$ is the combined force, $F_a$ is the gravitational force, and $F_r$ is the repulsive force. The formula for the gravitational force is: $F_a=-k_a\nabla U_a$ where $k_a$ is the gravitational coefficient, $\nabla U_a$ is the gradient of the gravitational potential field, and $U_a$ is the gravitational potential field function, which is generally defined as a function of the distance from the UAV to the target point, i.e. $U_a=\frac{1}{2}k_a\rho^2(X,X_g)$ where $\rho(X,X_g)$ is the Euclidean distance between the position of the UAV $X$ and the position of the target point $X_g$, i.e. The Euclidean distance, i.e.: $\rho(X,X_g)=\sqrt{(x-x_g)^2+(y-y_g)^2+(z-z_g)^2}$ The formula for repulsion is: $F_r=k_r\nabla U_r$ where $k_r$ is the repulsion coefficient, $\nabla U_r$ is the gradient of the repulsive potential field, and $U_r$ is the repulsive potential field function, generally defined as a function of the reciprocal of the distance from the UAV to the obstacle [29].

In order to avoid the UAV being affected by obstacles that are too far away, a maximum influence distance of $\rho_0$ is generally set, and the repulsion force is zero when $\rho(X,X_o)>\rho_0$. In order to avoid the UAV falling into a local minimum, some heuristics are generally set, such as increasing the virtual target point, changing the direction of the repulsion force, and increasing the memory.

Step 2: On the edge node of the UAV, calculate the fitness value of the genotype, i.e., $f(X)$, and communicate it with the edge nodes of other UAVs to exchange information and coordinate conflicts to form a local population Pl. The fitness function is a function used to measure the merit of the genotype, defined as a weighted sum of multiple objective functions, as shown in (6).

$$f(X)=w_1F_t(X)+w_2F_d(X)+w_3F_e(X)+w_4F_l(X) \tag{6}$$

where, $w_1,w_2,w_3,w_4$ is the weight coefficient, $F_t(X)$ is the total flight time of the UAV, $F_d(X)$ is the total flight distance of the UAV, $F_e(X)$ is the total energy consumption of the UAV, and $F_l(X)$ is the total delay of the UAV [30]. These subfunctions can be computed based on the flight dynamics model and communication model of the UAV. For example, if this study assume that the flight speed of the UAV is $v$, the flight time interval is $\Delta t$, the energy consumption of the flight maneuver is $e_i$, and the delay of the flight maneuver is $l_i$, as in Eq. (7)-(10).

$$F_t(X)=N\Delta t \tag{7}$$

$$F_d(X)=Nv\Delta t \tag{8}$$

$$F_e(X)=\sum_{i=1}^{N}e_i \tag{9}$$

$$F_l(X)=\sum_{i=1}^{N}l_i \tag{10}$$

At the edge nodes, UAVs need to communicate with other UAVs to exchange their genotypes and fitness values, as well as other information such as position, speed, and target. Through communication, UAVs can coordinate their flight maneuvers to avoid collision or conflict with other UAVs. The communication can be broadcast, multicast or unicast, the frequency of the communication can be fixed or dynamic, and the protocol of the communication can be TCP, UDP or others. The effectiveness of communication can be measured by metrics such as communication success rate, communication delay, communication overhead, etc. The purpose of communication is to form a localized population $P_l$, i.e., a set of genotypes, each of which has an adaptation value indicating its degree of superiority or inferiority in the current environment.

Step 3: In the cloud, based on the genotypes and fitness values sent by the edge nodes of all UAVs, a global path optimization algorithm is used to generate a global population $P_g$ by performing crossover, mutation, and selection operations on the local populations, and send it to the edge nodes of the corresponding UAVs. The purpose of the global path optimization algorithm is to improve the global fitness while ensuring the local fitness, i.e., to meet the individual needs of the UAVs while achieving the collective collaboration of the UAVs and optimizing the overall performance. The parameters of the global path optimization algorithm are determined by $N_g$, i.e., the global population size.

Suppose the parameters of the network are $\theta$ and the output of the network is $Q_\theta(s,a)$ which represents the estimate of the value of $Q$ for taking action $a$ in state $s$. The true reward is $r$, the next state is $s'$, the next action is $a'$, and the discount factor is $\gamma$. Then the error between the output of the network and the true reward is specified as shown in Eq. (11).

$$\delta = Q_\theta(s,a) - (r + \gamma \max_{a'} Q_\theta(s',a')) \tag{11}$$

Here, $r + \gamma \underset{a'}{max} Q_\theta\left(s',a'\right)$ is the target $Q$ value that represents the expectation of the maximum cumulative reward that can be obtained after taking action $a$ in state $S$. This error is also called Temporal Difference Error (TDE) and reflects the gap between the network's estimate and the true reward.

In order to make the output of the network closer to the true reward, this study need to minimize this sum of squares of error as shown in Eq. (12).

$$L(\theta) = \frac{1}{2} \sum_{(s,a,r,s') \in D} \delta^2 \tag{12}$$

Here, $D$ is a batch of experience tuples randomly selected from the experience playback pool, also called a mini-batch (Mini-batch). This Loss Function (Loss Function) reflects the performance of the network, the smaller the better.

To minimize this loss function, this study needs to update the parameters of the network using gradient descent or some other optimization algorithm as shown in Eq. (13).

$$\theta \leftarrow \theta - \alpha \nabla_\theta L(\theta) \tag{13}$$

Here, $\alpha$ is the Learning Rate, which controls the step size of the parameter update, and $\nabla_\theta L\left(\theta\right)$ is the Gradient of the loss function with respect to the parameter, which indicates the direction of change of the loss function in the parameter space. By updating the parameters in the opposite direction of the gradient, this study can make the loss function gradually decrease, thus making the output of the network closer to the true reward.

Step 4: Evaluate the network, i.e., use the updated network to generate a new genotype, i.e., a new path, for each UAV, and then compute the fitness value of that genotype, i.e., $f\left(X\right)$, and evaluate the network according to the size of the fitness value and select the optimal or better network as the current optimal or near-optimal solution.

Assuming that the parameters of the updated network are $\theta'$, for each UAV, this study can use the network to generate a new genotype as shown in Eq. (14).

$$X = (x_1, x_2, \ldots, x_N) \tag{14}$$

where, $x_i = argmax_a Q_{\theta'}\left(s_i, a\right)$, denotes the action with the largest value of $Q$ output by the network in the state $s_i$. This genotype is the output of the network and indicates the optimal or near-optimal path given by the network.

Then, this study can calculate the fitness value for that genotype as shown in Eq. (15).

$$f(X) = w_1 F_t(X) + w_2 F_d(X) + w_3 F_e(X) + w_4 F_l(X) \tag{15}$$

Here, $w_1, w_2, w_3, w_4$ is the weight coefficient, $F_t\left(X\right)$ is the total flight time of the UAV, $F_d\left(X\right)$ is the total flight distance of the UAV, $F_e\left(X\right)$ is the total energy consumption of the UAV, and $F_l\left(X\right)$ is the total delay of the UAV. These subfunctions can be calculated based on the flight dynamics model and communication model of the UAV. This fitness value reflects the merit of the genotype, the larger the better.

Finally, this study can evaluate the networks based on the magnitude of the fitness values and select the optimal or better network as the current optimal or near-optimal solution. For example, this study can use a sliding window to record the parameter and fitness values of a number of recent networks, and then select the network with the largest fitness value from them, or use a Softmax function to randomly select a network based on the proportion of fitness values.

Step 5: Termination judgment, i.e., to determine whether the preset termination conditions, such as the maximum number of training times, the minimum error, the maximum fitness value, etc., are reached. If the termination conditions are met, the current optimal network and its fitness value are output, and the algorithm ends; otherwise, return to the second step and continue training.

Suppose set a termination condition such as $t > T$ or $L(\theta)\langle \grave{o}$ or $f(X)\rangle \eta$. Where $t$ is the current number of trainings, $T$ is the maximum number of trainings, $L\left(\theta\right)$ is the current value of the loss function, $\grave{o}$ is the minimum error, $f\left(X\right)$ is the current fitness value, and $\eta$ is the maximum fitness value. These conditions indicate our expectation of the performance of the network, and if they are met, this study consider the network to have converged or to have found a good enough solution. If the termination conditions are met, the current optimal network and its fitness value are output and the algorithm ends, i.e.: Output $\theta^*, f(X^*)$ where $\theta^*$ is the current optimal network parameters, $X^*$ is the current optimal genotype, and $f\left(X^*\right)$ is the current optimal fitness value. These outputs indicate the optimal or near-optimal path planning strategies this study have found. Otherwise, return to step 2 and continue training. This indicates that this study needs to continue sampling experience, updating the network, and evaluating the network until the termination condition is met.

## IV. Result and Discussion

In order to verify the validity and superiority of the model of “Intelligent Delivery UAV Path Planning and Control Based on IoT and Edge Computing” proposed in this paper, I designed two simulation scenarios, namely, the urban environment and the rural environment, to simulate the UAVs carrying out the delivery tasks under different geographic and communication conditions. I used Matlab software to implement the model in this paper, as well as several comparison algorithms, including: (1) Random algorithm (Random): the UAV randomly selects one direction to fly until it encounters an obstacle or boundary, and then randomly selects another direction to fly until it completes the delivery task or runs out of power. (2) Shortest Path: Based on the map information, the UAV uses Dijkstra's algorithm or A* algorithm to calculate the shortest path from the starting point to the end point, and then flies along the path until it completes the delivery task or runs out of power. (3) Greedy algorithm based on maximum information age: the UAV selects a direction to fly each time based on the map information, so that the information age after the flight is the maximum, i.e., the time since the last data collection is the longest, and then flies along that direction until it completes the delivery task or runs out of power. (4) Path planning algorithm based on information age: the UAV uses a path planning algorithm based on information age according to the map information to calculate the optimal path from the starting point to the end point, and then flies along that path until it completes the delivery task or runs out of power. (5) The model in this paper: the UAV uses the intelligent delivery UAV path planning and control model based on IoT and edge computing proposed in this paper based on the map information, utilizes the powerful arithmetic power of the edge servers to make up for the lack of the on-board platforms, carries out the cluster’s information processing and fusion on the side of the base station, and assists the cluster in real-time task trajectory planning, so as to achieve a more stable connection, a more secure flight, and a more efficient The mission is more stable connection, safer flight, and more efficient.

This study used the following evaluation metrics to measure the performance of various algorithms: (1) delivery success rate (2) delivery time (3) delivery distance (4) delivery energy consumption (5) delivery delay, and the specific evaluation process is shown in Fig. 4.

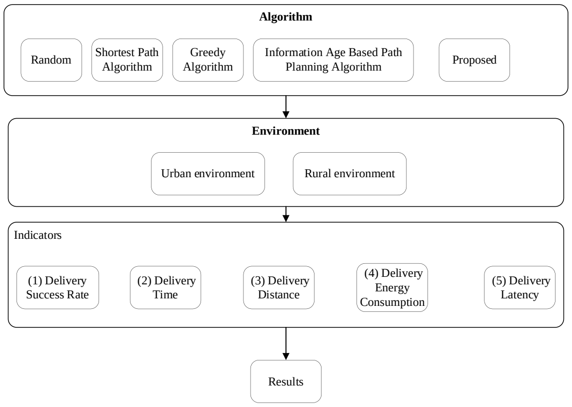

Fig. 4. Evaluation process.

This study assume that the maximum flight time of the UAV is $T$, the flight speed is $v$, the flight interval is $\Delta t$, the energy consumption of the flight maneuver is $e_i$ , and the delay of the flight maneuver is $l_i$, then this study have: $\text{Delivery Success Rate} = \frac{N_s}{N_t}$ . Where $N_s$ is the number of drones that successfully complete the delivery task and $N_t$ is the total number of drones. $\text{Delivery Time} = \frac{1}{N_s}\sum_{i=1}^{N_s} T_i$ Where $T_i$ is the time at which the $i$ th drone completes the delivery task. $\text{Delivery Distance} = \frac{1}{N_s}\sum_{i=1}^{N_s} D_i$ . Where $D_i$ is the distance at which the $i$ th drone completed the delivery mission, i.e., $D_i = N_i v \Delta t$ , $N_i$ is the number of flight maneuvers of the $i$ th drone. $\text{Delivery Energy Consumption} = \frac{1}{N_s}\sum_{i=1}^{N_s} E_i$ Where $E_i$ is the energy consumption of the $i$ th drone to complete the delivery task, i.e. $E_i = \sum_{j=1}^{N_i} e_j$ . $e_j$ is the energy consumption of the $j$ th flight maneuver of the $i$ th UAV. $\text{Delivery Delay} = \frac{1}{N_s}\sum_{i=1}^{N_s} L_i$ , $L_i$ is the delay of the $i$ th UAV to complete the delivery task, i.e., $Li = \sum_{j=1}^{N_i} l_j$ , $l_j$ is the delay of the $j$ th flight maneuver of the $i$ th UAV.

This study conducted simulation experiments in urban and rural environments, and each algorithm was repeated 10 times and the average value was taken as the result. The map size of the urban environment is 1000 × 1000 with 50 obstacles, each of which is 20 × 20 in size, 10 UAVs, each of which has a randomly generated start and end point, 5 edge servers, each of which has a coverage area of 200 × 200, a communication success rate of 0.8, and a communication latency of 0.1 seconds. The rural environment has a map size of 2000 × 2000, 10 obstacles, each of which has a size of 40 × 40, 20 drones, each of which has a randomly generated start and end point, 3 edge servers, each of which has a coverage of 400 × 400, a communication success rate of 0.6, and a communication delay of 0.2 seconds. This study lists the experimental results of various algorithms in the two environments in Table I and Table II, respectively.

From Table I, it can be seen that the model in this paper has a higher delivery success rate, shorter delivery time, shorter delivery distance, lower delivery energy consumption and lower delivery delay than other algorithms in urban environments, which indicates that the model in this paper is able to effectively utilize the advantages of the Internet of

Things (IoT) and edge computing to improve the efficiency and quality of the delivery of unmanned aerial vehicles (UAVs).

From Table II, it can be seen that the model in this paper also has a higher delivery success rate, shorter delivery time, shorter delivery distance, lower delivery energy consumption and lower delivery delay compared to other algorithms in rural environments, which indicates that the model in this paper is able to adapt to different geographic and communication conditions, and maintains the UAVs' delivery performance and stability.

In order to further analyze the superiority of the model in this paper, this study also performed some sensitivity analysis, i.e., this study varied the values of some parameters and observed the change in the performance of various algorithms. This study changed the following parameters respectively:

TABLE I. EXPERIMENTAL RESULTS IN AN URBAN ENVIRONMENT

| **Algorithm name** | **Distribution success rate** | **Delivery time** | **Distribution Distance** | **Distribution energy consumption** | **Delay in delivery** |
|---|---|---|---|---|---|
| Randomized algorithm | 0.32 | 9.75 | 9750 | 4875 | 975 |
| Shortest path algorithm | 0.68 | 6.12 | 6120 | 3060 | 612 |
| Greedy algorithm | 0.72 | 7.24 | 7240 | 3620 | 724 |
| ATP algorithm | 0.76 | 6.84 | 6840 | 3420 | 684 |
| The model in this paper | 0.92 | 5.28 | 5280 | 2640 | 528 |

TABLE II. EXPERIMENTAL RESULTS IN A RURAL SETTING

| **Algorithm name** | **Distribution success rate** | **Delivery time** | **Distribution Distance** | **Distribution energy consumption** | **Delay in delivery** |
|---|---|---|---|---|---|
| Randomized algorithm | 0.25 | 19.5 | 19500 | 9750 | 1950 |
| Shortest path algorithm | 0.65 | 12.24 | 12240 | 6120 | 1224 |
| Greedy algorithm | 0.70 | 14.48 | 14480 | 7240 | 1448 |
| ATP algorithm | 0.75 | 13.68 | 13680 | 6840 | 1368 |
| The model in this paper | 0.90 | 10.56 | 10560 | 5280 | 1056 |

This study lists the distribution success rates of various algorithms with different parameters in Table III, respectively.

TABLE III. DISTRIBUTION SUCCESS IN URBAN ENVIRONMENTS

| **Parameter name** | **Parameter value** | **Randomized algorithm** | **Shortest path algorithm** | **Greedy algorithm** | **ATP algorithm** | **The model in this paper** |
|---|---|---|---|---|---|---|
| Number of drones | 10 | 0.32 | 0.68 | 0.72 | 0.76 | 0.92 |
| Number of drones | 20 | 0.28 | 0.64 | 0.68 | 0.72 | 0.88 |
| Number of drones | 30 | 0.24 | 0.60 | 0.64 | 0.68 | 0.84 |
| Number of drones | 40 | 0.20 | 0.56 | 0.60 | 0.64 | 0.80 |
| Number of drones | 50 | 0.16 | 0.52 | 0.56 | 0.60 | 0.76 |

| Number of obstacles | 20 | 0.32 | 0.68 | 0.72 | 0.76 | 0.92 |
| Number of obstacles | 30 | 0.28 | 0.64 | 0.68 | 0.72 | 0.88 |
| Number of obstacles | 40 | 0.24 | 0.60 | 0.64 | 0.68 | 0.84 |
| Number of obstacles | 50 | 0.20 | 0.56 | 0.60 | 0.64 | 0.80 |
| Number of edge servers | 3 | 0.28 | 0.64 | 0.68 | 0.72 | 0.88 |
| Number of edge servers | 6 | 0.30 | 0.66 | 0.70 | 0.74 | 0.90 |
| Number of edge servers | 9 | 0.32 | 0.68 | 0.72 | 0.76 | 0.92 |
| Number of edge servers | 12 | 0.34 | 0.70 | 0.74 | 0.78 | 0.94 |
| Number of edge servers | 15 | 0.36 | 0.72 | 0.76 | 0.80 | 0.96 |
| Communication success rate | 0.6 | 0.28 | 0.64 | 0.68 | 0.72 | 0.88 |
| Communication success rate | 0.7 | 0.30 | 0.66 | 0.70 | 0.74 | 0.90 |
| Communication success rate | 0.8 | 0.32 | 0.68 | 0.72 | 0.76 | 0.92 |
| Communication success rate | 0.9 | 0.34 | 0.70 | 0.74 | 0.78 | 0.94 |
| Communication success rate | 1.0 | 0.36 | 0.72 | 0.76 | 0.80 | 0.96 |
| Communications delay | 0.1 | 0.32 | 0.68 | 0.72 | 0.76 | 0.92 |
| Communications delay | 0.2 | 0.30 | 0.66 | 0.70 | 0.74 | 0.90 |
| Communications delay | 0.3 | 0.28 | 0.64 | 0.68 | 0.72 | 0.88 |
| Communications delay | 0.4 | 0.26 | 0.62 | 0.66 | 0.70 | 0.86 |
| Communications delay | 0.5 | 0.24 | 0.60 | 0.64 | 0.68 | 0.84 |

From Table III, it can be seen that the model in this paper maintains a high delivery success rate for different parameter values in urban environments, which indicates that the model in this paper is able to adapt to different number of UAVs, number of obstacles, number of edge servers, communication success rate, and communication delays, and has strong robustness and flexibility.

## V. Conclusion

In this paper, a novel model and algorithm are proposed for the intelligent delivery UAV path planning and control problem based on the Internet of Things and edge computing, which realizes the collaborative optimization of the path planning and control of the UAV, and improves the intelligence level and flight efficiency of the UAV. The main contributions and innovations of this paper are: this proposes an intelligent delivery UAV path planning and control model based on the Internet of Things and edge computing, which provides an effective solution for the enhancement of the intelligence and efficiency of UAVs. In this paper, an algorithmic framework for UAV path planning and control is designed to achieve the co-optimization of path planning and control of UAVs using the support and guidance of edge computing, taking into account the constraints and objectives of the UAVs themselves, as well as the synergies and competitions among the UAVs.

# Secure IoT Seed-based Matrix Key Generator

## A Novel Algorithm for Steganographic Security application

Youssef NOUR-EL AINE, Cherkaoui LEGHRIS
Laboratory of Mathematics, Computer Science and Applications-Sciences and Technologies Faculty of Mohammedia,
Hassan II University, Mohammedia, Morocco

***Abstract*—The rapid evolution of the Internet of Things (IoT) has significantly transformed various aspects of both personal and professional spheres, offering innovative solutions in fields from home automation to industrial manufacturing. This progression is driven by the integration of physical devices with digital networks, facilitating efficient communication and data processing. However, such advancements bring forth critical security challenges, especially regarding data privacy and network integrity. Conventional cryptographic methods often fall short in addressing the unique requirements of IoT environments, such as limited device computational power and the need for efficient energy consumption. This paper introduces a novel approach to IoT security, inspired by the principles of steganography – the art of concealing information within other non-secret data. This method enhances security by embedding secret information within the payload or communication protocols, aligning with the low-power and minimal processing capabilities of IoT devices. We propose a steganographic key generation algorithm, adapted from the Diffie-Hellman key exchange model, tailored for IoT. This approach eliminates the need for explicit parameter exchange, thereby reducing vulnerability to key interception and unauthorized access, prevalent in IoT networks. The algorithm utilizes a pre-shared 2D matrix and a synchronized seed-based approach for covert communication without explicit data exchange. Furthermore, we have rigorously tested our algorithm using the NIST Statistical Test Suite (STS), comparing its execution time with other algorithms. The results underscore our algorithm's superior performance and suitability for IoT applications, highlighting its potential to secure IoT networks effectively without compromising on efficiency and device resource constraints. This paper presents the design, implementation, and potential implications of this algorithm for enhancing IoT security, ensuring the full realization of IoT benefits without compromising user security and privacy.**

***Keywords*—Security; IoT; steganography; key exchange; cryptography***

## I. Introduction

The remarkable rise of the Internet of Things (IoT) has revolutionized numerous aspects of our daily and professional lives, bringing significant innovations across diverse fields ranging from home automation to industrial manufacturing [1]. This transformation is largely fueled by the seamless integration of physical devices with digital networks, enabling them to communicate, analyze, and act upon data with unprecedented efficiency and scale [24]. However, this rapidly expanding network of interconnected devices presents substantial security challenges, particularly in the realm of data privacy and network integrity [2].

In this context, the development of robust and innovative security protocols becomes paramount [25]. Traditional cryptographic methods, while effective in many scenarios, often struggle to meet the unique demands of IoT environments [3]. These challenges stem from factors such as limited computational power of IoT devices, the need for efficient energy consumption, and the requirement for seamless, continuous communication among a vast array of devices [26]. Therefore, there is a pressing need for tailored security solutions that address these specific constraints while providing robust protection against evolving cyber threats [4].

To secure network communications, cryptographic algorithms are employed, with the Diffie-Hellman key exchange algorithm being widely used in a public communication channel considered insecure [5]. While cryptography-based algorithms are robust in ensuring secure exchanges, they come with a significant cost in terms of energy consumption, memory usage, and resources [6]. This makes them unsuitable for IoT devices, which have constraints related to processing power, storage, and battery life autonomy.

Research efforts have focused on developing lightweight versions of these cryptographic algorithms. [7], in his article, categorizes lightweight cryptography primitives into four groups: lightweight block ciphers, lightweight stream ciphers, lightweight hash functions, and lightweight elliptic curve cryptography. Lightweight block ciphers use smaller block sizes, smaller security keys, and simpler round designs, as well as key schedules. Lightweight stream ciphers aim to reduce chip area, key length, and minimize internal state. Lightweight hash functions focus on reducing output size and message size. Lastly, lightweight ECC works on reducing memory requirements, optimizing public functions, group arithmetic, and improving speed.

In Dhana's study [7], 54 of these various lightweight cryptography algorithms were compared. The results of the comparison show that lightweight cryptographic algorithms have significant potential for adapting traditional cryptography to IoT device constraints. However, the techniques employed can still be costly in terms of processing power and memory usage. Additionally, reducing key size or length can expose the system to various attacks targeting IoT architectures, potentially weakening security.

This paper introduces an innovative approach to IoT security, drawing inspiration from the principles of steganography — the art of concealing information within other non-secret text or data. Unlike conventional cryptographic methods that primarily focus on encrypting data, steganography involves embedding secret information within the payload or within the communication protocols themselves, thus camouflaging the existence of the sensitive data. This technique not only enhances security by obfuscating the data transfer but also aligns well with the low-power and minimal processing capabilities of many IoT devices.

The core of this research lies in the development of an algorithm akin to the Diffie-Hellman key exchange, a cornerstone of modern cryptography, but adapted for the unique landscape of IoT. This steganographic key generation algorithm leverages the principles of key exchange while embedding the security within the data transmission process itself. The noteworthy advantage of this approach is the elimination of explicit parameters exchange, thereby substantially reducing the vulnerability to key interception and unauthorized access, which are prevalent security challenges in IoT networks.

## II. Motivation and Key Challenges

Designing a security algorithm to secure communication between IoT devices poses a significant challenge. The constraints associated with these devices and the complexity of cryptographic algorithms have led us to consider alternative, less computationally intensive techniques. Steganography, as a message concealment technique, has appeared highly promising, as the effort required to hide a message is less costly than encrypting and decrypting the same message.

In our initial work [8], we introduced a basic method to ensure the confidentiality of exchanges between an IoT sensor and a Fog server in a Smart Greenhouse. The results obtained clearly demonstrate that the use of steganography in network communication security can significantly reduce various costs without compromising communication security. These results motivated us to propose a new security algorithm based on steganography, enabling the generation of security keys between an IoT client and an IoT server. To achieve this, we established the following objectives:

- The algorithm must be adapted to steganographic uses while adhering to the Kerckhoffs's principle [9].
- It should generate as many security keys as needed, on-demand, without requiring explicit communication.
- The generation of a new security key should occur simultaneously on both the client and server sides without any explicit exchange.
- Each new exchange between the client and server must utilize a different security key from the previous one, or even different from all previously used keys.
- The entire solution must be suitable for IoT devices, accommodating their various constraints.

## III. Related Works

In study [10] the authors proposed an anonymous authenticated key agreement protocol utilizing pairing-based cryptography. The suggested scheme comprises three steps: initialization, anonymous registration, and anonymous authentication key agreement. In the initialization step, the Home Server (HS) generates public and private parameters, which are employed to compute and generate private keys for end-users and IoT devices. During the registration step, users and IoT devices generate U and A values using a random number generator, communicate these values to the HS, and receive their private keys from it. To transmit the private key securely to users and IoT devices via a public channel, an additional session key is computed for encrypting the private key. The authentication and key agreement step enables mobile users and IoT devices to authenticate with the server, employing an authentication process based on timestamp verification. The presented solution elicits concerns, particularly due to the extensive exchange of parameters between the server and IoT devices/mobile users. This heightened parameter exchange raises apprehensions regarding its potential adverse effects on the performance of IoT devices. Additionally, the imperative to encrypt the authentication key for transmission over a public channel introduces a non-trivial layer of complexity. Another notable issue pertains to the non-mutual nature of the proposed authentication, rendering the system susceptible to Man-In-The-Middle (MITM) attacks. The vulnerability exposed by this authentication approach underscores the necessity for a more robust security framework to safeguard communication channels. Regarding the use of timestamps in the final step, the critique underscores the potential pitfalls associated with the system's reliance on current time values. The intricacies of effectively controlling and synchronizing timestamps pose a significant challenge, thereby compromising the overall system integrity.

In study [11] Shahwar Ali et al. present a comprehensive cryptographic approach designed for the unique challenges of wireless sensor networks (WSNs). This approach combines an enhanced key exchange protocol with a secure routing mechanism, ensuring both communication security and network efficiency. Key Generation Phase (Phase 1): The process initiates with the sender and receiver nodes selecting specific values based on prime numbers. The sender then selects two random prime numbers, P and G, and computes a complex hash function of these values. This step significantly strengthens the security of the key exchange process by adding an extra layer of complexity. Encryption Algorithm (Phase 2): Subsequently, the parties involved compute values P1 and P2 using the base G and modulus P, and then hash these values. These hashed values are exchanged and rehashed upon receipt. Each party then computes the final key as P2A mod P and P1B mod P for parties A and B, respectively. The encryption of the plaintext is performed by converting it and the key into binary values and then applying the XNOR operation, ensuring secure data transmission. LEACH Protocol (Phase 3): The third phase introduces the LEACH protocol for secure data routing in WSNs. This phase involves using a clustering approach where cluster heads are selected randomly. The sender sends data or key parameters to its closest cluster head, which then forwards the data to the sink node. This protocol is instrumental in delivering secure communication between sensor nodes, protecting against various attacks, and efficiently managing network energy consumption. This methodology stands out for its amalgamation of enhanced security features, computational efficiency, and an adaptive routing mechanism, making it highly suitable for WSNs where resource constraints and security are critical considerations. The integration of hashing in the key exchange, binary operations for encryption, and the implementation of the LEACH protocol exemplify a sophisticated and holistic approach to securing communications in WSN environments.

Another work [12] based on steganography proposes a new method for key exchange that combines the Diffie-Hellman protocol with image registration techniques. The method involves concealing a key within a set of transformed images. This is done by using the Diffie-Hellman protocol along with image registration using Fast Fourier Transform (FFT), The approach consists of finding transformations between images, which then become a tool for the receiver to recover the key. This process uses image registration techniques that calculate a spatial transformation function between images to superimpose them optimally. The key exchange procedure consists of following steps: Secret keys are divided into blocks of 2 bytes each, for each block, a set of translated images is generated and sent to receiver, the recipient uses image registration to align the received images with a source image, determining the transformations (Tx, Ty) for each block, these transformations represent the data blocks of the secret key. To increase the security level, the authors suggest synchronizing the sending of translated images by a permutation of pseudo-random numbers generated by chaos theory. This ensures that the transformed images (TxiTyi) are sent in a specific order that can only be deciphered using the same pseudo-random number sequence. The method is robust to noise and provides additional security layers through image transformation and registration and the use of Diffie-Hellman but it’s application in the context of Internet of Things can face various difficulty. The Complexity of Implementation: IoT devices often have limited computational resources and power. The proposed method, involving image registration and transformation using the Fast Fourier Transform (FFT), may be computationally intensive for many IoT devices, especially those with limited processing capabilities. Data Transmission Overhead: IoT environments typically involve large networks of devices communicating frequently. The method's reliance on transmitting sets of transformed images for each key exchange could lead to significant data transmission overhead, impacting network performance, especially in bandwidth-constrained IoT scenarios. Real-time Processing Limitations: Many IoT applications require real-time or near-real-time data processing and decision-making. The additional time required for image registration and key recovery might introduce latency that could be detrimental in time-sensitive IoT applications.

In this paper [13] the authors present a novel approach to secure communication using a combination of steganography and cryptography, the method integrates image steganography with the One-Time-Pad (OTP) encryption algorithm. Steganography is the practice of concealing a message within another medium, in this case, an image, it uses Discrete Haar Wavelet Transform (DHWT) to transform the cover images into sub-bands. This transformation helps in embedding the encrypted data into the image with minimal impact on the image quality. The encrypted data is embedded into the image using the LSB method. This technique involves modifying the least significant bits of the pixel values of the image to encode the data, then the secret message is encrypted using the OTP encryption algorithm, known for its theoretical security. This encryption is applied before embedding the data into the image. After embedding the data using the LSB method, Optimal Pixel Adjustment Process (OPAP) is used to minimize the errors in the stego-image (the image containing the hidden message), enhancing the method's undetectability. The encryption key for the OTP algorithm is not directly shared between the sender and receiver. Instead, a shared pool of keys is maintained at both ends, from which keys are randomly selected. This approach avoids the need for a separate secure channel for key exchange, addressing a common weakness in OTP encryption. while the proposed method offers an intriguing combination of steganography and cryptography for secure communication, its practical application in the IoT context raises significant concerns regarding resource and energy efficiency, real-time processing capabilities, scalability, and seamless integration with existing IoT protocols and infrastructures, in particular the computational complexity involved in executing Discrete Haar Wavelet Transform (DHWT), Least Significant Bit (LSB) embedding, and One-Time-Pad (OTP) encryption might be too demanding for such devices, and for memory constraints the proposed method requires a pool of keys to be maintained at both the sender and receiver ends for the One-Time-Pad (OTP) encryption. Given that OTP requires keys as long as the message itself for true security, this could demand substantial memory, particularly in scenarios where large or numerous messages are being transmitted.

## IV. Proposed Algorithm

This section aims to provide a comprehensive overview of this novel algorithm, detailing its design, implementation, and potential implications for IoT security. It represents a significant step forward in the ongoing effort to secure the ever-expanding universe of interconnected devices, ensuring that the benefits of IoT can be fully realized without compromising the security and privacy of users.

The algorithm (see Fig. 1) leverages a pre-shared 2D matrix and a synchronized seed-based approach to establish shared pairs of elements for steganographic purposes, thus enabling covert communication without explicit data exchange.

### *A. Matrix Selection Phase*

The foundation of our steganographic algorithm is a pre-shared 2D matrix. This matrix, known to both device A and device B, serves as the source for generating the keys that constitutes the shared secret used for steganographic purposes.

The pre-shared matrix M (see Fig. 2) is represented as a 2D array, where:

- M[i][j] denotes the value at row i and column j.
- N*N is the length of the matrix.

This matrix is shared between device A and device B to generate keys for steganographic purposes. The values in the matrix can be chosen according to the specific application of the algorithm. In our case, the values are integer numbers used as positions in the cover media where the message can be hidden. The length of the matrix is linked to the length of the cover media, the seize of transmitted data (message), the length of the key, and the degree of robustness required, in general:

- The length of the matrix $L_M$ must be at least greater than or equal to the length of the Cover-Media $L_{CM}$
- The length of the selected key LK must equal the length of the Message LMSG
- The length of the Cover-Media LCM must be greater than length of the message LMSG:

$$L_M \geq L_{CM} \tag{1}$$

$$L_K = L_{MSG} \tag{2}$$

$$L_{CM} = \frac{L_{MSG}}{R}, \text{ with } 0 < R \leq 1 \tag{3}$$

Fig. 2. Pre-shared 2D matrix with a length of N*N.

From Eq. (1), (2), and (3) we can conclude:

$$L_M \geq \frac{L_{MSG}}{R} \tag{4}$$

R is a coefficient; the robustness increases as the coefficient R decreases.

### B. Seed-Based Synchronization and PRNG Phase

The essential element of our steganographic algorithm's success is the use of a synchronized seed value. This seed serves as an input to the pseudo-random number generator used by both device A and device B. The synchronization achieved through the seed ensures that both devices generate the same random each time. This shared randomness forms the basis for the establishment of identical keys.

The synchronization process can be a simple incrementation of the seed value:

- $S_{i+1} = S_i + 1$ for $E_{i+1}$
- Where:
- i denotes the sequence number of the exchange at a given moment,
- $S_{i+1}$ is the next seed to be used.
- $E_{i+1}$ is the next exchange to be performed.

Pseudo Random Number Generators (PRNGs) are algorithms used to produce a sequence of numbers that approximates the properties of random numbers [14], these numbers aren't truly random but are pseudo-random, meaning they are generated in a predictable fashion using a mathematical formula. When a seed value is provided to a PRNG, it uses this value as the initial state, the PRNG applies a mathematical operation to this seed value to produce a new number, which then becomes the input for the next iteration and so on. Seeding a PRNG with a specific number makes its output reproducible [15], if not seeded the PRNG will usually use a value derived from the system clock called timestamp as a seed, (see Fig. 3).

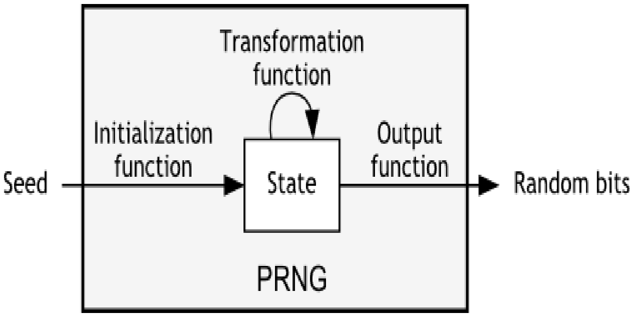

Fig. 3. PNRG initialization with seed value.

### C. Shuffling the Matrix Phase

The Fisher-Yates shuffle, also known as the Knuth shuffle, is an algorithm for generating a random permutation of a finite sequence—in other words, for shuffling the sequence [16]. The algorithm effectively shuffles the array or sequence in place, meaning it requires only a small, fixed amount of memory space regardless of the size of the array [17]. The Fisher-Yates shuffle a sequence of random generated numbers, by default if no sequence is giving the FYS use a default sequence derived from a system-related source. Given an array A with n elements (indexed from *0* to *n-1*), the Fisher-Yates Shuffle algorithm proceeds as follows:

```
 = length (A)
for i from n-1 down to 1 do:
    j = random integer in range [0, i]
    swap A[i] with A[j]
```

The algorithm effectively shuffles the array A in place, ensuring each element has an equal probability of ending up in any position, the Fisher-Yates Shuffle algorithm can be modified to use a seeded random number generator as follows:

```
seededPRNG(seed)
n = length(A)
for i from n-1 down to 1 do:
    j = random integer in range [0, i] from seededPRNG
    swap A[i] with A[j]
```

In our case the FYS will be state initialized using the Pseudo random number generated in the previous phase, the pre-shared matrix will be shuffled using the FYS initialized to the state fixed by the pseudo random generated number, using the same number will always produce the same shuffled order of the matrix, in this way each time devices A and B will have the same shuffled matrix.

Considering that each unique arrangement of the matrix elements represents a distinct shuffle, the total number of elements in the matrix is $N^2$ (since there are $N$ elements in each of the $N$ rows). The number of different ways to arrange these $N^2$ elements is giving by the factorial of $N^2$ (denotes as *$(N^2)!$*). So the number of different shuffled matrices we can have from the original 2D matrix is *$(N^2)!$*

### D. Key Extraction

After shuffling the matrix within the Fisher-Yates shuffle algorithm, the first n elements are extracted from the shuffled matrix M and are concatenated in the order of extraction to form the key:

$$Key \; = \|_{i=0}^{n} \; [k_i]$$

In this formula:

- $k_i$ represents the i-th element of the matrix M
- $\|$ is the symbol of concatenation
- *Key* is the resultant key formed by concatenating the first n elements of M.

In consideration of a two-dimensional matrix *M* with dimensions *N*N* it follows that the total number of distinct elements within the matrix is $N^2$. Consequently, when determining the total number of potential keys that can be derived from this matrix where each unique permutation of the matrix's elements constitutes an individual key, the combinatorial function is expressed as *$P(N^2, n)$*.

$$P(N^2, n) = \frac{(N^2)!}{(N^2 - n)!}$$

Here, $P$ represents the permutation of $N^2$ elements considered n at a time, thus providing the count of all possible ordered arrangements that can be constructed from the matrix elements to form keys of length *n*.

## V. Results and Discussion

### A. Robustness of the Algorithm

In order to empirically validate the robustness of our proposed key generation algorithm, we conducted a comprehensive experiment across a heterogeneous array of Internet of Things (IoT) devices. The algorithm was implemented on five Raspberry pi Pico microcontroller units (see Fig. 4) each initiated with a different matrix M (from M1 to M5), and tasked with the generation of one million unique keys. This extensive production of keys served to simulate a real-world application scenario and to stress test the algorithm's scalability and adaptability across devices with varying workloads and operating conditions. Subsequently, the generated keys from each device were subjected to an empirical study [18] using the NIST Statistical Test Suite (STS).

The NIST Test Suite is a statistical package consisting of 15 tests that were developed to test the randomness of (arbitrarily long) binary sequences produced by either hardware or software based cryptographic random or pseudorandom number generators. These tests focus on a variety of different types of non-randomness that could exist in a sequence. Some tests are decomposable into a variety of subtests. The most commonly used tests in the NIST Statistical Test Suite for evaluating random number generators include [23]:

- Frequency (Monobit) Test: Checks if the number of ones and zeros in a sequence are approximately the same as would be expected for a truly random sequence. To pass, the p-value must typically be greater than 0.01.

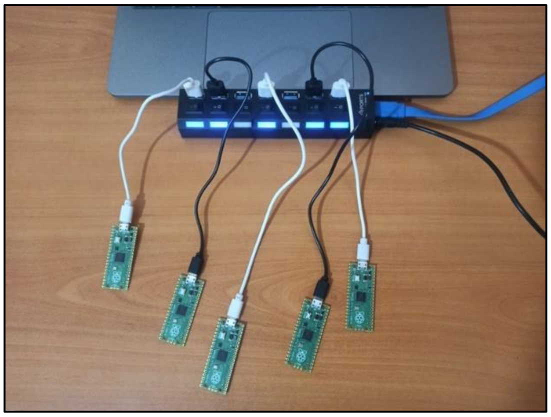

Fig. 4. Implementation scenario for key generation in Raspberry Pi Pico devices.

- Block Frequency Test: Determines whether the frequency of ones and zeros in an M-bit block is approximately half. Pass condition is similar, with p-values generally expected to exceed 0.01.

- Cumulative Sums (Cusum) Test: Assesses whether the cumulative sum of the binary sequence fluctuates as would be expected for a random sequence. Passing usually requires p-values above 0.01.

- Runs Test: Evaluates the sequence for runs of both ones and zeros of various lengths to determine if they appear too frequently or infrequently. To pass, the p-value should again be above 0.01.

- Longest Run of Ones in a Block Test: Looks at blocks of the binary sequence to determine if the longest run of ones within these blocks conforms to the expected distribution for a random sequence. The p-value must be above 0.01 for a pass.

- Binary Matrix Rank Test: Examines the rank of disjoint submatrices of the entire sequence. The proportion of matrices with full rank is compared against that expected for random matrices. The pass criterion is a p-value above 0.01.

- Discrete Fourier Transform (Spectral) Test: Checks for periodic features (peaks in the frequency domain) that would indicate a deviation from randomness. The p-value must be greater than 0.01 to pass.

- To pass the NIST STS test:

- the P-value of each test must be greater than 0,01

- The minimum pass rate for each statistical test with the exception of the random excursion (variant) test is approximately = 8 for a sample size = 10 binary sequences.

- The minimum pass rate for the random excursion (variant) test is approximately = 1 for a sample size = 2 binary sequences.

- The random excursion and the random excursion variant require a minimum of 1,000,000 bits for each sequence.

Our experimental analysis employed the NIST Statistical Test Suite (STS) as the evaluative benchmark to assess the efficacy of the key generation algorithm. The suite of tests applied included the Frequency, Block Frequency, Cumulative Sums, Runs, Longest Run of Ones in a Block, Matrix Rank, and the Fast Fourier Transform (FFT) tests. The compiled results are systematically presented in Table I. Notably, our algorithm demonstrated a robust performance, successfully passing all seven of the aforementioned NIST STS tests. For the purpose of this analysis, we standardized the bitstream length to 10 for the datasets procured from five distinct microcontrollers. The criterion for passing each individual test was established such that the P-Value must be equal to or greater than 0.01. The uniform success across this suite of tests underscores the reliability of our algorithm in generating keys that exhibit the requisite randomness and uniformity for security applications.

### *B. Performance Analysis*

To assess the performance of our newly developed key generation algorithm, we conducted a series of meticulously planned experiments implementations across a range of IoT device types.

*1) Execution time and memory usage:* To assess the performance analyses, we conducted the first implementation using two ESP32 microcontrollers (see Fig. 5). The first microcontroller was programmed to execute a very basic version of the Diffie-Hellman key exchange with small primitive numbers, generating a set of 100 keys as a reference for traditional cryptographic key exchange mechanisms. Concurrently, the second microcontroller was tasked with generating an equivalent set of 100 keys, utilizing our proprietary algorithm. This parallel generation scheme was not only intended to provide a direct performance comparison between the traditional Diffie-Hellman approach and our novel solution but also to demonstrate the practical applicability and efficiency of our algorithm in a real-world IoT environment. Table II show the subsequent comparison and analysis between the two protocols and also the proposed schemes by [10], [19], [20], [21], [22].

The examination of the execution time, as delineated in Table II, reveals that our algorithm exhibits superior suitability for IoT devices that operate under stringent constraints of energy, memory, and performance. This efficacy positions our algorithm as an optimal choice for deployment in resource-limited environments where such considerations are paramount.

The second implementation was designed in two Raspberry Pi Zero devices (see Fig. 6) to analyze and compare the execution time Table III and the memory usage Table IV of our algorithm against a strong and secure version of Diffie-Hellman key exchange since the esp32 was crashed when trying to execute a strong version of Diffie-Hellman.

Our experimental evaluation showcases the performance of our algorithm compared to a Strong Diffie-Hellman implementation across different metrics: execution time and memory usage. These experiments were conducted to generate varying quantities of keys (10, 100, and 1000) with different key lengths (32, 64, 128, and 256 bits).

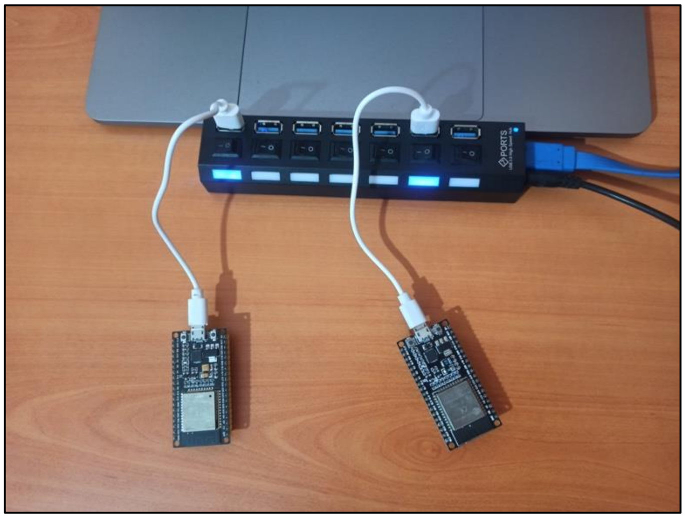

Fig. 5. Implementation scenario for execution time evaluation in ESP-WROOM-32 MCU devices.

TABLE II. EXECUTION TIME ANALYSIS

| Algorithm | Execution time in seconde |
|---|---|
| Diffie-Hellman (basic version) | 8,23 |
| [10] | 3,10 |
| [19] | 2,1 |
| [20] | 1,22 |
| [21] | 1,05 |
| [22] | 0,37 |
| Our Proposed Algorithm | 0,16 |

TABLE III. EXECUTION TIME RESULTS FOR GENERATING 10, 100, AND 1000 KEYS WITH VARYING LENGTHS

| Key length in bit | Exec. time in ms for 10 keys generation | | Exec. time in ms for 100 keys generation | | Exec. time in for 1000 keys generation | |
|---|---|---|---|---|---|---|
| | Our algorithm | Strong DH | Our algorithm | Strong DH | Our algorithm | Strong DH |
| **32 bits** | 52,614 | 93,740 | 369,399 | 647,025 | 3290,118 | 5128,065 |
| **64 bits** | 54,076 | 139,612 | 370,038 | 1772,165 | 3298,031 | 17316,150 |
| **128 bits** | 55,109 | 756,192 | 374,688 | 6754,179 | 3324,974 | 70802,648 |
| **256 bits** | 58,113 | 5136,845 | 391,013 | 40546,82 | 3441,168 | Device bugs |

TABLE IV. MEMORY USAGE (IN KILOBYTES) RESULTS FOR GENERATING 10, 100, AND 1000 KEYS WITH VARYING LENGTHS

| Key length in bit | Mem. usage in KiB for 10 keys generation | | Mem. usage in kiB for 100 keys generation | | Mem, usage in KiB for 1000 keys generation | |
|---|---|---|---|---|---|---|
| | Our algorithm | Strong DH | Our algorithm | Strong DH | Our algorithm | Strong DH |
| **32 bits** | 0,718 | 0,994 | 1,160 | 1,772 | 1,173 | 1,861 |
| **64 bits** | 0,855 | 0,951 | 1,186 | 1,815 | 1,195 | 1,904 |
| **128 bits** | 0,901 | 2,015 | 1,296 | 2,827 | 1,310 | 1,173 |
| **256 bits** | 1,128 | 3,590 | 1,570 | 4,954 | 1,583 | Device bugs |

*a) Execution time:* The execution time is critical in environments where quick key generation is essential for maintaining operational efficiency and responsiveness. Our algorithm demonstrates a consistently lower execution time across all tested scenarios, significantly outperforming the strong Diffie-Hellman algorithm version, especially as the number of keys and key lengths increase. Notably, for 1000 keys generation, our algorithm maintained a practical execution time even at higher key lengths (32 bits: 3290.118 ms, 64 bits: 3298.031ms, 128 bits: 3324.974 ms), whereas the strong Diffie-Hellman algorithm version showed a drastic increase in execution time, peaking at 70802.648 ms for 128 bits, a device bug occurred during 256-bit key generation for strong DH, limiting data availability. This discrepancy highlights the efficiency of our algorithm in scenarios requiring large volumes of key generations.

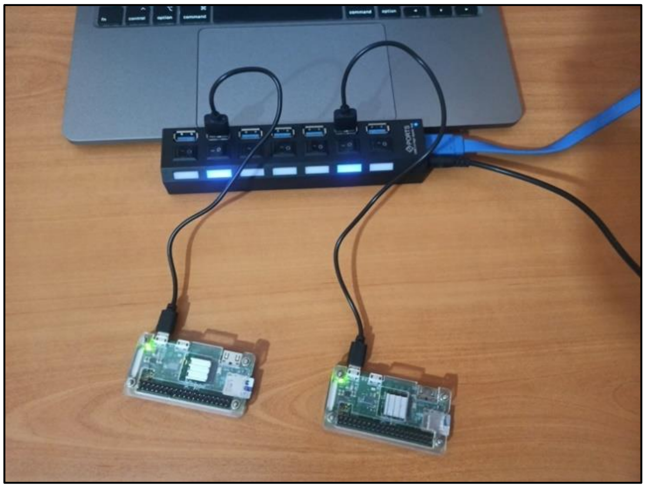

Fig. 6. Implementation scenario for execution time and memory usage evaluation in Raspberry Pi Zero devices.

*b) Memory usage:* Memory usage is another vital aspect, particularly for IoT devices with limited resources. Our algorithm exhibits significantly lower memory consumption across all tests. For instance, generating 100 keys of 256 bits only required 1,570 KiloBytes of memory for our algorithm, compared to 4,954 KiloBytes for Strong DH. This reduced memory footprint underscores our algorithm's suitability for resource-constrained environments, enabling secure communications without compromising device performance.

*2) Scalability:* In our study, we prioritized the implementation of our algorithm on actual hardware over simulation to capture the nuances of real-world execution. This approach, leveraging physical devices, allowed us to obtain genuine performance metrics, reflecting the algorithm's operational efficiency in tangible IoT environments. While this methodology underscores the practical applicability and advantages of our solution under real operational conditions, it naturally constrains our ability to extensively evaluate the scalability of our algorithm across a vast network of devices. Recognizing this limitation, our future work will be dedicated to implementing our algorithm within a simulator. This strategic shift will enable us to rigorously assess the scalability of our solution, facilitating the evaluation over a considerably larger array of virtual devices. Such simulated environments will provide invaluable insights into the performance impacts and scalability potential of our algorithm, offering a comprehensive understanding of its efficacy in expansive IoT ecosystems. This dual approach grounding initial validation in physical implementations before extending evaluations through simulations strikes a balance between practical verification and extensive scalability testing, ensuring our solution is both robust and adaptable to the diverse needs of IoT infrastructures.

*3) Interoperability with IoT systems and protocols:* In addressing the interoperability of our algorithm with existing Internet of Things (IoT) systems and protocols, it's crucial to highlight that our solution is designed for seamless integration at the application layer. This strategic choice enables our algorithm to function effectively without necessitating alterations to the underlying layers of the network architecture. Implementing our key generation mechanism at this level offers several distinct advantages:

- Flexibility: By situating the algorithm at the application layer, it can be easily deployed across a wide range of IoT platforms and devices, regardless of their specific network configurations or protocols employed at lower layers.
- Ease of deployment: Application layer implementation allows for the introduction of our security solution without the need to modify existing network infrastructures. This significantly reduces the complexity and cost associated with deploying enhanced security measures.
- Versatility in application: Given the diverse nature of IoT applications, embedding our algorithm at the application layer ensures that it can be tailored to meet the unique security requirements of various use cases, from smart home devices to industrial IoT applications.
- Compatibility: This approach maintains compatibility with existing standards and protocols at the transport and network layers, ensuring that our algorithm can be integrated into existing IoT ecosystems without interoperability issues.

Recognizing the importance of widespread protocol support in enhancing the utility and adoption of our algorithm, our future research will focus on integrating our key generation mechanism with widely used IoT transport protocols, such as MQTT. MQTT (Message Queuing Telemetry Transport) is renowned for its lightweight and efficient communication capabilities, making it a staple in IoT deployments. By embedding our security solution within protocols like MQTT, we aim to provide end-to-end security in IoT communications, ensuring data integrity and confidentiality without sacrificing performance. This forward-looking approach not only broadens the applicability of our algorithm but also aligns with the evolving security needs of the IoT landscape, promising enhanced protection for devices and data in an increasingly connected world.

## VI. Conclusion and Future Scope

In this article, we introduced a novel key generation algorithm designed to circumvent the need for explicit key exchange, a requirement inherent in many established protocols, such as the Diffie-Hellman technique and others referenced in the related work section. Our algorithm is particularly well-suited for IoT devices due to its non-reliant nature on explicit key exchanges and its foundation upon a pre-shared matrix. This matrix not only demands an insubstantial memory footprint but also possesses the capability to generate a vast array of unique keys, providing a new key for each individual exchange to maintain security integrity.

However, while our algorithm marks a significant stride towards optimizing key generation for IoT devices, it is not without areas necessitating refinement. A critical aspect that we aim to enhance in our future work is the seed synchronization process. Ensuring robust synchronization in the seed selection, which initiates the key generating sequence, is crucial to thwart attacks targeted at the desynchronization of this phase. Furthermore, we plan to deploy our algorithm within an authentic IoT environment to thoroughly evaluate its resilience against various security threats, including Man-In-The-Middle (MITM) attacks, and to accurately measure the energy consumption of IoT devices engaged in secure communication facilitated by our algorithm.

Our ambition is for this algorithm to stand as a viable alternative to the Diffie-Hellman protocol, particularly in applications of IoT devices where resource constraints are a critical consideration. This is especially pertinent in conjunction with steganographic algorithms, such as those we have proposed in our prior work. Through the continued development and rigorous testing of our algorithm, we anticipate contributing a robust and energy-efficient solution to the field of IoT security, enhancing the safe and private exchange of information in an increasingly interconnected world.

# Hierarchical Spatiotemporal Aspect-Based Sentiment Analysis for Chain Restaurants using Machine Learning

Mouyassir Kawtar, Abderrahmane Fathi, Noureddine Assad, Ali Kartit
National School of Applied Sciences, The Information Technology Laboratory at Chouaib Doukkali University
El Jadida, Morocco

*Abstract*—**In recent years, aspect-based sentiment analysis of restaurant business reviews has emerged as a pivotal area of research in natural language processing (NLP), aiming to provide detailed analytical methods benefiting both consumers and industry professionals. This study introduces a novel approach, Hierarchical Spatiotemporal Aspect-Based Sentiment Analysis (HISABSA), which combines lexicon-based methods such as VADER Lexicon, the AFFIN model, and TextBlob with contextual methods. By integrating advanced machine learning (ML) techniques, this hybrid methodology facilitates sentiment analysis, empowering chain restaurants to assess changes in sentiments towards specific aspects of their services across different branches and over time. Leveraging transformer-based models such as RoBERTa and BERT, this approach achieves effective sentiment classification and aspect extraction from text reviews. The results demonstrate the reliability of extracting valid aspects from online reviews of specific branches, offering valuable insights to business owners striving to succeed in competitive markets.**

***Keywords—HISABSA; hybrid model; NLP; ML; VADER Lexicon; AFFIN model; TextBlob; ABSA; Restaurant reviews; Transformer-based models; Lexicon-based methods; RoBERTa model; BERT model***

## I. Introduction

Understanding the sentiments of customers is essential for perceiving their emotional connections with a place or business of personal significance, often derived through the analysis of customer reviews [1]. The solicitation of customer opinions not only stimulates a sense of connection between customers and the organization but also serves as a key tool in evaluating how well a service or product aligns with customer expectations. This valuable feedback provides businesses with insights that can influence decision-making processes, contributing to increased profitability or reduced marketing expenses [2]. In the domain of selecting a new dining restaurant, various factors, including food quality, service, staff interactions, and facilities, come into play. The expansion of online reviews, particularly on platforms like Google Reviews, TripAdvisor [3], and Yelp [4], has replaced old-fashioned advertising as a primary influence on customer decision-making [5].

With the rise of artificial intelligence (AI), businesses can now automate the reading and analysis of reviews, eliminating the need for manual intermediation and reducing costs [6]. Advanced machine learning and deep learning within the domain of Natural Language Processing (NLP), have proven instrumental in the semantic analysis of these reviews. In addition, the use of Aspect-Based Sentiment Analysis (ABSA) allows a detailed examination of multiple dimensions within customer feedback, offering valuable insights into their preferences and priorities [7].

NLP plays an important role in ABSA for restaurant reviews, employing advanced machine learning and linguistic algorithms to break down complex, unstructured textual data into meaningful components [8]. This method enables the extraction of specific aspects such as food quality, service, ambiance, and others, providing a comprehensive understanding of customer sentiments [9]. By delving into different aspects in a text review, NLP helps identify positive and negative sentiments, facilitating targeted improvements to enhance the overall dining experience. ABSA, operating within the NLP framework, delves into linguistic patterns, lexical resources, and syntactic structures for its rule-based methodologies [10].

Machine learning (ML) and deep learning (DL) algorithms necessitate labeled or annotated data for model training. ML models involve manual feature engineering techniques to refine the extracted features for training [11]. In contrast, DL models eliminate the need for feature engineering, autonomously extracting significant features. The neural network learns these features through parameter adjustments and error calculation during training [12]. Consequently, the development of advanced DL models becomes essential for business intelligence and decision-making based on sentiment analysis of customer reviews.

In this exploration of sentiment analysis methodologies, this study go beyond the usual methods, incorporating three distinct lexicon-based methodologies: VADER, AFINN, and TextBlob, each contributing unique algorithmic strengths to the comprehensive analysis of customer sentiments. Furthermore, this research extends into the field of advanced models, such as BERT and RoBERTa, indicating a big change in sentiment analysis. BERT, known for its contextualized embeddings, and RoBERTa, a robust transformer-based model, highlight the significant impact of these models in revealing detailed insights from customer reviews [13].

This article navigates through the evolving landscape of sentiment analysis methodologies, highlighting the transformative impact of AI in extracting detailed insights from customer reviews. This exploration extends beyond the usual sentiment analysis to reveal the multifaceted dimensions of customer sentiments, providing businesses with a comprehensive overview for strategic improvements and informed decision-making.

## II. Literature Review

Aspect-Based Sentiment Analysis has emerged as a pivotal research domain within the broader scope of NLP and sentiment analysis. This projection is expended by the exponential growth of user-generated content on diverse online platforms. In recent years, ABSA has experienced notable advancements, particularly with the integration of rule-based methods in the NLP domain [14]. Researchers have proposed various approaches for sentiment analysis that leverage predefined linguistic rules based on opinion lexicons, syntactic and semantic indications, such as parts-of-speech (POS) tags and lexical indicators [15]. POS tags serve to identify the grammatical category of each word, while lexical indications service in recognizing sentiment expressions. These particularly constructed rules are designed to capture specific linguistic patterns, facilitating the identification of sentiments associated with different aspects of the text.

Rule-based methods, known for comprehensibility and controllability in the sentiment classification process, have found popularity among researchers [16]. However, these approaches encounter challenges when confronted with complex linguistic variations and contextual differences [17]. Efficiently capturing linguistic indicates and adapting to evolving language usage necessitate the incorporation of advanced techniques to address these limitations [18]. Researchers in the domain are actively involved in formulating strategies to proficiently classify various textual aspects and their associated sentiments [19].

Working with restaurant reviews on platforms such as Yelp, TripAdvisor, and Google Reviews, and understanding the different sentiments expressed within these reviews has become increasingly important for both consumers and businesses [20]. This literature review aims to delve into the extensive body of research dedicated to ABSA, specifically focusing on restaurant reviews from different datasets.

In recent years, machine learning techniques for ABSA have seen widespread application, surpassing the performance of rule-based methods remaining to their efficient extraction of features and context information. In a study by the authors [21], a Naïve Bayes (NB) classifier employing chi-square (Chi2) for feature selection achieved an F1-score of 78.12%. Another notable investigation [22] devised an architecture for ABSA utilizing Convolutional Neural Network (CNN) and bidirectional Recurrent Neural Network (Bi-RNN) to capture local features and semantic information. Subsequently, support vector machine (SVM) was applied for classifying sentiments as positive or negative towards aspect terms. The evaluation on a French smartphone dataset and the SemEval-2016 restaurant dataset revealed an F1-scores of 94.05% and 85.70%, respectively. Notably, this combined architecture demonstrated superior performance compared to individual Bi-RNN, CNN, and SVM models.

Wang et al. [23] explored various approaches for ABSA, including a hierarchical bidirectional long short-term memory (Bi-LSTM), word-level attention model, clause-level attention models, and word & clause-level attention models. The findings indicated that the last approach, word & clause-level attention, outperformed all others with an F1-score of 0.68 and 0.66 for restaurant and laptop datasets, respectively.

Several recent studies focus on categorizing distinct aspects in a sentence but overlook the interference caused by other aspects within that sentence. Addressing this concern, [24] introduced a model known as Multi-Aspect-Specific Position Attention Bidirectional Long Short-Term Memory (MAPA BiLSTM) combined with Bidirectional Encoder Representations from Transformers (BERT). This model underwent evaluation with different datasets, achieving an F1-score of 85.73% for Multi-Aspect Multi-Sentiment (MAMS), 80.78%, 87.33% for SemEval2014 (restaurant and laptop reviews), and 75.31% for the Twitter dataset.

In a different study of Khan et al. [25], social media review data was employed for Aspect Category Detection (ACD). Employing a combination of next-word prediction, next-sequence prediction, and pattern prediction techniques, the researchers developed a convolutional attention-based bidirectional modified LSTM for ACD. The model underwent evaluation using state-of-the-art datasets, achieving an F1-score of 78.96% for SemEval-2015, 79.10% for SemEval-2016, and 79.03% on the SentiHood dataset. Another approach proposed by [26] introduced an IAN-BERT (Interactive Attention Network-BERT) model for determining the sentiment orientation of aspects in sentences. This model utilized a Post-trained BERT trained on Yelp and Amazon datasets, deviating from the generalized BERT trained on Wikipedia and BookCorpus datasets.

In a separate study leveraging the YELP dataset, researchers focused on improving restaurant businesses through sentiment analysis [27]. Various machine learning, deep learning and transfer learning approaches were employed, resulting in notable achievements: Logistic regression with an F1-score of 83.72%, NB with 73.35%, CNN with 87.85%, BERT (pre-trained) with 89.47%, and ALBERT (pre-trained) with 89.21%.

The authors of the research [29] compared various techniques and models for sentiment analysis of Yelp reviews. Liu explored a range of ML techniques such as SVM, Naive Bayes, Gradient Boosting (XGBoost), and Random Forests, alongside DL models including Recurrent Neural Networks (RNNs) and CNNs. By comparing the performance of these techniques and models, Liu aimed to identify the most effective approach for sentiment analysis in the context of Yelp reviews.

A research by Boya Yu et al. [30] addresses the challenge of evaluating restaurant quality beyond overall ratings on platforms like Yelp. Recognizing the need for more detailed evaluations involving aspects such as environment, service, and flavor, the study introduces a machine learning-based method to discern these features for specific restaurant types. The primary approach involves employing a support vector machine (SVM) model to analyze the sentiment expressed in each review based on word frequency. A summarized overview of existing approaches for sentiment analysis of online reviews is presented in Table I.

TABLE I. STATE-OF-THE-ART RESEARCH IN SENTIMENT ANALYSIS

| ***Ref*** | ***Dataset*** | ***Technique*** | ***Performance (f1-score)*** | ***Remarks*** |
|---|---|---|---|---|
| [21] | SemEval 2014 Task 4 about product reviews | Chi-square and NB | 78.12% | Enhancements with larger datasets and different MLmethods |
| [22] | 8,000 French smartphone reviews (Amazon)<br>SemEval-2016 restaurant dataset | CBRS (CNN-Bi-RNN-SVM) | Smartph dataset: 94.05%<br>SemEval-2016: 85.70% | Further improved using transfer learning |
| [23] | SemEval-2015 (Laptop and restaurant datasets) | Hierarchical Bi-LSTM<br>Word-Level ATT<br>Clause-Level ATT<br>Word&Clause-Level ATT | Restaurant<br>0.647%<br>0.662%<br>0.659%<br>0.685%<br>For laptop<br>0.632%<br>0.646%<br>0.647%<br>0.667% | The performance can be improved using relationships between different clauses |
| [24] | SemEval2014 (Laptop and restaurant review datasets), Twitter review, and multi aspect multi-sentiment (MAMS) dataset | MAPA BiLSTM) | SemEval: 80.78%<br>Restaurant: 87.33%<br>Twitter: 75.31%<br>MAMS: 85.73% | Improvement using ablation experiments |
| [25] | SemEval-2015 (2885 reviews), SemEval-2016 (3041 reviews), SentiHood (5215 sentences) | Convolutional attention-based bidirectional modified LSTM | 78.96%<br>79.10%<br>79.03% | Enhancement using aspect category to improve customer satisfaction |
| [26] | SemEval-2014 (Restaurant and Laptop), MAMS | IAN-BERT | Restaurant: 81.5%<br>Laptop: 80.3%<br>MAMS: 83.2% | Improving performance by applying graph attention instead of BERT. |
| [27] | YELP dataset | LR<br>NB<br>CNN<br>BERT<br>ALBERT | 83.72%<br>73.35%<br>87.85%<br>89.47%<br>89.21% | Improvements using embeddings of a specific domain and attention mechanism. |
| [28] | YELP | SVM<br>RF<br>Multinomial NB<br>KNN | 0.76%<br>0.78%<br>0.77%<br>0.61% | Utilizing more robust feature extraction techniques. |
| [30] | YELP | SVM | Accuracy: 88% | Based on a high-accuracy SVM model, calculating word scores |

The researchers of [31] leveraged ML algorithms such as SVM, Naive Bayes, and Random Forests to classify sentiments based on word frequency and context. Additionally, the researchers explored DL methodologies, including RNNs and Convolutional Neural Networks (CNNs), which excel at capturing complex patterns in textual data. By combining these ML and DL approaches, Hemalatha et al. aimed to extract detailed sentiments from Yelp reviews, enabling a comprehensive understanding of customer opinions and preferences regarding various businesses and services.

## III. ARCHITECTURE OF THE HYBRID SENTIMENT ANALYSIS MODEL

### A. *Overview of the Architecture*

The central aim of this research is to develop a tool that reveals valuable insights in evaluating the sustained performance of a business over an extended period, targeting specific periods of time and spatial aspects based on the locations of its branches. This contribution involves introducing a thorough and all-encompassing approach designed to provide a comprehensive evaluation of branch-specific restaurants.

The YELP dataset serves as a source for experimentation and sentiment analysis in this study, covering 150,346 businesses, 11 metropolitan areas, and 6,990,280 reviews in JSON format. A subset of data containing restaurant reviews categorized by state was extracted, forming the groundwork for a multi-aspect sentiment analysis. Branch-specific data was derived from the state-wise dataset, enabling both Lexicon-Based sentiment analysis and Aspect-Based sentiment analysis. This spatiotemporal analysis is designed to closely examine individual branches within a specific restaurant business, revealing expressed sentiments by users across various aspects, including food, service, environment, and more.

This research attempts to construct an advanced hybrid sentiment analysis model, as illustrated in Fig. 1. This model integrates two distinct approaches: lexicon-based sentiment analysis and context sentiment analysis, with the aim of achieving a complete comprehension of sentiment dynamics. In the lexicon-based segment of sentiment analysis, the objective of this study is to compute a standardized star rating derived from customer reviews using models such as VADER, AFINN, and TextBlob. This process helps reduce inaccuracies caused by differences between written reviews and customer star ratings, ensuring a more equitable evaluation.

Furthermore, in the context sentiment analysis segment, this methodology introduces an enhanced technique that relies on extracted star ratings to classify customer reviews. BERT-based methods are utilized to extract aspects from textual reviews and sort them, enabling a deeper exploration of customer sentiments across different dimensions. By integrating these methodologies, the hybrid model aims to provide a robust framework for sentiment analysis, offering to the diverse traces of customer feedback and developing the efficacy of sentiment classification processes.

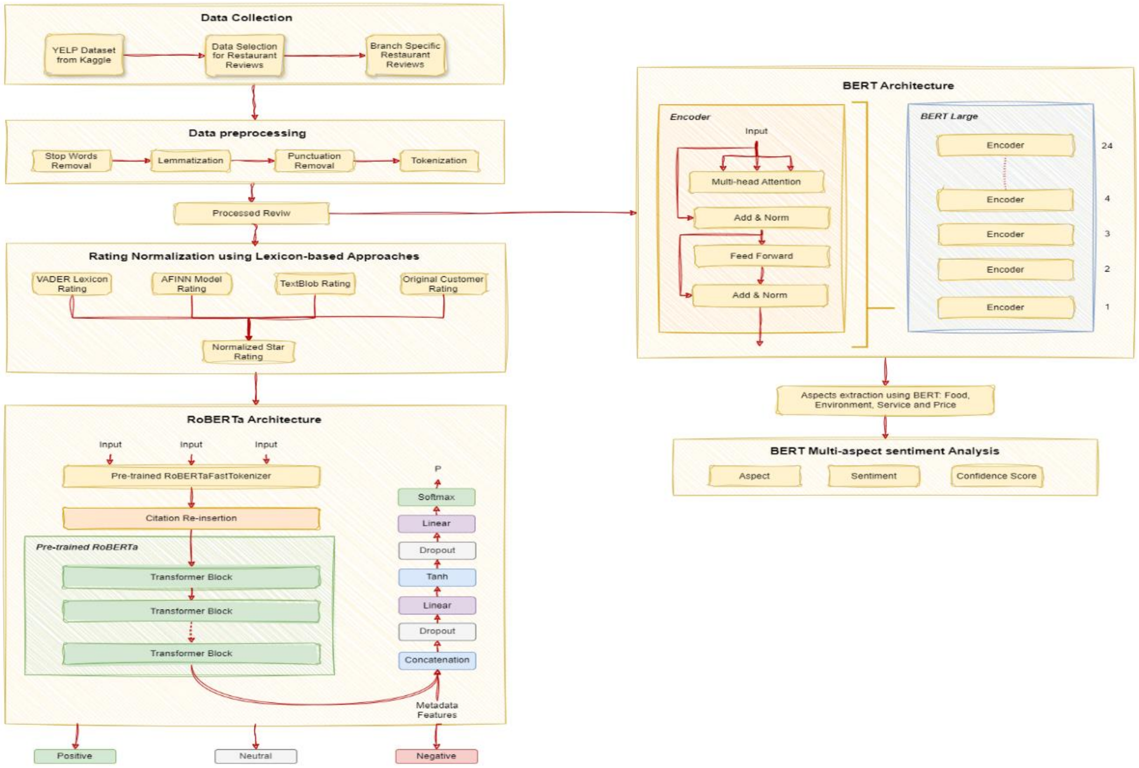

Fig. 1. Hybrid Approach for Hierarchical Spatiotemporal ABSA of Branch specific restaurant.

### B. Lexicon-Based Sentiment Analysis

*1) VADER Lexicon:* VADER, short for Valence Aware Dictionary and sEntiment Reasoner, employs a pre-built lexicon that assigns sentiment scores to individual words. This lexicon is not only focus on the polarity of words but takes into account additional aspects such as their intensity and valence. The comprehensive nature of this lexicon allows VADER to determine the complex emotional embedded in each word, facilitating a more advanced examination of sentiment in textual data [32].

In the VADER methodology, a crucial step involves computing a composite score for each review, serving as an aggregate measure of sentiment. This score considers the collective impact of individual words and their respective sentiment scores, providing an overall evaluation of sentiment within the entire review. A positive score indicates a general positive sentiment, while a negative score suggests a predominant negative sentiment. Scores close to zero imply a more neutral or balanced sentiment, reflecting the complex interaction of emotions expressed in the text.

This approach makes VADER a powerful tool for sentiment analysis, especially in contexts where the detailed and contextual understanding of sentiments is essential. By factoring in intensity and valence alongside polarity, VADER ensures a more refined interpretation of sentiment in textual data, contributing to a deeper comprehension of the emotional subtleties expressed in reviews.

*2) AFINN Model:* AFINN, a sentiment analysis tool developed by Finn Årup Nielsen, is based on a pre-built list of English words, each assigned a numerical score reflecting its sentiment polarity. With scores ranging from -5 (indicating a highly negative sentiment) to +5 (indicating a highly positive sentiment), AFINN offers a simple yet effective way to measure sentiment in textual data [33]. Unlike more complex models, AFINN's simplicity depends on individual words rather than complex linguistic structures. This approach makes it computationally efficient and particularly suitable for applications where a quick evaluation of sentiment is essential.

In the context of this research, AFINN plays a crucial role in the lexicon-based sentiment analysis of customer reviews. By employing AFINN, we use its existing sentiment scores to assess the emotional tone of words in the reviews. This efficient process aligns with the objective of this research to comprehensively analyze sentiments across a multitude of reviews, contributing valuable insights into client perceptions. The use of AFINN, in aggregation with other sentiment analysis methodologies, improves the depth and accuracy of this sentiment analysis process, to capture the wealth of customer sentiments expressed in the diverse array of reviews from online platforms like Yelp.

*3) TextBlob:* TextBlob is a Python library that simplifies natural language processing tasks, including sentiment analysis. It employs a pre-trained sentiment analysis model to sort text into different sentiment categories such as positive, negative, or neutral. Similar to VADER and AFINN, TextBlob allows for the quick and efficient analysis of sentiments within textual data.

In the context of this study, TextBlob contributes to a comprehensive sentiment analysis approach by providing an additional layer of analysis. By integrating TextBlob, the capacity to identify subtle sentiments is improved within customer reviews. TextBlob's integral capability to understand and categorize sentiment in a more delicate manner adds depth to this sentiment analysis, ensuring a more refined interpretation of customer sentiments [34]. This multi-method sentiment analysis strategy, combining the strengths of tools like VADER, AFINN, and TextBlob, is essential to extract a unified understanding of the diverse sentiments expressed in customer reviews, thereby contributing to a more thorough examination of the customer experience.

The scores computed by VADER, AFINN, and TextBlob are subsequently combined within a classification model. This model is designed to determine whether the sentiment associated with the input occurrence leans towards positivity or negativity. By unifying the sentiment scores from these three models, a more comprehensive and detailed sentiment classification system is constructed.

### C. Advanced Transformer Models for Sentiment Analysis

*1) BERT:* BERT, or Bidirectional Encoder Representations from Transformers, represents an evolutionary progression in NLP that has significantly developed the understanding and analysis of textual data. Developed by Devlin et al. in their influential work titled "BERT: Pre-training of Deep Bidirectional Transformers for Language Understanding" [35], BERT operates on an advanced neural network architecture. What distinguishes BERT is its ability to consider the context of a word within a sentence from both directions, capturing bidirectional context and contextual information. This pre-training on an extensive dataset enables BERT to achieve a profound understanding of language complexities, making it a powerful tool for various NLP tasks.

In this methodology, the capabilities of BERT were exploited to systematically extract essential attributes, including Food, Service, Price, and Environment, from textual reviews. The pre-trained BERT model serves as the backbone, to delve into the complex aspects within reviews and categorize them based on their sentiment. Following the principles outlined in Devlin et al.'s work, BERT-based approach not only extracts specific aspects from reviews but also classifies these aspects into sentiment categories (positive, neutral, and negative). The confidence scores associated with each aspect guide this classification process, resulting in a more detailed and comprehensive representation of sentiments expressed in the analyzed reviews. Overall, BERT's advanced capabilities enhance the sophistication of this sentiment analysis, providing a deeper insight into the multifaceted opinions expressed in textual data.

*2) RoBERTa:* RoBERTa, another advanced neural network model, improves the bidirectional encoding approach by emphasizing robust pre-training methodologies [36]. Its integration into this hybrid model is designed to augment its capacity to recognize delicate sentiment patterns, particularly in perplex or diverse textual occurrences. By refining the bidirectional encoding approach, RoBERTa contributes to the model's ability to capture complex distinctions in sentiment expression, further enriching the sentiment analysis process. To achieve this objective, the dataset was divided into proportions of 80:10:10, designated for the training, validation, and testing subsets, respectively. This partitioning approach allows for a comprehensive evaluation of the model's performance on unseen data, minimizing the potential for overfitting and underfitting issues.

The integration of both BERT and RoBERTa into this fusion introduces an extra layer of sophistication, empowering the model to achieve a better understanding of sentiment across a diverse range of textual contexts. This approach ensures that the sentiment analysis is not only complete but also adaptable to the complexities present in various forms of textual data essential.

### D. Hierarchical Algorithm

In this study, we employed an innovative algorithm for the Hierarchical Spatiotemporal Aspect-based Sentiment Analysis (HISABSA). Specifically designed for unraveling complex layers of sentiment within online reviews, this algorithm is a pioneering approach, leveraging advanced NLP techniques to delve into the spatiotemporal dynamics of sentiment trends and aspect-based categorization. Developed to explore the customer perceptions in the dynamic area of restaurant reviews, HISABSA serves as a cutting-edge tool for extracting valuable insights.

This approach is precisely detailed in Algorithm 1, illustrating a systematic pipeline. Starting with the YELP dataset (D), we applied an iterative algorithm that progresses through hierarchical geographical levels, moving from states to cities and ultimately to individual branches. For each unique branch, reviews (d) within a defined time frame (T) and state (S) were processed. Factors like the time period (T) affect temporal scope, with shorter periods capturing immediate trends and longer ones providing broader perspectives.

The geographical scope defined by the list of states/regions (S) expands analysis breadth but may lead to data sparsity, while the list of cities for each state (C) determines granularity, enhancing detail but increasing computational demands. Branch-specific parameters, like branch size or popularity thresholds, can also impact the reliability of sentiment analysis results locally. Considering these factors can enhance the accuracy of sentiment trends and aspect categorization within each branch.

Following this processing, star ratings were computed using lexicon-based methods, specifically AFINN, VADER, and Textblob. To neutralize potential bias in the original ratings, these derived ratings were normalized by incorporating the original rating. By employing the normalized ratings specific to individual branch reviews, a RoBERTa-based approach is utilized for refined classification. Concurrently, employing a BERT-based methodology, aspects were extracted from the reviews, and associated confidence scores were calculated. The combination of BERT's aspect extraction and lexicon-based rating normalization offers a comprehensive insight into sentiment patterns within restaurant chains.

**Algorithm 1:** Hierarchical Spatiotemporal Aspect-based Sentiment Analysis (HISABSA)

```
1.Input: D (YELP Dataset), T (Time period), S (List of
states/regions), C (List of cities for each state)
2:Output: Hierarchical sentiment, aspect-based categorization, and
rating trend RT for branches in each city within each state during
time T .
3: D_load ← LOAD(D)
4: T_set ← T
5: D_restaurant ← FILTER(D_load, ”restaurant”)
6: for s ∈ S do
7: Ds ← FILTER(D_restaurant, s)
8:    for c ∈ C do
9:      $D_{s,c}$ ← FILTER($D_{s,c}$)
10:     for b ∈ B do    —▷ Iterate through branches in city c
11:            ($D_{s,c,b,T}$)← FILTER($D_{s,c,b,T}$)
12:                  for d ∈ ($D_{s,c,b,T}$) do
13:                        dprocessed ← PROCESS(d)
14:            R ← RoBERTa_EXTRACT RATINGS(dprocessed)
15:         A ← BERT_EXTRACT ASPECTS(dprocessed)
16:                  SAb ← ANALYZE SENTIMENT($D_{s,c,b, T}$)
                     end for — ▷ Branch-specific sentiment analysis
17:            RT ← CALCULATE REVIEW TREND(R, T )
18:     end for
19:   end for
20:end for
21: $HS_b$ ← GROUP($SA_b$)
22  DISPLAY/STORE $HS_b$
23:RETURN $HS_b$, RT
```

- Input: The algorithm takes the following inputs D (YELP Dataset)
  - ✓ T (Time period): The specific time frame under consideration.
  - ✓ S (List of states/regions): The geographical regions or states relevant to the analysis.
  - ✓ C (List of cities for each state): The cities within each state.
- The Yelp dataset is loaded (D_load), and the subset related to restaurants (D_restaurant) is filtered.
- The algorithm iterates through each state (S) and, within each state, iterates through the cities (C).
- For each city, the algorithm iterates through the branches (B).
- Reviews are filtered based on the specified time period (T) for each branch in each city within each state.
- Each review is processed (dprocessed) as a pre-processing step.
- RoBERTa is employed to extract ratings (R) from the processed review (Line 14).
- BERT is used to extract aspects (A) from the processed review (Line 15).
- The sentiment of each branch (SAb) is analyzed based on the processed reviews (Line 16).
- The rating trend (RT) is calculated based on the extracted ratings and the specified time period (Line 17).
- The results are grouped based on sentiment (HSb) and then either displayed or stored for further analysis (Lines 21-22).
- Output: The algorithm returns the hierarchical sentiment (HSb) and the calculated rating trend (RT) (Line 23).

In essence, this algorithm meticulously examines Yelp reviews, conducting sentiment analysis adapted to individual branches, taking into account distinct time frames and geographic locations. The outcomes are subsequently organized, offering insights into sentiment patterns and the factors shaping customer perspectives across various restaurant branches. This method enables a detailed understanding of customer sentiments, facilitating informed decision-making and strategic improvements fitted to each branch's unique context.

## IV. Data Processing Pipeline for Sentiment Analysis

In this data processing pipeline for sentiment analysis, a systematic approach is employed to extract valuable insights from textual data. Employing advanced NLP techniques, the data was preprocessed to ensure its cleanliness and consistency, removing noise and irrelevant information. Through tokenization and embedding, raw text is transformed into a format suitable for analysis models.

Additionally, feature engineering methods are incorporated to capture essential characteristics of the text, improving the accuracy and relevance of this sentiment analysis. This pipeline integrates seamlessly with state-of-the-art sentiment analysis models, facilitating the extraction of detailed sentiments and insights from the data, and to provide decision-makers with actionable intelligence.

### *A. Data Collection*

The cornerstone of this research is the Yelp Dataset Challenge (YDC), a rich collection of business reviews that is readily available on both Kaggle and Yelp's official website. This dataset, sourced from Kaggle, comprises various JSON files including business profiles, user data, reviews, check-ins, and tips, offering a comprehensive perspective on consumer experiences and feedback within the Yelp network. This extensive dataset serves as the primary resource for this investigation to extract various aspects of customer sentiment and behavior in the context of business reviews.

Fig. 2 illustrates the distribution of reviews over the years, highlighting restaurants as the most prevalent category with reviews. Consequently, we have opted to concentrate this study on the restaurant category, given its substantial presence and significance within the dataset.

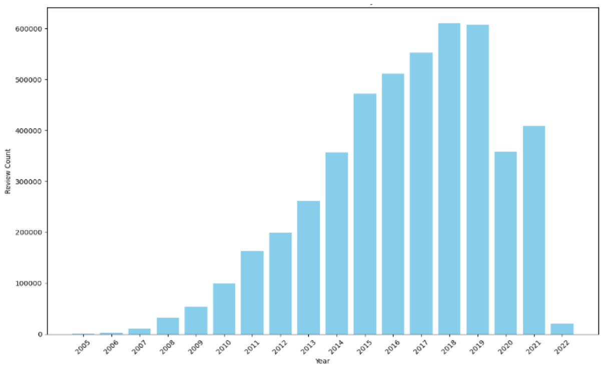

Fig. 2. Year wise restaurant reviews.

## B. Data Cleaning and Filtering

In the preliminary phases of this data analysis, significant importance is placed on foundational procedures in data cleaning and filtration to enhance the quality and applicability of the extracted data. This involved a methodical approach to eliminating irrelevant elements such as stop words, numerical figures, and punctuation symbols from the dataset, with the overarching goal of minimizing interference and accentuating substantive content. Through the particular method the dataset underwent a process of refinement that guaranteed subsequent analytical actions, and provided the most pertinent and contextually meaningful textual data [37].

## C. Lemmatization

Lemmatization is a linguistic process used in NLP to reduce words to their base or root form, known as a lemma, which helps in standardizing and simplifying text analysis. Unlike stemming, which reduces words to their root form without considering the meaning of the word as illustrated in Fig. 3, lemmatization considers the context and meaning of words resulting in more accurate transformations [38].

The primary objective of lemmatization is to transform inflected or derived words into their base form to facilitate text analysis and improve the accuracy of downstream NLP tasks such as sentiment analysis, information retrieval, and machine translation. For example, lemmatization would convert words like "running" to "run," "better" to "good," and "meeting" to "meet". Lemmatization relies on dictionaries and structural analysis to determine the base form of a word. It considers the part of speech (POS) of each word and applies specific rules to accurately derive the lemma. For instance, verbs are lemmatized to their infinitive forms, nouns to their singular forms, and adjectives to their positive forms.

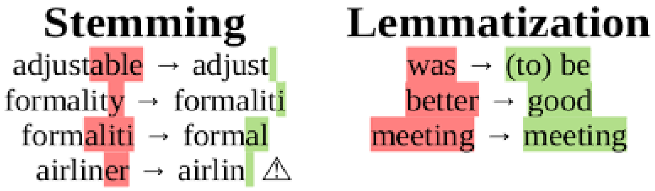

Fig. 3. Stemming vs. Lemmatization.

One advantage of lemmatization over stemming is its ability to produce valid words, as it ensures that the transformed words are present in the dictionary [39]. This helps maintain the semantic integrity of the text and improves the interpretability of the analysis results. In summary, lemmatization is a crucial preprocessing technique that improves the accuracy of text analysis and plays a vital role in various NLP applications by standardizing text data and improving the quality of linguistic analysis.

## D. Tokenization

The tokenization of reviews played a pivotal role in increasing the interpretability and analysis of textual data. Tokenization involved segmenting the reviews into meaningful units, such as individual words or phrases, providing a structured foundation for further analysis [40]. Breaking down the text into these discrete units allowed for a more granular understanding of the language used in customer reviews, enabling a detailed exploration of sentiments and opinions.

This process not only facilitated the identification of key terms but also enabled a more accurate examination of linguistic patterns and trends. The use of tokenization as illustrated in Table II. It was instrumental in preparing the textual data for subsequent analyses, contributing to the overall effectiveness of this study by providing a structured and comprehensive source for the exploration of customer experiences across various restaurant branches.

TABLE II. BRANCH SPECIFIC RESTAURANTS PROCESSED REVIEWS

| *Original Reviews* | *Processed Reviews* |
|---|---|
| We were a bit weary about trying the Shellfish... | bit, weary, trying, Shellfish... |
| I love trying fresh seafood on piers, wharfs a... | love, trying, fresh, seafood, piers, , wharfs... |
| Super delish!! No frills! Just great sea food,... | Super, delish, frills, great, sea, food... |
| For a seafood restaurant at the edge of pear expectations… | seafood, restaurant, edge, pear, expectations... |

## E. Data Refinement

Exclusively extracted restaurant-related reviews from the dataset, and this improved dataset went through further filtering according to predetermined time frames (T) and geographical states (S), specifically targeting select cities (C) within each state. The goal of this detailed filtering as explained in the HISABSA algorithm, was to ensure that this analysis remained focused and directly pertinent to businesses falling under the restaurant category. This process, illustrated in Fig. 4 increases the precision and relevance to meet research objectives.

However, it is worth mentioning the substantial variability in the quantity of reviews across different restaurants. This diversity underscores the broad spectrum of customer engagements perceived among various restaurants. The primary attention is directed towards the top five restaurant chains: McDonald’s, Subway, Taco Bell, Burger King, and Wendy’s. Fig. 5 supplements this analysis by visually depicting the branch distribution for each of these leading restaurants. This data augments the understanding by providing insights into both the volume of reviews and the geographic dispersion of branches among these prominent establishments.

05
Branch-wise Reviews
Finally, branch-specific restaurant reviews are extracted.
Selected Dataset

Fig. 4. Branch specific dataset collection.

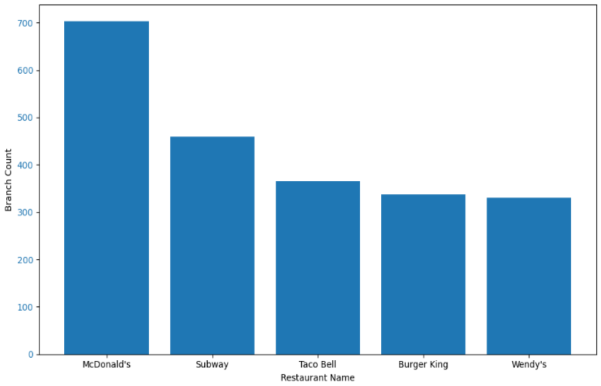

Fig. 5. Branch wise count of top 5 restaurant businesses.

In this study, the analysis was accurately structured to provide a thorough examination of restaurant data, categorizing it systematically by the state and city of each establishment. This methodical approach facilitated a detailed investigation into the individual branches of every restaurant, allowing the collection and analysis of reviews tailored to each location over time. Through Fig. 5 and Fig. 6, the accumulation of customer feedback for every branch of a restaurant chain over its operational lifetime was visually depicted.

Additionally, this study revealed that McDonald's has the highest number of branches compared to other restaurants. This finding underscores McDonald's widespread presence and popularity across various regions. Furthermore, it was found that McDonald's also had the highest number of reviews compared to other restaurants in this analysis. This observation can be attributed to McDonald's status as a globally recognized fast-food chain, attracting a larger customer base and generating more feedback due to its widespread popularity and availability.

Fig. 7 further supports the findings illustrated in Fig. 6 demonstrating that among the top five restaurants, McDonald's stands out with the largest number of reviews, totaling 17,359. This notable volume of reviews underscores McDonald's prominence in customer interactions and feedback, highlighting its significant presence in the restaurant industry. Through this systematic categorization and analytical approach, the accuracy and depth of the findings are enhanced, providing valuable insights into the customer experience across various restaurant locations in diverse regions. This structured analysis enables capturing detailed trends and patterns within the customer feedback landscape, highlighting the dynamics of customer engagement and satisfaction levels across different branches of restaurants.

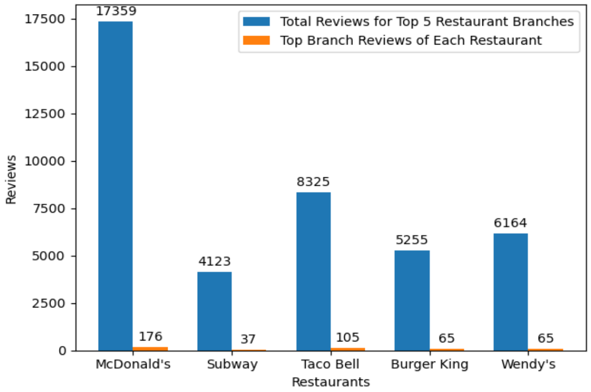

Fig. 6. Reviews count of all restaurant branches and top branch reviews.

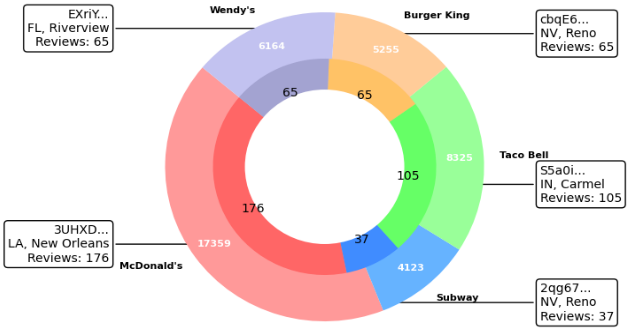

Fig. 7. Reviews count of all restaurant branches and top branch within a particular state and city.

## F. Experimental Setup

In our research of developing sentiment classification within the area of service industry reviews, we opted for the adoption of a pre-trained RoBERTa model. This decision was driven by the model's robust linguistic comprehension, enabling it to interpret a diverse dataset consisting of reviews from various McDonald's branches. The computational backbone of this framework was the NVIDIA A100 GPU, boasting an ample 80 GB of memory, which played a pivotal role in accelerating both training and experimentation phases.

This hardware choice proved crucial in managing the scale of the data and the computational demands essential in fine-tuning RoBERTa for this specific task requirements. Additionally, a BERT-based approach is implemented for aspect-based sentiment analysis, focusing on sentiment trends. The computational infrastructure supporting the BERT-based methodology included high-performance computing resources, notably featuring multi-core processors and sufficient RAM capacity to handle the computational demands of processing large volumes of textual data.

Moreover, cloud-based platforms equipped with robust GPU acceleration capabilities were leveraged, enhancing the efficiency and speed of the aspect extraction and sentiment analysis tasks. This approach successfully condensed the overall general aspects of a review into these specific categories, along with the assignment of confidence scores.

## V. Unveiling Sentiment Analysis: From Lexicons to Transformers

### A. Refining Sentiment Analysis: VADER, AFINN, and TextBlob Integration

This study employed the VADER sentiment analysis tool to evaluate and quantify the sentiments expressed in customer reviews. This process uses the VADER analyzer that starts with the calculation of sentiment percentages for each review, breaking down the sentiments into positive, negative, and neutral components. These values were then utilized to derive an average sentiment score, referred to as the 'VADER rating'.

Additionally, statistical summary metrics such as maximum, minimum, and average values are computed to offer a comprehensive understanding of the sentiment distribution in the dataset. The categorization of sentiment scores further improves the interpretability of the results, providing a more detailed perspective on customer sentiments. The systematic integration of the VADER tool into this analysis framework contributes to a robust and quantifiable assessment of sentiment trends in the context of restaurant reviews [41].

Moreover, AFINN sentiment analysis tool is employed to measure the overall sentiment in processed reviews, with a particular focus on positive scores that were assumed correlated with positive sentiments. The intentional classification of these positive scores into five specific groups was carefully designed to include a detailed range similar to a star rating system, covering from 1 star to 5 stars. This categorization provides a more granular understanding of sentiment distribution, allowing the differentiation between various levels of positivity in the dataset.

AFINN's attributes simplicity, speed, linguistic approach, and interpretability, make it able for typical sentiment analysis tasks. Its unified implementation and efficiency in handling large datasets facilitate quick assessments of sentiment polarity. Ultimately, the practical application of AFINN in this sentiment analysis is guided by its efficiency in swiftly providing insights into sentiment polarity, aligning with a simplified yet meaningful star rating framework.

The TextBlob library is utilized to perform sentiment analysis on the processed reviews. The code extracts polarity and subjectivity scores using TextBlob's sentiment analysis capabilities, providing insights into the sentiment's positivity (polarity) and its level of objectivity [42]. This score is a numerical representation of the sentiment, computed as the division of polarity by subjectivity aspects as shown in Eq. (1), incorporating a small constant in the denominator to avoid division by zero. The subsequent categorization of the scores into five classes, based on predefined entries, contributes to a detailed understanding of sentiment distribution within the dataset. The resulting 'TextBlob rating' represents these categorized sentiment scores.

$$Score = \frac{polarity}{subjectivity + \epsilon} \tag{1}$$

The study further enriches its sentiment analysis by integrating TextBlob's results with other sentiment scores, including those derived from AFINN and VADER, as well as the original star ratings provided by the customers. This integrated approach aims to offer a comprehensive and multi-faceted evaluation of sentiment.

### B. Exploring Sentiment Analysis with RoBERTa and BERT Transformers

A systematic framework is established for this approach, incorporating revolutionary DL models, namely RoBERTa and BERT, in an innovative manner. Both models operate on transformer-based architectures, representing NLP advancements remaining to their deep learning structures. Their bidirectional training proves particularly effective for sentiment analysis, capturing sensitive implications embedded in word order and sentence structure that significantly influence sentiment. Adjusted to this specific dataset, these models excel in sentiment analysis, serving as foundational tools that provide scalable solutions adaptable to a diverse range of languages and domains.

In this research, BERT was initially employed as a powerful transformer-based model, to process and analyze textual data from customer reviews. BERT played a crucial role in this methodology by extracting important aspects from the text, such as food quality, service standards, and pricing perceptions. Its sophisticated architecture allowed the categorization of these aspects and effectively captured and classified diverse elements within the reviews, contributing to a comprehensive understanding of customer feedback and preferences.

Following the initial analysis with BERT, RoBERTa was integrated into this methodology for sentiment classification. RoBERTa, another transformer-based model, that excels in understanding and interpreting the semantic distinctions present in text data. In this research, RoBERTa was assigned to the pivotal role of sentiment classification within the reviews. By exploiting its robust linguistic comprehension and sophisticated algorithms, RoBERTa effectively categorized the sentiments expressed by customers as positive, negative, or neutral. The integration of RoBERTa enhanced the accuracy and depth of this sentiment analysis, providing valuable insights into the overall sentiment trends across different restaurant branches and customer interactions [43].

The dataset is balanced by down sampling the negative class and then shuffled to create a balanced dataset. The RoBERTa model is utilized to create a neural network with bidirectional Long Short-Term Memory (LSTM) layers, which are optimized on the balanced dataset. Moreover, the model is then compiled using the AdamWeightDecay optimizer and categorical cross entropy loss function. The model's architecture includes bidirectional LSTM layers followed by dense layers with dropout and batch normalization. The RoBERTa embeddings are used as input to these layers, then the model is trained on the prepared training and validation data, then its performance is evaluated using the Categorical Accuracy metric.

Finally, a tokenizer specific to RoBERTa is employed to preprocess text data for predictions. The 'predict' function takes a text input, preprocesses it, and utilizes the trained model to predict the sentiment, returning the corresponding index of the predicted sentiment category (Positive, Negative, or Neutral). The study aims to employ the capabilities of transformer-based models like RoBERTa to achieve robust sentiment analysis results on the provided dataset.

## VI. Results

### A. *Evaluation of Lexicon based Approaches*

In this section, the sentiment analysis is augmented by integrating outcomes from VADER, AFINN, and TextBlob, in addition to the original star ratings provided by customers. This comprehensive approach ensures a detailed understanding of customer feedback, transcending the limitations of numerical ratings and offering a more comprehensive representation of their sentiments. Through a meticulously structured analytical process outlined in Table III, each of the three methodologies contributes valuable insights to the overarching sentiment analysis.

TABLE III. Normalized Extracted Rating Using Lexicon Based Approaches

| *Original Reviews* | *Original Rating* | *VADER Rating* | *AFINN Rating* | *TextBlob Rating* | *Normalized Extracted Rating* |
|---|---|---|---|---|---|
| We were a bit weary about trying the Shellfish... | 4 | 2 | 5 | 4 | 3.6 |
| I love trying fresh seafood on piers, wharfs a... | 4 | 2 | 5 | 4 | 3.6 |
| Super delish!! No frills! Just great sea food,... | 4 | 4 | 2 | 4 | 3.3 |
| For a seafood restaurant at the edge of pear expectations… | 3 | 2 | 4 | 3 | 3.0 |

Acknowledging that numerical ratings may lack granularity in conveying specific preferences or concerns, these methodologies were employed to extract normalized ratings from the textual content of reviews. This method aims to provide a more pertinent and insightful understanding of what aspects customers appreciate. The strength of these results lies in their ability to capture detailed sentiments expressed in textual reviews, thereby enriching the analysis and offering deeper insights into customer preferences and concerns.

### B. *Evaluation of Transformer Models*

The results of the normalized extracted ratings were leveraged as a training dataset for the BERT and RoBERTa models. The dataset was partitioned into an 80% training set, a 10% validation set, and a 10% test set. This strategic division allowed training the model on a substantial portion of the data, validate the performance on a separate set to adjusted parameters, and ultimately assess the generalization on an independent test set. The normalized ratings, derived from the lexicon-based methodologies and reflecting sentiments from customer reviews, served as valuable inputs for training our model. This approach aimed to expand the models' understanding of sentiment distinctions and improve the accuracy in predicting sentiment labels across various customer feedback scenarios.

Conducting a Hierarchical Spatiotemporal Aspect-Based Sentiment Analysis (HISABSA), the city of Indianapolis was selected since it hosts a substantial number of reviews with relevant aspects. The dataset includes 176 customer reviews for a McDonald's branch in Indianapolis, Indiana. The primary aspects of Food, Service, Environment, and Price were carefully extracted for analysis. The findings are visually represented in Fig. 8 and Fig. 9 showcasing the temporal trends for each aspect and the overall rating trend for complete reviews over time, respectively. Upon visually interpreting these two figures, a discernible shift in sentiment across various aspects of the restaurant branch becomes evident.

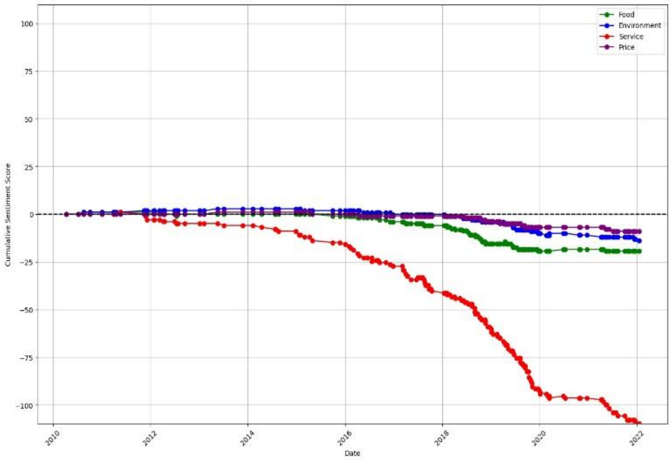

Fig. 8. Cumulative sentiment trends of restaurant branch aspects in Indianapolis, Indiana over time.

Fig. 8 illustrates the cumulative sentiment trends related to Food, Environment, Service, and Price, revealing a substantial decline in sentiment scores, particularly noticeable from 2018 to 2022. This trend signals a change in customer perceptions regarding different aspects of the restaurant branch during this period. The decrease in sentiment scores implies possible issues or alterations in customer experiences, prompting the need for deeper exploration into the factors driving these changes. Moreover, analyzing the specific time frames corresponding to sentiment score decreases can provide valuable insights into areas for potential improvement or refinement within the restaurant's operations and services.

Upon thorough examination, it's clear that the 'Service' aspect undergoes the most significant decline in sentiment, indicating a intensified sensitivity among customers towards the perceived quality of service during this period. In contrast, 'Food' and 'Environment' show a more gradual decline, while 'Price' demonstrates relatively lower volatility but still trends negatively. Addressing these findings necessitates a comprehensive strategy that encompasses all aspects of the restaurant's offerings. Potential interventions may involve reviewing pricing strategies, re-evaluating menu items and food quality, improving the dining ambiance, and investing in customer service training.

Fig. 9 serves as a supplementary illustration to the initial findings, presenting the trajectory of overall star ratings over time. Similarly, a noteworthy concentration of lower star ratings is evident, specifically occurring the latter part of the period between 2018 and 2022. This alignment implies a consistent decline not only in specific aspects of the customer experience but also in overall satisfaction. The temporal correlation implies that the restaurant faced challenges during this timeframe, influencing various facets of its operations. The simultaneous decline across all four aspects indicates that the negative sentiment was not confined to a singular area but rather filtered different elements of the dining experience.

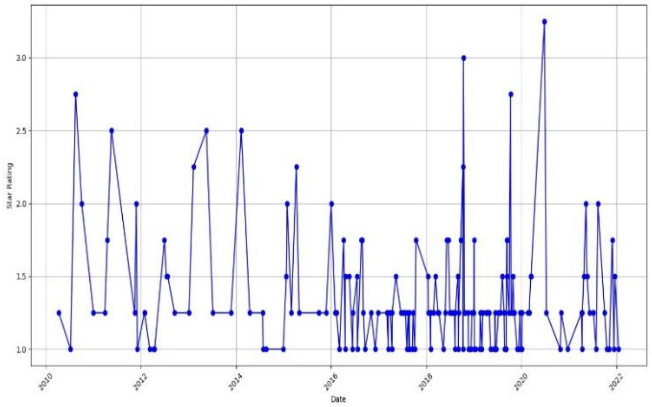

Fig. 9. Star rating trend of restaurant branch in state in, city, Indianapolis over time

The research aims to comprehensively understand both internal operations and external influences shaping customer perceptions. Through this complete interpretation, the restaurant can devise an effective plan for recovery and enrichment. By delving deeper into customer sentiments and preferences, businesses can orient their approaches to improve satisfaction, foster brand loyalty, and ultimately sustain profitability. Exploiting the insights gathered from this research, companies can navigate competitive markets with informed decisions that drive growth and success.

### C. Evaluation Metrics

The dataset underwent thorough preprocessing to align with the input expectations of the RoBERTa architecture, including the normalization of star ratings to serve as labels in supervised learning. The training procedure was fine-tuned to optimize the model's performance across three sentiment classes, representing a range of customer opinions. Rigorous validation ensured the robustness and applicability of the model, with these findings illuminated by a confusion matrix showcasing the model's differentiation among sentiment classes.

The evaluation of the refined RoBERTa model demonstrated praiseworthy precision, recall, and F1-score metrics, averaging approximately 0.92, 0.93, and 0.90, respectively, across sentiment classes, resulting in an overall accuracy of 92%. These outcomes represent a significant enhancement over existing state-of-the-art models in sentiment analysis within the restaurant review context. The confusion matrix in Fig. 10 further substantiates the model's efficacy, illustrating a high degree of accuracy in class predictions with minimal misclassification.

Table IV illustrates that the model reveals its ability to accurately identify positive, negative, and neutral sentiments expressed in customer reviews. High recall values, notably reaching 0.98 for negative sentiment, signify the model's proficiency in retrieving relevant instances of each sentiment class from the dataset. The F1-Score values, ranging from 0.90 to 0.95, reflect a balanced trade-off between precision and recall, indicating the model's robustness in handling sentiment classification tasks. These findings affirm the HISABSA approach as a robust and accurate framework for sentiment analysis, offering valuable insights into customer perceptions and feedback within the restaurant industry.

The HISABSA study stands out among other sentiment analysis approaches, as demonstrated by the results summarized in Table V. While previous studies have achieved varying levels of performance across different techniques on the YELP dataset, our approach consistently outperformed these studies in terms of accuracy and F1-score. For instance, in one study [31] using the YELP dataset, techniques such as Logistic Regression, Naive Bayes, and Support Vector Clustering returned accuracies ranging from 73.22% to 79.12%. Furthermore, in another experiment utilizing the YELP dataset, various techniques including Multinomial Naive Bayes and Support Vector Machine achieved F1-scores ranging from 0.701 to 0.757. In contrast, the HISABSA approach utilizing RoBERTA achieved an impressive accuracy of 92%, surpassing the performance of other methods and showcasing its competitive performance against traditional methods.

These results highlight the effectiveness of this study’s approach in sentiment analysis, particularly in the context of restaurant reviews. By leveraging advanced techniques such as RoBERTA and fitting this methodology to the specific characteristics of the dataset, we were able to achieve superior performance in accurately classifying sentiments expressed in customer reviews. This underscores the robustness and reliability of the HISABSA framework in extracting valuable insights from textual data and contributing to a deeper understanding of customer sentiments in the restaurant industry.

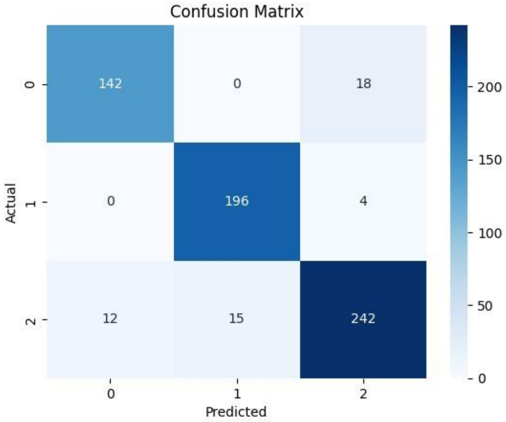

Fig. 10. Confusion matrix of the RoBERTa classification model.

TABLE IV. RESULTS OF THE ROBERTA BASED APPROACH TO CLASSIFY RESTAURANT REVIEWS

| *Sentiment Class* | *Precision* | *Recall* | *F1-Score* | *Accuracy* |
|---|---|---|---|---|
| 0 (Positive) | 0.92 | 0.89 | 0.90 | 0.92 |
| 1 (Negative) | 0.93 | 0.98 | 0.95 | 0.92 |
| 2 (Neutral) | 0.92 | 0.90 | 0.91 | 0.92 |

## VII. DISCUSSION

The strength of this study lies in its comprehensive approach towards understanding customer sentiments within the restaurant industry, addressing the challenges inherent in sentiment analysis and offering valuable insights for managerial decision-making. By introducing the Hierarchical Spatiotemporal Aspect-Based Sentiment Analysis (HISABSA) methodology, this research bridges the gap between traditional sentiment analysis methods and the complex dynamics of customer feedback in the restaurant sector. Considering both textual content and numerical ratings, our model achieves a sophisticated understanding of customer feedback, leading to more detailed insights and more accurate sentiment analysis results.

Based on the results, the proposed model has been fine-tuned to optimize its parameters, resulting in robust performance that outperforms existing studies. One of the main strengths of HISABSA model is its integration of diverse sentiment analysis methodologies, including lexicon-based approaches alongside advanced transformer models. This hybrid model enables a thorough examination of customer sentiments, capturing subtle distinctions and providing a more accurate interpretation of their experiences.

Moreover, the model's robust performance, as demonstrated by the evaluation metrics, underscores its effectiveness in accurately analyzing and categorizing customer feedback. The high precision, recall, and F1-score metrics, along with the remarkable 92% accuracy in sentiment classification, highlight the model's capability to differentiate among sentiment classes and provide reliable insights for decision-making. This heightened level of accuracy can be attributed to the hybrid model that combines various techniques, leveraging the strengths of each approach to effectively capture diverse aspects of the input data.

The findings of this study highlight a distinct need for improvements across various facets within the restaurants. Systematically addressing the decline in customer sentiment across the aspects and comprehending the root causes will enable the restaurant to elevate customer satisfaction and restore its reputation moving forward. It is imperative for the branch manager to delve deeper into the sentiment of each aspect, correlating them with specific timeframes and external events.

In meeting the challenges faced by the restaurant industry, this study offers actionable insights for improving customer satisfaction and enhancing business performance. By delving into specific aspects such as food quality, service standards, and pricing perceptions, the model provides a complete view of customer sentiments, enabling restaurants to identify areas for improvement and tailor their strategies accordingly. Therefore, it can be concluded that the combination of these fundamental models within a classification model has excelled in facilitating performance enhancement by capturing distinct features of the input data based on their respective operational modes.

## VIII. CONCLUSION

In summary, this research aims to uncover the intricacies of customer sentiments within the restaurant industry by employing a comprehensive methodology. It combines lexicon-based approaches, utilizing VADER, AFINN, and TextBlob, with innovative transformer models like BERT and RoBERTa, to gain a thorough understanding of customer feedback. Recognizing the inherent limitations of numerical star ratings provided by customers, leveraging lexicon-based methodologies extracts detailed and standardized ratings from customer reviews. This approach fosters a more refined understanding of sentiments, serving as a crucial training dataset for the transformer models. This integration aims to empower this study's model to capture the subtle complexities of customer sentiments, providing a more accurate interpretation of their experiences.

The primary objective of this study was to develop an advanced hybrid sentiment analysis model capable of accurately analyzing and categorizing customer feedback from restaurant reviews. Conducting an in-depth examination of Hierarchical Spatiotemporal Aspect-Based Sentiment Analysis (HISABSA), this research meticulously analyzes 176 customer reviews from a specific McDonald's branch in Indianapolis, Indiana. This extensive analysis delves into primary aspects such as Food, Service, Environment, and Price, providing a comprehensive investigation. Moreover, the optimized RoBERTa model, trained on the dataset derived from lexicon-based methodologies, achieves creditable precision, recall, and F1-score metrics, outperforming existing state-of-the-art models. The confusion matrix underscores the model's efficacy, highlighting its nuanced differentiation among sentiment classes. The experimental results demonstrate the successful achievement of this objective, with HISABSA the model showcasing a outstanding results in classifying sentiments across positive, negative, and neutral categories.

Visual representations reveal evident changes in sentiment over time, particularly highlighting notable declines in service. The simultaneous decline across all aspects between 2018 and 2022 suggests challenges faced by the restaurant, highlighting the need for comprehensive improvements across various operational facets. To contextualize these results, it is crucial to consider the challenges inherent in sentiment analysis within the restaurant industry. Restaurants face the daunting task of deciphering and understanding the diverse sentiments expressed by customers across various dimensions such as food quality, service standards, and pricing perceptions. The hybrid model developed in this study addresses these challenges by integrating both lexicon-based and context-based approaches, thereby providing a comprehensive understanding of customer sentiments. These findings not only contribute to the advancement of ABSA but also hold significant implications for business intelligence, offering decision-makers clear insights into customer needs and providing a robust framework for decision-making.

In conclusion, the HISABSA findings underscore the importance of systematically addressing specific aspects to develop overall customer satisfaction and restore a restaurant's reputation. By delving into the sentiment of each aspect, correlating them with specific timeframes and external events, restaurant managers can make informed decisions for a comprehensive development of customer satisfaction. This study contributes a unified framework for sentiment analysis in the restaurant industry, offering actionable insights for managerial decision-making, continuous improvement, and sustained success.

In future research, optimizing model parameters, expanding analysis to include multiple languages, and incorporating dynamic sentiment analysis techniques offer opportunities to enhance the hybrid sentiment analysis model's performance and applicability. Integrating user-generated content from diverse sources and incorporating domain-specific knowledge further refine sentiment analysis methodologies for the restaurant industry.

*Abstract*—**Forecasting water quality is critical to environmental management because it facilitates quick decision-making and resource allocation. On the opposite hand, current methods are not always able to produce reliable forecasts, which is often due to challenges in parameter optimization for complex models. This research presents a novel approach to enhance the forecasting accuracy of water quality by optimizing neuro-fuzzy models using Tunicate Swarm Optimisation (TSO). The introduction highlights the limitations of current techniques as well as the necessity for precise estimates of water quality. One of the drawbacks is that neuro-fuzzy models are not well-modelled, which makes it harder for them to identify the minute patterns in data on water quality. The suggested approach is unique in that it applies TSO, an optimization algorithm inspired by nature that emulates tunicates' behaviour, to the neuro-fuzzy models' parameter optimization process. The highly complex parameter space is effectively navigated by TSO's swarm intelligence, which strikes a balance between exploration and exploitation to improve model performance. To optimize model parameters, the process comprises three steps: creating an objective function, defining the neuro-fuzzy model, and seamlessly integrating TSO. By mimicking the motions of tunicates as they look for the best conditions in the marine environment, TSO constantly optimizes the variables. Experiments demonstrate that the proposed strategy is more effective than traditional optimization techniques in forecasting water quality. As seen by the optimised neuro-fuzzy model's increased prediction accuracy and several dataset validations, Tunicate Swarm Optimisation has potential for reliable environmental forecasting. This work presents a potential path for improved environmental decision-making systems by offering an optimisation strategy inspired by nature that overcomes the limitations of existing methods and enhances water quality forecasting tools.**

***Keywords*—Water quality forecasting; neuro-fuzzy models; tunicate swarm optimization; parameter optimization; environmental decision support**

## I. Introduction

Human activities are causing an increase in the variability of water quality in water bodies across the world. For instance, the incidence and length of hypo limnetic anoxia are rising in many lakes due to environmental and ecological changes, but waterbodies are facing stronger storms that start mixing and improving oxygen accessibility, leading to large every day fluctuations in oxygen levels [1]. The increased unpredictability of numerous water quality measurements exceeding a variety of historical circumstances makes estimating future water quality difficult, putting a significant pressure on management in charge of delivering essential lake and reservoir biological functions every day [2]. The burgeoning science of ecological prediction offers a fresh technique to proactively controlling dams and wetlands in the midst of rising water quality uncertainty. Environmental forecasting, or anticipating future ecology qualities based on observable unanticipated factors is a valuable tool for management. Prediction provides managers with probability projections for probable water quality circumstances in a focus lake or reserve tank, enabling them to take pre-emptive management activities that decrease or prevent water degradation [3].

Water quality is defined as the biological, chemical, and physical characteristics of water according to an array of water quality criteria. The decline in water quality resulted in major management initiatives to enhance and safeguard water quality, particularly in developing nations. In recent years, modelling and predicting river water quality for growth possibilities have played an essential role in environmental, ecological, and water resource management choices [4]. The field of computers and statistics has enhanced modelling tools for recognizing trends in water resources' data collected over time to correctly anticipate future events and enhance water resource management. The simulation and forecasting of water quality variables are normally carried out using one of two methodologies. The first strategy is based on the process of flow and the chemical and physical characteristics of water, and it has been widely used in many basins [5]. This sort of water quality modelling frequently requires substantial information, including simulation settings and outside sources or drains. Also, when there is little monitoring data or insufficient background knowledge available, it might be challenging to mimic water quality systems using this model. The second methodology employs statistical and intelligence-based technologies. Artificial intelligence has grown rapidly in recent years, providing different ways to regression and better accuracy in a number of circumstances [6]. Water quality is influenced by a larger number of factors, including hydrological, biological, weather-related, and human activity. Because of interconnections among water quality factors, these variables are nonlinear, time variable, unpredictable, and postponed. As a result, it is distinct to represent such factors quantitatively using correct statistical representations and to create an accurate, nonlinear model for forecasting using conventional approaches [7].

A river's water quality varies over time and place, hence constant monitoring and analysis are required for successful river water quality management. A wide range of models and novel approaches have been presented for anticipating and managing shifts in water quality. Methods for evaluating and predicting these alterations in water quality are broadly classified as conceptual, deterministically models or models that include mathematical and stochastic methodologies [8]. The numeric approach necessitates a large quantity of data input, making it difficult to predict the optimal value. In addition, the user's subjective nature frequently causes problems with the estimate process. The stochastic method, however, has the benefit of being able to calculate the optimum parameters using time-series information on the water rather than simulating the water's physical, chemical, and biological features. Furthermore, the stochastic approach may be used for both long- and short-term projections by creating relatively unlimited input and output. In recent years, an AI system suited for nonlinear forecasting was used for water quality predicting to remove the user's subjectivity during parameter evaluation [9]. Artificial intelligence algorithms are increasingly being used for discharging forecasting research. The amount of things available for real-time automated measurements is limited, and obtaining all of the required input variables is challenging. As a result, the stochastic framework is regarded to be an excellent tool for analysing and forecasting fluctuations in the water's quality at continual surveillance stations, water intake infrastructure, and areas of frequent floods where continuous monitoring and immediate control are needed [10]. The main factors that will be examined are dissolved oxygen and total organic carbon [11].

Water quality forecasting is critical to good environmental administration because it provides essential information for rapid choices and appropriate resource allocation. As communities deal with the growing complexity of environmental behaviour, the accuracy of water quality projections becomes critical. However, present forecasting systems have substantial shortcomings, notably in the difficult issue of parameter optimization for complicated neuro-fuzzy models. The difficulties in making credible forecasts are frequently linked to inadequate parameters, which limits the models' capacity to detect the intricate patterns present in water quality data. This work tackles these constraints by introducing a novel approach that uses Tunicate Swarm Optimisation (TSO) to optimize neuro-fuzzy models, increasing the accuracy and resilience of water quality forecasts. Existing approaches require significant improvement due to difficulties with detailed parameter optimization, which limits their ability to capture every aspect of water quality changes. The proposed method uses TSO, an optimisation algorithm affected by the collective behaviour of tunicates, to construct a novel framework. By attempting to get beyond the limitations of conventional optimisation techniques, TSO integration offers a fresh approach to negotiating the complex parameter space connected to neuro-fuzzy models. The proposed method makes use of the swarm intelligence of TSO to carefully balance exploration and exploitation, ultimately leading to improved model performance. This introduction highlights the need of accurate water quality forecasts, points out the drawbacks of existing methods, and lays the foundation for the innovative methodology used in this study. The key contributions of this work are as follows:

*1)* The study goes on by offering a unique method for improving neuro-fuzzy algorithms for water quality forecasting, getting beyond parameterization issues that usually limit accurate forecasts.

*2)* TSO integration functions as a novel nature-inspired optimisation tactic, enhancing the ability to explore and utilise the complex parameter space of neuro-fuzzy models.

*3)* When compared to current optimization approaches, the proposed strategy significantly improves the projected accuracy of water quality forecasts, indicating the practical use of TSO.

*4)* By confirming the improved neuro-fuzzy model on several datasets, highlighting its capacity for generalisation and robust performance under diverse environmental circumstances.

*5)* Through this study, the limits of current methodologies are overcome, opening the door to the development of improved environmental systems supporting decision-making and providing a potential path towards more precise and informed environmental management decision-making.

The remaining of the paper is as follows: Section II explains an overall of previous studies on water quality forecasting approaches, setting the stage for the suggested strategy. In Section III, the report goes into the highlighted research gaps within current techniques, establishing the groundwork for the novel integration of TSO into neuro-fuzzy models. Results and discussion is given in Section IV. Finally, Section V concludes the paper.

## II. Related Works

### A. *Enhancing Water Quality Forecasting with Ensemble Data Assimilation*

Loos et al. [12] explain that one of the most pressing concerns facing civilization in the 21st decade is the safety of river water. Precise and dependable rapid forecast of water quality is an efficient adaptation strategy for dealing with water quality challenges including accidental leaks and major algal blooms. To improve the precision and skill of the water quality forecasts three distinct ensemble data assimilation (DA) methods were investigated two associated methods that can improve the starting point for non-linear calculations or reduce the time required for computation y determining the Kalman gain employing a time-lagged ensemble. Twin testing using artificial data of three species of algae and concentrations of phosphate with extremely small ensemble sizes demonstrated that each of the DA techniques improved prediction precision and skills, with only minimal variations between them. They all increased the model's precision at downstream places, with comparable results, but due to false membership, accuracy at upstream locations decreased somewhat. The studies likewise found no clear pattern of augmentation when the group as a whole size increased from 8 to 64. The real-world research, which included real-life observations of three varieties of algae and phosphorus levels, yielded fewer improvements than the two independent tests. Model accuracy can be enhanced by alternate state parameter definitions, the utilisation of distinct disturbances and inaccuracy in modelling parameters and/or improved calibrating of the stochastic water quality model.

### B. *Improving Water Quality Forecasting with Deep Learning*

Water is necessary for the survival and sustenance of all living beings. River water quality has declined in recent years due to harmful waste and pollution. This growing contamination of water is an important cause of concern since it degrades water quality, making it unfit for any use. Water quality modeling using machine learning algorithms has grown in popularity in the past few years, and it has the potential to be extremely useful in ecological and the administration of water resources. They usually encounter a high level of computation and forecast inaccuracy. Because of its excellent performance, time-series information was processed using a deep neural network that includes a LSTM. Khullar and Singh [13] explains that the deep learning-based Bi-LSTM method is used to forecast water quality features in India's Yamuna River. The previous systems fail to perform imputation of missing values and instead focus solely on learning management, with no repercussions mechanism for training failures. The proposed model employs an innovative approach in which the initial phase involves missing value imputation, the second step generates map features from the information at hand, the third step incorporates a Bi-LSTM architecture to improve the learning process, followed by an optimized loss function to reduce training error. As a result, the proposed model enhances predictive accuracy. Several water quality indicators were collected monthly at several places around the Delhi area across. The experimental findings show that the expected results of the model's parameters and the actual outcomes were perfectly consistent, which might indicate a future trend. The model's efficacy was compared to various novel approaches, such as SVR, random forest models, artificial neural networks (ANN), LSTM, and CNN-LSTM.

### C. *Enhancing Water Quality Monitoring in Aquaculture*

Global changes in climate and water contamination have generated several challenges for fish/shrimp growers, such as early death before harvest. It is critical to understand methods to track and handle water quality to assist farmers in addressing this issue. Water quality monitoring is critical for designing IoT systems, particularly in fisheries and aquaculture. Researchers can regulate water quality by tracking real-time sensor data signals (such as salinity, pH, water temperature, and dissolved oxygen) and predicting them to acquire early warning, therefore gathering quantities as well as quality in shrimp/fish rearing. Thai-Ngheet al. [14] introduce A framework with an approach to forecasting for IoT devices used for tracking water quality in fisheries and aquaculture. Because these indicators are gathered daily, they constitute sequential/time series data. Researchers suggest using deep learning with the LSTM method to forecast these parameters. The experimental findings on many data sets demonstrate that the suggested technique works effectively and can be used in actual systems.

### D. *Revolutionizing Irrigation Water Quality Assessment*

Conventional methods for evaluating irrigation water quality are frequently costly and time-consuming for farmers, especially in underdeveloped nations. However the use of artificial intelligence algorithms can address this issue by anticipating and analysing irrigation water quality indices in aquifer systems utilizing physical factors as features. El Bilali et al. [15] aims The variables Total Dissolved Solid (TDS), Magnesium Adsorption techniques Ratio (MAR), PS, Interchangeable Sodium Percentage, Sodium Adsorption Ratio (SAR), and Remaining Sodium Carbonates (RSC) are projected using electrical conductivity (EC), temperatures (T), and pH. To do this, researchers developed and tested adaptive boost, RF, ANN, and SVR algorithms using 520 data samples associated with 14 qualitative groundwater metrics from Morocco's Berrechid aquifer. The data show that Adaboost and RF approaches outperformed SVR and ANN in terms of overall prediction accuracy. However, generalisation ability and sensitivity to input studies show that ANN and SVR approaches are more adaptable and less susceptible to input factors than Adaboost and RF. The algorithms developed throughout the world are effective for predicting irrigation water quality characteristics and may assist producers and managers in managing irrigation water strategies. The suggested approaches in this study have showed the promise in inexpensive and real-time estimates of groundwater quality using physical information as input variables.

### E. *Deep Learning-based Approaches for Water Quality Forecasting*

Various contaminants have posed a danger to water quality in recent years. As a result, modelling and forecasting water quality have grown to be critical tools for mitigating water pollution. Aldhyani et al. [16], Advanced artificial intelligence approaches are being developed to anticipate the water quality index (WQI) and classification (WQC). Artificial neural network models, notably the nonlinear autoregressive model neural network (NARNET) and the LSTM deep neural networks approach, were developed for WQI prediction. Additionally, three machine learning algorithms, support vector machine (SVM), k-nearest neighbor (K-NN), and Naive Bayes, were used for WQC forecasting. The dataset used comprises seven major components, and the resulting models were evaluated using a variety of statistical criteria. The results suggest that the suggested models may properly predict WQI and water quality because of greater resilience. Prediction results showed that the NARNET methods performed somewhat better than the LSTM in forecasting WQI values, while the SVM approach had the greatest prediction accuracy in WQC. Also, the NARNET and LSTM equations obtained identical accuracy throughout testing, with just minor changes in the regression coefficient. This intriguing research could have a huge impact on water management.

Water quality management is a crucial concern for civilizations, and precise real-time prediction is required to solve situations like unintentional spills and dangerous algal blooms. Three ensemble integrations of data approaches were examined to enhance water quality forecasts overall increase in prediction accuracy [15]. Meanwhile, a deep learning-based Bi-LSTM algorithm was presented for forecasting water quality variables in India's Yamuna River, surpassing several cutting-edge methodologies. Furthermore, the combination of IoT systems and deep learning with LSTM was investigated for tracking and predicting water quality parameters in aquaculture and fisheries, resulting in early alerts.Artificial intelligence models, like as Adaboost, RF, ANN, and SVR, were designed and tested for forecasting variables in Morocco's Berrechid aquifer. Finally, sophisticated AI algorithms such as NARNET and LSTM were used to forecast the index of water quality and categorization, with promising accuracy and resilience. These studies emphasize the possibility of data integration, machine learning, and IoT technologies in improving water quality prediction and administration on various scales and in varied geographical situations.

### F. *Problem Statement*

The current limitation in water quality forecasting approaches is the poor modelling of neuro-fuzzy models, which impairs their capacity to effectively capture the subtle trends that characterize water quality data. Traditional optimization algorithms frequently struggle to navigate the high-dimensional parameter array successfully, resulting in unsatisfactory model performance. This paper addresses this challenge by describing a novel approach that incorporates Tunicate Swarm Optimisation (TSO) into the parameter optimization method for neuro-fuzzy models, therefore improving the dependability of water quality forecasts. The TSO, which is based on the collective behaviour of tunicates, offers an effective optimization technique based on nature for exploring and using the parameter space. The limitations of conventional optimization techniques are overcome by the swarm intelligence of TSO, which allows a more robust and efficient search for the optimum model parameters. By combining TSO with neuro-fuzzy systems, it is possible to improve environmental decision-making systems and increase the accuracy and dependability of water quality prediction while also addressing the drawbacks of current methods.

## III. Integrating Tunicate Swarm Optimization with Neuro-Fuzzy Models

The approach section illustrates how to optimize neuro-fuzzy systems for water quality forecasts by using TSO in a new way. The techniques involve developing the neuro-fuzzy model, specifying an objective operation, and smoothly integrating TSO into the optimization process. The section includes how TSO's swarm intelligence is utilized to efficiently investigate the highly dimensional variable space while establishing a balance between utilizing it to enhance model performance. The emphasis is on iteratively improving model parameters, which mimic tunicates' motions in pursuit of optimal conditions in the marine environment. The methodology covers the rigorous procedure for ensuring that TSO merges with the optimal neuro-fuzzy model architecture. The comprehensive methodology is designed to assist academics and practitioners in replicating and using this unique optimization technique in water quality forecasting.

### A. *Data Collection*

The goal is to determine the spatial quality of water as an indicator of the strength of hydrogen (pH) values on the other day utilizing data from water measurement indices. The PH value for the following day is generated using the given input data’s, which consists of historical information from several water measurements indices. The input information contains everyday samples from 36 sites in Georgia, USA, which provide information about pH values. The input parameters include 11 typical indications such as the amount of dissolved oxygen, temperature, and specific conductivity [17]. The expected outcome is a measurement of 'pH, water, raw, field, standard units (median)'.

### B. *Adaptive Neuro-Fuzzy Model*

The adaptive neuro-fuzzy inference system (ANFIS) Combines neural networks and fuzzy theories. The ANFIS modifies its relationship function and management rules based on both inputs and outputs data collected from the controlling environment to correspond with the object under control. The ANFIS outperforms a BP-based multi-layer perceptron in matching an excessively nonlinear environment. The ANFIS model takes longer because the hybrid training rule demands more computation. The ANFIS's fundamental learning strategy is to change the preceding variable from the backward path by the variation of the squared error for the outcome of each node [18]. The previous parameter defines the form of the member function, while the parameter value $\{b^i,d^i\}$ and determines the squared error of E by calculating the breadth and centre of the function defining membership. To lower the amount of E, the next maximum gradient approach is applied over and over to the preceding variable which is shown in Eq. (1-3): Fig. 1 shows the structure of ANFIS.

$$b^i(t+1) = b^i(t) - \eta \frac{\partial E}{\partial b^i} \tag{1}$$

$$d^i(t+1) = d^i(t) - \eta \frac{\partial E}{\partial d^i} \quad (2)$$

$$\eta = \frac{k}{\sqrt{\sum \alpha (\frac{\partial E}{\partial \alpha})^2}} \quad (3)$$

The preceding parameter (α) and the shifting distance (k) of the gradient vectors in the field of parameters impact the rate of converging. Eq. (4) expresses the overall result of f as a linear mixture of the subsequent parameters $\{p^i, q^i, r^i\}$:

$$f = \overline{\omega^1} f^1 + \overline{\omega^2} f^2 = (\overline{\omega^1} x)p^1 + (\overline{\omega^1} y)q^1 + (\overline{\omega^1})r^1 + (\overline{\omega^2} x)p^2 + (\overline{\omega^1} y)q^2 + (\overline{\omega^2})r^2 \quad (4)$$

According to the Sugeno and Takagi category, a system for Fuzzy reasoning has a pair of inputs along with a single output.

Rule 1:$f^1$=$p^1 x + q^1 y + r^1$ as $x$ is$A^1$and $y$ is $B^1$

Rule 2:$f^2 = p^2 x + q^2 y + r^2$ as $x$ is $A^2$ and $y$ is $B^2$

The first layer: In this particular layer, using a node functions, every node $i$ is a squared node which is given in Eq. (5).

$$O_1^i = \mu A^i(x) \quad (5)$$

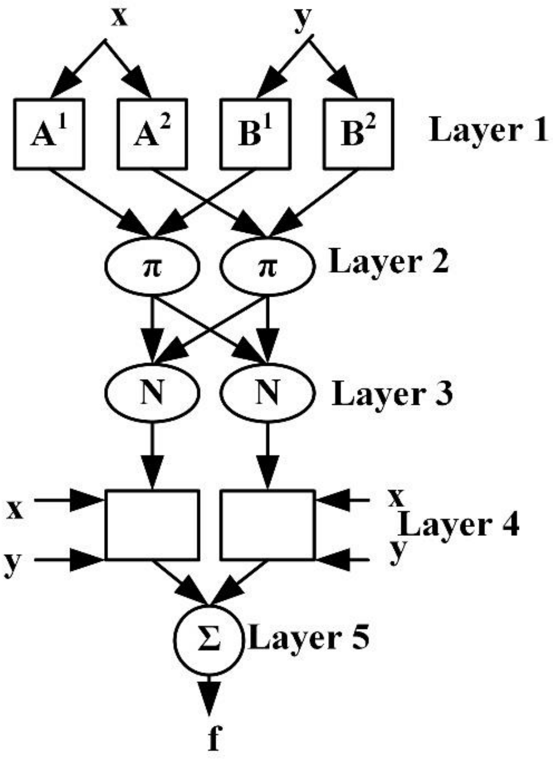

Fig. 1. ANFIS structure.

$x$ is the source to node $i$, whereas $A^i$ is the syntactical branding associated with the nodal functions. With this findings, $O_1^i$ becomes a relationship mapping to $A^i$. The functions for relationship is denoted by $\mu A^i(x)$, where the greatest value is 1 and the smallest is 0, and in the generic bell mappings or Gaussians mapping process, as detailed below Eq. (6) and (7).

$$\mu A^i(x) = \frac{1}{1+[(\frac{x-c^i}{a^i})^2]^{b^i}} \quad (6)$$

$$\mu A^i(x) = e^{[-(\frac{x-c^i}{a^i})^2]} \quad (7)$$

The data set is denoted as $\{a^i, b^i, c^i\}$. If a result, if the parameters vary, it will impact the bell-like mapping. Thus, in differentiated mapping, a frequency will be in a triangle or trapezoid form, which is an important component of the node's position in this layer [19].

The second layer: Each in this layer is a circular node, which products signals that arrive and outputs the products. For example, Eq. (8):

$$O_2^i = W^i = \mu c^i(x) \times \mu e^i(x), \quad i = 1,2,3 \ldots \quad (8)$$

The result of every node indicates the fires power of a rule.

Third layer: In this layer's structure in Eq. (9), every nodes is a circular nodes marked N. The $i$th node computes the proportion of the $i$th rule's fired intensity to the total of all rules' fired intensities.

$$O_3^i = W^i = \frac{W^i}{W^1 + W^2}, \quad i = 1,2,3 \ldots \quad (9)$$

For simplicity, the results of this particular layer would be referred to as normalized fired intensity.

Fourth layer: Each node $i$in the tier is a squared node containing a nodal function of Eq. (10).

$$O_4^i = \overline{w}^i f^i = \overline{w}^i = \overline{w}^i(p^i x + q^i y + r^i) \quad (10)$$

The outcome of layer 3 is $\overline{w}^i$, and the parameter value collection is ($p^i$,$q^i$,$n^i$). Variables in this level will be referenced as subsequent variables.

Fifth layer: This layer's solitary nodes are a marked circular node that calculates the total outcome as the total of all the signals that arrive in Eq. (11), i.e.

$$O_5^i = \sum \overline{w}^i f^i = \sum_i w^i f^i / \sum_i w^i \quad (11)$$

This results in an adaptive networks that is virtually comparable to a type of three fuzzy inference systems.

### C. Tunicate Swarm Optimization

Tunicates are cylindrical-shaped organisms that have just one of their two ends open and travel at jet-like speeds over the water's surface. They may seek nutrition in the sea, regardless of whether they are unsure where to begin. The tunicates' jet-like speed and clever swarming form the foundation for the TSA optimization approach. When responding to the TSA's optimization quandary, the food supplier is the best solution. Certain requirements must be accomplished to correctly recreate TSA jet propulsion motions. Before continuing, two prerequisites must be fulfilled: In the initial stages, the tunicates must avoid fighting. Second, they must continue looking for their greatest search agent. Finally, they need to keep close to the agent [20]. The swarm knowledge of the additional tunicates in a statistical framework is employed for updating their locations relative to the ideal solution. The theoretical system is defined as follows:

*1) Conditions:* There should be no disagreements between the search agents. To prevent conflicts amongst search agents, use the next vectors to determine their relative locations of Eq. (12) to Eq. (14).

$$\vec{a} = \frac{\vec{g}}{\vec{m}} \tag{12}$$

$$\vec{g} = c_2 + c_3 - \vec{f} \tag{13}$$

$$\vec{f} = 2 * c_1 \tag{14}$$

The gravitational force is symbolized by $\vec{g}$, whereas $\vec{f}$ represents the fluctuation in temperatures of the deeper seawater stream. To determine social forces among tunicates (represented by vector $\vec{m}$), apply the subsequent formula: $c_3$, $c_2$, and $c_1$ are random numbers with values ranging from zero to one.

$P^{min}$ and $P^{max}$represents the initial and secondary speeds of social contact. During this optimization phase, it is important to ensure that the tunicate moves in a certain direction.

$$\overrightarrow{PD} = \left|\overrightarrow{FS} - r^{and} * \overrightarrow{P^p(x)}\right| \tag{15}$$

Eq. (15) gives the present iteration's cycle is marked by $x$, the separation between the supply of food and search agents is indicated by $\overrightarrow{PD}$, the exact spot of search agents is denoted by $\overrightarrow{P^p(x)}$, the exact location of food source is represented by $\overrightarrow{FS}$, and the value of the random variables$r^{and}$ is determined in an amount of 0 to 1.

Moving towards the greatest search agent. To do this, the search agents are reorganized as follows in Eq. (16):

$$\overrightarrow{P^p(x')} = \begin{cases} \overrightarrow{FS} + \vec{a} * \overrightarrow{PD}, & if\ r^{and} \geq 0.5 \\ \overrightarrow{FS} - \vec{a} * \overrightarrow{PD}, & if\ r^{and} \leq 0.5 \end{cases} \tag{16}$$

$\overrightarrow{P^p(x')}$ reflects the search agent's present position relative to the available food supply. The first two best answers are saved and utilized to adjust the positioning of the additional tunicates to simulate swarm activity. This Eq. (17) is a mathematical illustration of a swarm.

$$\overrightarrow{P^p(x+1)} = \frac{\overrightarrow{P^p(x)} + \overrightarrow{P^p(x+1)}}{2+c^1} \tag{17}$$

The key stages for demonstrating the flow of the initial TSO are shown here for clarity. Fig. 2 shows the flowchart for the TSO algorithm [20].

Set the starting population of tunicates, or $\vec{P}^p$ to the usual number.

Define the variable's starting values and the large amount of repetitions.

Each exploration agent's success score must be determined.

Lastly, the best-fitting agents are examined in the searching space supplied after assessing their fitness.

Investigate agents need to be improved. It's time to return the freshly strengthened agents to his or her location of origination.

Determine the suitability cost for a more sophisticated search agents.

When the initial response is no longer optimal, the best response $X^{best}$ is saved and $\vec{P}^p$ is improved.

The implementation of TSO into the neuro-fuzzy model's optimisation process entails expressing alternative solutions as people in a swarm, with each matching to a distinct set of neuro-fuzzy model variables. TSO uses swarm ability, inspired by tunicate activity, to dynamically balance both discovery and extraction in the highly dimensional variable space. Members in the swarm adjust their locations through an iterative optimization process based on assessments of fitness utilizing the objective function, which commonly uses measures such as Mean Squared Error. The ultimate aim is to minimize the objective function, resulting in reliable water quality forecasts. The algorithm is guided by terminating conditions, such as attaining a desired fitness level, and the ideal parameters defined by the TSO are retrieved at the end. This integration intends to rise the reliability of water quality predicts by quickly traversing the vast range of parameters of neuro-fuzzy models.

## IV. Results and Discussions

The suggested neuro-fuzzy model optimized using TSO was evaluated primarily using MSE and perhaps additional regression-based measures. MSE measures the average squared variance among predicted and actual water quality measurements, indicating the model's accuracy. The outcomes of thorough trials demonstrate that the suggested methodology outperforms standard optimization methodologies. The optimized neuro-fuzzy model constantly has reduced MSE values, suggesting higher prediction accuracy. The model performs well over a wide range of datasets, demonstrating its generalizability. The comparison analysis shows a considerable improvement in water quality predictions over previous approaches, highlighting TSO's practical usefulness in traversing the highly dimensional variable space. These outcomes emphasize the possibility of Tunicate Swarm Optimisation as a reliable optimization approach for neuro-fuzzy algorithms for environmental forecasting, giving a viable route for enhanced decision-support tools in water quality management.

### A. Analysis

By incorporating Tunicate Swarm Optimization into neuro-fuzzy systems for water quality prediction, the suggested study presents a unique method. This novel method effectively navigates the intricate parameter space of neuro-fuzzy models, addressing the shortcomings of current approaches. Utilizing a thorough assessment of measures such as Mean Squared Error (MSE) and comparative studies, the research exhibits better performance than traditional optimization techniques. Through the use of swarm intelligence derived from tunicate behaviour, TSO improves model generalizability and accuracy on a variety of datasets. The investigation demonstrates TSO's potential as a trustworthy optimization approach for environmental forecasting, creating opportunities for enhanced instruments for water quality management decision-making. Future studies may include hybrid optimization strategies, scalability, and wider uses of TSO in environmental modelling.

### B. Performance Measurement

The suggested model's capability to forecast the WQI was evaluated using performance measuring methodologies such as MSE [21]. The statistical approaches utilized are described as follows:

Mean square error (MSE): The mathematical expression for MSE is shown in Eq. (18).

$$MSE = \frac{1}{N}\sum_{i=1}^{N}(y^i - \hat{y}^i)^2 \qquad (18)$$

Mean Absolute Error (MAE): The mathematical expression for MAE is shown in Eq. (19).

$$MAE = \frac{1}{N}\sum_{i=1}^{N}\left|y^i - \hat{y}^i\right| \qquad (19)$$

Root mean square error (RMSE): The equation for RMSE is given in Eq. (20) and Eq. (21).

$$RMSE = \sqrt{\sum_{i=1}^{N}\frac{(Y^i - \widehat{y^i})^2}{N}} \qquad (20)$$

$$R = \frac{n\sum(x\times y) - (\sum x)(\sum y)}{[n\sum(x^2) - \sum(x^2)]\times[n\sum(y^2) - \sum(y^2)]} \times 100\% \qquad (21)$$

where, $R$ is Pearson's correlation coefficient of Eq. (20), $x$ is the observational input information from the first batch of training information, $y$ is the observational input information from the following set of training data, and $n$ is the overall amount of input parameters.

### C. WQForecasting using the ANFIS Model

The suggested model technique was validated by training 70% of the available data with the ANFIS model and predicting the WQ. The training outcomes revealed that the ANFIS approach was particularly effective at predicting WQ. Table I summarises the forecasting outcomes of the WQ achieved by the ANFIS framework throughout training and testing periods.

Fig. 3 displays the mistakes in forecasting water quality with ANFIS over the training and testing stages. Errors are assessed using RMSE and MSE. The RMSE numbers are much greater than the MSE values in both stages, indicating a wider range of residual errors. The graphic shows a bar graph depicting inaccuracies in ANFIS-based water quality prediction. There are two bars, one labelled "Training" and the other "Testing". Every set possesses two metrics: RMSE and MSE. For both Training and Testing, RMSE exhibits a larger error rate. The y-axis is labelled "Errors" and ranges from 0 to 0.07. The x-axis is separated into two main groups: Training and Testing Metrics.

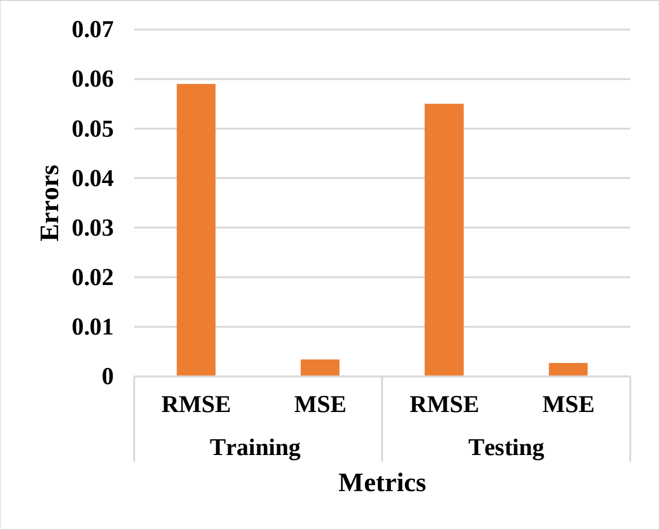

Fig. 3. Predicting water quality with ANFIS.

Fig. 4 shows two bars, one labelled "Testing" and the other "Training". The Y-axis is labelled "R (%)", suggesting that it reflects the Pearson coefficient as a percentage. The X-axis spans from 89.5% to 93%, representing the Pearson coefficients achieved. The "Testing" bar is substantially longer than the "Training" bar, going beyond 92%. The "Training" bar is slightly over 90%.

TABLE I. ABILITY OF ANFIS TO FORECAST WATER QUALITY

| Model | Training | | | | Testing | | | |
|---|---|---|---|---|---|---|---|---|
| | *RMSE* | *MSE* | *Mean Errors* | *R (%)* | *RMSE* | *MSE* | *Mean Errors* | *R (%)* |
| ANFIS | 0.0590 | 0.00338 | 0.006458 | 90.52 | 0.0550 | 0.0027 | 0.001350 | 92.37 |

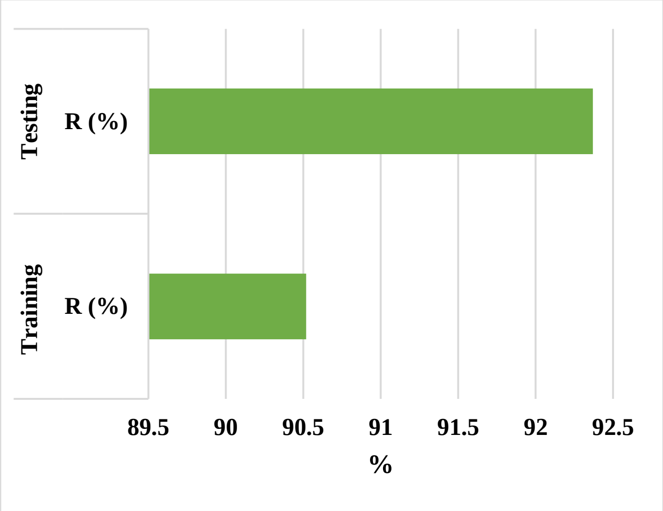

Fig. 4. Pearson correlation coefficient for training and testing.

Table II compares the efficacy of three models, including LSSVM, ANFIS-PSO, and ANFIS, in terms of MAE (mg/l). The smaller the MAE number, the more effectively the model performs. As shown in the table, the model based on ANFIS has the smallest MAE of 12 mg/l, next to ANFIS-PSO at 13 mg/l. The LSSVM model has the greatest MAE value (13.2 mg/l).

Fig. 5 shows the MSE Loss Functions of the training and validation datasets for predicting water quality. The x-axis most likely reflects the total number of times or iterations, whilst the y-axis shows the MSE value. Both training and testing mistakes fall quickly at first but subsequently, level, showing that the system is learning successfully but eventually reaches a point when further development is negligible.

The graph in Fig. 6 shows the MAE in mg/g for three distinct models: LSSVM, ANFIS-PSO, and ANFIS. The y-axis is marked "MAE (mg/g)" and varies between 11.4 and 13.4. The x-axis is marked "Models," and each model's name appears under its bar. There are three bars for each framework: LSSVM, ANFIS-PSO, and ANFIS. The LSSVM model has the greatest MAE at around 13.2 mg/g, then ANFIS-PSO with an MAE of approximately 12.8 mg/g, and ANFIS has the smallest MAE at around 12 mg/g.

TABLE II. COMPARISON OF MODEL PERFORMANCE

| Models | MAE (mg/l) |
|---|---|
| LSSVM | 13.2 |
| ANFIS-PSO | 13 |
| ANFIS | 12 |

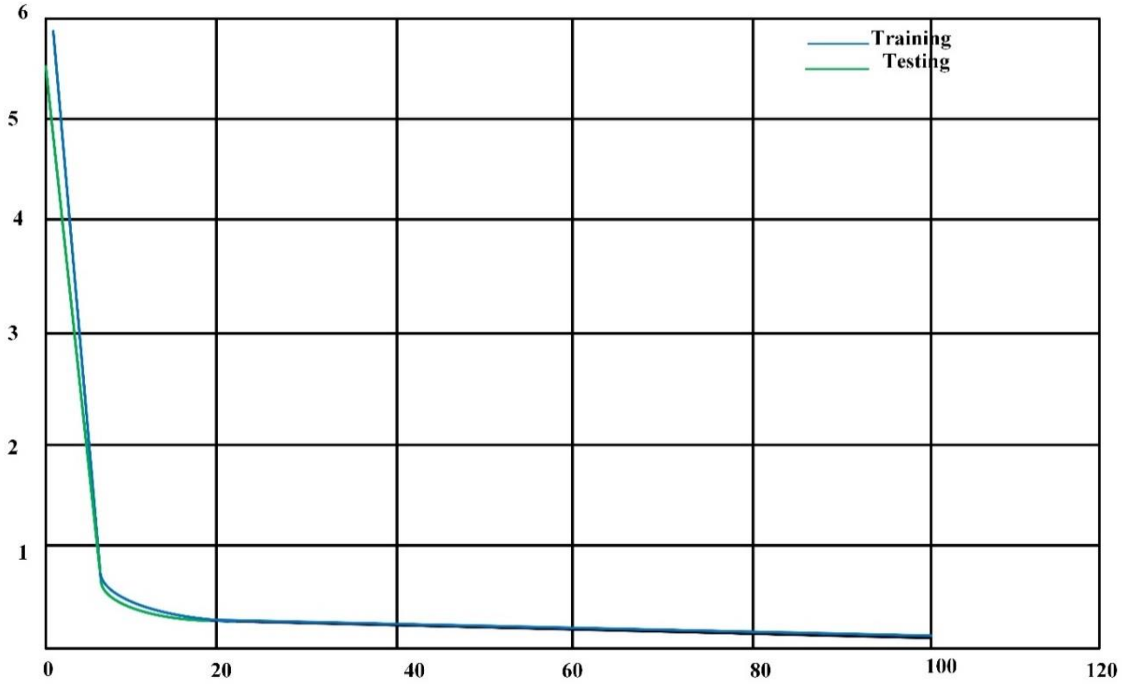

Fig. 5. MSE loss function comparison of training and testing dataset.

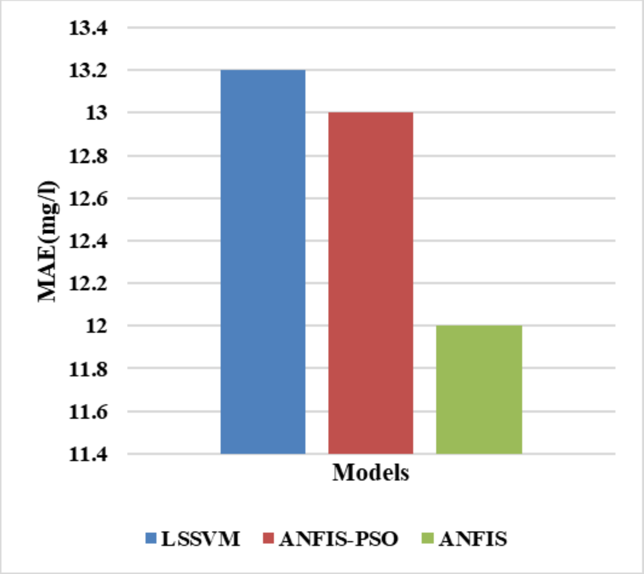

Fig. 6. Comparison of model performance.

### D. Discussion

The transforming effect of including TSO into the optimization procedure for neuro-fuzzy systems for water quality prediction. The findings highlight the need for precise water quality forecasts in environmental administration and decision-making, as well as the limits of present approaches caused by poor parameterization. The current shortcoming in water quality projection methods originates from the poorly constructed neuro-fuzzy models, which hinders their ability to accurately represent the nuanced patterns seen in water quality data [22]. The unique technique proposed in this study solves these issues by smoothly adding TSO, a nature-inspired optimization method, into the parameter optimization process. The swarm knowledge of tunicates is used to explore the complex and highly dimensional parameter set of neuro-fuzzy models, achieving an equilibrium between investigation and exploitation. The incorporation considerably improves the prediction performance of the neuro-fuzzy approach, as proven by convincing findings gained from extensive tests across varied datasets.

Furthermore, the discussion expands on the wider consequences of the suggested technique, indicating a possible route for enhanced environmental decision-making systems. The optimized neuro-fuzzy model's strong performance demonstrates TSO's ability to outperform existing optimization techniques in terms of water quality forecasts. The work not only advances forecasting methodology but also highlights the possibility of nature-inspired optimization strategies in solving complex environmental concerns. The application of TSO for parameter optimization might provide computational difficulties because of the algorithm's intricacy and resource needs. Subsequent investigations ought to concentrate on broadening the scope of TSO's application in various environmental forecasting domains, improving its amalgamation with neuro-fuzzy designs, scrutinising discrepancies in swarm behaviour, appraising its scalability for extensive water quality forecasting, and investigating hybrid optimisation tactics to augment the forecasting resilience.

## V. Conclusion

A novel strategy for optimizing neuro-fuzzy scenarios in the area of water quality predictions based on the creative integration of TSO. The study begins by highlighting the importance of precise water quality forecasts in environmental management, as well as the limitations of current techniques, notably in the realm of inadequate modelling. The suggested technique, which incorporates TSO, appears as a persuasive solution to these restrictions. By emulating tunicates' shared intelligence, TSO effectively navigates the complicated and high-dimensional parameter range that comes with neuro-fuzzy systems. This effortless integration is demonstrated in the detailed methodology section, which describes the configuration of neuro-fuzzy designs, the development of a function with objectives, and the continuous parameter optimization process utilizing TSO. Extensive trials have validated the usefulness of the suggested strategy, exhibiting improved water quality forecasts compared to existing optimization methods. The optimized neuro-fuzzy model regularly exceeds previous approaches across a variety of datasets, demonstrating its resilience and generalizability. Beyond its immediate use, the study advances the field by offering a nature-inspired optimization approach that shows promise for solving issues in environmental systems that support decisions. This work represents a substantial development in water quality forecasting approaches, marking a vital step towards more reliable and precise environmental forecasts, and giving new pathways for the incorporation of nature-inspired algorithms into environmental science and administration.

To expand the application of TSO, future studies should examine how it may be modified to fit a variety of environmental forecasting scenarios. Further research should concentrate on enhancing the TSO using neuro-fuzzy designs combination, examining variations in swarm behaviour, and evaluating the approach's suitability for massive amounts water quality forecasting systems. Moreover, research endeavours can concentrate on hybrid optimization tactics that merge TSO with other nature-inspired algorithms to leverage synergies and enhance the robustness of environmental prediction techniques. Future work may focus on extending TSO to other optimization tasks in environmental modelling. Additionally, investigating hybrid optimization approaches and integrating real-time data streams could enhance the applicability and robustness of the proposed methodology.

***Abstract*—Machine learning (ML) is a versatile technology that has the potential to revolutionize various industries. ML can predict future trends in customer expectations that allow organizations to develop new products accordingly. ML is a crucial field of data science that uses different algorithms to predict insights and improve decision-making. The widespread acceptance of ML algorithms ML can provide helpful information using the enormous volume of health data generated regularly. Quicker diagnoses by doctors can be delivered by adopting ML techniques that can bring down medical charges and applying pattern identification algorithms to examine medical images. Every technology brings its challenges; in the same way, ML also has several challenges in healthcare that need to be acknowledged before we witness complete automation in medical diagnosis. People are still forbidden to share their personal information with intermediaries for treatment. Medical record governance is essential to ensure that health records are not missed. Manual diagnosis often goes in the wrong direction, as doctors are also human. Lack of communication between medical workers and patients, considering the insufficient data to diagnose disease, sometimes results in deteriorating health conditions. This paper deals with an introduction to machine learning. These ML algorithms are widely used for health diagnosis, a comparison analysis of literature work that has been done so far, existing challenges of the healthcare system, healthcare industry using machine learning applications, real-life use cases, practical implementation of disease prediction, and conclusion with its future scope.**

## I. Introduction

Machine learning is a disruptive technology that allows computers to gain knowledge automatically based on the historical data provided. In the last couple of years, this technology has delivered innovative services that have profoundly impacted the human lifestyle. Human beings have the unique ability to learn new things by themselves, depending on their surroundings by healthcare enterprises has fast-tracked medical diagnosis. Training of machine learning algorithms can be done in various ways. ML is the subcategory of artificial intelligence (AI), which mainly deals with developing innovative machinery that holds the capacity to perform work [1] that requires human intelligence. Arthur Samuel is known as the father of AI. ML algorithms are built for computers to get an insight into the outcome based on previous experience. A specific quantity of past data, termed a training data set, is considered. Decisions are being made without the need to be explicitly programmed by developing a mathematical model.

The higher the amount of training data, the greater the performance of the predictive model will be [2]. The historical dataset is given as an input, based on which the ML model builds, and computers predict the result when new data is imparted. Handling complex jobs where human lives can be at stake can be successfully solved by using robots that are programmed using ML algorithms [3]. The precision of the result totally depends on the quantity of the dataset. Transparent ML techniques that develop the proper drug as human safety should always be prioritized [14]. High accuracy can only be achieved by giving machines large amounts of data [18]. Presently, we can recognize various applications of ML such as friend suggestion used by Meta, prediction of traffic by Google Maps, Speech recognition by Google on smart devices, item recommendation on e-commerce websites such as Amazon and Myntra, and email spam identification used in Gmail.

The rest of the paper deals with following sections: Overview of different categories of ML algorithms and its significance in performing decision makingis given in Section I, Section II discusses about the importance of ML in health diagnosis by detecting the disease in early stage and providing customized treatment plan and briefly defined the support of NLP in assisting pharmaceutical industry. Section III presents the literature review of the work carried forwarded by the researchers in this area. Existing challenges of healthcare sector is pointed out in Section IV and Section V involves the applications of ML in addressing the existing challenges. Section VI presents the popular case studies of this sector. Practical implementation of random forest model on diabetic dataset is performed in Section VII. Barriers that are obscuring the complete adoption of ML implementation are mentioned in Section VIII. Lastly, in Section IX, we have concluded our work by stating the promising outcome that will be achieved by intersecting ML with healthcare diagnosis and the limitations that are hindering within the pharma industry.

### A. Supervised Learning

The machine learning model is trained with the help of labeled data. The process of gathering raw data such as text, audio, video, or images and the addition of a few appropriate labels in a way that an ML solution can easily identify what data is all about is termed ad data labeling. A training dataset is imported into supervised learning [15]. The training dataset is a large dataset that is used to train ML solutions for predicting the result. The accuracy of any machine learning solution highly depends on the quality and quantity of the training dataset being fed. The dataset contains the input parameters as well as the right outcome [5]. Due to this reason, supervised machine learning is considered to be a learning that is gained under the supervision of an instructor. For example, if an individual wants to know how much duration it will take them to reach their destination, then the labeled data would be whether it is a weekday or weekend, at what time they will depart from the source, and the live weather conditions [16]. If it is a rainy day, then the individual will take longer to reach their destination [6]. The training dataset of the given situation will contain these parameters to predict how much time an individual will take to reach their destination.

### B. Unsupervised Learning

In this type of learning, models are not instructed with the help of a training dataset. Machine learning solution themselves looks for the hidden pattern. In other words, the ML model is trained based on an unlabeled dataset [8]. The input parameter is present, but the output is absent inside the dataset. This technique is beneficial for researchers and scientists who are not aware of what they are searching for inside the dataset. Unlabeled data is easily accessible as compared to labeled data. Unknown or hidden insights can be found that are not possible with supervised learning techniques [17]. Labeling of data might cause a manual error, but, in this case, the chances get lowered [7]. Let's assume that an unsupervised learning technique is provided with input that consists of various images of lions and tigers. On this dataset, the algorithm is never trained. The algorithm is not aware of the dataset characteristics. The algorithm will detect similar images and group them all together.

## II. MACHINE LEARNING IN HEALTH DIAGNOSIS

Detection of tumors with accuracy and on time is very much vital to saving human lives in the field of oncology. ML algorithms can identify whether the tumor is benign or malignant in a few seconds. Benign only grows in a specific part of a person's body, and it doesn't turn into cancer. Malignant tumor leads to cancer when the cells grow in multiple numbers and infect the rest of the body parts. World Health Organization (WHO), in their report of the year 2017 for mental illness, mentioned that India has experienced an extreme number of psychological cases as compared to their report in year 1990 [1]. Fig. 1 represents the digital deals that were signed while focusing on enhancing the healthcare sector. Psychological illness has increased since COVID-19 as people have faced personal and economic loss [9]. With biomarkers that help clinicians to identify the disease, ML can identify and analyze who is prone to a specific illness.

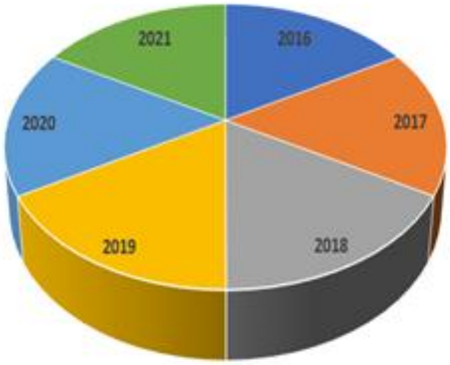

Fig. 1. Digital healthcare deals took place from year 2016 – 2021.

Support Vector Machine (SVM) is categorized under supervised learning to address various diseases. Multiple medical diseases, such as blood pressure and diabetes, can be cured with appropriate computational power and healthcare analytics. Cancer can be diagnosed using SVM [11]. The labeled dataset goes through training and testing datasets, respectively. SVM solution is developed for high accuracy. Based on the mammogram data, detection of breast cancer is done. Factors that are vital to detecting diabetics are blood glucose, age, and body mass index [19]. The SVM model takes these parameters for diagnosing diabetics. Three classes for the output are taken into consideration: diabetic patients, people with a genetic history of diabetes, and non-diabetic people [12]. Regression and classification are used for identifying blood pressure. SVM has flexible implementation and much better performance as compared to the rest of the algorithms. This algorithm is not appropriate when dealing with large amounts of datasets.

### A. Motivation

ML has brought down the healthcare cost by replacing manual duties with dedicated technology. Early predication of disease also reduces the chances of complications and preventive initiatives can be taken on time. Worldwide security protocols need to be established to safeguard how ML utilizes data. The quality of health services can be accessed by using image recognition techniques to examine patterns in X-ray reports. New medicine discoveries can be made quickly due to large data gathered from pharmaceutical trials to enhance patients' safety [12]; health tracking can be done actively, which provides pre-emptive recommendations through which future diseases can be avoided. There are various organizations that implement digital healthcare solutions, such as pharmaceuticals, the technological sector, and the government. ML in medical diagnosis is going forward for brining proactive healthcare smart solutions.

### B. Research Questions

In this paper, we will look to answer the below questions pertaining to our research.

RQ1.What are the capabilities that can benefit healthcare institutions in terms of accurately providing treatment services [13]? Machine learning facilitates the responsibilities of medical experts by effectively analysing the health condition and predicting the progression of disease.

RQ2. Is there any real use case of machine learning solutions for delivering quality healthcare? What is the outcome of ML-based health solutions? There are various reputed organizations such as Pizer, Google, IBM, and Tebra that are continuously working on providing health services in different areas and have done extremely well to fulfill the health requirements of end users.

RQ3. Is there any hindrance that is blocking the path of machine learning from getting complete acceptance by stakeholders such as pharma professionals, patients, and third-party organizations? The high performance of machine learning solutions profoundly depends on the quality of the dataset being used. Acknowledging the challenges enables individuals to collect resources that can handle them.

## III. Literature Review

Hock Guan Goh et al. [1] presented a machine-learning approach for identifying the growth of diabetes accurately and also predicted complications such as neurological disbalances, heart ailment, and kidney issues that might arise in the future. Various ML techniques, including genetic algorithms, Bayesian networks, and artificial neural networks, are being implemented to treat diabetes. Due to an insufficient volume of historical data for testing and training purposes, there is limited accuracy. The result obtained by applying a large amount of dataset gives a higher performance as compared to those algorithms where only a small quantity of dataset is being applied. Poor output is responsible for high operational charges and also lowers the ML adoption rate. Data fusion is used in the proposed architecture that combines datasets from different sources.

Hamid R. Arabnia et al. [2], in their review paper, discussed the applications of ML for IoT in healthcare. ML can monitor the patient and analyse the health situation depending on the present and previous dataset. The existing health pattern and future complexities of a new disease can be predicted by using a training dataset. The sleeping habit differs from person to person, from a child to a senior citizen. The storage condition of each medication varies in terms of temperature. Annually, there is a huge waste of medicines due to refrigerator failure. IoT sensor technology can be used to track the drug condition and monitory loss can also be eradicated. IoT gathers data from smart devices and makes decisions by using ML algorithms.

Ahmad Shaker Abdalrada et al. [3] worked on cardiac autonomic neuropathy that arises in diabetic patients. Designed an ML-based model to predict the occurrence of this disease in the early stage. Used a dataset containing 200 cardiac autonomic neuropathy test type 2 diabetic patients that are more than 2000. Patients with this disease have increased in past years. Patient records such as gender, age, and health history are stored in the dataset. Parameters such as blood pressure, blood glucose, cholesterol, and body mass index values are also stored. The proposed model has obtained 87% accuracy for the early prediction of this disease.

Ibrahim Mahmood Ibrahim et al. [4] have talked about the key importance of ML in diagnosing disease, and the cooperating sector is working on these techniques for drug discovery. A brief introduction to identifying and predicting diseases with ML is mentioned. Classification algorithms are most commonly applied in the clinical domain that develops training data, and after that, the output is executed on testing data to get precision. The performance of the Support Vector Machine (SVM) degrades when the data load gets increased. Naïve Bayes is suitable for large datasets. K- Nearest Neighbour has complex computation. Decision is used for both classification and regression problems. Random forest consumes lists of time for training. Deep learning can be implemented on different categories of datasets.

Carlo Menon et al. [5] have worked on various ML algorithms by taking multiple bio-signals under consideration. Existing strengths and challenges are discussed that will give insight into future growth in detecting anxiety disorder. The study is done on 102 entities. Reinforcement Learning and SVM are commonly enforced to achieve good output, but the output solely depends on feature selection. Neural Network has given very good output where this method doesn't need any feature selection.

Junhua Yan et al. [6] 2022 worked on a review paper for diagnosing eye diseases such as Glaucoma, and diabetic hypertension that lead to permanent vision loss if not detected in the beginning. ML techniques are being discussed to treat retinal issues that were not implemented in the past. Applications of deep learning models to assist the research in this field are mentioned in depth. A comparative analysis of the background work is given, showing the current and potential scope of ML in eye treatment.

## IV. Challenges of Existing Healthcare System

Technology has emerged as a ray of hope to overcome the constraints of the healthcare system. There are qualified healthcare professionals, tech-equipped health devices, and hospitals on one end, and at the same time, the increasing cost of medical facilities exists on the other end [15]. Initially, it is important to accept and acknowledge the challenges of healthcare associated with different parameters. Below, we have discussed the existing healthcare challenges.

### A. *Cyber Vulnerability*

There is inter-connected portable medical equipment that stores patient's medical records. The corporate sector is moving towards digitalization [11]. All India Institute of Medical Sciences, New Delhi, India, faced a ransomware attack at the end of the year 2022 [16]. The attack lasted for 15 days. Records of around 4 crore patients were put at stake, and terabytes of records were encrypted. Cloudsek has disclosed that cyber vulnerabilities in the health industry have witnessed an increase of 95% worldwide in just the beginning four months of the year 2022.

### B. *Rise Up in Healthcare Costing*

Multiple stakeholders, beginning from the manufacturing of equipment and drugs to insurance providers regulate the price of healthcare [17]. Rising costs demoralize people in different aspects, such as undergoing laboratory tests and regular visits to health practitioners, which affects patient health. Spending a major part of their earning in paying out the medical expenses puts a great burden on people economically [18]. As we know taking prevention is always better than taking cure after a medical situation. The 2019 pandemic has also inflated medical prices globally.

### *C. Absence of Proper Logistics*

Software integrated with AI delivers a huge volume of patient data to pharmaceutical industries. Different data such as patient surveys, transcripts, smart device data, and patient's personal medical data are kept with the health sector. Lack of highly advanced infrastructure leads to mismanagement of data collected from multiple sources [19] [20]. Training of medical staff on the ongoing technology should take place at regular intervals as technology continues to upgrade every time.

## V. Emerging Applications of Machine Learning in Healthcare

Healthcare practitioners can deliver effective medical treatment that is customized to particular end users by crushing the vast amount of pharmaceutical data [18]. AI and ML are anticipated to play a vital role in curing chronic diseases. ML based healthcare use cases of year 2020 are presented visually in Fig. 2. ML can help health professionals anticipate the response of patients regarding different medications, which will benefit the organizations in knowing which patients will not face any side effects of the drug. We have below discussed the emerging health applications of ML.

### *A. Smart Record Management*

Powerful medical diagnosis is performed by utilizing huge data to deliver customized end user experience. Enhancing the end-user experience increases the brand value as the company is able to undertake better decision-making [14]. Data entry of patients on online platforms is still arduous and consumes lots of time. Unrevealed hidden parameters are brought into the limelight, which reduces the existing healthcare gap [10]. Electronic Health Record totally depends on the medical records that are inputted inside it. ML can eliminate the challenges of data duplication, billing mistakes, and data loss.

### *B. Clinical Research*

Healthcare companies invest large amounts in finding appropriate individuals who can successfully test new drugs. Maximum percentage of clinical trials results in failure. In the medical field, organizations don’t have the option to take risks regarding the outcome of drug trials [7]. If there is a single error in drug development, then it can lead to loss of innocent lives. Appropriate ML algorithms can look for reliable medical testers that can be retained for a longer duration. ML-based clinical trials will enhance the current scenario by examining past trials.

### *C. Recognizing and Diagnosing Ailments*

Earlier, recognizing and curing cancers in the initial stage was very tough. Based on the data entered and the patient’s symptoms, ML Can provide diagnostic recommendations. Suitable medications can also be suggested by ML based on the prescription. Side effects of the medications taken can also be predicted [8]. Eko is a healthcare organization in California that is working on AI and ML to fight against lung and heart ailments. SENSORA is an Eko platform for detecting cardiac diseases by bringing machine learning and omnipresent medical equipment together.

## VI. Case Studies

Machine learning has provided a remarkable output in terms of processing medical records, disease detection, developing treatment roadmaps, and preventing further complications. Less time consumption, low cost, and efficient management of health data have overall helped doctors to make informed decisions for providing personalized patient care [10]. Below, we have mentioned real-life case studies of renewed organizations that are working on machine learning solutions in the health industry.

### *A. InnerEye by Microsoft*

InnerEye implements ML and computer vision to identify anatomy and tumors separately by harnessing radiological pictures that guide health practitioners in surgical and radiation therapy [17]. The aim of Microsoft is to deliver drugs that are customized according to the requirements of each individual.

### *B. Datavant Switchboard by Ciox Health*

Ciox Health was established in 1976 to work on ML for its product Datavant Switchboard, which allows biopharma groups to quickly retrieve patient information [12]. Strict privacy consent guidelines are adhered to by this organization with regard to patient’s health records. The pharmaceutical sector benefits from this platform as industries can develop a customizable control that enables their workers to put forward requests for particular data.

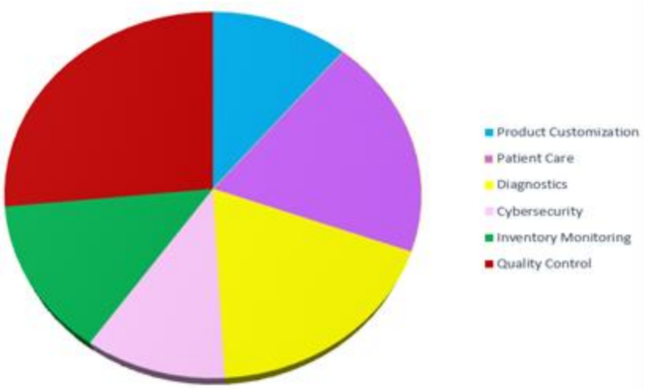

Fig. 2. ML use cases in healthcare in the year 2020.

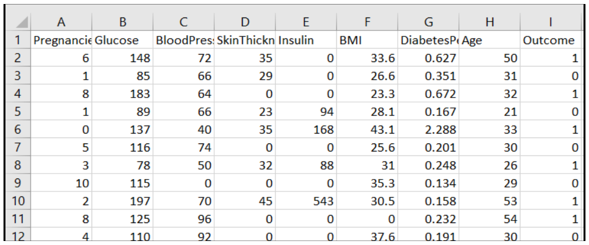
### *C. IBM’s Watson AI by Pfizer*

Natural Language Processing and ML, along with IBM’s product Watson AI, are used by Pfizer towards oncological research on how the individual’s body can fight back against cancer [13]. Analysis of tons of patients' health information is undertaken by Pfizer to build quick awareness for developing efficient treatment in the field of oncology.

## VII. Practical Implementation

Following are the steps we have implemented to build our random forest classifier with Python.

We have imported the dataset of diabetes prediction from Kaggle. Fig. 3 represents the dataset stored in CSV format, and Fig. 4 shows the successful import of the dataset. There are nine parameters taken into consideration for the dataset, which include pregnancies, glucose, blood pressure, skin thickness, insulin level, body mass index, diabetic pedigree function, age, and outcome. NumPy, pandas, matplotlib, seaborn, sklearn and a few more libraries are used, which is represented in Fig. 5.



|  | A | B | C | D | E | F | G | H | I |
|---|---|---|---|---|---|---|---|---|---|
| 1 | Pregnancie | Glucose | BloodPres | SkinThickn | Insulin | BMI | DiabetesPe | Age | Outcome |
| 2 | 6 | 148 | 72 | 35 | 0 | 33.6 | 0.627 | 50 | 1 |
| 3 | 1 | 85 | 66 | 29 | 0 | 26.6 | 0.351 | 31 | 0 |
| 4 | 8 | 183 | 64 | 0 | 0 | 23.3 | 0.672 | 32 | 1 |
| 5 | 1 | 89 | 66 | 23 | 94 | 28.1 | 0.167 | 21 | 0 |
| 6 | 0 | 137 | 40 | 35 | 168 | 43.1 | 2.288 | 33 | 1 |
| 7 | 5 | 116 | 74 | 0 | 0 | 25.6 | 0.201 | 30 | 0 |
| 8 | 3 | 78 | 50 | 32 | 88 | 31 | 0.248 | 26 | 1 |
| 9 | 10 | 115 | 0 | 0 | 0 | 35.3 | 0.134 | 29 | 0 |
| 10 | 2 | 197 | 70 | 45 | 543 | 30.5 | 0.158 | 53 | 1 |
| 11 | 8 | 125 | 96 | 0 | 0 | 0 | 0.232 | 54 | 1 |
| 12 | 4 | 110 | 92 | 0 | 0 | 37.6 | 0.191 | 30 | 0 |

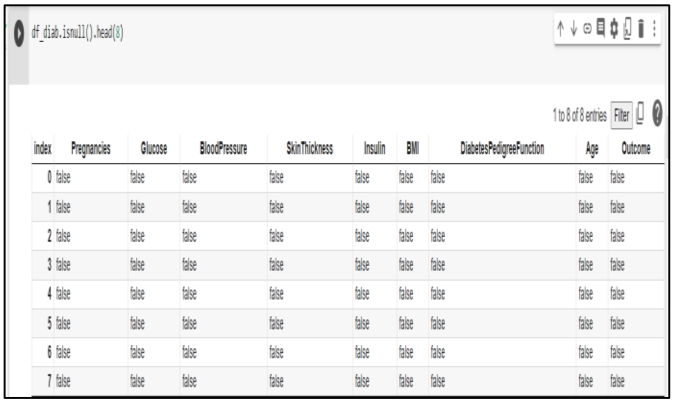
Fig. 7. Describing the dataset.

While collecting data from multiple sources, many times missing values lead to low performance of the ML model. Missing values or null values are very common. Checking for null values in the dataset by using the isnull method, which is predefined. To see the first 8 rows with null values, the head function is used (Fig. 8).

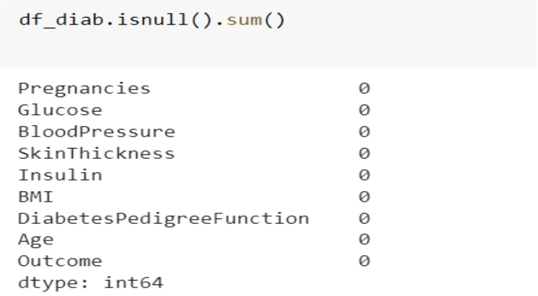


```
df_diab.isnull().head(8)
```

| index | Pregnancies | Glucose | BloodPressure | SkinThickness | Insulin | BMI | DiabetesPedigreeFunction | Age | Outcome |
|---|---|---|---|---|---|---|---|---|---|
| 0 | false | false | false | false | false | false | false | false | false |
| 1 | false | false | false | false | false | false | false | false | false |
| 2 | false | false | false | false | false | false | false | false | false |
| 3 | false | false | false | false | false | false | false | false | false |
| 4 | false | false | false | false | false | false | false | false | false |
| 5 | false | false | false | false | false | false | false | false | false |
| 6 | false | false | false | false | false | false | false | false | false |
| 7 | false | false | false | false | false | false | false | false | false |

Fig. 8. Checking for null values.

As dataset contains null values, so will take the sum of those null values using sum function. In Fig. 9, all the null values are denoted with 0.

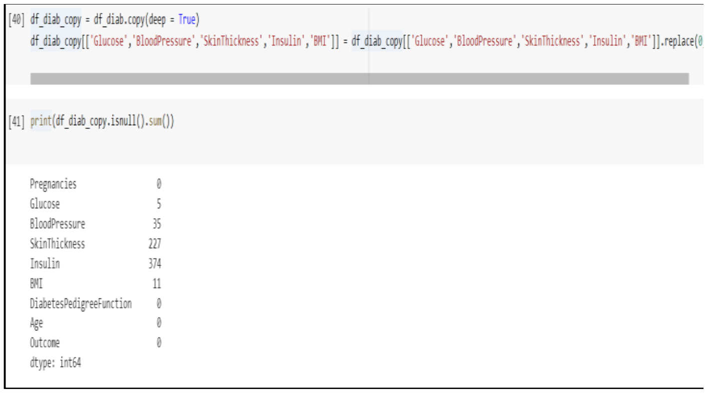


```
df_diab.isnull().sum()

Pregnancies                 0
Glucose                     0
BloodPressure               0
SkinThickness               0
Insulin                     0
BMI                         0
DiabetesPedigreeFunction    0
Age                         0
Outcome                     0
dtype: int64
```

Fig. 9. Number of null values.

Fig. 10 shows the replaced null values that were represented 0 with NaN (Not a Number).



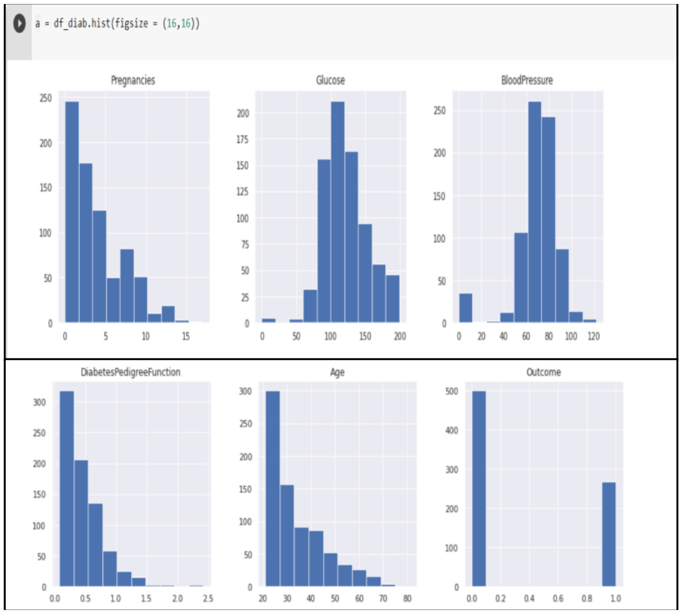
```
[40] df_diab_copy = df_diab.copy(deep = True)
     df_diab_copy[['Glucose','BloodPressure','SkinThickness','Insulin','BMI']] = df_diab_copy[['Glucose','BloodPressure','SkinThickness','Insulin','BMI']].replace(0

[41] print(df_diab_copy.isnull().sum())

     Pregnancies                 0
     Glucose                     5
     BloodPressure              35
     SkinThickness             227
     Insulin                   374
     BMI                        11
     DiabetesPedigreeFunction    0
     Age                         0
     Outcome                     0
     dtype: int64
```

Fig. 10. Replacing the null values.

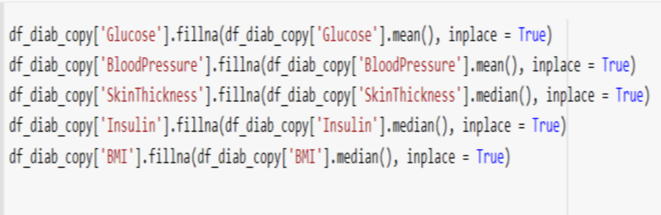
Data distribution is done in Fig. 11 before removal of null values.



```
a = df_diab.hist(figsize = (16,16))
```

Fig. 11. Plotting data distribution with null values.

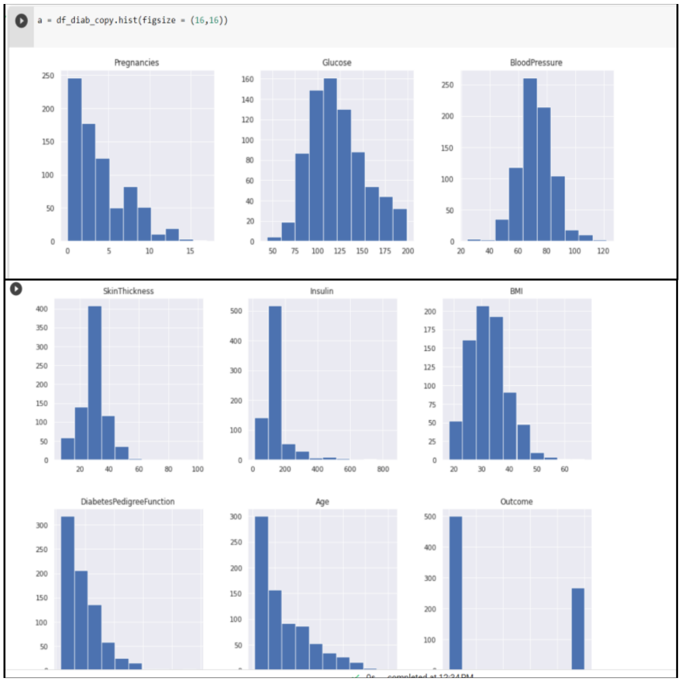
Fig. 12 deals with inserting the mean values of the columns where the missing values were identified in previous steps.



```
df_diab_copy['Glucose'].fillna(df_diab_copy['Glucose'].mean(), inplace = True)
df_diab_copy['BloodPressure'].fillna(df_diab_copy['BloodPressure'].mean(), inplace = True)
df_diab_copy['SkinThickness'].fillna(df_diab_copy['SkinThickness'].median(), inplace = True)
df_diab_copy['Insulin'].fillna(df_diab_copy['Insulin'].median(), inplace = True)
df_diab_copy['BMI'].fillna(df_diab_copy['BMI'].median(), inplace = True)
```

Fig. 12. Setting the mean values.

Plot distribution after removal of null values is shown in Fig. 13.



```
a = df_diab_copy.hist(figsize = (16,16))
```

Fig. 13. Distributing after removing null values.

Below bar graph shows that no null values exist in the dataset (Fig. 14).

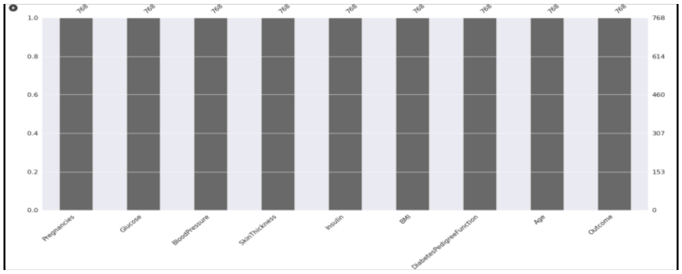


Fig. 14. Counting null values analysis.

The total number of diabetic patients are half of the rest of non-diabetic patients (see Fig. 15 and 16).

Fig. 25. Accuracy.

We have implemented a random forest model for predicting diabetics (Fig. 23 and 24). Various parameters including age, insulin level, BMI, blood pressure are taken into consideration. Fig. 26 shows the flowchart of the random forest-based prediction model. Data distribution of these parameters is represented graphically. Null values are eliminated from the dataset after setting up the mean values. This shows that the total strength of diabetic patients is half of the total number of non-diabetic patients. After scaling, the dataset is divided into testing and training dataset where all the features have a correlation coefficient of 1, represents that all the features present in the dataset are positively correlated with rest of the features (see Fig. 19 and 20). Accuracy of the model is 0.76377952755, which represents a high accuracy.

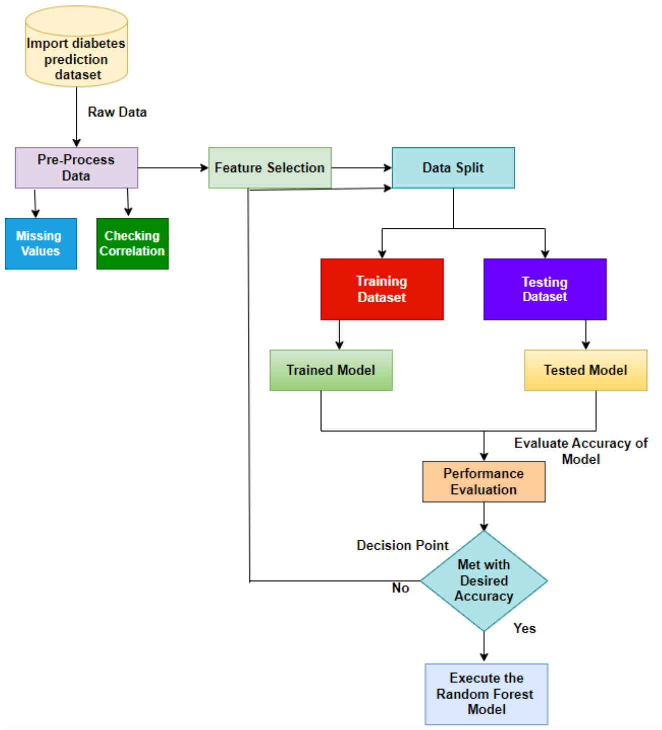

Fig. 26. Flowchart of prediction model.

## VIII. Barriers in Machine Learning Implementation

Primary care mistake has an edge of error. Lots of patients' lives can be put at stake just because of a single error. Radiological scans based on machine learning might fail to scan a tumor [4]. More questions could arise if a user consumes the wrong drug recommended by the healthcare model [10]. Table I presents the list of companies that are working on healthcare sector. Machine learning can manage tasks quickly that were earlier handled by humans manually.

### A. *Privacy Invasion*

Privacy remains a topic of concern regarding patient data. Even after applying different measures, the presence of malicious attackers that are trying hard to breach the security of smart systems. Personal data of patients carries very sensitive identification details, including bill payment information [6]. Machine learning has the ability to predict patient information even when the model is not fed with any data. The University of Washington faced a security incident in the year 2022 when fraudulently gained access to the university network system.

### B. *Bias Nature*

Discrimination in the machine learning model occurs when data is imported from a particular source, and the output that is obtained can only be beneficial for that particular source [17]. Suppose that data imported from an academic health science center is fed to the ML system. That system might not give fruitful results to those population that belongs to the rest of the areas except for the academic medical center [18]. Similarly, while using speech recognition in recording notes, the model might show low efficiency when the user belongs to a different race.

### C. *Faulty Diagnosis*

We are already aware that the quality of the machine learning model entirely depends on the dataset being provided. There is the potential risk of a negative diagnosis [8]. The dataset being imported might not contain a sufficient amount of information from different socio-economic backgrounds. Medical professionals might be held accountable if the ML model makes a wrong decision because the doctor was the one who used the smart model to make health decisions.

TABLE I. Companies Utilizing Technology in Healthcare

| S.No. | Healthcare Companies | Area of Treatment | Technology Leveraged |
|---|---|---|---|
| 1 | Google DeepMind | Breast cancer diagnosis | Machine Learning and Image Processing |
| 2 | IBM Watson Health | Breast cancer treatment and faster drug delivery | Cognitive Computing |
| 3 | CloudMedX hEALTH | Heart failure and liver cancer | Natural Language Processing and Deep Learning |
| 4 | Oncora Medical | Radiation therapy for cancer treatment | Machine Learning and Natural Language Processing |
| 5 | Babylon Health | Primary Healthcare | Deep Learning |
| 6 | Corti | Cardiac disease | Artificial Neural Network |
| 7 | Butterfly Network | Ultrasound and MRI examination | Artificial Intelligence and Cloud Computing |

## IX. Conclusion and Future Scope

The objective of this study was to analyze different ML techniques in revolutionizing medical diagnosis. To achieve the same, we have accessed various literature work starting from year 2018-2023. We have recognized four major databases: Springer Link, IEEE, IGI Global and De Gruyter. We have examined the key benefits of ML in eliminating the existing healthcare challenges. The studies done so far has shown significant improvement in their results, Our study have shown that ML not only brings down the entire treatment cost but along with this recognizes the hidden pattern that indicate disease in initial stage itself. Machine learning has been disruptive technology, from predicting diseases in the early stages by examining radiological images to moving towards a fast, efficient, and smart healthcare system that can become the savior of tons of human lives. We have discussed about the most popular case studies of pharma industry and how those solutions are assisting individuals in tackling medical conditions. Implemented random forest model for diabetic's prediction which showed an accuracy of 76377952755. This study would give researchers a primary knowledge to carry forward their work. We have not considered the work that is presented in any other language. So in the upcoming years we can consider the resources that have been neglected as those can also provide valuable insights.

Accurate medical diagnosis and personalized health treatment have excessively refined medical research. Its capability to quickly analyses large quantities of clinical records assists medical practitioners in recognizing disease in the early stage. Although there are potential challenges, it is clearly visible that machine learning will lay a foundation for enhancing the worldwide health ecosystem. Together with machine learning, people are conscious of the importance of a healthy lifestyle. By mitigating treatment costs and high-quality patient care, machine learning has impressively transformed the healthcare system and human lives as well.

***Abstract*—In recent years, the status of ceramics in fields such as art, culture, and historical research has been continuously improving. However, the increase in malicious counterfeiting and forgery of ceramics has disrupted the normal order of the ceramic market and brought challenges to the identification of authenticity. Due to the intricate and interfered nature of the microscopic characteristics of ceramics, traditional identification methods have been suffering from issues of low accuracy and efficiency. To address these issues, there is a proposal for a multi-scale fusion bottleneck structure and a chunking attention module to improve the neural network model of Resnet50 and perform ceramic microscopic image classification and recognition. Firstly, the original bottleneck structure has been replaced with a multi-scale fusion bottleneck structure, which can establish a feature pyramid and establish associations between different feature layers, effectively focusing on features at different scales. Then, chunking attention modules are added to both the shallow and deep networks, respectively, to establish remote dependencies in low-level detail features and high-level semantic features, to reduce the impact of convolutional receptive field restrictions. The experimental results show that, in terms of classification accuracy and other indicators, this model surpasses the mainstream neural network models with a better classification accuracy of 3.98% compared to the benchmark model Resnet50, achieving 98.74%. Meanwhile, in comparison with non-convolutional network models, it has been found that convolutional models are more suitable for the recognition of ceramic microscopic features.**

***Keywords*—Deep learning; ceramic anti-counterfeiting; image classification; attention mechanism***

## I. Introduction

Ceramics is a material and product discovered and produced by humans in their daily lives on Earth [1]. It is a hard product made from minerals such as clay through a series of physical and chemical reactions in a high-temperature environment. Due to its high practical value, the ceramic preparation process has been passed down through generations, and over time, this process has become increasingly refined. Throughout different historical periods, there are representative ceramic masterpieces characterized by a unique style, which to some extent, reflects the levels of productivity in different periods. Driven by this historical value, the trend of collecting ceramics has naturally flourished, while also endows ceramics with significant economic value. However, with the improvement of the technological level, the considerable economic benefits of ceramics have also given rise to the imitation industry. The rough and deliberately made products maliciously infiltrate every corner of the ceramics culture and trading market. This phenomenon not only infringes on the legitimate rights and interests of consumers. It also affects the dissemination and promotion of ceramic art and culture. Therefore, adopting a scientific and effective identification method is particularly important.

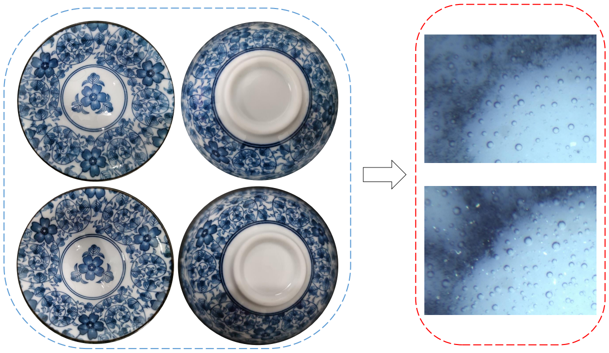

Fig. 1. Ceramic identification objects: macroscopic and microscopic images.

In recent years, with the rapid development of the field of computer vision, various universal visual tasks have been continuously refreshed with optimal indicators. At the early stage of the development of visual methods, visual feature extraction was mainly carried out by designing manual features [2]. In order to reduce the cost of feature engineering, the deep learning method represented by Convolutional neural network gradually has replaced the traditional manual feature method and achieved an excellent performance in basic visual tasks such as object detection and image segmentation [3], [4]. In the field of ceramic identification, this image-based identification method does not cause secondary damage to ceramics, and with the help of visual algorithms, it can achieve good differentiation of different ceramics. Therefore, scholars have also invested in the study of ceramic images [5]. At present, research on ceramic image identification has been mainly based on a macro perspective, by designing manual features or deep features for feature extraction, followed by feature classification. However, with the advancement of the ceramic manufacturing process, it is now possible to replicate the macroscopic appearance of ceramics completely (as shown in the left side of Fig. 1). It is less likely to guarantee the accuracy of the identification results by solely relying on ceramic images for identification. During the physical and chemical process of ceramic firing, microscopic features such as crystallization and bubbles would emerge on the surface (as shown in the right side of Fig. 1). Even ceramics with similar macroscopic textures would exhibit certain differences when observed from a microscopic perspective. These randomly distributed microscopic features and texture variations are akin to the fingerprints of ceramics, endowing them with uniqueness. Therefore, the microscopic images of ceramics are more suited for the task of identification. On the other hand, currently, there is a lack of publicly available ceramic microscopic feature datasets in the market. In addition, personally-collected microscopic datasets of ceramics are limited in scale, and the complexity and non-uniformity of microscopic visual features pose challenges in feature recognition. Therefore, there is an urgent need for a specialized method in ceramic identification through microscopic visual analysis.

Therefore, this paper proposes a multi-scale fusion bottleneck structure and chunking attention module to solve the above problems and constructs a deep residual multi-scale network for feature classification of micro images of Jingdezhen and Dehua ceramics. The main contributions can be summarized as follows:

1) Shifting the research object in the field of ceramic identification from ceramic composition and macroscopic images to the study of microscopic images of ceramics. By collecting 12 pairs of microscopic images of ceramics with similar macroscopic features and conducting classification experiments, the effectiveness of this study was verified, and to some extent, the risks brought by ceramic imitation were solved.
2) Proposing a multi-scale fusion bottleneck structure and a chunking attention module for capturing features of different scales in images and reducing the computational cost of establishing feature remote dependencies. They can be easily embedded into deep neural networks.
3) Making a model improvement was made on the classic deep residual network and incorporating the two modules mentioned above. A deep residual network based on multi-scale fusion and attention mechanism was proposed, and in the collected ceramic micro datasets, it surpassed the current mainstream classification models and achieved the optimal results of benchmark testing.

The structure of this paper is arranged as follows: Section II will discuss related work. Section III mainly illustrates the relevant modules and algorithm processes in the model. Section IV mainly focuses on the microscopic data and experimental situation of ceramics and analyzes them. Section V discusses and summarizes the research content of this paper.

## II. Related Work

In recent years, there have been many studies using images as a medium in the field of porcelain product recognition. Mu et al. [6] constructed manual visual features based on the contour, texture, and other information of macroscopic images of ancient ceramics and achieved a recognition rate of over 95% in ceramic recognition. However, this manual feature-based recognition method is only applicable to ancient ceramics with relatively fixed shapes and cannot adapt to the increasingly diverse types of modern ceramics. The development of deep learning has somewhat solved the limitations brought by manual features. Jiapeng et al. [7] used neural networks to classify ceramic images of different macroscopic shapes and achieved an accuracy of 92.62%. Yi et al. [8] constructed a set of ceramic classification standards for visual elements such as shape, color, and pattern of ceramics and achieved 72% pattern classification accuracy through target detection by using neural networks, ultimately formed a ceramic classification system. Chetouani et al. [9], [10] automatically classified the ceramic fragment images by constructing a Convolutional neural network and achieved the best accuracy. These studies have improved the archaeological efficiency and verified the superiority of neural networks in the field of ceramic classification. The above research on macroscopic images of ceramics still has certain limitations in scenarios with similar macroscopic features.

Therefore, another type of ceramic recognition research designed the microscopic images of ceramics. Wang et al. [11] proposed a fractal reconstruction method for high-temperature ceramic surface images and established a fractal Convolutional neural network model for image recognition, which achieved a classification accuracy of 93.74%. Min et al. [12] recognized the microscopic characteristics of ceramics through a Convolutional neural network and then carried out feature detection. Although these studies have shown some significant effects in their respective application fields, they have not yet taken into account the similarity in macroscopic appearance in ceramic identification. In addition, ceramic microscopic images can also be used for studying the properties and identifying the composition of ceramics. Hogan et al. [13] discovered the relationship between compression testing and microstructure changes by conducting uniaxial and biaxial compression experiments on ceramics and conducting stress analysis while observing changes in ceramic microscopic images. Aprile et al. [14], [15] identified the composition of ceramics through microscopic image acquisition methods such as OM and conducted modal analysis. This method of detection can avoid complex component extraction processes. In terms of detection, Guang et al. [16] improved the YOLO v5 model by combining the attention mechanism and depth separable convolution to detect defects in ceramic tile surface images. Huiliang et al. [17] used a graph structure clustering algorithm and Convolutional neural network to detect defects on ceramic tile surfaces. These studies have shown that Convolutional neural networks can also be used in ceramic detection tasks.

On the other hand, convolutional neural networks are not exclusive to pure image modal data. Yong et al. [18] used a full Convolutional neural network to classify the components of Jian kiln black glaze porcelain from the Song Dynasty in Fujian Province, thereby assisting in the classification of ceramics. This research also brought the possibility of multimodal analysis of ceramics through a Convolutional neural network and also had the prospect of using this technology in the field of ceramic identification. In terms of ceramic anti-counterfeiting, in addition to studying the characteristics of ceramics themselves, some scholars have also added anti-counterfeiting components to achieve ceramic anti-counterfeiting. Jae et al. [19] invented an anti-counterfeiting material through spray pyrolysis and applied it to the field of ceramic anti-counterfeiting. However, the identification cost and threshold of the identification end cannot be avoided by anti-counterfeiting in this way. Therefore, the pure image method has its unique advantages in the identification of ceramic authenticity. Nevertheless, current image recognition algorithms face certain bottlenecks in the identification of ceramic microscopic images. Methods based on manual features exhibit low accuracy and poor generalization in identifying ceramic microstructures, failing to meet the demands of complex and diverse ceramic microscopic image recognition. In order to address this issue, this paper enhances deep residual networks by combining multi-scale fusion and attention mechanisms, aiming to achieve high-accuracy identification of ceramic microscopic images.

## III. Model Design

In the field of image classification, the Convolutional neural network has always been a simple and effective model. The depth residual Convolutional neural network proposed by this paper, which is based on the combination of multi-scale and attention mechanisms, is an efficient and effective Convolutional neural network that has obvious performance advantages in the field of ceramic microscopic image data and can effectively characterize complex ceramic microscopic characteristics. In this chapter, we will introduce the principles and techniques related to the proposed multi-scale fusion bottleneck structure and chunking attention mechanism. Additionally, we will present the main details of the model used for this ceramic microscopic image classification task.

### A. Multi-scale Fusion Module

In the design process of a Convolutional neural network, to improve the feature extraction ability of the model, it is often necessary to expand the scale of the model in a variety of ways, the most representative of which is widening and deepening [20], [21].Since the proposal of Resnet [22], this field has, for the first time, expanded the depth of the model to a scale greater than three digits, while also avoiding the risks of model degradation and overfitting. The residual connection and bottleneck structure proposed in this paper have also had a profound impact on subsequent research [23]. In addition, some researchers believe that the performance of the model is confined by the local dependency of convolution operations. Therefore, to make the model globally dependent, models represented by attention mechanisms have emerged [24].

On the other hand, it has been observed that there are a large number of bubble features and micro-texture information in ceramic micro images, and there are also certain differences in the background information of these key features. Therefore, this background information is also worth utilizing. Based on this motivation, a feature pyramid approach has been introduced to fuse ceramic micro background information at different scales. This multi-scale feature extraction method can effectively improve the recognition ability of the model [25].

However, the current mainstream multi-scale feature extraction methods have just simply stacked features, ignoring the correlation and importance between different scale feature maps. In order to integrate multi-scale features of the model and explore the correlation between different scale features for weighted fusion, this module establishes cross-correlations for different scale features through the attention mechanism and improves on the traditional bottleneck structure to form a new multi-scale fusion bottleneck structure.

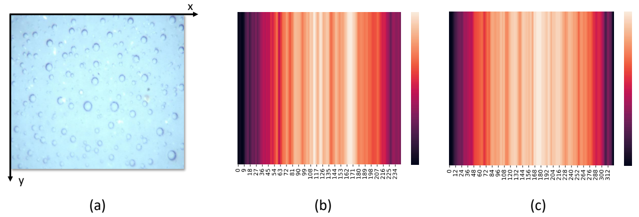

Fig. 2. Example diagram of ceramic microscopic characteristic coordinate axis pooling.

*1) Cross-scale coordinate attention mechanism:* The cross-scale coordinate attention mechanism can be seen as a feature weighting operation for features from different scales. From Fig. 2 (a), it can be observed that ceramic micro features exhibit different distributions along the X and Y coordinate axes, and their grayscale pooling features thermal maps are shown in Fig. 2 (b) and Fig. 2 (c). Therefore, modeling the information extracted from the X-axis and Y-axis directions in ceramic microscopic images can enhance the model's attention to important features.

This attention mechanism accepts any two feature tensor inputs of different scales, let it be set as $X_x = [x_1^x,\ x_2^x,\ ...,\ x_C^x]$ , $X_y = [x_1^y,\ x_2^y,\ ...,\ x_C^y]$, where $X_x,\ X_y \in \mathbb{R}^{C\times H\times W}$. Firstly, encode the different channels of input features along the X and Y axes to form two one-dimensional feature sequences. The calculation process uses two global feature pooling operations, represented as follows:

$$\begin{cases} y_c^x\left(h\right) = \frac{1}{W}\sum_{i=1}^{W} x_c^x\left(h,\ i\right) \\ \\ y_c^y\left(w\right) = \frac{1}{H}\sum_{i=1}^{H} x_c^y\left(w,\ i\right) \end{cases} \tag{1}$$

where, $Y_x = [y_1^x,\ y_2^x,\ ...,\ y_C^x]$ and $Y_y = [x_1^y,\ x_2^y,\ ...,\ x_C^y]$ represent the two coding sequences $Y_x \in \mathbb{R}^{C\times H\times 1}$ and $Y_y \in \mathbb{R}^{C\times W\times 1}$. This step captures the global position information of the coordinate axis direction from different scale feature maps, enhancing information sharing in the direction.

The second step is to concatenate the above features to form a new feature whole. In order to make the features from two scales interact effectively, it is usually considered to map the tensor to another linear space. Therefore, using a $1 \times 1$ convolutional kernel can perform linear transformations on the channel of the feature map, followed by feature activation and other operations, represented as follows:

$$\mathcal{X} = \mathcal{R}\left(\mathcal{B}\left(Conv_{c\to c/r}^{1\times 1}\left(\left[Y_x,\ Y_y\right]\right)\right)\right) \tag{2}$$

where, $\mathcal{X} \in \mathbb{R}^{\frac{C}{r}\times(H+W)\times 1}$. $Conv$ refers to convolution operation, and $r$ refers to the compression ratio of the feature channel. Generally, this number is an integral power of 2. In this paper, $r = 32$, $\mathcal{B}$ refers to Batch Normalization, and $\mathcal{R}$

refers to the Activation function of a kind of deformation of RELU, which can limit the data range to 0 to 1 to better adapt to image characteristics. After that, the calculated feature is taken as the initial attention score of the attention mechanism, weight the feature, and then segment the size feature corresponding to the original X-axis and Y-axis. For the features corresponding to the X-axis and Y-axis, we also pass two sets of $1 \times 1$ convolution kernel is inversely mapped into the linear space of the original input, and the activation function is used to normalize the corresponding axis attention score, which is expressed as follows:

$$\begin{cases} \mathcal{D}_x = \mathcal{F}\left(Conv^{1\times1}_{c/(hr)\to c}\left(\mathcal{V}^H\right)\right) \\ \\ \mathcal{D}_y = \mathcal{F}\left(Conv^{1\times1}_{c/(wr)\to c}\left(\mathcal{V}^W\right)\right) \end{cases} \tag{3}$$

where, $\mathcal{V}^H \in \mathbb{R}^{\frac{C}{r}\times H\times 1}$, $\mathcal{V}^W \in \mathbb{R}^{\frac{C}{r}\times W\times 1}$ represent the feature inputs corresponding to X-axis and Y-axis, and $\mathcal{D}_x \in \mathbb{R}^{C\times H\times 1}$, $\mathcal{D}_y \in \mathbb{R}^{C\times W\times 1}$ represent the feature outputs corresponding to X-axis and Y-axis. The activation function $\mathcal{F}$ is a sigmoid function, which exhibits an S-shaped growth curve in biology. By applying this function during normalization, it performs a nonlinear transformation of features, enabling the model to recognize more complex features.

Finally, the original tensor has been weighted with the attention fraction of the coordinate axis in the X-axis and Y-axis directions as follows:

$$\mathcal{Y} = X_x \odot \mathcal{D}_x \odot \mathcal{D}_y \tag{4}$$

where, $\odot$ represents the point multiplication operation of the tensor, and $\mathcal{Y} \in \mathbb{R}^{C\times H\times W}$ represents the weighting result of the tensor along the channel for its own X-axis feature and the Y-axis feature of other scale tensors.

The above are the details of the cross-scale coordinate attention mechanism. It should be noted that this module focuses on the cross-influence between scales. Therefore, for feature input, it is necessary to ensure that the size of the feature tensor of the two scales is consistent. The specific process is shown in Algorithm 1.

**Algorithm 1** Cross-scale coordinate attention algorithm.

```
Input: Different scale feature $X_x$, $X_y$, squeeze ratio r.
Output: Cross-scale coordinate attention-weighted feature $\mathcal{Y}$.
Compute $Y_x, Y_y$ according to Eq. (1)
Compute $\mathcal{X}$ according to Eq. (2)
Compute $S$ according to Eq. (2) without $\mathcal{R}$
$\mathcal{V} = \mathcal{X} \odot S$
$\mathcal{V}^H, \mathcal{V}^W = Split\left(\mathcal{V}\right)$
Compute $\mathcal{D}_x, \mathcal{D}_y$ according to Eq. (3)
Compute $\mathcal{Y}$ according to Eq. (4)
return $\mathcal{Y}$
```

2) *Multi-scale fusion bottleneck structure:* The traditional residual bottleneck structure is composed of two $1 \times 1$ and a $3 \times 3$ convolution kernel stack. On this basis, the multi-scale fusion bottleneck structure replaces the $3\times3$ convolution kernel with multiple $3 \times 3$ convolution kernels and introduces the cross-scale coordinate attention mechanism to mine the correlation between different scales.

Specifically, after the feature passes through the first $1 \times 1$ convolution kernel, it is divided into s parts according to the number of channels. Where the first $s - 1$ sub-features each have a $3 \times 3$ convolution kernel corresponding to them one-to-one, and the features entering the current convolution operation are those formed as a result of the mutual accumulation of the output of the previous convolution operation and the current sub-feature. After the scale feature pyramid operation, distinctive features such as bubbles will undergo further enhancement through a chain of convolutional operations. This operation can be represented as follows:

$$y_i = \begin{cases} Conv^{3\times3}_{c/r\to c/r}\left(x_i\right), & i = 1 \\ \\ Conv^{3\times3}_{c/r\to c/r}\left(y_{i-1} + x_i\right), & 1 < i < s \\ \\ x_i, & i = s \end{cases} \tag{5}$$

where, $x_i \in \mathbb{R}^{\frac{C}{s}\times H\times W}$ and $y_i \in \mathbb{R}^{\frac{C}{s}\times H\times W}$ denote the input and output features, respectively. The variable $s$ represents the number of scale divisions, which is a factor of channel number $C$.

However, it is important to note that the presence of noise points in the feature map can contaminate the subject features during the convolutional operation chain. This method overlooks the differences and correlations between adjacent scales, and the straightforward superposition of features can magnify this error. Therefore, a cross-scale coordinate attention mechanism has been introduced between adjacent scale features to enable the model to accurately identify important

**Algorithm 2** Multi-scale fusion bottleneck structure.

```

return $Y$
```

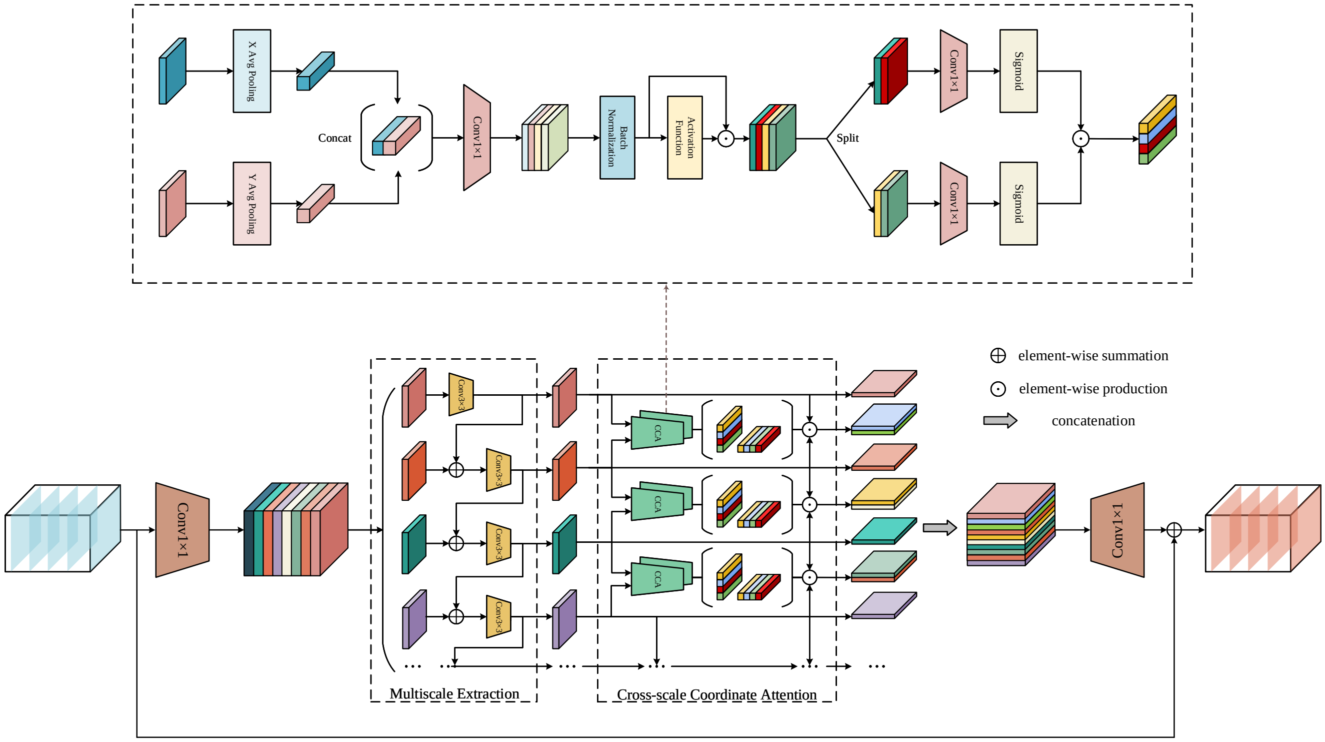

Fig. 3. Flowchart of the multiscale fusion bottleneck structure when s = 4.

features. When calculating attention features between different scales, it is important to consider both the influence of oneself on adjacent scales and the influence of adjacent scales on oneself. As a result, the total output quantity of the operation is $s + 2 \times (s - 1)$. Here, s represents the amount of channel segmentation for the original feature. This operation can be represented as follows:

$$z_i = Concat\left(\mathit{\Phi}\left(y_{i-1},\ y_i\right),\ \mathit{\Phi}\left(y_i,\ y_{i-1}\right)\right),\ 1 < i \le s \tag{6}$$

where, $z_i \in \mathbb{R}^{2\times\frac{C}{s}\times H\times W}$ represents the cross-scale coordinate attention feature between adjacent scales, $Concat$ represents the connection operation between channels and $\mathit{\Phi}$ represents the cross-scale coordinate attention operation.

Fig. 3 illustrates the multi-scale fusion bottleneck structure when $s = 4$. After the aforementioned computations have resulted in a feature map with a channel number of $3 \times s - 2$, a second $1 \times 1$ convolution is utilized to transform the channel number to the standard quantity. The specific process is as shown in Algorithm 2.

## B. Chunking Attention Module

Since Self Attention [26], [27] has been proposed, it has played a role in both computer vision and Natural language processing. On this basis, many classic architectures have also emerged [3], [4]. In contrast, the Convolutional neural network lacks the ability to establish a long-distance global dependency, so intuitively, it is very likely to establish such global dependency for the Convolutional neural network by introducing the Self Attention mechanism. However, the computational cost of Self Attention is unexpectedly high, so there has been a series of efforts to improve the problem and propose corresponding solutions for different fields [28], [29]. In this section, a method has been proposed based on Self Attention to establish attention-weighted features between local and global blocks through block partitioning. This approach effectively reduces computational complexity while still enabling the establishment of long-distance dependencies. This section describes the techniques and principles of spatial chunking attention and channel chunking attention.

*1) Overview of self attention:* The Self Attention mechanism considers a feature tensor, respectively, as Query, Key, and Value, and obtains its important features through the operation between them. The calculation method is as follows:

$$Attention\left(Q,\ K,\ V\right) = Softmax\left(\frac{Q \otimes K^T}{\sqrt{d_k}}\right) \otimes V \tag{7}$$

where, $\otimes$ represents the Matrix multiplication of the tensor, and $Q,\ K,\ V \in \mathbb{R}^{n\times d_k}$ represents the input characteristic tensor. $T$ represents the matrix transpose operation. In the field of vision, the value of n is generally the size of the image $h \times w$, and $d_k$ represents the number of feature channels. This formula includes two Matrix multiplications. First, through the operation between Query and Key, and $Softmax$, the attention score of each pixel in the global is calculated. The Softmax formula is as follows:

$$Softmax\left(X_{ij}\right) = e^{X_{ij}} / \sum_{z=1}^{n} e^{X_{iz}} \tag{8}$$

Then, the global pixels are weighted by the second Matrix multiplication. It is not difficult to find that the computational complexity of this operation is $\Omega\left(2n^2 d_k\right)$. However, this computational complexity is unacceptable before the feature map undergoes multi-layer downsampling. It is noticed that pixels interact with the entire feature map during the calculation of the global attention score, which is the fundamental reason for the increase in computational complexity. Therefore, Query, Key, and Value have been redesigned to reduce computational complexity.

*2) Spatial chunking attention:* The Spatial Chunking Attention module starts by dividing the feature map into uniform spatial patches. Inspired by the divide-and-conquer algorithm, it independently computes attention-weighted features for each sub-patch. Finally, these features are merged to form the Spatial Chunking Attention features. Fig. 4 illustrates the calculation process of the Spatial Chunking Attention module, which consists of the following specific steps:

Set the input feature tensor as $X \in \mathbb{R}^{C\times H\times W}$. Similarly, before calculating attention scores, form preliminary Query, Key, and Value tensors through a set of learnable convolutional kernels, which are represented as follows:

$$\begin{cases} Query = Conv_{C\to C/r}^{1\times 1}(X) \\ Key = Conv_{C\to C/r}^{1\times 1}(X) \\ Value = Conv_{C\to C}^{1\times 1}(X) \end{cases} \tag{9}$$

where, $Query,\ Key \in \mathbb{R}^{\frac{C}{r}\times H\times W}$, $Value \in \mathbb{R}^{C\times H\times W}$. Next, we divide the Query and Value inputs uniformly to create two sets of patch sequences ($K_h = \sqrt{H},\ K_w = \sqrt{W}$), namely $Q \in \mathbb{R}^{K_h\times K_w\times\sqrt{HW}\times\frac{C}{r}}$ and $V \in \mathbb{R}^{K_h\times K_w\times\sqrt{HW}\times C}$. For the definition of Key, if the Self Attention setting is followed, the sub-patch will only have its own local dependency. Therefore, perform global feature mean pooling and sample a set of globally abstract features as $K$, which is represented as follows:

$$\begin{cases} K_{c/r}^{<i,\ j>} = \frac{1}{\sqrt{H\times W}}\sum_{s=1}^{\sqrt{H}}\sum_{t=1}^{\sqrt{W}} Key_{c/r}(u,\ v) \\ u = (i-1)\times\sqrt{H}+s, \quad 1\le i\le K_h \\ v = (j-1)\times\sqrt{W}+t, \quad 1\le j\le K_w \end{cases} \tag{10}$$

where, $K_{c/r} \in \mathbb{R}^{\sqrt{HW}\times\frac{C}{r}}$. By solving attention scores with globally abstract features, global dependencies can be effectively established. At this point, the Spatial Chunking Attention feature can be obtained through Eq. (8), which is calculated as follows:

$$Y_c^{<i,\ j>} = Softmax\left(\frac{Q_{c/r}^{<i,\ j>}\otimes K_{c/r}^{T}}{\sqrt{c/r}}\right)\otimes V_c^{<i,\ j>} \tag{11}$$

where, $Y_c^{<i,\ j>} \in \mathbb{R}^{\sqrt{HW}\times C}$ represents the attention weighted features of each patch. Afterward, merge the patch features by location to restore spatial attention features $Y \in \mathbb{R}^{C\times H\times W}$.

Finally, a learnable feature has been proposed for modeling momentum representation in Spatial Chunking Attention, which is represented as follows:

$$\begin{cases} momentum = 0.5\odot gamma/(1+|gamma|)+0.5 \\ Z = momentum\odot Y+(1-momentum)\odot X \end{cases} \tag{12}$$

where, $momentum \in \mathbb{R}^{1\times 1}$ represents the learnable momentum value, with a range of $[0,1]$. $Z \in \mathbb{R}^{C\times H\times W}$ represents the Spatial Chunking Attention weighted feature. At this point, the solution for Spatial Chunking Attention is obtained. It is worth noting that when partitioning the feature map, it is necessary to ensure that the dimensions $H$ and $W$ are perfect square numbers. Therefore, has been the prerequisite is not met, the feature map needs to be padded along the borders. This paper employs mirror padding, where the mirrored content of the original feature map is filled symmetrically with respect to the border.

Fig. 4. Flowchart of the spatial chunking attention module.

*3) Channel chunking attention:* In the process of image downsampling, each highly abstract channel graph can be regarded as a special class response, and the response relationship between these channels together constitutes the semantic information of the target. In order to identify complex and disordered bubbles and other features in ceramic micro images, the analysis of the response relationship between channel graphs can help the model understand the semantic information of ceramic micro images, and then improve the accuracy of recognition. Similarly, using Self Attention for channel global interaction can easily cause the unacceptable computational complexity of the model. Also, the idea of the divide and conquer algorithm con be used to divide the channel graph evenly, calculate the attention characteristics of each subpatch independently, and finally merge to form the Channel Chunking Attention. The calculation process is as shown in Fig. 5. The specific calculation steps are as follows:

Firstly, transform the number of channels in the feature map using a set of $1 \times 1$ convolutional kernels, which is represented as follows:

$$\begin{cases} Query = Conv_{C\to SC}^{1\times 1}\left(X\right) \\ Key = Conv_{C\to SC}^{1\times 1}\left(X\right) \\ Value = Conv_{C\to SC}^{1\times 1}\left(X\right) \end{cases} \tag{13}$$

where, $X \in \mathbb{R}^{C\times H\times W}$ and $Query,\ Key,\ Value \in \mathbb{R}^{SC\times H\times W}$. $SC$ is the perfect square number greater than the original number of channels. Similarly, after reconstructing the number of channels, perform the average segmentation to form two sets of $K_{ch}\times K_{cw}$ patch sequences ($K_{ch} = K_{cw} = \sqrt[4]{SC}$), namely $Q,\ V \in \mathbb{R}^{K_{ch}\times K_{cw}\times\sqrt{SC}\times HW}$, for Query and Value. For Key, use global feature mean pooling to obtain a set of feature K, whose operation is represented as follows:

$$\begin{cases} K_{sc}^{<i,\ j>} = \frac{1}{\sqrt{SC}}\sum_{s=1}^{K_{ch}}\sum_{t=1}^{K_{cw}} Key_{sc}\left(u,\ v\right) \\ u = \left(i-1\right)\times K_{ch}+s, \quad 1\leq i\leq K_{ch} \\ v = \left(j-1\right)\times K_{cw}+t, \quad 1\leq j\leq K_{cw} \end{cases} \tag{14}$$

where, $K_{sc} \in \mathbb{R}^{\sqrt{SC}\times HW}$. Afterward, we can establish a global dependency on the channel through Eq. (8), which is represented as follows:

$$Y_{sc}^{<i,\ j>} = Softmax\left(\frac{Q_{sc}^{<i,\ j>}\otimes K_{sc}^{T}}{\sqrt{H\times W}}\right)\otimes V_{sc}^{<i,\ j>} \tag{15}$$

where, $Y_{sc}^{<i,\ j>} \in \mathbb{R}^{\sqrt{SC}\times HW}$ represents the attention-weighted feature of each channel patch. In addition, to restore the feature dimension, it is necessary not only to merge each channel patch but also apply a set of $1\times 1$ convolutional kernels to restore the number of channels. The representation is as follows:

$$P = Conv_{SC\to C}^{1\times 1}\left(Y\right) \tag{16}$$

where, $Y \in \mathbb{R}^{SC\times H\times W}$ represents the result of merging patch features by channel, and $P \in \mathbb{R}^{C\times H\times W}$ represents the result of restoring the number of feature channels. Similarly, according to Eq. (12), a set of learnable momentum representations have also been designed for Channel Chunking Attention. At this point, the solution for Channel Chunking Attention is completed.

Fig. 5. Flowchart of the channel chunking attention module.

*4) Complexity analytics:* The Spatial Chunking Attention mechanism divides the spatial plane into $K_h \times K_w$ sub-patches on average. To simplify the analysis, it is assumed that the tensor dimensions $H$ and $W$ are perfect square numbers, so the size of each sub-patch is $\sqrt{H}\times\sqrt{W}\times C/r$. Therefore, the Time complexity of solving attention score is $\varOmega\left(K_hK_w\left(\sqrt{HW}\right)^2 C/r\right)$. The second part of the operation is Matrix multiplication between the spatial attention score and the $K_h\times K_w$ sub-patches of $V$, where $V \in \mathbb{R}^{K_h\times K_w\times\sqrt{HW}\times C}$ and $Score \in \mathbb{R}^{K_h\times K_w\times\sqrt{HW}\times\sqrt{HW}}$. Therefore, the Time complexity of this part is $\varOmega\left(K_hK_w\left(\sqrt{HW}\right)^2 C\right)$. Based on the above, the overall time complexity of this module is denoted as $\varOmega\left(\left(\sqrt{HW}\right)^3\left(1/r+1\right)C\right)$.

Similarly, the Channel Chunking Attention mechanism divides channels into $K_{ch} \times K_{cw}$ sub-patches on average. The number of channels is assumed as a second-order perfect square number, that is, $SC$ and $\left(\lfloor\sqrt[4]{SC}\rfloor\right)^4$ are equal. For the first part of the calculation of attention score, it is the Matrix multiplication between $Q \in \mathbb{R}^{K_{ch}\times K_{cw}\times\sqrt{SC}\times HW}$ and $K^T \in \mathbb{R}^{HW\times\sqrt{SC}}$, and the Time complexity is

$\Omega\left(K_{ch}K_{cw}\left(\sqrt{SC}\right)^2 HW\right)$. The operation of the second part is Matrix multiplication between the channel attention score and the $K_{ch} \times K_{cw}$ sub-patches of $V$. Where $V \in \mathbb{R}^{K_{ch}\times K_{cw}\times\sqrt{SC}\times HW}$ and $Score \in \mathbb{R}^{K_{ch}\times K_{cw}\times\sqrt{SC}\times\sqrt{SC}}$. It is not difficult to find that the Time complexity of this part is $\Omega\left(K_{ch}K_{cw}\left(\sqrt{SC}\right)^2 HW\right)$. Therefore, the time complexity of the Channel Chunking Attention module is $\Omega\left(2\left(\sqrt{SC}\right)^3 HW\right)$.

### C. Model Backbone Architecture

The overall structure of this model is as shown in Fig. 6 (a), where the backbone network will be designed according to the 4-stage principle [22]. Due to the different image representation capabilities of each stage block, shallow stage blocks retain more ceramic microscopic details, while deep stage blocks have a higher level of abstraction ability for ceramic microscopic images, which can extract higher-level semantic information. Based on the above characteristics, the chunking attention module has been added to the first and fourth stage blocks, respectively, to enable the model to model global key features, thereby combining low-level detail features with high-level semantic features. In this way, the model can fully utilize global contextual information and generate a more accurate characterization of ceramic microscopic images.

The number of 4-stage bottleneck structures in the entire backbone network is 3, 4, 6, and 3, respectively. In terms of feature channel changes, the model first performs feature convolution on the input image through a $7 \times 7$ large convolution kernel, and its output is a 64-channel feature tensor. Next, in the first bottleneck structure in stage-1, the number of channels is expanded to four times the original number, and the number of internal channels remains unchanged. Therefore, the feature output of this layer is a feature tensor of 256 channels. Afterward, the next three stage blocks will undergo the feature transfer in this form. The difference is that the first bottleneck structure of each remaining stage will be expanded by twice the number of channels, resulting in a final feature output channel of 2048. In terms of feature size changes, for the first bottleneck structure of each stage block, the convolution operations will be used to downsample the features transmitted from the shallow layer while maintaining the same feature size within each stage block. Therefore, the corresponding feature sizes within the four stage blocks are $(H/4) \times (W/4)$, $(H/8) \times (W/8)$, $(H/16) \times (W/16)$, and $(H/32) \times (W/32)$.

For the bottleneck structure proposed in this paper, in terms of cross-multi-scale fusion, the segmentation number of $s = 4$ has mainly been adopted to divide the feature channels. In terms of Chunking Attention, it is noted note that Spatial Chunking Attention helps the model capture spatial relationships and local details in images, while Channel Chunking Attention helps the model understand the interaction and importance of different channels. Therefore, the reasonable combination of Spatial Chunking Attention and Channel Chunking Attention can make the model extract more robust semantic features, so as to enhance the recognition ability of the model. In order to effectively integrate the key features obtained by the two modules, it is necessary to design a serial and parallel feature computing structure, as shown in Fig. 6 (b) and Fig. 6 (c). In the serial structure, it is designed to cascade the two modules and obtain the final feature representation through sequential calculation. In parallel architecture, it is designed to fuse the features of the two modules by adding them point by point. Experiments have shown that both structures exhibit excellent performance.

## IV. Experiments and Analysis

The experimental environment for the algorithm in this paper is a 64-bit Ubuntu 16.04.1 operating system with an Intel Core i9-10900k processor, 64GB of memory, an NVIDIA GeForce RTX 2080Ti graphics card, and a tensor operation library version of pytorch-1.8.1-cuda-10.1. This chapter will first introduce the collection of ceramic microscopic data, algorithm evaluation indicators, and experimental results, and analyze the results.

### A. Ceramic Microscopic Image Dataset

In this paper, a camera of 600 times optical is used to collect microscopic images of 12 pairs of 24 Blue and white pottery tea cups from Jingdezhen and Dehua Fig. 7). After manual filtering of some pictures that are not correctly focused, the final size of this ceramic data set is 1548 pictures. In terms of dataset production, 24 tea cups have been divided into 24 categories, and their data formats were defined according to the ImageNet dataset. The division ratio between the training set and the test set is 7 : 3.

To simulate the real ceramic imitation scene, the macroscopic shape of each pair of blue and white porcelain tea cups in the experiment will tend to be consistent. Therefore, if the model correctly classifies all the pictures on this dataset, especially the same pair of Blue and white pottery tea cups can be correctly classified. So, it can be considered that this model has high anti-counterfeiting performance for ceramics and can capture more essential and discriminative features in ceramic microscopic images. The number of samples collected for each pair of ceramic microscopic images is as shown in Fig. 8.

### B. Evaluation Indicators

To objectively and fairly evaluate the performance of the proposed model and its performance on ceramic microscope image data, this paper will select evaluation indicators widely used in machine learning to test the effectiveness of the proposed model. Mainly including Accuracy(Acc), Precision(Pre), Recall(Rec), F1-Score(F1) and Kappa(Kap). This paper also calculates mAUC and mAP based on the Receiver Operating Characteristic(ROC) curve and Precision-Recall (PR) curve, respectively.

$$mAUC = \frac{1}{n} \times \sum_{i\in n} AUC_i \tag{17}$$

$$mAP = \frac{1}{n} \times \sum_{i\in n} AP_i \tag{18}$$

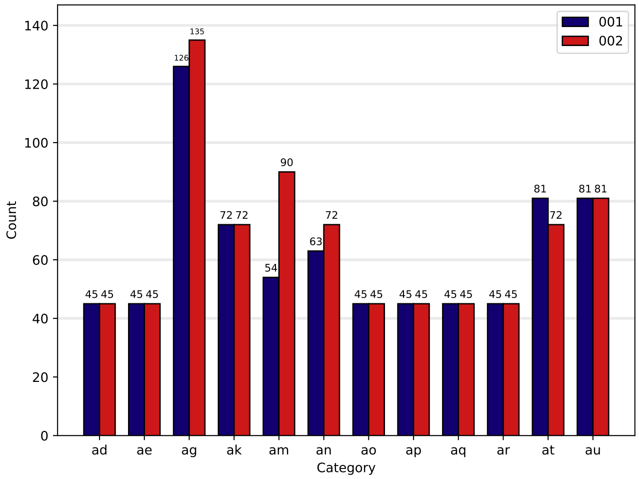

Fig. 8. The quantity distribution of ceramic microscopic image datasets.

In addition, due to the large number of learnable parameter weights in the neural network model used in this paper, including fully connected layers, convolutional layers, etc., its spatial and temporal costs are also worth paying attention to. Therefore, this paper will introduce Params, FLOPs, and inference time to evaluate the running cost of the model. Among them, Params represent the parameter quantity of the model, and FLOPs represent the number of floating-point operations of the model. It is worth noting that due to the presence of memory access costs (MAC), FLOPs cannot be equivalent to inference time. Therefore, we will calculate the average inference time for each ITERATION in the model.

### C. Ablation Experiments

This study adopted a classic image classification experimental process. In the pre-processing stage, it is scheduled to randomly cut the original image to 224 × 224 pixels of standard size and randomly flip it with a probability of 50% to enhance the robustness of the model to interference. For neural network parameter optimization, the AdamW optimizer has been chosen with an initial learning rate of 0.001, a momentum of 0.9, and a weight regularization term of 0.1. To ensure that the model is not heavily influenced by significant updates in the wrong direction during the early stages of training, a linear warm-up learning rate strategy, which gradually increases the learning rate from 0.0001 to the initial value of 0.001 over

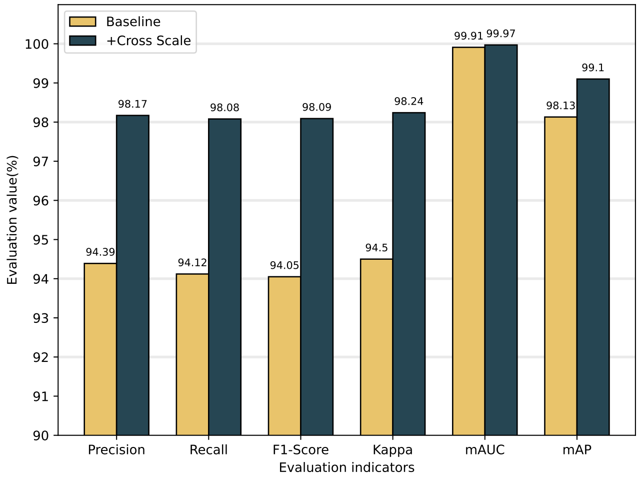

Fig. 9. Evaluation of the multi-scale fusion bottleneck structure in different indicators.

the first 30 epochs has been adopted. Then, for the following 370 epochs, a cosine annealing learning rate decay strategy has been employed. Through this training scheme, a total of 400 epochs, have been trained on the ceramic micro dataset and comprehensively evaluated the performance of the model on various indicators.

*1) Effect of the multi-scale fusion bottleneck structure on the experimental results:* To verify the effectiveness of the multi-scale fusion bottleneck structure on the ceramic microscope image dataset, the classic Resnet50 [22] has been selected as the benchmark and compared the changes in different evaluation indicators before and after replacing the multi-scale fusion bottleneck structure (see Table I). The results showed that the replacement of the multi-scale fusion bottleneck structure increased the Top1 Accuracy by 3.56%, reaching 98.32%, while the Top2 Accuracy increased by 0.42%, reaching 100%. From the gap between Top1 Accuracy and Top2 Accuracy, it can be seen that the model still has some performance degradation even when factors such as texture are consistent.

| Model | Params (M) | FLOPs (G) | Time (MS) | Top1-acc (%) | Top2-acc (%) |
|---|---|---|---|---|---|
| Baseline | 23.557 | 4.109 | 102.65 | 94.76 | 99.58 |
| +Cross Scale | 36.1 | 6.535 | 76.9 | 98.32 | 100.00 |

In terms of the number of parameters and the number of floating-point operations, due to the model's use of scale segmentation and the introduction of more convolutional kernels and cross-attention calculations, both indicators have correspondingly increased. It is worth noting that although the computational complexity of the model has increased, the adoption of a multi-scale fusion bottleneck structure with segmented scales enables the model to have a higher parallelism. According to the inference time test conducted on the GPU for the last batch of data in the test sample, the network that replaced this module showed a lower average inference time, reduced by 25.75ms.

Fig. 10. The evaluation performance of multi-scale fusion bottleneck structure in ROC and PR curves and the area under their curves.

As shown in Fig. 9, the Resnet50 model, which replaces the multi-scale fusion bottleneck structure, has improved all the six indicators in the figure. Among them, the Precision, Recall, F1 Score, and Kappa coefficients have significantly increased, with an increase of about 3%; While the increase of mAUC and mAP is relatively low, to explore the performance results of this module in the Receiver operating characteristic and PR curve, Data and information visualization have been conducted on the evaluation of various categories of ceramic microscopic images:

First, in Fig. 10 (a) ROC curve, the multi-scale fusion bottleneck structure is closer to the upper left corner than the baseline model in most cases, and the baseline model has some area gaps in most categories. Secondly, in Fig. 10 (b) PR curve, it can be intuitively observed that the multi-scale fusion bottleneck structure is generally closer to the upper right corner. Based on the above two points, it indicates that the improved multi-scale fusion bottleneck structure is effective in improving the classification accuracy of various categories.

On the other hand, for each class of ROC curves and PR curves, the AUC and AP metrics can be derived, respectively. As shown in Fig. 10 (c) and Fig. 10 (d), the performance of the baseline model and the multi-scale fusion bottleneck structure for these two metrics in the 24 categories of ceramic microscope image data. It can be observed that the multi-scale fusion bottleneck structure outperforms the baseline model

TABLE II. Comparison of Partial Results of the Chunking Attention under the Original Bottleneck Structure

| Model | Params (M) | FLOPs (G) | Time (MS) | Top1-acc (%) | Top2-acc (%) |
|---|---|---|---|---|---|
| Baseline | 23.557 | 4.109 | 102.65 | 94.76 | 99.58 |
| +PA | 37.143 | 6.06 | 74.80 | 94.76 | 99.58 |
| +CA | 49.966 | 6.677 | 92.42 | 95.39 | 99.79 |
| +PCA-Serial | 63.551 | 8.627 | 81.37 | 96.44 | 99.79 |
| +PCA-Parallel | 63.551 | 8.627 | 107.06 | 94.97 | 99.79 |

in most of the categories, especially on the data with more complex features like ap-002, which also has a higher recognition rate. To further verify whether the multi-scale fusion bottleneck structure is significantly superior to the baseline model in these two indicators, Wilcoxon signed rank test, a non-parametric hypothesis testing method that can compare the overall distribution differences between two paired samples have also been conducted. Here, R+ and R- respectively indicate the sum of ranks where the baseline model is greater than and less than the multi-scale fusion model in paired samples. In the testing process, the minimum value has been mainly chosen between these two as the test statistic. The larger the test statistic is the more significant the difference in the indicators will be. In this paper, hypothesis tests have been conducted at a significance level of $\alpha = 0.05$. For the AUC and AP metrics, the corresponding p-values are 0.0041 and 0.0027, both of which are smaller than the significance level $\alpha$; therefore, it is necessary to reject the null hypothesis $H_0$ and accept the alternative hypothesis $H_1$. This indicates that the multi-scale fusion bottleneck structure exhibits significant differences compared to the baseline model in both of these metrics.

In summary, in the ceramic microscope image recognition task, the multi-scale fusion bottleneck structure of this model is superior to the $3 \times 3$ convolution in the baseline bottleneck structure. In the improvement of related tasks, it can be considered to replace it with this module to achieve higher recognition accuracy.

*2) Effect of the chunking attention module combined with primitive bottleneck structure on experimental results:* To verify the effectiveness of the chunking attention module, Resnet50 has still been used as the baseline model in this section and trained spatial chunking attention (PA) and channel chunking attention (CA), as well as their serial fusion structure (PCA Serial) and parallel fusion structure (PCA Parallel). The changes have also been evaluated in different indicators on the ceramic microscopic image dataset (see Table II). Under the original bottleneck structure, the results showed that the PA module was able to achieve the same accuracy as the baseline model with an average inference time reduction of 27.85ms, while the CA module increased Top1 Accuracy and Top2 Accuracy by 0.63% and 0.21%, respectively, based on an average inference time reduction of 10.03ms. In the serial and parallel structures fused with PA and CA, the Top1 Accuracy has been improved by 1.68% and 0.21%, respectively, but there is a significant difference in time between the two structures.

It is observed that in the parallel structure, Top1 Accuracy decreased by 0.42% compared to the CA module. This difference may be related to the limited ability of $3 \times 3$ convolutions in the original bottleneck structure for feature extraction. Therefore, in a parallel structure, the PA and CA modules calculate two feature tensors with significant distribution differences, and adding them up may interfere with the high-quality features extracted by the channel attention module, thereby reducing the recognition performance of the model. On the contrary, cascaded serial structures can further model the relationships between channels based on global spatial modeling, thus being able to identify more significant ceramic microscopic features. Therefore, when the feature extraction ability of bottleneck structure is limited, priority should be given to using serial fusion to avoid performance degradation results from distribution differences.

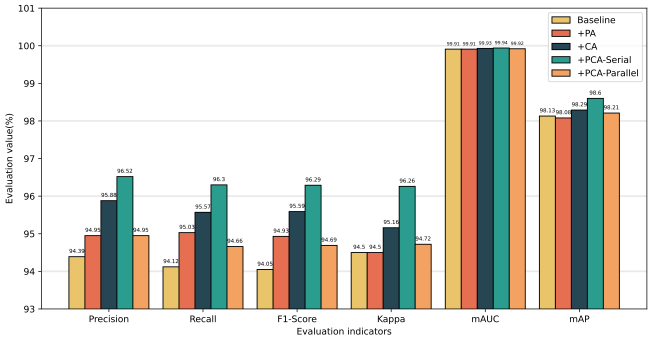

Fig. 11. Evaluation of the chunking attention module for different metrics in the original bottleneck structure.

Fig. 11 shows the performance of this module in other indicators, demonstrating the optimal effect by integrating spatial and channel chunking attention through a serial structure. At the same time, the improved model with only Spatial Chunking Attention and Channel Chunking Attention also has some improvement compared to the benchmark model, indicating that this module can further improve the micro recognition ability of the model in the benchmark model with comparatively limited representation ability.

In addition, when evaluating mAUC and mAP, the performance of different categories has been examined separately. From Fig. 12, it can be seen that the baseline structure with the addition of the PCA-Serial module exhibits the optimal level of classification ability for all categories. Table III shows the Wilcoxon signed rank test results for the baseline model and ablation module. Under the two evaluation indicators of AUC and AP, it can be concluded that the PCA-Serial module is significantly superior to the benchmark model, thus proving the effectiveness of the block-based attention module proposed in this paper.

*3) Effect of the chunking attention modules combined with multi-scale fusion bottleneck structure on experimental results:* To verify the effectiveness of the proposed chunking attention module in feature extraction modules with strong representation capabilities, this paper has been devoted to replacing the original bottleneck structure of Resnet50 with a multi-scale fusion bottleneck structure and using this as a baseline model for ablation experiments of spatial chunking attention (PA) and channel chunking attention (CA). According to the results in Table IV and Fig. 13, the model with the addition of the CA module showed significant improvement in various

indicators, while the PA module had almost no improvement in the model's recognition ability and even had inhibitory effects on certain indicators. It is believed that this suppression effect may be due to the modeling of multi-scale fusion structure and PA modules in the spatial dimension, resulting in mutual redundancy and suppression, exacerbating noise in the spatial dimension, and ultimately losing the recognition ability of some key features. However, in the module that integrates PA and CA, the channel chunking attention introduces much more robust channel information, which offsets the aforementioned suppression effect. Therefore, it further improves the recognition performance in both serial and parallel fusion structures. In particular, the parallel fusion structure further optimizes the inference time and achieves optimal results in all metrics compared to adding PA and CA modules separately.

## V. DISCUSSION AND CONCLUSIONS

In addition, it was observed in Fig. 14 that the model with PCA-Parallel showed a decrease in AUC and AP in very few ceramic samples, but according to the test results in Table V, the difference between these two indicators was not so significant compared to the baseline model. Based on the performance of various indicators, PCA-Parallel is still the best choice for ceramic microscope image recognition.

*1) Effect of different block attention embedding structures on experimental results:* Considering the potential impact of PA and CA on different stage blocks of the backbone model in the ceramic microscope image dataset, a series of combined experiments with different embedding structures have been designed to determine the optimal neural network architecture. As shown in Table VII, four embedding methods have been demonstrated: Version A represents embedding chunking attention modules into each stage block, which results in the maximum space and time overhead of the model. Version B only embeds chunking attention in stages like stage-1 and stage-4. It is believed that this structure can effectively establish the remote dependencies between low-level detail features and high-level semantic features. Version C means that all stages except stage-1 are embedded with chunking attention. This way will abandon the modeling of low-level details and focus on the expression of semantic information at different levels of abstraction. The D version only embeds chunking attention in the stage-4 stage, and compared to versions a, b, and c, the D version has the smallest space and time overhead.

As shown in Table VI, this section of the experiments was conducted on the three best-performing models from previous experiments. These models include the one based on

the original bottleneck structure with the addition of PCA-Serial and the one based on a multi-scale fusion bottleneck structure with the addition of PCA-Serial and PCA-Parallel, respectively. The experimental results are shown as follows:

In the original Resnet50 with the addition of PCA-Serial, the embedding structure of version A performed the best. From the evaluation results of different embedding structures, it can be found that the results of different indicators also show an overall upward trend as the number of chunking attention embeddings increases. This is consistent with the motivation of this study to explore the insufficient recognition ability of basic bottleneck structures. Therefore, chunking attention can effectively alleviate this defect and improve the performance of the model.

In the model with the addition of PCA-Serial and replacement of the multi-scale fusion bottleneck structure, chunked attention did not show a significant ability to improve, with versions B and D performing the best, with version D showing the best level of performance across a wide range of metrics. It is believed that the global modeling capabilities of the chunking attention fusion module and the multi-scale fusion bottleneck structure in a serial structure are equivalent. In some features, there is a coupling relationship between the recognition of these two structures. Therefore, simply modeling high-level semantic features can improve the effectiveness. However, in indicators sensitive to positive and negative samples, there is still some room for improvement in this structure. On the other hand, compared to the original Resnet50 model, this model has achieved an improvement of approximately 1% to 3%, further demonstrating the superiority of the multi-scale fusion bottleneck structure.

Finally, in the model that added PCA-Parallel and replaced the multi-scale fusion bottleneck structure, version B showed the best performance among all versions. Therefore, it is believed that the method of modeling remote dependencies based on both low-level and high-level semantic features proposed in this paper is effective. However, from other versions of this chunking attention fusion method, it can also be found that this method is more sensitive to the recognition ability of other

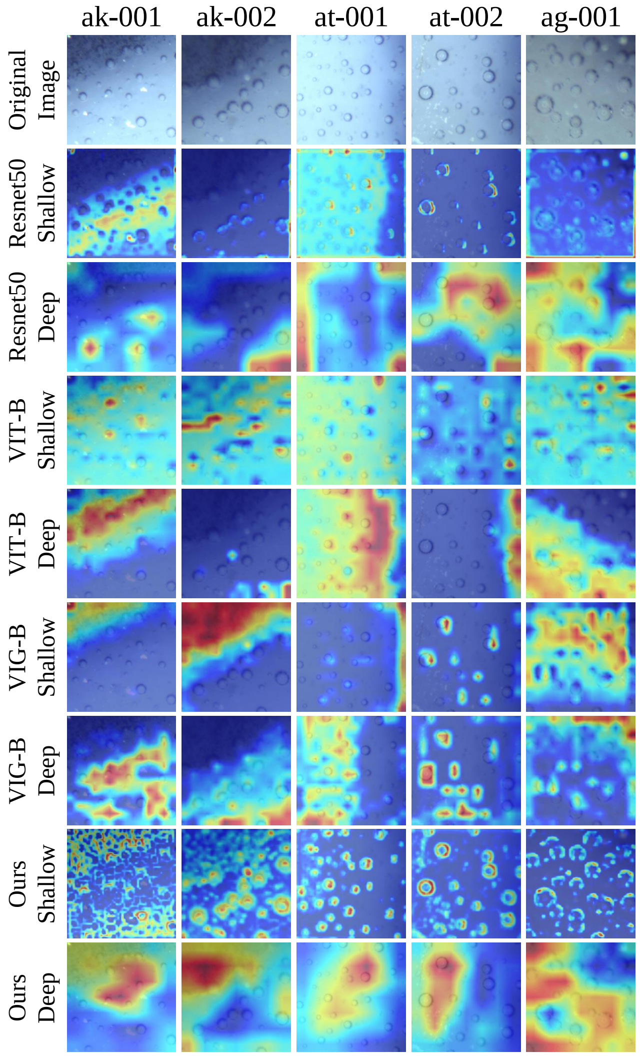

Fig. 16. Compare the Grad-CAM visualization results of deep and shallow modules in different models.

modules. For most application scenarios, there are serial fusion structures have better adaptability. Therefore, when selecting a model, specific data characteristics should be considered.

In summary, by integrating spatial and channel chunking attention modules into the network in different ways, it is very likely to maximize the advantages of each stage block of the model and enhance its performance in semantic feature extraction and recognition. These research results have further expanded the understanding of the attention mechanism of ceramic microscopic image data and provided valuable references for future similar map image classification tasks.

### A. Comparative Experiments

In this section, the proposed model has been proposed with the most classic and advanced backbone models in different fields of neural networks in recent years: VGG11[33], WResnet50[30], Resnext50[31], Densenet121[34], SEResnet50[24], Vision Transformer(VIT-B)[3], Conformer[35], MLP-mixer[36], Resnest50[32], Vision GNN (VIG-B)[38] and Hornet[37].

The detailed comparison results are as shown in Table VIII, indicating that the model proposed in this paper has achieved the best performance among all evaluation indicators. Fig. 15 shows the Confusion matrix of this model. It can be seen that all types of models show accurate prediction ability, and the matrix is approximately a diagonal matrix, which indicates that this model has good feature recognition ability. The first four Resnet-type models have shown relatively cutting-edge performance in ceramic microscope image recognition. In recent years, the improvement direction has mainly focused on attention mechanisms. The algorithm of combining chunking attention with multi-scale fusion bottleneck structure in this paper has refreshed the performance of various indicators of this type of model, providing a new baseline for subsequent research.

On the other hand, the results show that most models of the non-Resnet type models have a significantly lower recognition ability than this type of model. This is because compared to Resnet-type models, the extraction ability of other models is insufficient when modeling the relationship between global and local features, especially in the complex microstructure of ceramics, which can be amplified. Unlike this, models such as convolutions typically have stronger feature extraction capabilities. For example, convolutional-dependent networks such as Densenet121 and Conformer perform similarly to Resnet-type networks, and our improvement direction only needs to overcome the local dependencies of convolutional operations. Therefore, when dealing with ceramic micro recognition tasks, especially fine-grained image classification problems, priority should be given to neural network models such as convolution.

In addition, it is worth noting that VIG-B, a modeling method based on the relationship between Tokens, still has certain competitiveness in classification. The feature space belonging to this method is different from the Euclidean space adapted by traditional attention mechanisms. The relationship graph structure can make the extracted features more robust, so this is also a research direction worth exploring in future work.

### B. Visualization Analysis

To further demonstrate the superiority of this model, this model has been selected, Resnet50, VIT-B, and VIG-B, and five images have been randomly selected from the dataset for Grad-CAM class activation map visualization. The gradient thermal maps have been produced for both shallow and deep modules of each model.

From Fig. 16, it can be observed that in the shallow module section, this model captures the details of ceramic micro images more comprehensively than other models, and can effectively identify fine-grained details, such as bubble features and texture features on the ceramic micro surface. In the task of ceramic anti-counterfeiting recognition, the accurate recognition of this information directly affects the identification results. In contrast, although Resnet50 can capture individual details to some extent, its level of attention is limited. This also reflects the effectiveness of the chunking attention module and multi-scale fusion bottleneck structure in this model. Although both VIG-B based on graph structure and VIT-B based on self-attention can also cover some features, there are problems

| **Ours** | 2023 | 76.094 | 11.052 | 91.46 | **98.74** | **98.73** | **98.65** | **98.60** | **98.68** |

such as scattered and incomplete focus areas, which affect subsequent feature recognition. In the deep module section, due to the establishment of remote dependency and multi-scale fusion features in this model, it extracts more comprehensive semantic information. At the same time, our model reduces the attention to noise bubbles in some images, which is a key difference from models such as VIG-B, thereby improving the recognition accuracy of the model.

In addition, experiments have also been conducted by using the t-SNE feature clustering algorithm to cluster and visualize the model. It is designed to mainly compare the effects of VIT-B, VIG-B, Resnet50, MLP-mixer, and Hornet models. From Fig. 17, it can be observed that each model achieved certain results in partitioning 24 clusters. In comparison, convolution-based models are more effective in increasing the distance between different categories, whereas non-convolutional frameworks such as VIT-B and MLP-mixer are limited by their lower recognition accuracy and less clear boundaries between the output features. Compared to Resnet50, this model can reduce the spacing within the same cluster, which helps the model better complete feature classification tasks. This result further proves the effectiveness of the chunking attention module and multi-scale fusion bottleneck structure in this model.

Based on Resnet50, this study has proposed a segmented attention module and a multi-scale fusion bottleneck structure to improve the existing network model and applied it to the ceramic microscope image classification task for ceramic anti-counterfeiting. It is found that the current popular universal visual recognition deep learning model has certain limitations in complex ceramic micro feature recognition, and the recognition performance of Token-based models is not as good as that of convolutional-based models. However, the

Convolutional neural network model also has the problem of a limited Receptive field. Therefore, the two improved modules proposed in this study can break through this limitation to a certain extent and further enhance the recognition effect based on a Convolutional neural network.

After experimental verification, this model has improved recognition accuracy by 3.98% compared to the baseline model, and has also shown similar improvements in indicators such as recall rate. In the collected ceramic microscopic image dataset, this model has achieved a recognition accuracy of 98.74%, surpassing the recognition accuracy of mainstream models such as Vision Transformer by more than 20%. This result further confirms the viewpoint that convolution is more suitable for ceramic microscope image recognition tasks.

In summary, this improved model has demonstrated certain advantages in ceramic microscope image recognition and anti-counterfeiting tasks. In future work, it will note that ceramics also contain textual modal information such as place of origin, which may also play a certain role in ceramic recognition. However, effectively integrating data from different modalities and achieving consistent expected results is a relatively challenging challenge in this field. In the next step of our work, we plan to explore how to fuse features of different modalities to further improve the recognition accuracy of the model. We will focus on studying how to effectively integrate text information and image information to achieve more accurate ceramic recognition and anti-counterfeiting targets. At the same time, we also plan to explore the intrinsic characteristics of ceramics to further enhance the level of anti-counterfeiting technology. These works will provide certain assistance and promotion for the development and application of the ceramic anti-counterfeiting field.

# Weighted PSO Ensemble using Diversity of CNN Classifiers and Color Space for Endoscopy Image Classification

Diah Arianti[1], Azizi Abdullah[2], Shahnorbanun Sahran[3], Wong Zhyqin[4]
Centre of Artificial Intelligence-Faculty of Information Science and Technology, Universiti Kebagsaan Malaysia[1,2,3]
Bangi, Malaysia 43650, Hospital-Universiti Kebangsaan Malaysia, Cheras, Malaysia[4]

***Abstract*—Endoscopic image is a manifestation of visualization technology to the human gastrointestinal tract, allowing detection of abnormalities, characterization of lesions, and guidance for therapeutic interventions. Accurate and reliable classification of endoscopy images remains challenging due to variations in image quality, diverse anatomical structures, and subtle abnormalities such as polyps and ulcers. Convolutional Neural Network (CNN) is widely used in modern medical imaging, especially for abnormality classification tasks. However, relying on a single CNN classifier limits the model's ability to capture endoscopy images' full complexity and variability. A potential solution to the problem involves employing ensemble learning, which combines multiple models to reach at a final decision. Nevertheless, this learning approach presents several challenges, notably a significant risk of data bias. This issue arises from the unequal influence of weak and strong learners in most ensemble strategies, such as standard voting, which usually depend on certain assumptions, including equal performance among the models. However, it reduces the capability towards diverse model collaboration. Therefore, this paper proposes two solutions to the problems. Firstly, we create a diverse pool of CNNs with end-to-end approach. This approach promotes model diversity and enhances confidence in making a final decision. Secondly, we propose employing Particle Swarm Optimization to enhance the weight of the members in the ensemble learner in order to create a more resilient and accurate model compared to the standard ensemble learning approach. The experiment demonstrates that the proposed ensemble model outperforms the baseline model on both the Kvasir 1 and Kvasir 2 datasets, highlighting the effectiveness of the suggested approach in integrating diverse information from the baseline model. This enhanced performance highlights the efficacy of capturing diverse information from the baseline model.**

***Keywords*—Convolution neural network; particle swarm optimization; diversity; weighted ensemble***

## I. Introduction

The role of endoscopy images in diagnosing and treating gastrointestinal diseases is crucial. They provide a visual representation of the gastrointestinal tract, enabling the identification of abnormalities, characterization of lesions, and guidance for therapeutic interventions. The precise and reliable classification of these images continues to pose a significant challenge because of variations in image quality, diverse anatomical structures, and subtle abnormalities. These challenges highlight the need for the development of advanced techniques that can enhance classification accuracy and improve the overall effectiveness of endoscopic examinations. Computer-Aided Diagnosis (CAD) systems use advanced image processing techniques along with Artificial Intelligent (AI), Machine Learning (ML) and Deep Learning (DL) to provide reliable diagnoses. One of the remaining challenges in CAD is designing a system that can deliver the best satisfactory results for the recognition or classification in the diagnostic process. Previous research has established a crucial foundation for using Support Vector Machines (SVM) in identifying illnesses such as polyps and ulcers, as well as for leveraging Convolutional Neural Networks (CNN) in detecting bleeding [1], [2], [3], [4], [5]. Previous studies have mostly used single models for analyzing endoscopy images. However, these models may not fully capture the complexity and variability of the images. To address this limitation, an effective solution is to employ ensemble learning. This approach combines multiple models to predict a common target and make conclusive decisions, effectively mitigating bias and ultimately yielding higher-quality predictions compared to using a single classifier.

Ensemble learning has emerged as a prominent research area over the past few decades. In classification tasks, ensemble learning combines the strengths of multiple classifiers to improve overall performance by leveraging their diversity. The learning scheme distinguishes between two classifier concepts: strong and weak learner. Strong learners typically yield a lower error rate compared to weak learner, whereas weak learner predictions outperform random guessing [6]. The concept of weak and strong learners has developed into a more advanced ensemble approach known as Adaboost. This approach has further established the principles of bootstrapping and stacking. However, in the field of ML today, ensemble learning primarily revolves around bagging, boosting, and stacking. Bagging, which was originally proposed [7], significantly enhances the performance of models by applying a parallel sampling scheme to the dataset. Boosting methods, introduced in [8], train each subsequent model to rectify the mistakes made by the previous one. The classifiers in boosting are interdependent and rely on each other, leading to a collaborative learning process. The errors made by one classifier directly impact the performance of the next classifier. On the other hand, stacking involves utilizing a training model to combine predictions from multiple base learners in a diverse manner. By leveraging both base and meta learners, stacking offers a robust framework. Nevertheless, ensemble learning in ML is distinct from DL.

The predominant approach in DL research is the utilization of DL models to construct diverse model structures. This necessitates meticulous consideration of hyperparameter values, a process that demands significant time. To overcome this issue, researchers have started exploring automated hyperparameter optimization techniques in DL. This technique commonly involving the use of algorithms such as Particle Swarm Optimization (PSO) and Genetic Algorithms to explore the hyperparameter space and find the best combination for better model performance [9], [10]. However, automatic tuning of huge number of parameters in CNN is costly. On the other hand, fine-tuning with pre-trained weights, such as ImageNet, has been questioned in some research because it was found that the performance did not surpass that of random initialization [11], [12]. In addition, combining the DL model with different ML algorithms generates fair performance [13], [14]. Therefore, ensemble learning in DL is often presented in a simple ensemble structure, such as a standard average and majority voting approach. In the other hand, combining multiple models using those voting methods raises challenges, such as the increased risk of bias, especially when the baseline models have imbalanced performance [15].

As the remedy to the earlier problems mentioned above, in this paper primarily focuses on investigating a deep ensemble learning mechanism that underscores two crucial aspects essential for achieving successful ensemble performance: diversity and quality. As an initial step, we establish a diverse pool of Convolutional Neural Networks (CNNs). Our proposal focuses on two key aspects: (a) color transformation, and (b) model component. Furthermore, rather than relying on the average vote of the final decision among the models, we utilize Particle Swarm Optimization (PSO) to calculate the optimal weight for each individual model. This approach amplifies the strength of the more capable learners, resulting in a more resilient and precise outcome. Our main goal in this paper is to create the best combinations of models to effectively handle the wide range of variations and subtle abnormalities in the Kvasir dataset [16]. We are highly motivated to conduct this research as it is crucial for our future objectives, particularly in regard to handling actual hospital data that encompasses a diverse range of disease categories and types. Moreover, this research has the potential to assist researchers and practitioners in developing even more effective algorithms for diagnosing gastrointestinal conditions in patients with different disease categories and varying disease conditions.

In this paper, we have dedicated Section II to comprehensively discuss the existing research pertaining to our study. Building upon this literature review, we will elaborate on the methodology that we are proposing in Section III. Then, in the Section IV, we will present details about the dataset utilized, followed by a thorough discussion of the experimental results in Section V, and finally, a comprehensive conclusion in Section VI.

## II. Related Works

In a previous study by [17], researchers implemented an ensemble scheme to detect ulcers in endoscopy images. The scheme integrated multiple models such as KNN, MLP, and SVM, using a majority voting approach. The final test conducted on various color space input images demonstrated the superiority of RGB color over HIS and YCrCb, achieving an impressive accuracy of approximately 91.25%. Despite these advancements, the proposed approach has raised concerns about overfitting due to its minimal training data requirement. While, in [18], an automatic detection method for cervical precancer screening was introduced, using a larger total number of images. The authors propose a combination of three DL architectures: RetinaNet, Deep SVDD, and CNN. The ensemble model outperforms individual models in terms of performance; however, the accuracy of the results is compromised due to the presence of image noise, such as blurring. Based on the literature provided above, the use of ensemble learning extends far beyond the mere modeling of classifiers. It encompasses a crucial aspect, which is the preparation of the data prior to its input into the model. From this, it is evident that the differentiating factors among various ensemble methods revolve around the construction of the model and the fusion of the ultimate decisions. Consequently, it is important to explore two principal aspects: (i) the diversity of models, and (ii) the quality of models.

### A. Diversity

Model diversity refers to the process of generating multiple classifiers in order to introduce variation in the decision-making of the classifiers. Most of research aims to promote diversity by modifying various aspects of the network architecture, such as pre-processing data, tuning hyperparameters, and initializing weights. Data preprocessing is essential for successful classification. For example, as shown in [2], converting image data to the HSV color space and segmenting affected areas is essential for defining ulcer boundaries, thus enhancing the model's identification process. Utilizing different color spaces, such as YCbCr [3], has notably improved curvature identification accuracy using MLP. Additionally, incorporating hybrid techniques like CLAHE and Retinex can enhance polyp detection by preserving important elements like edges and texture [4], [19]. While in study [2] the utilization of filters such as Log Gabor and SUSAN corner detection greatly enhances the precision in identifying polyp boundaries using SVM. Further, CNN has numerous hyperparameters, including layer type, number of feature maps, number of neurons, kernel size, and weight. Automatically tuning all these hyperparameters with an optimization algorithm can be both costly and time-consuming. Therefore, narrowing the focus of evaluation to specific parameter such as weight can result in cost reductions.

Weight initialization in DL can be done in two main ways. The first way is by using a random distribution. The second way is by using a data-driven process. Using random initialization methods based on the Gaussian distribution can lead to slow convergence and saturated activations. To address the mentioned issue, [20] introduces an alternative approach to the one proposed by 'He' [21]. 'Glorot' assumes linear activations, while 'He' uses the ReLU activation function to introduce non-linearity in hidden layers, making 'He' initialization superior to 'Glorot' in certain DL models. Meanwhile, another Gaussian-based filter, Gabor, is a highly effective technique used to detect edges and textures in endoscopy images [2]. The Gabor filter breaks down images into different scales and orientations, allowing for a more accurate analysis of texture patterns. The Eq. (1) showcases the complex form of the Gabor filter, underscoring its intricate yet powerful capabilities.

$$G(x,y,\sigma,\theta,\lambda,\gamma,\Psi) = (-\frac{x'^2 + y^2y'^2}{2\sigma^2})exp(i(2\Pi\frac{x'}{\lambda}) + \psi)$$
$$x' = ccos\theta + ysin\theta$$
$$y' = -csin\theta + ycos\theta \quad (1)$$

In contrast, the data-driven approach, such as [22], builds a set of patches using training images to construct new weights. The weight in this network was generated using PCA filters. The process has three stages. The first and second stages involve PCA convolution over the image patches. The third stage is the output layer, which includes data processing components like binary hashing and block-wise histogram. This filter extracts distinctive features by generating various textures for different datasets. Eq. (2) explains the process of generating PCA filters from image patches. The size of the patch in the first stage is represented by k1 and k2.

$$W_l^n = f_{k1k2}(q_1XX^T) \in R^{k1k2}, l = 1, 2, ..., L_i \quad (2)$$

$$g_i = \left[Bhist(T_i^1), ..., Bhist(T_i^{L1})\right]^T \in R^{(2^{L2})L_1B} \quad (3)$$

$f_{k1k2}$ is a function that maps patches to the matrix W, which will then be multiplied by the principal eigenvector $XX^T$ . While in the second stage, it is repeating the same process as in the first stage. Further, in the final stage encodes the $L_i$ images into histogram values in each block and combines them into one vector using Eq. (3). $T_i$ is the feature of the input image, while B is defined as blocks, and then the histogram of decimal value is denoted with $2^{L_2}$ . The PCA filter, however, requires $k1k2 \geq L_1, L_2$ .

### B. Quality

In terms of quality, it refers to consolidating the variance of all individual decisions. Many strategies for combining votes depend on a basic average, known as a standard method. The average vote suffers from a major drawback in making accurate predictions due to its strong bias towards weak learners [15]. While, another approach is majority voting [14], [23], [24], which collects predictions for each class label and selects the one with the highest number of votes. However, this computation becomes expensive in larger ensemble schemes and irrelevant in low-variance individual model decisions. In response to the above drawback, a weighted ensemble technique was introduced in some research. In weighted ensemble, when evaluating the weight by using validation accuracy as a metric yields comparable results to the average-based method. This is especially true when the learners demonstrate similar or slightly varied levels of accuracy. In study [25] the use of exponential function aiming for higher accuracy, however, finding the most suitable function for particular dataset for the optimal solution can be a challenging task. Therefore, in [26], different weights are automatically assigned to the learners, reflecting the unique contribution of each learner to the prediction. This method has the advantage of automatic adaptation to the new database.

## III. Methodology

In this paper, we present an ensemble learning approach that focuses on two key elements mentioned above: diversity and quality. Fig. 1 illustrates the five main processes of the proposed methodology, with detailed information as follows:

- Color-based transformation and cluster intensity – In previous work, different color space transformations were used to create sub-features for different illness categories and variation in endoscopy images. Further details in Section III(A).
- Heterogeneous network – To enhance the CNN model's extraction results, it is crucial to increase the variety of parameters and architectures utilized. Further details in Section III(B).
- Heterogeneous weight initializer – In addition to implementing various CNN architectures, it is important to utilize a range of weight initializers, such as He, Gabor, and PCA, to optimize the extraction of edges and textures within images. Further details in Section III(C).
- Classifier amplification – In the final phase, an optimized weighting was proposed to quantify the strong classifier's contribution within the ensemble. Further details in Section III(D).

### A. Color-based Transformation and Cluster Intensity

Endoscopy images commonly utilize the RGB color channel representation. However, other well-known color channel representations, such as HSV, CIE-LAB, and YCrCb, are frequently employed in diverse medical image analyses. Various representations reveal abnormal patterns, such as color and geometric characteristics observed in cases of polyps and ulcers [2], [4], [13]. Drawing inspiration from the image capturing procedure [27], where the light source moves along one side of the narrow path within the GI tract, we make the assumption that objects closer to the light source tend to have higher luminance. Considering this, we propose three distinct region to tackle the complexity of intensity variation in image samples:

- The outer area (C1) – This region offers the most intense illumination. This area is designed to clearly identify any protruding objects in this region, such as polyps and folds in the colon.
- The inner area (C2) - This area is adjacent to the '*outer*' area. In this region, the blue area that surrounds the polyps in the 'dyed' category is expected to be distinct from the protruding part of the polyp.
- The junction area (C3) - This region is the farthest area from the source of light. We aim to identify the shared characteristics of renowned landmarks in this particular region, including the cecum, pylorus, and z-line.

We apply the k-means algorithm, with a maximum of 3 clusters, to determine the optimal solution for the given assumptions above. For this clustering process, we consider the gray image in RGB, the 'L' or luminance component in LAB,

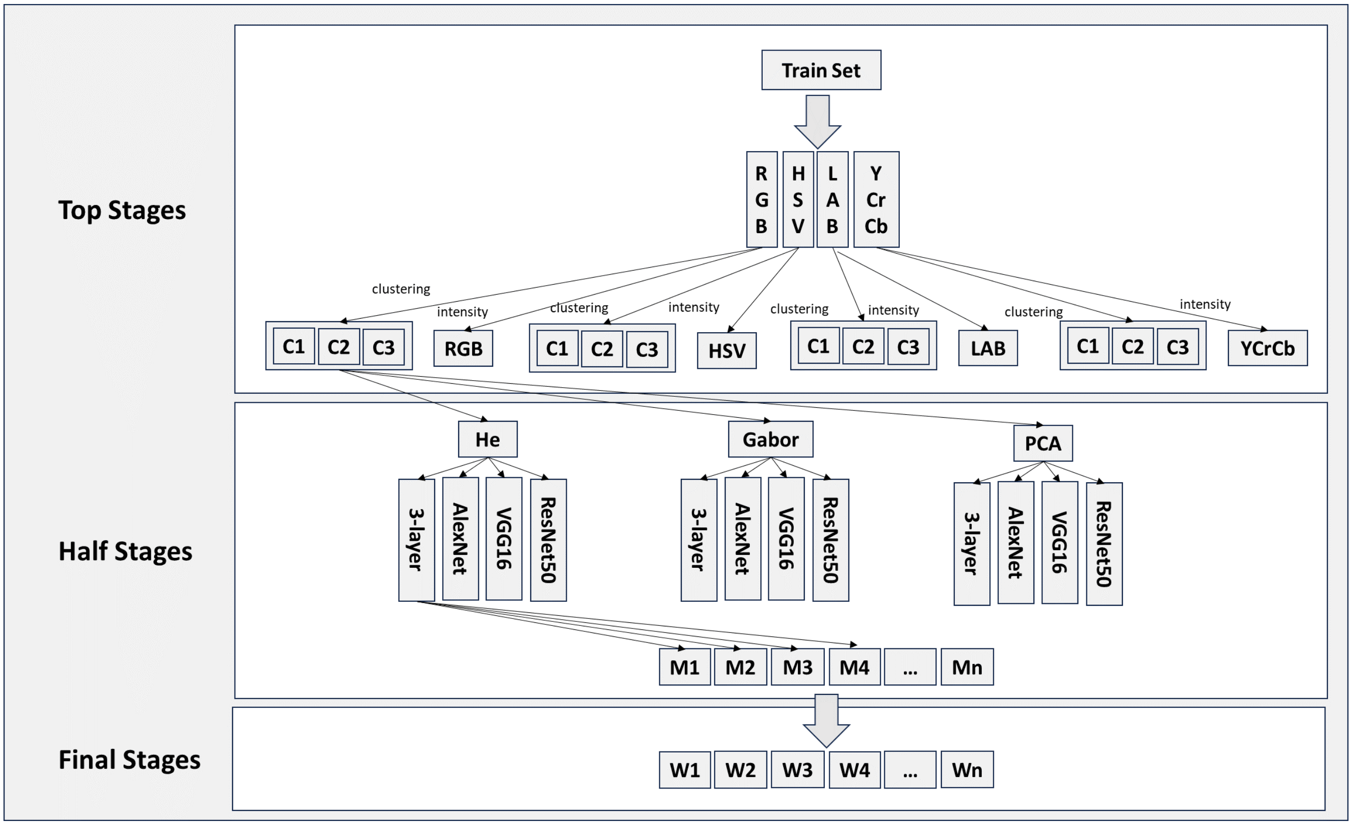

Fig. 1. The proposed ensemble architecture. The top stages focusing on preprocessing data, then in half stages focus on creating diverse CNN pool and the final stage focus more on classifier amplification.

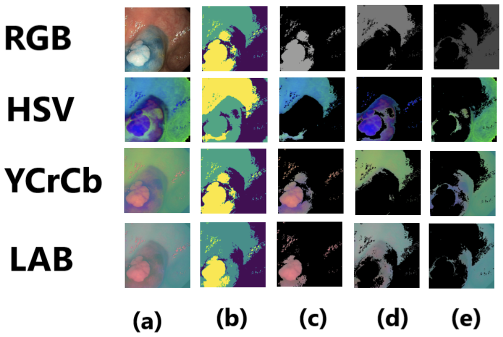

Fig. 2. Clustering of three distinct areas in the 'dyed lifted polyp' category: (a) Original image, (b) K-means cluster, (c) C1, (d) C2, (e) C3.

the 'Y' or luminance component in YCrCb, as well as the 'V' or value component in HSV. We use various intensity schemes to accurately represent tissue colors and ensure robustness to lighting variations. Fig. 2 displays an image transformation of four color channels from the Kvasir dataset in the 'dyed-lifted polyp' category. Column A shows the original images, while column B displays the three clusters obtained through the application of k-means clustering. Next, in column C, the outer area is revealed after the mask is applied to the original image. Column D showcases the inner area, followed by the junction area in column E.

### B. *Heterogenous Network*

Convolutional Neural Network (CNN) is widely regarded as one of the most popular deep neural network models. It is composed of powerful components such as convolutional layers, pooling layers, and non-linear activation functions [28]. In this paper investigates four different CNN architectures in the context of the study: a 3-layer CNN, AlexNet [28], VGG16 [29], and ResNet50 [30]. To emphasize the use of a shallow CNN architecture (3-layer network) in our proposed network, we have incorporated the branch CNN concept from [31]. The Branch CNN represents a new variation of the traditional CNN, implementing the concept of *"coarse to fine"* by establishing a separate branch on VGG16. One of the crucial features of this architecture is the inclusion of a weight in the loss function, which ensures a precise representation of the branch's influence on the overall loss.

$$L_j = \sum_{n=1}^{N} -W_n log \frac{e^{\mathrm{f}_y^a} j}{\sum_i e^{\mathrm{f}_i^a}} \tag{4}$$

Eq. (4) presents the entropy loss function ($L$) in conjunction with the weighted loss value. Branch implementation was not carried out in VGG16 as we had anticipated that the number of layers in AlexNet would align with those in VGG16 when incorporating branches. Furthermore, we are reducing the number of layers in AlexNet into 3-layer, while evaluating their potential to deliver equivalent performance improvements.

The weight loss values in the branch were determined by conducting three separate runs. This resulted in weight loss values of 0.4 for the 3-layers and 0.6 for AlexNet. In advanced configurations, the ReLU activation function is used along with the implementation of 8-fold cross-validation, ensuring a 70:30 ratio between training and validation. However, our focus lies on determining the highest level of accuracy from these variations. Furthermore, essential parameters such as the learning rate have been set at 0.001, while the optimizer follows the SGD algorithm. To mitigate the risk of overfitting, we have incorporated an early stopping mechanism, limiting the maximum epoch to 50.

### *C. Heterogeneous Weight Initializer*

This paper uses both the random-based and data-driven initialization techniques mentioned above, which are 'He' [12], Gabor, and PCA [22]. To create the "He" filter, we utilize existing libraries in Keras. On the other hand, for the Gabor filter, we generate a filter bank consisting of multiple filters with four different parameters ( $\sigma, \theta, \lambda, \gamma$ ). Considering that we employ a CNN consisting of multiple filters, we assume that the Gabor bank also consists of the same number of filters as the CNN. Next, PSO was utilized to obtain the parameters for Gabor filters. Inspired by [32] work, the proposed method apply SVM as an evaluator in order to find the best parameter values for each filter in the Gabor bank. Additionally, we anticipate addressing the distribution issue for each PSO particle value through a 'centroid' approach. Meanwhile, Fig. 3 exemplifies the outcomes of generating a filter using the PCANet concept on the Kvasir v1 datasetin training process. In part (a), we can observe the filter applied to VGG19, while in image (b) the filter is applied to AlexNet.

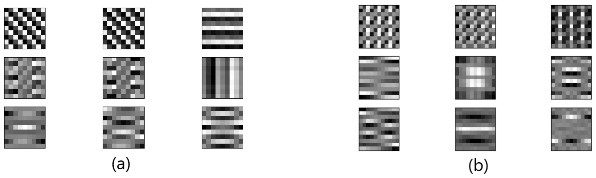

Fig. 3. Training samples of the PCANet with size 9x9 (a) VGG16 and 11x11 (b) on AlexNet using RGB-color data.

Finally, the various parameter combinations mentioned previously result in approximately 1536 models. Rather than generating the entire model as mentioned above, we opted for a simplified elimination strategy to expedite execution time. Our focus is on minimizing parameter variability in fold formation during cross-validation. This method entails selecting the best-performing model based on the average accuracy across folds. In this case, we simply choose RGB and YCrCb color transformation with the 'He' as part of this selection. The number of models in the experiment is reduced by approximately 87.5%. The proposed CNN pool finally contains a total of 192 baseline models.

### *D. Classifier Amplification*

Assuming a balanced performance across all learners, it is essential to assign equal weight to each classifier, similar to the standard average ensemble scheme. However, the diverse concepts in ensemble learning can lead to imbalanced performance, which can ultimately affect the overall performance. Thus, in the proposed approach, we utilize a swarm-based optimization algorithm, PSO to fine-tune the weight and achieve a balanced outcome. In [Eberhart, 1995] introduced PSO, a population-based evolutionary computational algorithm that solves optimization problems involving a lack of domain knowledge. The population is like a flock of birds that can maintain individual position and speed while flying in a specific direction. The standard PSO formulation is described by Eq. (5)

$$V_i = \omega V_i + c_1 r_1 (Pbest - X_i) + c_2 r_2 (Gbest - X_i) V_{i+1} = X_i + V_i \tag{5}$$

$V_i$ and $X_i$ represent the velocity and current position of particle i, while Pbest is the best personal position and Gbest is the best global position for all particles in the population. $\omega$ represents the inertia weight. c1 and c2 are the acceleration coefficients that improve the exploitation ability of each particle. r1 and r2 are the random numbers that increase exploration ability. PSO is more focused on searching for values in space based on velocity, in contrast to other optimization algorithms like Genetic Algorithm (GA). Therefore, PSO is suitable for continuous-valued problems and enables faster convergence [32]. Fig. 5 illustrates the proposed algorithm for fine-tuning the weights. In the beginning, it involves 20 particles, each representing an individual agent within the ensemble. These agents collaborate to discover the weight combination that delivers the highest accuracy performance. The accuracy of the ensemble, using the optimal weight from the best personal weight (pBest), is employed to compute f. If the pBest outperforms the current best global weight (gBest), then gBest is updated with the new pBest. Throughout the 100 epochs, the agent with the highest final accuracy in gBest is deemed the top agent. Eq. (6) is employed to initialize the PSO inertia weight.

$$\omega_i = \omega_{max} - (\frac{\omega_{max} - \omega_{min}}{max_{iter})}) * i \tag{6}$$

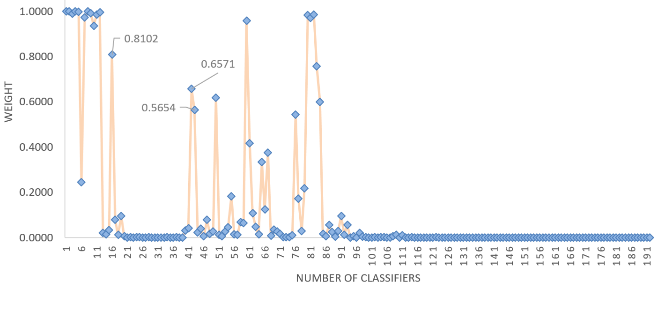

Fig. 4. The optimum PSO weight on the best performance of the proposed method.

## IV. Dataset and Metrics

### *A. Dataset*

We used the Kvasir dataset [16], which contains images of patients' upper and lower gastrointestinal tract including normal and pathological findings such as polyps and ulcers.

There are two versions of the Kvasir dataset, which are v1 and v2. The first version has 500 images in each class, with eight total classes. Thus, we have 4000 images. The dataset's original resolution varied from 720 × 576 to 1920 × 1072. Then, it is cropped and resized to a resolution of 227 x 227. While the second version contains 1000 images per category, half were available in the first version. Thus, since we use the first version for training, then in total, we have new test data from Kvasir v2, which is about 4000 total images. As in the training process, we use 80% of Kvasir v1. To reduce the risk of overfitting in our baseline model, we apply data augmentation techniques such as zoom, shear, rotate, and width shifting to the training set. Thus, after augmentation, the total training dataset contains 16,800 images. During testing, we used two datasets: Kvasir v1 with 800 images and Kvasir v2 with 4000 images.

### B. Metrics

This paper uses performance metrics such as accuracy, precision, sensitivity, and specificity to evaluate our baseline and proposed method. Accuracy describes the ability of the model to detect the correct classes in this classification as shown in Eq. (7):

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \tag{7}$$

TP (True Positive) is when the input is correctly predicted as positive. TN (True Negative) is when the input is correctly predicted as negative. FP (False Positive) is when the input is incorrectly predicted as positive. FN (False Negative) is when the input is incorrectly predicted as negative. In contrast, sensitivity is the ratio of true positives found to positives in the dataset as shown in Eq. (8).

$$Sensitivity = \frac{TP}{TP + FN} \tag{8}$$

Specificity is the ratio of true negatives found to negatives in the dataset as shown in Eq. (9).

$$Specificity = \frac{TN}{TN + FP} \tag{9}$$

Afterwards, the precision of the prediction can be measured by calculating the amount of positive predictive data, as indicated in Eq. (10).

$$Precision = \frac{TP}{TP + FP} \tag{10}$$

## V. Experimental Result

This section categorizes the experiment into two main objectives based on the insights gained from developing a solution. First, it delves into analyzing the impact diversity concept in ensemble learning. Second, identifying strong and weak learners is important for dealing with the significant impact of weight amplification in our system. This approach allows us to clearly observe the most influential learners in the proposed method.

### A. Diversity Impact in Proposed Scheme

In this context, three main group experiments need to be conducted. The first group comprises 12 models that utilize the RGB color space without clustering (see Table I-c and f). This group was formed to assess the impact of the classifiers, particularly those that demonstrate the higher accuracy within the pool. Next, in the second group, 48 models from 4 different color spaces (RGB, YCrCb, HSV, and LAB) without clustering were created to determine the comparison of contributions with the first group (see Table I (d) and (g)). The performance of groups 1 and 2 was significantly different, particularly regarding the RGB and non-RGB input models. Then the third group contains all the proposed models in the pool, namely 192 models (see Table I (e) and (h)).

In standard approach with Kvasir v1, the top-1 baseline accuracy for the third group was achieved using AlexNet and Gabor filter with RGB color space, without clustering. This single model accuracy, in training, reaches about 88.7% and in testing it achieved 84% accuracy. In this scenario, the standard ensemble enhances accuracy by approximately 1%. Further, by focusing only on the first group, the risk of overfitting was minimized. Further, the issue was resolved using the second group test. In this case, the accuracy of the model increased by approximately 6% compared to the baseline. While in the proposed method, experiments in the first group yielded significant results, as did those in groups two and three. As diversity increases, accuracy also increases. This demonstrates the presence of distinct features within each existing group. Interestingly, this stands in contrast to the performance of the standard method. However, in reality, maintaining a balance of performance among a collection of models can be quite challenging, particularly if the goal is to decrease the execution time for generating models. Based on the significant differences in tests in first groups (average accuracy is 81.9%) and second groups (average accuracy is 68.8%), there is no guarantee that maintaining balance in overall model performance will result in improved performance. This is a notable weakness of the standard ensemble model. Additionally, the data from Kvasir v2 showcases that experiments involving all three groups consistently show instability in standard approach, especially when compared to the proposed method.

### B. Strong and Weak Learner

In this scenario, the experiment was conducted 50 times, yielding results that demonstrate the tremendous potential of the proposed method in enhancing the accuracy of the maximum single model. Specifically, our findings reveal an improvement of 7%. (see Table I (b) and (h)). Although the model has imbalanced performance, the accuracy was improved after classifier amplification. Fig. 4 shows the optimum weight value after amplification on the training dataset. The strong learner is identified by a weight greater than the mean, while the weak learner is identified by a weight smaller than the mean. According to the data in Fig. 4, there are 30 strong learners in this group, with most of the top 15 strong learners coming from the RGB color space without clustering. However, there are three learners among the strong learners coming from YCrCb intensity clustering in C1 and C3 (it was labelled in Fig. 5 – C1 is 0.8102 and C3 with 0.6571 and 0.5654). Furthermore, the experiment was continued excluding

TABLE I. The Performance Comparison of the Proposed Scheme and Standard Scheme on Test Data

| Kvasir v1 | Accuracy | 0.6050 | 0.8400 | 0.8788 | 0.9000 | 0.8500 | 0.8900 | 0.8988 | 0.9100 |
| | Precision | 0.5975 | 0.8474 | 0.8820 | 0.9008 | 0.8576 | 0.8927 | 0.9000 | 0.9108 |
| | Sensitivity | 0.6057 | 0.8400 | 0.8788 | 0.9000 | 0.8500 | 0.8900 | 0.8988 | 0.9100 |
| | Specificity | 0.6063 | 0.8401 | 0.8788 | 0.9000 | 0.8502 | 0.8901 | 0.8988 | 0.9100 |
| Kvasir v2 | Accuracy | 0.8530 | 0.8918 | 0.9153 | 0.8540 | 0.8760 | 0.9143 | 0.9098 | 0.9158 |
| | Precision | 0.8614 | 0.8964 | 0.9179 | 0.8821 | 0.8882 | 0.9169 | 0.9175 | 0.9228 |
| | Sensitivity | 0.8530 | 0.8918 | 0.9153 | 0.8540 | 0.8760 | 0.9143 | 0.9098 | 0.9158 |
| | Specificity | 0.8532 | 0.8918 | 0.9153 | 0.8545 | 0.8763 | 0.9143 | 0.9099 | 0.9159 |

weak learners, and achieved the identical level of accuracy as when weak learners were involved, specifically 91%. However, performance decreased when tuning the weights for the 30 classifiers mentioned earlier, dropping by around 0.875%. Additionally, Table II demonstrates the impact of the proposed clustering method on various color spaces by showing the most influential learner based on color intensity clustering after 50 runs. It indicates that YCrCb is the only color space that influences significantly the performance of the proposed method. While the other learner still makes a contribution, their impact on the proposed scheme's performance is very limited.

## VI. Conclusion

This study introduces a CNN-based ensemble method designed to enhance the accuracy of classifying the Kvasir dataset. The experimental results demonstrate that the proposed method surpasses the standard approach by delivering consistent performance across diverse test datasets. The utilization of color intensity-based clustering prioritizes notable features, particularly in abnormal cases such as polyps, ulcers, esophagitis, and "dyed" categories. By employing various CNN hyperparameters to create a range of models in the ensemble, the risk of overfitting is reduced in both the standard and proposed methods. This approach not only enhances the learning process but also unveils the potential of features in various color space transformations and color intensity-based clustering.

In conclusion, we can summarize the findings and drawbacks as follows: Firstly, the Kvasir dataset displays unique characteristics when the data is converted into different color spaces, such as RGB, HSV, YCrCb, and LAB. Secondly, clustering a specific region within the image, specifically related to conditions like polyps and ulcers, leads to diverse responses and significantly impacts the overall performance of the model, particularly in the YCrCb color space. However, this imbalance in the overall model performance hinders the attainment of a high standard ensemble accuracy. Even after trying different pre-processing methods, the accuracy is still consistently lower compared to datasets that are not clustered. Moreover, it is essential to enhance the diversity of models in order to achieve optimal results with the proposed method. Simultaneously, by amplifying the learner, we can effectively mitigate the risk of overfitting in the standard scheme. It is important to note that both mechanisms are crucial for improving the scheme's overall performance. Moreover, the 3-layer network architecture is an integral part of AlexNet and incorporates the concept of branch CNN. Conducting experiments with other network types could potentially yield significant advantages in addressing the limitations of the proposed method, such as applying it to VGG16. Furthermore, we recommend utilizing alternative search algorithms, such as genetic algorithms or the Bee's algorithm, to boost mutation capacity during the training phase and decrease the execution time required to generate Gabor banks.

# Research Octane Number Prediction Based on Feature Selection and Multi-Model Fusion

Junlin Gu
Jiangsu Vocational College of Electronics and Information, China

***Abstract*—The catalytic cracking-based process for lightening heavy oil yields gasoline products with sulfur and olefin contents surpassing 95%, consequently diminishing the Research Octane Number (RON) of gasoline during desulfurization and olefin reduction stages. Hence, investigating methodologies to mitigate RON loss in gasoline while maintaining effective desulfurization is imperative. This study addresses this challenge by initially performing data cleaning and augmentation, employing box plot modeling and Grubbs' test for outlier detection and removal. Subsequently, through the integration of mutual information and the Lasso method, data dimensionality is reduced, with the top 30 variables selected as primary factors. A predictive model for RON loss is then established based on these 30 variables, utilizing random forest and Support Vector Regression (SVR) models. Employing this model enables the computation of RON loss for each data sample. Comparing with existing methods, our approach could ensure a balance between effective desulfurization and mitigated RON loss in gasoline products.**

***Keywords*—Feature selection; random forest model; support vector machine model; RON loss**

## I. Introduction

Gasoline stands as a cornerstone of automotive fuels, yet its combustion releases harmful substances into the atmosphere, notably sulfur and olefin components. Given that gasoline production predominantly hinges on heavy oil as a feedstock, characterized by high impurity levels, the quest for cleaner gasoline has emerged as a central concern within the industrial sphere.

The Research Octane Number (RON) serves as a crucial indicator of gasoline's ability to withstand compression ratios. In scenarios where gasoline attains high quality, devoid of impurities and undesired chemical substances, the RON stands as the most scientifically robust, precise, and widely embraced benchmark for evaluating gasoline's actual performance. However, the presence of desulfurization and olefin reduction technologies often leads to a decrease in gasoline's RON, directly impacting economic efficiency. Consequently, within the realm of catalytic cracking gasoline production, the focus has shifted towards reducing sulfur and olefin content while preserving RON.

Currently, numerous scholars are actively engaged in researching the accurate calculation of Research Octane Number (RON). Regression analysis methods are commonly employed for constructing RON prediction models owing to their simplicity and convenience [1]. However, in industrial settings, collected data may contain unnecessary redundancies, leading to collinearity issues among variables. To address this challenge, some researchers have proposed algorithmic enhancements aimed at eliminating data collinearity.

Kardamakis et al. [2] were among the first to utilize Linear Predictive Coding (LPC) to process noise and eliminate collinearity, subsequently employing the MLR algorithm to construct an RON prediction model based on near-infrared spectroscopy. Similarly, Benavides [3] introduced regularization to constrain the objective function of MLR, effectively resolving collinearity issues. They further combined ridge regression with near-infrared spectroscopy to develop an RON prediction model. Moreover, recognizing the limitations of traditional single models in addressing diverse and complex operating conditions, Xie et al. [4] proposed a research-based RON prediction model utilizing the random forest regression algorithm. Wang et al. [5], by optimizing the desulfurization process, established an RON loss model using residual analysis and the least squares method, analyzing the impact of reducing operational steps on decreasing RON loss during desulfurization. Furthermore, Liu et al. [6] incorporated gasoline RON as one of the modeling variables and constructed a prediction model based on the principles of random forest classification, with gasoline RON as the dependent variable, to predict RON loss during the desulfurization process.

Despite the significant progress made by numerous scholars in RON prediction research, meeting increasingly stringent fuel standards and the growing demand for accurate RON predictions remains challenging.

Given the complex and variable nature of operating conditions, this paper focuses on the RON and sulfur content of the products. To establish a predictive model for RON loss, we utilized a large volume of historical data accumulated over nearly four years from a petrochemical company's refining and desulfurization unit, and employed data mining techniques [7] to construct an optimization model. The main contributions of this paper are as follows:

1) We employed box plot modeling and Grubbs' test to pinpoint data samples and eliminate outliers. Subsequently, in conjunction with mutual information and the Lasso method [8], we performed dimensionality reduction on the data variables to select the key variables.
2) We established a prediction model for Research Octane Number (RON) loss using the random forest and support vector regression (SVR) models [9]. This model facilitated the computation of RON loss for each data sample.
3) We employed the conjugate gradient method [10] to

establish an optimization model for the key variables, ensuring that the sulfur content of the product does not exceed 5 $\mu$g/g while RON loss remains below 30%. We used the random forest model [11] to optimize the key variables in the data samples, progressively reducing RON loss by iteratively adjusting operational variables.

In the forthcoming sections of this paper, we delineate a structured approach. Section II furnishes the preliminary knowledge essential to our scheme, while Section III describes the details of our proposed solution. Section IV describes our experimental results and analysis. Finally, Section V offers a conclusion of our study.

## II. Preliminary Knowledge

The scheme proposed in this paper mainly involves techniques such as data preprocessing, feature selection, and feature extraction. This section provides an introduction to these pertinent technologies.

### A. Data Pre-processing

*1) Box plot model:* The samples of data that fall outside the operational range were detected and removed using the box plot method [12]. Box plot not only provides a visual representation of identifying outliers in the dataset, but also helps determine the dispersion and skewness of the data. It consists of five values: the minimum value (min), the lower quartile (Q1), the median, the upper quartile (Q3), and the maximum value (max). The lower quartile, median, and upper quartile together form a "box with whiskers" structure. A line extends from the upper quartile to the maximum value, and this line is referred to as the "whisker".

The whiskers in the box plot are used to identify and remove outliers from the skewed population. In this context, the maximum and minimum values are set as 1.5 times the interquartile range (IQR), which is the range between the upper and lower quartiles. Specifically, the whiskers extend up to a distance of 1.5 times the IQR from the upper and lower quartiles. The formula of IQR is as follows:

$$IQR = Q3 - Q1. \tag{1}$$

The IQR also represents the length of the box plot. Therefore, the minimum value (min) and maximum value (max) can be determined as follows:

$$min = Q1 - 1.5 \times IQR. \tag{2}$$

$$max = Q3 - 1.5 \times IQR. \tag{3}$$

When applying the box plot analysis to data, if there are outliers that fall below the minimum observed value, the lower whisker is set at the minimum observed value, and the outliers are individually marked as points. If there are no values lower than the minimum observed value, the lower whisker extends to the minimum value. Similarly, if there are outliers that exceed the maximum observed value, the upper whisker is set at the maximum observed value, and the outliers are individually marked as points. If there are no values greater than the maximum observed value, the upper whisker extends to the maximum value.

*2) Grubbs' criterion model:* Based on Grubbs' criterion ($3\sigma$ criterion) [13] for removing outliers from a sample, we first assume that the measured variable is measured with equal precision, resulting in $x_1$, $x_2$, ..., $x_n$. Then, we calculate the arithmetic mean $x$ and the residual errors $v_i = x_i - x$ (for i=1,2,...,n). Based on these variables, we use the Beale's formula to calculate the standard error $\sigma$. If there exists a measurement value $x_b$ with a residual error $v_b$ (1¡=b¡=n) satisfying —$v_b$—=—$x_b - x$—¿$3\sigma$, it is considered an outlier with a gross error and should be removed. The Beale's formula is given as follows:

$$\sigma = [\frac{1}{n-1}\sum_{i=1}^{n} {v_i}^2]^{1/2} = \{[\sum_{i=1}^{n} {x_i}^2 - (\sum_{i=1}^{n} x_i)^2/n]/(n-1)\}^{1/2} \tag{4}$$

### B. Feature Selection

*1) Mutual information model:* Mutual information [14] is a useful information measure in information theory that quantifies the amount of information contributed by the occurrence of one event to the occurrence of another event. It can be viewed as the amount of information about one random variable contained in another random variable or as the reduction in uncertainty of one random variable due to the knowledge of another random variable. Mutual information graph is shown in Fig. 1.

Let the joint distribution of two random variables (X,Y) be denoted as p(x,y), and their marginal distributions be denoted as p(x) and p(y), respectively. The mutual information I(X,Y) is the relative entropy between the joint distribution p(x,y) and the marginal distributions p(x), p(y). According to the definition of entropy, the derivation formulas are as follows.

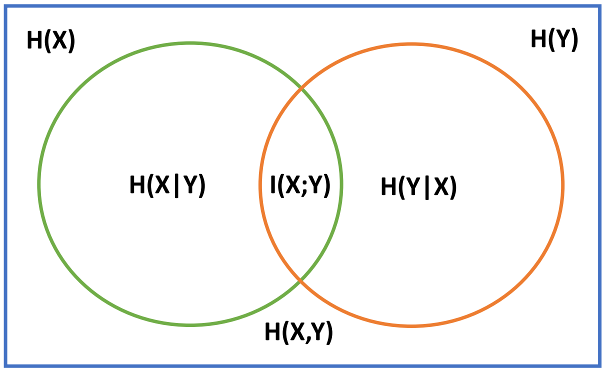

Fig. 1. Mutual information graph.

$$H(X,Y) = H(X) + H(Y|X) = H(Y) + H(X|Y), \tag{5}$$

$$H(X) - H(X|Y) = H(Y) - H(Y|X). \tag{6}$$

Therefore, the final calculation formula is as follow:

$$I(X;Y) = \sum_{x\in X}\sum_{y\in Y} p(x,y)log\frac{p(x,y)}{p(x)p(y)}. \tag{7}$$

*2) Lasso regression model:* The Lasso method is a compression estimation technique based on the idea of shrinking the variable set. By constructing a penalty function, it compresses the coefficients of the variables and forces some regression coefficients to become zero, thereby achieving variable selection.

Regularization [15] is a method to prevent overfitting, which usually occurs when there are too many variables or features. In such cases, the resulting equation can fit the training data very well, with a loss function that may be very close to or equal to zero.

However, such a curve may fail to generalize to new data samples. In regularization, all feature variables are retained, but the magnitude of the feature variables is reduced. When there are many feature variables, each variable can have some impact on the prediction. Lasso regression adds L1 regularization to the loss function. The coefficients trained by Lasso regression are sparse and can be used for feature selection. Because the absolute value function is not differentiable at zero, directly applying gradient descent is not feasible. Therefore, alternative algorithms such as coordinate descent are used. Coordinate descent method [16] updates one attribute at a time, and the loss function is given as follows:

$$L(w) = f(w) + \lambda \left\|w\right\|_1^1 = \left\|y - X^T w\right\|_2^2 + \lambda \left\|w\right\|_1^1. \tag{8}$$

### C. Regression Model

*1) Random forest model:* In machine learning [17], a random forest is a classifier that consists of multiple decision trees, and its output class is determined by the majority vote of individual tree outputs. Random forests have several advantages which can produce highly accurate classifiers for various types of data, handle a large number of input variables, and evaluate the importance of variables when determining class labels. During the construction of the forest, they can generate unbiased estimates of generalized errors, and they can balance errors for imbalanced classification datasets. The specific algorithm is as follows:

1) Let N represent the number of training examples and M represent the number of features.
2) Input the number m of features to determine the decision result at a node in the decision tree, where m should be much smaller than M.
3) Randomly sample N times with replacement from the N training examples (samples) to form a training set, and use the unsampled examples (samples) for prediction to evaluate their errors.
4) For each node, randomly select m features, and the decision at each node in the decision tree is based on these features. Based on these m features, compute the optimal splitting method.
5) Each tree grows fully without pruning, which may be adopted after building a complete tree-based classifier.

When tuning the parameters of a random forest using sklearn [18], it is significant to perform parameter tuning based on the relationship between generalization error and model complexity. By assessing the impact of parameters on the model, they can be sorted in descending order of influence, determining which parameters reduce model complexity and which ones increase it. Suitable parameters are then selected sequentially, and parameter tuning is carried out through methods such as plotting learning curves or performing grid searches, until the maximum accuracy score is achieved.

The prediction error rate of a random forest depends on two factors: the correlation between any two trees in the forest and the classification ability of each individual tree. Higher correlation leads to a higher error rate. The stronger the classification ability of an individual tree, the stronger the overall classification ability of the entire forest. If, within a tree, samples split based on a certain feature m are more likely or less likely to split on feature $k$, there exists a certain degree of interaction between $m$ and $k$.

The key issue in building a random forest is how to select the optimal value of $m$. To address this problem, the calculation of the out-of-bag error (oob error) [19] is crucial. One important advantage of random forests is that there is no need for cross-validation or an independent test set to obtain an unbiased estimate of the error. It can be internally evaluated, meaning that an unbiased estimate of the error can be established during the generation process. When constructing each tree, we utilize different bootstrap samples (randomly and with replacement) from the training set. Consequently, for each tree (let's assume the k-th tree), approximately one-third of the training instances are not involved in the generation of the k-th tree. These instances are referred to as the oob samples for the k-th tree.

Such sampling characteristics allow us to perform the oob estimation, and its calculation method is as follows:

1) For each sample, compute its classification by the trees for which it serves as an oob sample (approximately one-third of the trees).
2) Use a simple majority vote as the classification result for that sample.
3) Finally, calculate the oob error rate of the random forest as the ratio of misclassified samples to the total number of samples.

*2) Support vector regression model:* Support Vector Machine (SVM) [20] is a classification algorithm that can also be used for regression, offering different models based on the input data. By seeking to minimize structured risk, SVM enhances the generalization ability of the learning machine, achieving the minimization of empirical risk and confidence interval. This allows obtaining good statistical patterns even with limited statistical samples. In simple terms, SVM is a binary classification model, with the basic model defined as the linear classifier in feature space with the maximum margin, known as the maximal margin classifier. The learning strategy of SVM is to maximize the margin, ultimately transforming into solving a convex quadratic programming problem.

In Support Vector Regression (SVR) [21], the objective is to find a regression plane that minimizes the distance between the plane and a set of data points. SVR is an important application branch of Support Vector Machines (SVM). In traditional regression methods, a prediction is considered correct only if the regression function $f(x)$ is exactly equal to $y$. However, in support vector regression, a prediction is considered correct as long as the deviation between $f(x)$ and $y$ is not too large. In other words, if the absolute difference between the predicted value $y(x)$ and the target value $t$ is smaller than $\epsilon$, the error given by the error function is zero, where $\epsilon$ ¿ 0.

The regularization error function is as follows.

$$C\sum_{n}[E_{\varepsilon}(y_n-t_n)]+\frac{1}{2}\left\|w\right\|^2, y_n-\varepsilon\leq t_n\leq y_n+\varepsilon \quad (9)$$

The error function after introducing slack variables is as follows.

$$C\sum_{n}\{\widetilde{\xi}_n+\xi_n\}+\frac{1}{2}\left\|w\right\|^2 \quad (10)$$

The discriminant function is as follows.

$$y\left(x\right)=\sum_{n}\left(a_n-\widetilde{a}_n\right)k\left(x,x_n\right)+b \quad (11)$$

*3) The correlation coefficient model:* Correlation [22] is a non-deterministic relationship, and the correlation coefficient is a measure of the linear relationship between variables. Due to variations in the subjects under study, there are several different ways to define the correlation coefficient.

The simple correlation coefficient, also known as the correlation coefficient or linear correlation coefficient, is typically represented by a letter and is used to measure the linear relationship between two variables. The definition formula is as follows.

$$r\left(X,Y\right)=\frac{Cov\left(X,Y\right)}{\sqrt{Var\left(X\right)Var\left(Y\right)}} \quad (12)$$

In which, $Cov(X,Y)$ represents the covariance between $X$ and $Y$, $Var(X)$ represents the variance of $X$, $Var(Y)$ represents the variance of $Y$.

### *D. Optimization Algorithm*

The system of linear equations is known to be representable as $Ax=b$. When A is a real symmetric matrix, that is, the expression for the derivative of the quadratic form $f(x)=\frac{1}{2}x^TAx-b^Tx+c$ with respect to $x$ when it equals zero, is as follows.

$$f'(x)=\frac{1}{x}A^Tx+\frac{1}{2}Ax-b \quad (13)$$

When $A$ is a real symmetric matrix in the formula, $f'(x)=0$ is equivalent to $Ax=b$, and thus, solving the system of linear equations can be transformed into solving $minf(x)$.

From the knowledge of algebra, it is known that when the matrix $A$ is positive definite, positive semi-definite, negative definite, or indefinite, the equation set $Ax=b$ has different solutions, corresponding to different minimum values of $f'(x)=0$. The impact of different situations of matrix $A$ on equation $f(x)$ is shown in Fig. 2.

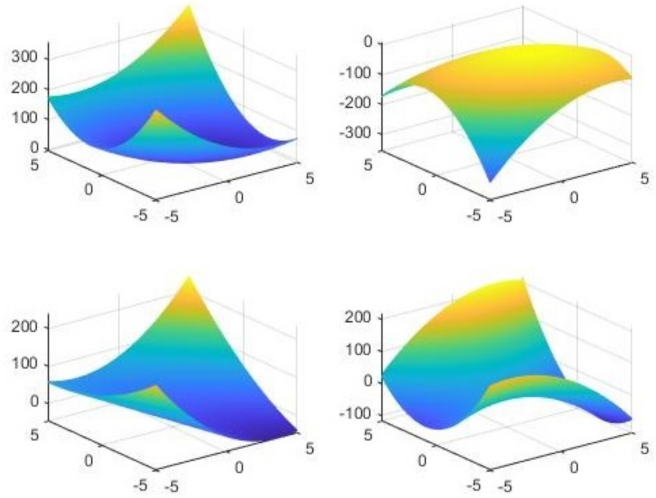

Fig. 2. Equation solution plot.

The distribution of solution patterns in Fig. 2 corresponds to $A$ being a positive definite, negative definite, positive semi-definite, and indefinite matrix, respectively. From the figure, it can be observed that when $A$ is an indefinite matrix, it is not possible to find the minimum value of $f(x)$ by setting its derivative to zero.

The conjugate gradient method [23] can solve the above problem. First, it is assumed that $A$ has good properties, namely, symmetry and positive definiteness. When seeking the minimum value of the function $f(x)$, its derivative leads to a sequence of solution vectors: $x_{(1)}$, $x_{(2)}$, $\ldots$, from which we obtain $f'(x_{(i)})=Ax_{(i)}-b$.

From calculus knowledge, we know that to consider $f(x_{(i+1)})$ as a function of $a_{(i)}$, and to find the most appropriate step length, we need to set it as follows:

$$\frac{d}{d\alpha_{(i)}}f(x_{(i+1)})=0 \quad (14)$$

By applying the chain rule [24], we find that $r_{(i)}$ is orthogonal to $r_{(i+1)}$, meaning that the step length for each step can be determined based on the current residual $r_{(i)}$.

Based on the iterative process of the steepest descent method [25], we can obtain $r^T_{(i+1)}r_{(i)}=0$. However, the steepest descent method has a significant issue: in order to converge to the vicinity of the solution, the same iteration direction may be followed more than once. To address this problem, if we can select a series of linearly independent direction vectors $d_{(0)}$, $d_{(1)}$, $d_{(2)}$, ..., $d_{(n-1)}$, and move along each direction only once, we can eventually reach the solution $x$ without encountering the issue of repeating the same direction. The most straightforward idea comes from the Cartesian coordinate system. If each direction is orthogonal, there will naturally be no problem of repeating the same direction. This leads to the condition $\alpha_{(i)} = -\frac{d_{(i)}^T e_{(i)}}{d_{(i)}^T d_{(i)}}$. Assuming that the selected series of direction vectors are all pairwise orthogonal with respect to matrix $A$, the formula of $\alpha_{(i)}$ is as follows.

$$\alpha_{(i)} = \frac{d_{(i)}^T r_{(i)}}{d_{(i)}^T A d_{(i)}} \tag{15}$$

According to this formula, for an n-order system of equations, it will take at most $n$ steps to converge to the correct solution.

From the above formulas, it is evident that the residuals between each iteration are mutually orthogonal. Therefore, we can define the residual $r_{(0)}, r_{(1)}, r_{(2)}, \ldots\ldots, r_{(n-1)}$ as the basis before conjugation. Since using conjugate directions for iteration requires at most $n$ steps, and each step eliminates the error in that direction, this set of bases is not only linearly independent but also possesses the desirable property of orthogonality.

## III. The Proposed Scheme

This article aims to construct a predictive model for octane loss. To achieve this, we first filter the data features, then build a predictive model to calculate potential octane loss. Furthermore, we employ optimization algorithms to adjust variables in order to reduce octane loss.

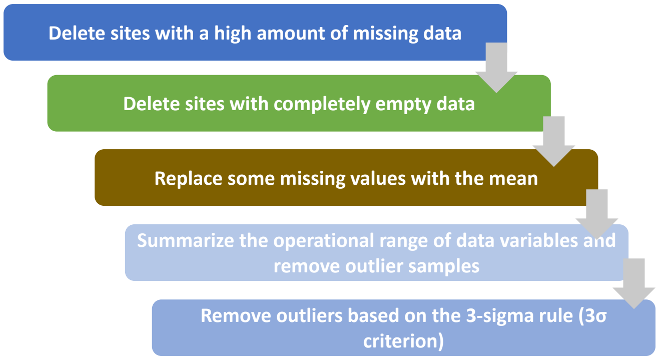
### A. Data Filtration

Industrial data often contain a significant amount of invalid and outlier data. For data with a high degree of missing values that cannot be filled, we delete sample data where all values are missing and use the average of data from the two hours before and after to fill in missing values. For samples that fall outside the original data variable operation range or contain outliers, we establish mathematical models for resolution. The entire data processing workflow is illustrated in Fig. 3.

### B. Feature Selection

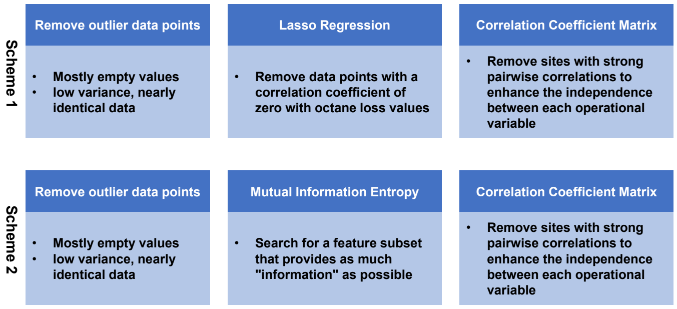
High-dimensional feature variables often increase the complexity of engineering problem analysis. In practical engineering applications, it's common to employ dimensionality reduction techniques before modeling. This approach can improve prediction accuracy, enable the construction of more efficient predictive models, and enhance the understanding and interpretability of the models. It helps in ignoring minor factors and identifying and analyzing the key variables and factors influencing the model.

To achieve this, we use mutual information entropy, correlation coefficients, and Lasso regression to select important features, making it easier to establish subsequent predictive models. As shown in Fig. 4, we adopt two different approaches for feature selection in this article. We use two combinations of methods to filter the main variables affecting octane loss: one approach uses mutual information and correlation coefficients, while the other employs Lasso regression.



Delete sites with a high amount of missing data
Delete sites with completely empty data
Replace some missing values with the mean
Summarize the operational range of data variables and remove outlier samples
Remove outliers based on the 3-sigma rule (3σ criterion)

Fig. 3. Data processing workflow. There are five steps, including deleting missing data, deleting empty data, replacing missing data, summarizing data distribution, and removing outlier data.



| | | | |
|---|---|---|---|
| Scheme 1 | Remove outlier data points | Lasso Regression | Correlation Coefficient Matrix |
| | • Mostly empty values<br>• low variance, nearly identical data | • Remove data points with a correlation coefficient of zero with octane loss values | • Remove sites with strong pairwise correlations to enhance the independence between each operational variable |
| Scheme 2 | Remove outlier data points | Mutual Information Entropy | Correlation Coefficient Matrix |
| | • Mostly empty values<br>• low variance, nearly identical data | • Search for a feature subset that provides as much "information" as possible | • Remove sites with strong pairwise correlations to enhance the independence between each operational variable |

Fig. 4. Scheme model diagram. The lasso regression and mutual information entropy are used to filter features.

### C. Development of RON Loss Prediction Model

In this section, we employ machine learning-based [17] models for regression prediction of RON as illustrated in the framework diagram in Fig. 5. Initially, the original data is subjected to outlier removal and standardization using box plots. After standardization, 80 percent of the samples are used for training, while the remaining 20 percent are reserved for testing. We establish RON loss prediction model using Random Forest prediction models and Support Vector Machine (SVM) techniques, followed by model validation.

## IV. Experiments

### A. Experiment settings

Dataset: We used a dataset comprising 325 data points obtained from actual production in a petrochemical enterprise. The dataset includes seven raw material properties, two properties of the adsorbents used in the initial adsorption stage, two properties of the adsorbents used in the regeneration stage, two product properties, and an additional 354 operating variables, totaling 367 variables.

Experimental Parameters: In our experiments, we set the standard deviation threshold to 0.3 in the Lasso regression process. For the random forest, we used 100 decision trees,

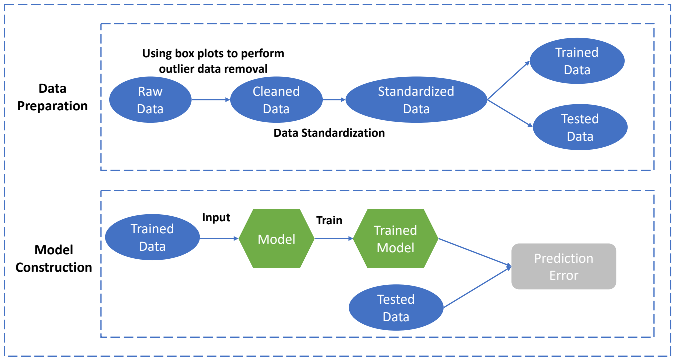


Fig. 5. Algorithm framework diagram.The data is first splited into training dataset and testing dataset. Then, we train models with the training dataset and the evaluate it on the testing dataset.

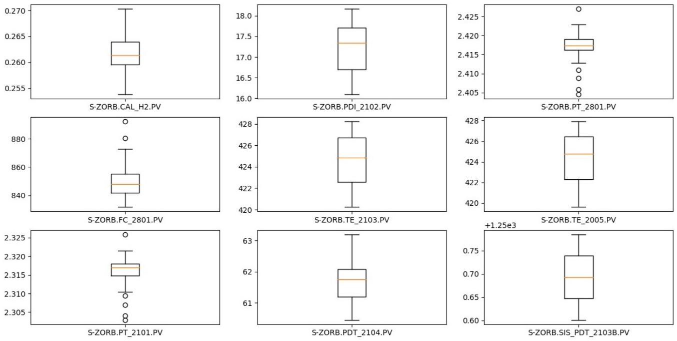

Fig. 6. Box Plot Method for Removing Sample Data Graph.

the Mean Absolute Error (MAE) as the error function, and a minimum sample size of 4 for leaf nodes. The support vector regression model had a penalty coefficient of 0.1 and a gamma value of 0.01.

### B. Data Filtering Results

Based on the box plot model, a check was conducted on data samples. Due to the large number of data points, it is not feasible to display all of them. Fig. 6 below shows only a portion of the data points in sample that need to be removed, as indicated in the graph. It is necessary to delete the data points in sample that fall outside the numerical range defined by the upper and lower ends of the box plot. Further examination using the Grubbs' test revealed that there were no outliers requiring removal in the samples.

### C. Primary Variable Selection

We employed two approaches for selection and then compared their effectiveness. First, we utilized the mutual information model to filter out 50 primary features.

Furthermore, we conducted additional filtering using the correlation coefficient model to identify 30 primary features.

Main feature variables can also be selected using Lasso regression, which involves the following steps:

TABLE I. Main Variables Selected by Lasso Regression

| | |
|---|---|

| S-ZORB.FC_1101.TOTAL | S-ZORB.FT_5204.TOTALIZERA.PV |
| S-ZORB.FT_9102.TOTAL | S-ZORB.FT_1001.TOTAL |

1) Calculate the standard deviation [26] for each of the 325 samples' variables. Variables with a standard deviation less than the threshold will be removed. The calculation formula is as follows.

$$\delta = \sqrt{\frac{\sum_{i=1}^{n}(x_i - \overline{x})^2}{n}} \tag{16}$$

When $\delta$¡ 0.3, the variable will be removed.

2) Count the number of zero elements in each variable. If the number of zeros exceeds 30% of the total elements in that column, the variable will be removed. If the number of zeros does not exceed 30% of the total elements in that column, the zero values in the variable will be replaced with the mean of its non-zero values.

3) Perform Lasso regression on the remaining variables to select 30 main variables, as shown in Table I.

For the two aforementioned approaches, we constructed the same model and then separately used the features selected by these two approaches for training and testing to assess the quality of the feature sets.

Specifically, we employed a support vector regression model with identical parameter settings as the base model to evaluate the quality of the feature sets based on its detection performance. The experimental results are presented in Table *.

In terms of specific metrics, we used the Mean Squared Error (MSE) between predicted values and actual values as the performance indicator. The features selected by the Lasso regression model ultimately resulted in an MSE of 0.0249, whereas the features selected using mutual information entropy yielded an MSE of 0.0258, slightly higher than that of the Lasso regression. Therefore, we opted for the Lasso regression model as the feature selection approach.

### D. RON Loss Prediction Performance

Based on the primary operating variable features, we utilized random forest and SVR (Support Vector Regression) for prediction separately.

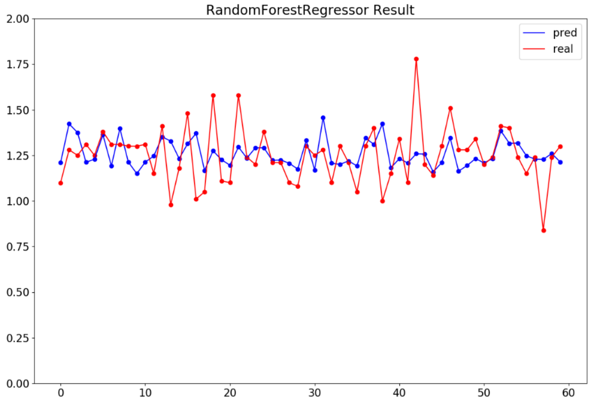

Fig. 7. Prediction performance graph of random forest regression model. The value of y-axis means the feature values.

TABLE II. The Regression Performance under Differnt SVR Kernels

| Kernel | Regression Performance | | |
|---|---|---|---|
| | R2 | MAE | RMSE |
| Linear | **0.9666** | **0.0757** | **0.1533** |
| Polynomial | 0.8258 | 0.2169 | 0.2657 |
| Gauss | 0.8803 | 0.1962 | 0.2396 |
| Laplace | 0.7364 | 0.3305 | 0.3129 |
| Sigmoid | -12.6431 | 2.0192 | 3.2221 |

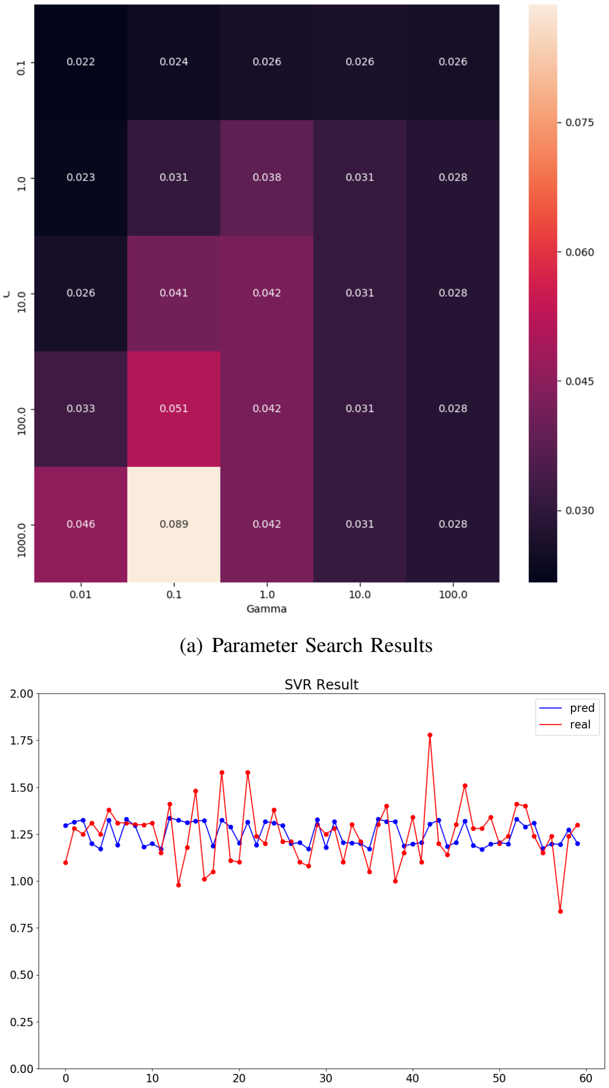
*1) Random Forest Prediction Performance:* Based on the selected primary operational variable features, we used a random forest for regression prediction. The random forest model involves multiple model parameters. To choose the model that best suits the current data, we conducted a grid search for parameter tuning.

From the search results, it can be observed that when the number of decision trees in the random forest is set to 100, the used error metric is MAE (Mean Absolute Error) [27], and the minimum samples per leaf node is 4, the model achieves its minimum prediction error of 0.233917. After concluding the parameter search, we constructed a new random forest model using the optimal parameters. The final model's predictive performance is illustrated in Fig. 7.

*2) Model prediction performance:* We also employed a support vector regression model for prediction. The support vector regression model involves multiple model parameters such as penalty coefficient [32] and Gamma value [33]. To select the model that best suits the current data, we conducted a grid search for the penalty coefficient and Gamma value.

TABLE III. Comparison with other Models

| Method | Regression Performance | | |
|---|---|---|---|
| | R2 | MAE | RMSE |
| Linear regression [28] | 0.4174 | 6.4373 | 43.3017 |
| Decision Tree [29] | 0.9483 | 0.0863 | 0.1720 |
| Simple DNN [30] | 0.6989 | 0.5980 | 1.3927 |
| RandomForest [31] | 0.9724 | 0.0526 | 0.1077 |
| SVR [21] | 0.9666 | 0.0757 | 0.1533 |
| RandomForest+SVR | **0.9868** | **0.0453** | **0.0973** |



(a) Parameter Search Results

(b) Model Prediction Performance

Fig. 8. The parameter search results and model prediction performance of support vector regression model.

The prediction errors obtained for different parameter configurations are shown in Fig. 8(a). From the search results, it can be observed that when the penalty coefficient for the support vector regression model is set to 0.1 and the Gamma value is set to 0.01, the model achieves its minimum prediction error of 0.022. After completing the parameter search, we constructed a new support vector regression model using the optimal parameters. The final model's predictive performance is illustrated in Fig. 8(b).

We also evaluated the fitting performance of Support Vector Regression (SVR) under different kernel functions. It is can be seen from Table II that our approach achieves optimal results when employing the linear kernel function. Under such settings, we compared the ensemble model and other models. As shown in Table III, our approach shows better regression performance. The combination of RandomForest and SVR could increase the accuracy of feature regression.

## V. Conclusion

Gasoline octane loss optimization has become a focal point of concern in the industry. In this paper, addressing the issue of RON loss optimization, we employed the lasso regression and correlation coefficient methods to feature selection, reducing the information redundancy that affects the octane loss model. We utilized random forest and support vector machine models to establish RON loss prediction models, training and testing them with well-preprocessed data to predict RON loss values. Combining Random Forest and SVR, our proposed solution achieves an R2 value of 0.9868, surpassing the performance of multiple existing models. In future work, we will further refine feature selection algorithms and explore the utilization of genetic algorithms to determine optimal parameters for the model.

# Spherical Fuzzy Z-Numbers-based CRITIC CRADIAS and MARCOS Approaches for Evaluating English Teacher Performance

Jie Niu
Department of Public and Basic Education, Hebi Polytechnic,
Hebi 458030, China

***Abstract*—Consider combining quantitative and qualitative data for these case studies, such as interviews with English teachers, student evaluations, classroom observations, and surveys. Contextual elements, including community support, resources, and school demographics, should also be taken into consideration. The assessment process in English teaching performance evaluation is very complicated and diverse, making it a perfect fit for use in the Multi-Attribute Group Decision Making (MAGDM) framework. The utilization of Spherical Fuzzy $\breve{Z}$-Number Sets ($SF\breve{Z}N$S) is essential in Multi-Attribute Group Decision Making (MAGDM) to handle intricate problems. These sets are significantly more capable of handling higher levels of uncertainty than the fuzzy set designs used today. Here, we provide a method, Compromise Ranking of Alternatives from Distance to Ideal Solution (CRADIAS), designed to address MAGDM problems in $SF\breve{Z}N$S, particularly in cases when attribute weights are opaque. Attribute weights may be found by applying the CRITIC technique. The first section of the research covers the examination of spherical fuzzy Z numbers, their accuracy and scoring functions, and the main concept behind their functioning. We then propose the use of spherical fuzzy $\breve{Z}$-Number data to handle MAGDM cases in a decision-making process. This work strengthens the topic's theoretical underpinnings as well as its practical applicability. By conducting a comparison study, we apply the MARCOS approach to validate and illustrate the validity of our findings. This methodical approach guarantees a thorough evaluation of the suggested method's effectiveness and adds to the current discussion on how to make wise decisions in difficult and uncertain situations.**

***Keywords*—$SF\breve{Z}NS$; CRITRIC technique; CRADIAS method; MARCOS method**

## I. Introduction

At its essence, this case study is propelled by an unwavering conviction, asserting that effective English teaching transcends a mere static concept; rather, it is a dynamic and ever-evolving tapestry woven with intricate threads of innovation, empathy, and adaptability. While traditional metrics undeniably offer valuable insights, their limitations are evident in the confined shadows they cast on the comprehensive impact of English teaching. It is against this backdrop that the imperative to explore diverse evaluation methods, including but not limited to classroom observations, self-assessment, student feedback, peer reviews, and performance data, emerges. By purposefully weaving together these diverse strands of evaluation, this study endeavors not only to uncover the symphony of English teaching effectiveness but also to delve into the nuanced notes within. It is within these subtleties that the potential for targeted support and development lies, poised to bring about transformative harmonies that enrich the educational experience for both English teachers and students alike. In embracing the multifaceted nature of effective English teaching, this study aims to contribute to the ongoing dialogue surrounding pedagogical excellence and the continuous refinement of educational practices. The application of Multi-Attribute Group Decision Making in the context of English teaching performance evaluation presents a promising avenue for creating a comprehensive and inclusive assessment framework. By considering diverse criteria, involving multiple stakeholders, and utilizing decision support systems, MAGDM can contribute to a more nuanced and robust evaluation process, ultimately fostering continuous improvement in English teaching practices and enhancing the overall quality of education.

### A. Literature Review

A mathematical foundation for handling ambiguity and imprecision in decision-making processes is offered by fuzzy set theory. Fuzzy set theory permits partial membership, enabling things to belong to a set to variable degrees, in contrast to classical set theory, which classifies components as either belonging to or not belonging to a set. Fuzzy set theory is especially useful in situations involving decision-making when ambiguity and uncertainty are common because of its versatility. The notion of fuzzy sets (FS) was first presented by Zadeh [1] in 1965 as a ground-breaking method for managing the complexity of ambiguity in decision-making. Fuzzy sets offer a more nuanced view of membership by enabling the attribution of degrees of satisfaction between 0 and 1. Fuzzy set theory was first introduced and has since become well known as an important concept with a wide range of applications in various scientific and industrial fields. To satisfy these strict requirements, Atanasov [2] developed the idea of "intuitionistic fuzzy sets (IFS)". It has the formula $0 \leq \epsilon(\psi) + \varsigma(\psi) \leq 1$, in which the variables $\varphi(\psi)$ and $\epsilon(\psi)$ denote different levels of pleasure and discontent. IFS and fuzzy sets (FS) are related instruments for dealing with complex issues resulting from uncertainty, which frequently originate from flaws in parameter estimate methods. It can be more difficult to arrive at a suitable result under the IFS model when combining membership degrees in situations where the total might be more than one. This strategy, however, has drawbacks since it includes traits that are inherent to humans, such as constraint and refuse. Cuong and Kreinovich (2013) [3] introduced the idea of picture fuzzy sets (PFS), which was an important innovation. Three components, $\epsilon(\psi)$, $\nu(\psi)$, and $\varphi(\psi)$, which stand for different degrees of neutrality, displeasure, and satisfaction, define these PFS. $0 \leq \epsilon(\psi) + \nu(\psi) + \varsigma(\psi) \leq 1$ is a critical condition for PFS.

A Russian professor named Molodtsov [4] established the notion of soft sets (SS) in 1999 as a practical answer to a common problem. This novel idea presents a unique categorization strategy that is useful in several domains, including decision-making and function smoothness evaluation. There are many different fields in which soft sets find practical use. An important extension was the incorporation of entropy into intuitionistic fuzzy soft sets (IFSS) by Jiang et al. [5]. Although the distinction between "degrees of abstention" ($\varsigma$) and "degrees of contentment" ($\epsilon$) seems clear-cut, Fuzzy Sets (FSS) and Intuitionistic Fuzzy Sets (IFSS) struggle with errors and uncertainty. When decision-makers choose values of 0.5 for degrees of satisfaction (MG) and 0.7 for degrees of abstention (NMG) in the IFSS framework, this presents a problem because it goes against the constraint $0.8 + 0.9 > 1$. Yager [6] developed the idea of pythagorean fuzzy sets (PFS) to overcome this restriction, rewriting the fundamental constraints as $0 \leq \epsilon^2 + \varsigma^2 \leq 1$ instead of $0 \leq \epsilon + \varsigma \leq 1$. Peng et al. [7] cleverly integrated the idea of pythagorean fuzzy sets (PFS) with Soft Sets (SS), Novel information measures for Fermatean fuzzy sets introduced by [8], Ashraf work on Spherical q-linear Diophantine fuzzy aggregation information [9] and whereas Yager [10] suggested q-Rung Orthopair fuzzy sets as an expansion of IFSS. Remarkably, given their structural underpinnings, FSS and IFSS are both special instances in the q-ROFS paradigm. But even while the q-ROFS framework has been helpful in addressing a number of issues with multi-attribute decision-making (MAGDM) [11], it is not without limitations.

Spherical fuzzy sets (SFSs), first proposed by Ashraf [12], express membership, neutrality, and degrees of abstentions, and increase the dimensionality of membership gradations, such as $\epsilon(\psi)$, $\nu(\psi)$, and $\varsigma(\psi)$. The requirement $0 \leq \epsilon^2(\psi) + \nu^2(\psi) + \varsigma^2(\psi) \leq 1$ is rigorously followed by SFSs.

### B. Motivation

As part of an ongoing effort to improve fuzzy set theory, Zadeh presented the ground-breaking concept of $\breve{z}$-numbers in 2011 [13]. By combining ordered pairs with fuzzy numbers, these $\breve{z}$ numbers outperform traditional fuzzy numbers. Ashraf [14] presented the idea of sets of spherical fuzzy $\breve{z}$-numbers ($SF\breve{Z}N$S) in a different line of inquiry. $0 \leq \tau_{\epsilon^2(\psi)} + \tau_{\nu^2(\psi)} + \tau_{\backepsilon^2(\psi)} \leq 1$ and $0 \leq \tau_{\epsilon^2(\psi)} + \tau_{\nu^2(\psi)} + \tau_{\backepsilon^2(\psi)} \leq 1$ are the two requirements that these sets meet. The three values in this context are $\epsilon(\psi)$, $\nu(\psi)$, and $\backepsilon\ (\psi)$, which represent satisfaction, abstinence, and dissatisfaction; the indicators, on the other hand, are $\tau_{\epsilon(\psi)}$, $\tau_{\nu(\psi)}$, and $\tau_{\backepsilon(\psi)}$, which represent the dependability of these levels.

Ashraf [15] introduced the pythagorean fuzzy Z-numbers, Ashraf [16] introduced Sugeno Weber Model under Spherical Fuzzy Z-numbers. Information Sciences, 120428.Notable applications of pythagorean fuzzy sets [17], A new Pythagorean fuzzy based decision framework for assessing healthcare waste treatment [18], Novel Distance Measure and CRADIS Method in Picture Fuzzy Environment [19], and Market assessment of pear varieties in Serbia using fuzzy CRADIS and CRITIC methods [20]. Application of fuzzy TRUST CRADIS method for selection of sustainable suppliers in agribusiness [21], A complex spherical fuzzy CRADIS method based Fine-Kinney framework for occupational risk evaluation in natural gas pipeline construction [22], Fuzzy multi-criteria analyses on green supplier selection in an agri-food company [23], A Hybrid Improved Fuzzy SWARA and Fuzzy CRADIS Approach [24], and An Integrated Spherical Fuzzy Multi-criterion Group Decision-Making Approach and Its Application in Digital Marketing Technology Assessment [25]. A new fuzzy MARCOS method for road traffic risk analysis [26], MCDM under the MARCOS method [27], Evaluation software of project management by using (MARCOS) method. [28], MARCOS method [29], Supplier selection for steelmaking company by using combined Grey MARCOS methods [30], CRITIC MARCOS method with spherical fuzzy information [31], Spherical fuzzy SWARA MARCOS approach for green supplier selection [32], and Road safety assessment and risks prioritization using an integrated SWARA and MARCOS approach under SFS environment [33]. Extension of WASPAS with spherical fuzzy sets [34], multiple attribute group decision making (MAGDM) [35], and Market assessment of pear varieties in Serbia using fuzzy CRADIS and CRITIC methods [36]. Attributes' weight using CRITRIC method [37] resolves numerical problems by employing compromise ranking of alternatives from distance to ideal solution (CRADIAS) [38], and for comparative analysis, measurement of alternatives and ranking according to compromise solution MARCOS method is utilized [39].

The principal motivation for the creation and implementation of CRADIAS in the context of Spherical Fuzzy $\breve{Z}$-Numbers is its capacity to manage intricate situations involving several criteria. Multiple factors must be taken into consideration while making decisions in real-world circumstances, as opposed to relying just on one criterion. When faced with several criteria, CRADIAS offers a methodical way to assess and prioritize possibilities. By combining criteria using the weighted sum product method, CRADIAS helps decision-makers get a clear picture of how well options perform overall in a variety of areas. The systematic and transparent integration of many aspects in the decision-making process is facilitated by this aggregation strategy.

### C. *Significance of the Study*

The research proposal delineates the core aims as follows:

- Analyze the applicability and performance of CRADIAS for spherical fuzzy $\breve{Z}$-Numbers.
- Handle decision making tasks that require weighing several factors or criteria that are considered while analyzing possibilities in their whole.
- By properly combining the contributions of each criterion, the weighted sum product method employed in CRADIAS offers a thorough evaluation of the options.
- To improve the way that uncertainty is represented in decision-making by using Spherical Fuzzy Z Numbers ($SF\breve{Z}N$). This goal acknowledges $SF\breve{Z}N$'s exceptional capacity to manage uncertainty in both direction and magnitude, giving decision-makers a more realistic representation of the inherent imprecision and ambiguity in choice criteria.
- In order to guarantee that the decision model is in line with the complexities of spherical fuzzy information, this entails giving decision-makers an organized method that takes into consideration the spherical representation of uncertainties.

### D. *Organization of the Study*

The article is structured as follows: Section II introduces fundamental preliminary operations, encompassing related operators, scoring and accuracy functions, SF$\breve{Z}$N distance measure and SF$\breve{Z}$N CRITRIC method to calculate the attributes weights.. Section III provides an overview of the methodology of CRADIAS method in $SF\breve{Z}N$ environment for Multiple Attributes Group Decision Making (MAGDM). Section IV delves into numerical aspects related to Evaluating Teaching Performance in a Secondary School Setting. Section V conducts a comparative analysis between CRADIAS and MARCOS method based on $SF\breve{Z}N$ environment. Finally, in Section VI, we offer concluding remarks and present the study's findings.

## II. Preliminaries

This section introduces several fundamental definitions and operations that played a crucial role in developing the proposed tasks.

**Definition II.1.** [1] The fuzzy set Identified under the Entire Set $\Xi$ is

$$\widetilde{\wp} = \{(\daleth, \varphi_{\widetilde{\wp}}(\psi)|\daleth \in \Xi)\}$$

where $\varphi_{\widetilde{\nu}}(\psi)$ degrees of contentment,of $\varsigma$ in $\widetilde{\widetilde{\Xi}}$ and $\varphi_{\widetilde{\widetilde{\Xi}}} : \Xi \to [0, 1]$.

**Definition II.2.** [13] A $\breve{z}$-numbers is an ordered pair of fuzzy number embodied by $Z = (\imath, \tau\imath)$ the $\imath$ component is the contentment While $\tau\imath$ is the reliability of the $\imath$.

**Definition II.3.** [12] The spherical fuzzy set is Identified under the Entire Set $\Xi$ :

$$\widetilde{\nu} = \left\{ \left(\daleth, \left(\varphi(\psi), \tau(\psi), o(\psi)\right)\right) |\daleth \in \Xi\right\}$$

such that $\varphi : \Xi \to [0, 1]$ and $\tau : \Xi \to [0, 1]$ are degrees of contentment and abstention respectively in a set $\Xi$. Where,

$$0 \leq (\varphi(\psi))^2 + (\tau(\psi))^2 + (o(\psi))^2 \leq 1$$

**Definition II.4.** [14] Suppose $\Xi$ is the Entire Set then $SF\breve{Z}N$s is Identified as:

$$\pounds_{\diamond} = \{\varsigma, (\epsilon, \tau_{\epsilon})(\psi), (\nu, \tau_{\nu})(\psi), (\backepsilon, \tau_{\backepsilon})(\psi)|\varsigma \in \Xi\}$$

such that $(\epsilon, \tau_{\epsilon})) : \Xi \longrightarrow [0, 1]$ ,$(\nu, \tau_{\nu}) : \Xi \longrightarrow [0, 1]$ and $(\backepsilon, \tau_{\backepsilon}) : \Xi \longrightarrow [0, 1]$ are the order pair of degrees of contentment, and abstention respectively in a set $\nu$ and second component is spherical measure of intergrity for first component along all the conditions.

$$0 \leq \epsilon^2(\psi) + \nu^2(\psi) + \backepsilon^2\ (\psi) \leq 1$$

and

$$0 \leq \tau_{\epsilon}^2(\psi) + \tau_{\nu}^2(\psi) + \tau_{\backepsilon}^2(\psi) \leq 1$$

**Definition II.5.** [14]

Suppose $\pounds_{\diamond_1} = \Big\{(\epsilon_1, \tau_{\epsilon_1}), (\nu_1, \tau_{\nu_1}), (\backepsilon_1, \tau_{\backepsilon_1})\Big\}$ and $\pounds_{\diamond_2} = \Big\{(\epsilon_2, \tau_{\epsilon_2}), (\nu_2, \tau_{\nu_2}), (\backepsilon_2, \tau_{\backepsilon_2})\Big\}$ be any two $SF\breve{Z}N$s and $\lambda \geq 0$ then the following operation Identified as:

1) $\pounds_{\diamond_1} \supseteq \pounds_{\diamond_2} \Leftrightarrow \epsilon_2 \geq \epsilon_1, \tau_{\epsilon_2} \geq \tau_{\epsilon_1}, \nu_2 \leq \nu_1, \tau_{\nu_2} \leq \tau_{\nu_1}, \ni_2 \leq \ni_1, \tau_{\ni_2} \leq \tau_{\ni_1}$.
2) $\pounds_{\diamond_1} = \pounds_{\diamond_2} \Leftrightarrow \pounds_{\diamond_1} \supseteq \pounds_{\diamond_2}$ and $\pounds_{\diamond_1} \subseteq \pounds_{\diamond_2}$.
3) $\pounds_{\diamond_1} \cup \pounds_{\diamond_2} = \Big\{(\epsilon_1 \vee \epsilon_2, \tau_{\epsilon_1} \vee \tau_{\epsilon_2}), (\nu_1 \wedge \nu_2, \tau_{\nu_1} \wedge \tau_{\nu_2}), (\ni_1 \wedge \ni_2, \tau_{\ni_1} \wedge \tau_{\ni_2})\Big\}$.
4) $\pounds_{\diamond_1} \cap \pounds_{\diamond_2} = \Big\{(\epsilon_1 \wedge \epsilon_2, \tau_{\epsilon_1} \wedge \tau_{\epsilon_2}), (\nu_1 \wedge \nu_2, \tau_{\nu_1} \wedge \tau_{\nu_2}), (\ni_1 \vee \ni_2, \tau_{\ni_1} \vee \tau_{\ni_2})\Big\}$.
5) $(\pounds_{\diamond_1})^c = \Big\{(\epsilon_1, \tau_{\epsilon_1}), (\nu_1, \tau_{\nu_1}), (\ni_1, \tau_{\ni_1})\Big\}^c = \Big\{(\ni_1, \tau_{\ni_1}), (\nu_1, \tau_{\nu_1}), (\epsilon_1, \tau_{\epsilon_1})\Big\}$.
6) $\pounds_{\diamond_1} \oplus \pounds_{\diamond_2} = \left\{ \begin{array}{c} \left(\sqrt{\epsilon_1^2 + \epsilon_2^2 - \epsilon_1^2\epsilon_2^2}, \sqrt{\tau_{\epsilon_1}^2 + \tau_{\epsilon_2}^2 - \tau_{\epsilon_1}^2\tau_{\epsilon_2}^2}\right), \\ \left(\nu_1\nu_2, \tau_{\nu_1}\tau_{\nu_2}\right), \left(\ni_1\ni_2, \tau_{\ni_1}\tau_{\ni_2}\right). \end{array} \right\}$.
7) $\pounds_{\diamond_1} \otimes \pounds_{\diamond_2} = \left\{ \begin{array}{c} (\epsilon_1\epsilon_2, \tau_{\epsilon_1}\tau_{\epsilon_2}), , (\nu_1\nu_2, \tau_{\nu_1}\tau_{\nu_2}), \\ \left(\sqrt{{\ni_1}^2 + {\ni_2}^2 - {\ni_1}^2{\ni_2}^2}, \sqrt{\tau_{\ni_1}^2 + \tau_{\ni_2}^2 - \tau_{\ni_1}^2\tau_{\ni_2}^2}\right) \end{array} \right\}$.
8) $\lambda\pounds_{\diamond_1} = \left\{ \begin{array}{c} \left(\sqrt{1-(1-\epsilon_1^2)^\lambda}, \sqrt{1-(1-\tau_{\epsilon_1}^2)^\lambda}\right), \\ \left(\nu_1^\lambda\tau_{\nu_1}^\lambda\right), \left(\ni_1^\lambda\ \tau_{\ni_1}^\lambda\right) \end{array} \right\}$.
9) $(\pounds_{\diamond_1})^\lambda = \left\{ \begin{array}{c} \left(\epsilon_1^\lambda\tau_{\epsilon_1}^\lambda\right), \left(\nu_1^\lambda\tau_{\nu_1}^\lambda\right), \\ \left(\sqrt{1-(1-{\ni_1}^2)^\lambda}, \sqrt{1-(1-\tau_{\ni_1}^2)^\lambda}\right) \end{array} \right\}$.

**Definition II.6.** [14]

Suppose $\pounds_{\diamond_i} = \Big\{(\epsilon_i, \tau_{\epsilon_i}), (\nu_i, \tau_{\nu_i}), (\ni_i, \tau_{\ni_i})\Big\}$ be $SF\breve{Z}N$s and then the algebraic and geometric aggregation operator Identified as:

$$SF\breve{Z}NWA(\pounds_{\diamond_1}, \pounds_{\diamond_2}, \pounds_{\diamond 3}..., \pounds_{\diamond n}) = \sum_{i=1}^{n} \breve{\Omega}_i \pounds_{\diamond_i}$$

where $\sum_{i=1}^n \breve{\Omega}_i = 1$ , $\breve{\Omega}_i \in [0,1]$

$$= \left\{ \begin{array}{c} \left(\sqrt{1-\prod_{i=1}^n (1-(\epsilon_i)^2)^{\breve{\Omega}_i}}, \right. \\ \left. \sqrt{1-\prod_{i=1}^n (1-(\tau_{\epsilon_i})^2)^{\breve{\Omega}_i}}\right) \\ \left(\prod_{i=1}^n ((\nu_i))^{\breve{\Omega}_i}, \prod_{i=1}^n (\tau_{\nu_i})^{\breve{\Omega}_i}\right) \\ \left(\prod_{i=1}^n ((\ni_i))^{\breve{\Omega}_i}, \prod_{i=1}^n (\tau_{\ni_i})^{\breve{\Omega}_i}\right) \end{array} \right\}.$$

$$SF\breve{Z}NWG(\pounds_{\diamond_1}, \pounds_{\diamond_2}, \pounds_{\diamond 3}..., \pounds_{\diamond n}) = \prod_{i=1}^{n} {\pounds_{\diamond_i}}^{\breve{\Omega}_i}$$

where $\sum_{i=1}^n \breve{\Omega}_i = 1$ , $\breve{\Omega}_i \in [0,1]$

$$= \left\{ \begin{array}{c} \left(\prod_{i=1}^n ((\epsilon_i))^{\breve{\Omega}_i}, \prod_{i=1}^n (\tau_{\epsilon_i})^{\breve{\Omega}_i}\right) \\ \left(\prod_{i=1}^n ((\nu_i))^{\breve{\Omega}_i}, \prod_{i=1}^n (\tau_{\nu_i})^{\breve{\Omega}_i}\right) \\ \left(\sqrt{1-\prod_{i=1}^n (1-(\ni_i)^2)^{\breve{\Omega}_i}}, \right. \\ \left. \sqrt{1-\prod_{i=1}^n (1-(\tau_{\ni_i})^2)^{\breve{\Omega}_i}}\right) \end{array} \right\}.$$

**Definition II.7.** To compare $SF\breve{Z}N$ $\pounds_{\diamond_i} = \Big\{(\epsilon_i, \tau_{\epsilon_i}), (\nu_i, \tau_{\nu_i}), (\ni_i, \tau_{\ni_i})\Big\}$ we introduced the score function as

$$\Im(\pounds_{\diamond_i}) = \frac{2 + ((\epsilon_i)(\tau_{\epsilon_i})) - ((\nu_i)(\tau_{\nu_i})) - ((\ni_i)(\tau_{\ni_i}))}{3}$$

$\Im(\pounds_{\diamond_i}) \in [-1,1]$
if $\Im(\pounds_{\diamond_i}) = \Im(\pounds'_{\diamond_i})$ then calculate the accuracy function

$$\Re(\pounds_{\diamond_i}) = \frac{((\epsilon_i)(\tau_{\epsilon_i})) - ((\nu_i)(\tau_{\nu_i})) - ((\ni_i)(\tau_{\ni_i}))}{3}$$

$\Re(\pounds_{\diamond_i}) \in [0,1]$

**Definition II.8.** Suppose $\pounds_{\diamond_1} = \Big\{(\epsilon_1, \tau_{\epsilon_1}), (\nu_1, \tau_{\nu_1}), (\ni_1, \tau_{\ni_1})\Big\}$ and $\pounds_{\diamond_2} = \Big\{(\epsilon_2, \tau_{\epsilon_2}), (\nu_2, \tau_{\nu_2}), (\ni_2, \tau_{\ni_2})\Big\}$ be any two $SF\breve{Z}N$s then the Euclidean distance between them as follows:
$d(\pounds_{\diamond_1}, \pounds_{\diamond_2}) =$

$$\left( \begin{array}{c} \Big(\big((\epsilon_1.\tau_{\epsilon_1}) - (\epsilon_2.\tau_{\epsilon_2})\big)^2 + \big((\nu_1.\tau_{\nu_1}) - (\nu_2.\tau_{\nu_2})\big)^2 + \\ \big((\ni_1.\tau_{\ni_1}) - (\ni_2.\tau_{\ni_2})\big)^2\Big)^{\frac{1}{2}} \end{array} \right).$$

## III. CRADIAS [38] Method under $SF\breve{Z}N$ for Multi Attributes Group Decision Making

In this section, we have formulated an algorithm to tackle the Multiple Attributes Decision Making (MAGDM) problem using Compromise Ranking of Alternatives from Distance to Ideal Solution (CRADIAS) [38]. Additionally, we provided an MAGDM example to illustrate the application of these operators. Let's assume we have a collection of alternatives represented as $\top = \{\top_1, \top_2, \top_3, ...\top_n\}$, and a collection of attributes represented as $\yen = \{\yen_1, \yen_2, \yen_3, ...\yen_n\}$, with their respective weight vectors $\breve{\Omega} = \{\breve{\Omega}_1, \breve{\Omega}_2, ....\breve{\Omega}_n\}$. The weight vectors must satisfy the requirement that the weights belong to a closed unit interval (i.e., ranging from 0 to 1) and that their sum must be equal to 1, ensuring a valid weighting scheme. Suppose the spherical Fuzzy spherical Fuzzy $\breve{Z}$- Number decision matrix denoted by $\pounds_\diamond^k = [\pounds_{\diamond_{ij}}^k]_{m\times n}$.

**Algorithm** Enhanced Decision making in $SF\breve{Z}N$: A novel approach with CRADIAS method

1) Decision matrices by the experts.
2) Using aggregation operators to to aggregate all individuals spherical fuzzy $\breve{z}$-numbers decision matrices into collective spherical fuzzy $\breve{z}$-numbers decision matrix $\pounds_{\diamond_{ij}} = [\pounds_{\diamond_{ij}}]_{m\times n}$
3) The attribute weights are calculated by CRITRIC method. calculate attributes weights by using following equation: Compute the score values of decision matrix.

$$\Im(\pounds_{\diamond_{ij}}) = \frac{2+((\epsilon_{ij})(\tau_{\epsilon_{ij}}))-((\nu_{ij})(\tau_{\nu_{ij}}))-((\backepsilon_{ij})(\tau_{\backepsilon_{ij}}))}{3} \quad \forall i,j. \ .$$

$$\overbrace{\Im(\pounds_{\diamond_{ij}})} = \begin{cases} \dfrac{\Im(\pounds_{\diamond_{ij}}) \ - \ \Im(\pounds_{\diamond_{ij}})^{-}}{\Im(\pounds_{\diamond_{ij}})^{+} \ - \ \Im(\pounds_{\diamond_{ij}})^{-}}, & j \in \mathrm{R_b}. \\[2ex] \dfrac{\Im(\pounds_{\diamond_{ij}})^{+} \ -\Im(\pounds_{\diamond_{ij}})}{\Im(\pounds_{\diamond_{ij}})^{+} \ - \ \Im(\pounds_{\diamond_{ij}})^{-}}, & j \in \mathrm{R_c}. \end{cases}$$

where $\mathrm{R_b}$ and $\mathrm{R_c}$ are the benefit and cost type of criteria sets respectively. $\Im(\pounds_{\diamond_{ij}})^{-} = min_i \Im(\pounds_{\diamond_{ij}})$ and $\Im(\pounds_{\diamond_{ij}})^{+} = max_i \Im(\pounds_{\diamond_{ij}})$

Calculate the standard deviation by using the following equation:

$$\S_j = \sqrt{\frac{\sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{ij}})} - \overline{\Im(\pounds_{\diamond_{ij}})}\right)^2}{m}}.$$

Where $\overline{\Im(\pounds_{\diamond_{ij}})} = \dfrac{\overbrace{\Im(\pounds_{\diamond_{ij}})}}{m}$.

Calculate the correlation between criteria pairs by using the following equation:

$$\Upsilon_{jl} = \frac{\sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{ij}})} - \overline{\Im(\pounds_{\diamond_{ij}})}\right)\left(\overbrace{\Im(\pounds_{\diamond_{il}})} - \overline{\Im(\pounds_{\diamond_{il}})}\right)}{\sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{ij}})} - \overline{\Im(\pounds_{\diamond_{ij}})}\right)^2 \sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{il}})} - \overline{\Im(\pounds_{\diamond_{il}})}\right)^2}. \ .$$

Calculate each criterion's information amount using the formula below:

$$\Gamma_j = \sum_{l=1}^{n}(1 - \Upsilon_{jl})$$

Calculated the weight of each attribute b using following equation:

$$\breve{\Omega} = \frac{\Gamma_j}{\sum_{j=1}^{n}\Gamma_j}$$

4) Normalize the decision matrices.
Normalize by using following equation:

$$\pounds_{\diamond_{ij}} = \begin{cases} \pounds_{\diamond_{ij}} = \\ \Big\{(\epsilon_{ij}, \tau_{\epsilon_{ij}}), (\nu_{ij}, \tau_{\nu_{ij}}), (\backepsilon_{ij}, \tau_{\backepsilon_{ij}})\Big\}, & j \in \mathrm{R_b}, \\ {\pounds_{\diamond_{ij}}}^{c} = \\ \Big\{(\backepsilon_{ij}, \tau_{\backepsilon_{ij}}), (\nu_{ij}, \tau_{\nu_{ij}}), (\epsilon_{ij}, \tau_{\epsilon_{ig}})\Big\}, & j \in \mathrm{R_c}, \end{cases}$$

where $\mathrm{R_b}$ and $\mathrm{R_c}$ are the benefit and cost type of criteria set respectively.

5) Calculate weighted form of normalized $SF\breve{Z}N$ decision matrix.
The weighted form of normalized $SF\breve{Z}N$ decision matrix is estimated as below:

$$\breve{\pounds}_{\diamond_{ij}} = \sum_{i=1}^{n}\breve{\Omega}_j \pounds_{\diamond_{ij}} = \left\{ \begin{array}{c} \left(\sqrt{1-\prod_{i=1}^{n}(1-(\epsilon_{ij})^2)^{\breve{\Omega}_j}}, \right. \\ \left. \sqrt{1-\prod_{i=1}^{n}(1-(\tau_{\epsilon_{ij}})^2)^{\breve{\Omega}_j}}\right) \\ \left(\prod_{i=1}^{n}((\nu_{ij}))^{\breve{\Omega}_j}, \prod_{i=1}^{n}(\tau_{\nu_{ij}})^{\breve{\Omega}_j}\right) \\ \left(\prod_{i=1}^{n}((\backepsilon_{ij}))^{\breve{\Omega}_j}, \prod_{i=1}^{n}(\tau_{\backepsilon_{ij}})^{\breve{\Omega}_j}\right) \end{array} \right\}.$$

6) Compute the ideal $t_j^{+}$ and anti ideal $t_j^{-}$ solution.

$$t_j^{+} = \left\{ \begin{array}{c} (\max_{i=1,\ldots m}\epsilon_j, \max_{i=1,\ldots m}\tau_{\epsilon_j}), \\ (\min_{i=1,\ldots m}\nu_j, \min_{i=1,\ldots m}\tau_{\nu_{ij}}), \\ (\min_{i=1,\ldots m}\backepsilon_{ij}, \min_{i=1,\ldots m}\tau_{\backepsilon_{ij}}) \end{array} \right\}.$$

$$t_j^{-} = \left\{ \begin{array}{c} (\min_{i=1,\ldots m}\epsilon_j, \min_{i=1,\ldots m}\tau_{\epsilon_j}), \\ (\min_{i=1,\ldots m}\nu_j, \min_{i=1,\ldots m}\tau_{\nu_{ij}}), \\ (\max_{i=1,\ldots m}\backepsilon_{ij}, \max_{i=1,\ldots m}\tau_{\backepsilon_{ij}}) \end{array} \right\}.$$

7) Compute distance between weighted normalized decision matrix and Ideal solution $d_{ij}^{+}$ and weighted normalized decision matrix and Anti Ideal solution $d_{ij}^{+}$

$$d_{ij}^{+} = d^{+}(\breve{\pounds}_{\diamond_{ij}}, t_j^{+})$$

$$= \left\{ \begin{array}{c} \left(\left((\epsilon_{ij}.\tau_{\epsilon_{ij}}) - (\epsilon_j^{+}.\tau_{\epsilon_j}^{+})\right)^2 + \right. \\ \left((\nu_{ij}.\tau_{\nu_{ij}}) - (\nu_j^{+}.\tau_{\nu_j}^{+})\right)^2 + \\ \left. \left((\backepsilon_{ij}.\tau_{\backepsilon_{ij}}) - (\backepsilon_j^{+}.\tau_{\backepsilon_j}^{+})\right)^2\right)^{\frac{1}{2}} \end{array} \right\}.$$

$$d_{ij}^{-} = d^{-}(\breve{\pounds}_{\diamond_{ij}}, t_j^{-})$$

$$= \left\{ \begin{array}{c} \left(\left((\epsilon_{ij}.\tau_{\epsilon_{ij}}) - (\epsilon_j^{-}.\tau_{\epsilon_j}^{-})\right)^2 + \right. \\ \left((\nu_{ij}.\tau_{\nu_{ij}}) - (\nu_j^{-}.\tau_{\nu_j}^{-})\right)^2 + \\ \left. \left((\backepsilon_{ij}.\tau_{\backepsilon_{ij}}) - (\backepsilon_j^{-}.\tau_{\backepsilon_j}^{-})\right)^2\right)^{\frac{1}{2}} \end{array} \right\}.$$

8) Compute the degree of deviation of every option from ideal and anti ideal solution.

$$\mathfrak{S}_{\mathrm{i}}^{+} = \sum_{j=1}^{n} d_{ij}^{+}$$

$$\mathfrak{S}_{\mathrm{i}}^{-} = \sum_{j=1}^{n} d_{ij}^{-}$$

9) Compute the utility function of each alternative. The utility function of each alternative is estimated as:

$$\mathrm{K_i}^{+} = \frac{\mathfrak{S}_{\diamond}^{+}}{\mathfrak{S}_{\mathrm{i}}^{+}}$$

$$\mathrm{K_i}^{-} = \frac{\mathfrak{S}_{\mathrm{i}}^{-}}{\mathfrak{S}_{\diamond}^{-}}$$

Where $\mathfrak{S}_{\diamond}^{-}$ is the best option that is the furthest away from the anti ideal solution and $\mathfrak{S}_{\diamond}^{+}$ is the best option that is the closest to the ideal solution.

10) Calculate the average departure of the options. The average departure of the options is computed as:

$$\mathrm{Q_i} = \frac{\mathrm{K_i}^{+} + \mathrm{K_i}^{-}}{2}$$

11) To rank all alternatives in descending order and choose the best one.

## IV. Case Study

In this segment of the article, we present a Multi-Attributes Decision Group Making (MAGDM) problem to demonstrate the applicability and efficacy of this approach in tackling complex decision-making challenges. To exemplify this, we present a scenario of Evaluating Teaching Performance in a Secondary School Setting. Within this context, we have deliberately selected four distinct attributes for evaluating the performance of these operations: Effectiveness of Instructional Strategies, Classroom Management and Learning Environment, Student Assessment and Feedback, and Professional Development Engagement. We have identified four potential alternatives: Peer Mentoring and Collaborative Learning, Student-Led Assessments and Portfolios, Degree Evaluation, and Innovative Professional Development Formats.

In the tapestry of education, English teachers stand as architects, sculptors, and mentors, shaping the intellectual, practical, and ethical dimensions of students. The heartbeat of this transformative process lies in the nuanced artistry of English teaching. Evaluating English teaching performance emerges not merely as an administrative exercise but as a compass guiding educators to refine their pedagogical artistry, adapt to the diverse and evolving needs of learners, and ultimately elevate the quality of education. In the crucible of secondary education, where students stand at the crossroads of their academic journey, the significance of effective English teaching takes center stage. This case study seeks to embark on an intricate exploration of the multifaceted process of evaluating English teaching performance, unveiling that the essence of excellence in English teaching transcends traditional metrics, embracing a holistic and student-centric paradigm. At its core, this case study is animated by the unwavering belief that effective English teaching is an ever-evolving masterpiece, intricately woven with threads of innovation, empathy, and adaptability. While traditional metrics offer a glimpse into the multifaceted world of English teaching, they often cast a confined shadow on the profound and holistic impact of educators. Hence, the imperative exploration of a myriad of evaluation methods, including but not limited to classroom observations, self-assessment, student feedback, peer reviews, and performance data.

In this symphony of methodologies, the study seeks not merely to uncover the melodies of English teaching effectiveness but to discern the subtle notes where targeted support and development can orchestrate transformative harmonies, enriching the educational experience for both English teachers and students alike. Classroom observations serve as a key lens through which the study gains insights into the daily practices of educators. By immersing itself in the classroom environment, it captures the dynamic interplay between English teachers and students, the strategies employed, and the overall atmosphere conducive to learning. However, the study does not stop at mere observation; it extends its reach to the introspective domain of self-assessment. Encouraging educators to reflect on their own practices, strengths, and areas for improvement, self-assessment becomes a reflective tool. It fosters a culture of continuous improvement, empowering English teachers to refine their approaches and pedagogical strategies. In this process, the study seeks to unearth the inherent potential for growth and development that lies within each educator. Moreover, the symphony of evaluation methods resonates with the harmonious notes of student feedback. Acknowledging the unique perspective students bring, the study values their voices as integral components in the evaluation process. Students, as active participants in their own education, offer invaluable insights into the effectiveness of English teaching methods, communication styles, and the overall impact on their learning journey.

Peer reviews add another layer to this melodic exploration. They bring a collaborative dimension, fostering a community of practice among educators. The insights shared among peers create a supportive network for professional development, allowing English teachers to learn from each other's experiences and expertise. Lastly, the study recognizes the significance of performance data as a quantitative measure. It acknowledges the role of data in providing tangible evidence of English teaching effectiveness, adding a quantitative dimension to the qualitative aspects explored through other methods. The significance of this case study reverberates through the ethos of education as it grapples with dynamic changes. It recognizes English teaching as an art form where practitioners continuously evolve, adapting to the ever-changing needs of learners and the broader educational landscape. In challenging the limitations of traditional metrics, the study aspires to illuminate the path toward a more nuanced understanding of English teaching impact. Through this, it seeks to contribute to the narrative of education as a living, breathing entity, shaped by the innovative spirit, compassionate heart, and resilient adaptability of educators.

Within the expansive canvas of secondary education, this study casts its gaze upon a tapestry of educators, each weaving their unique narrative into the educational fabric. Through the interplay of qualitative and quantitative research methods, the study endeavors not only to unravel the patterns, strengths, and areas for improvement in English teaching performance but to illuminate the individual brushstrokes that form the broader masterpiece. The ultimate aspiration is to craft recommendations that transcend the ordinary, guiding educators through a continuous journey of professional growth, fostering collaborative environments that resonate with the harmonies of effective English teaching, and inspiring the evolution of institutional policies that acknowledge and nurture the diverse facets of English teacher evaluation. In the ever-evolving landscape of education, where tradition meets innovation, and where learners bring diverse perspectives into the classroom, this case study unfolds. It acknowledges that effective English teaching is a dynamic dance, where the rhythm is set by the pulse of innovation and the melody by the empathetic understanding of diverse learner needs. The study recognizes that the pursuit of excellence in English teaching requires an intricate balance, where tradition provides the foundation, and innovation propels educators into uncharted territories of pedagogical exploration.

There are four Attributes

Effectiveness of Instructional Strategies ($\yen_1$):

Assess the impact and efficiency of instructional methods employed by english teachers. Evaluate the alignment of instructional strategies with diverse learning styles and educational objectives. Measure the engagement and participation levels of students during various instructional activities. Examine the integration of technology and other innovative approaches in enhancing the overall learning experience.

Classroom Management and Learning Environment ($\yen_2$):

Evaluate the effectiveness of classroom management strategies in maintaining a positive and inclusive learning environment. Assess the organization and physical layout of the classroom to optimize student engagement. Consider the implementation of behavior management techniques and their impact on student behavior and focus. Explore the incorporation of culturally responsive practices in creating an inclusive classroom atmosphere.

Student Assessment and Feedback ($\yen_3$):

Examine the design and implementation of assessments to measure student understanding and progress. Evaluate the timeliness and quality of feedback provided to students to support their learning. Analyze the alignment between assessments and learning objectives. Explore the use of formative assessments as tools for ongoing evaluation and adjustment of instructional strategies.

Professional Development Engagement ($\yen_4$):

Assess english teachers' participation in professional development activities related to pedagogy, technology, and content knowledge. Evaluate the impact of professional development on english teaching practices and student outcomes. Explore english teachers' proactive engagement in seeking continuous learning opportunities. Consider the alignment between professional development activities and identified areas for improvement.

There are four Alternatives

Peer Mentoring and Collaborative Learning ($\top_1$):

Implement a peer mentoring program where english teachers collaborate and share successful english teaching practices. Encourage collaborative lesson planning and team english teaching among educators. Facilitate regular forums for english teachers to discuss challenges and successes in a supportive community.

Student-Led Assessments and Portfolios ($\top_2$):

Explore alternative assessment methods, such as student-led conferences or portfolios, to capture a more comprehensive view of student progress. Encourage students to actively participate in setting learning goals and self-assessing their performance. Incorporate reflective exercises where students assess their own learning journey.

Degree Evaluation ($\top_3$):

Expand the evaluation process to include input from students, parents, and colleagues through degree feedback. Implement student and parent surveys to gather perspectives on english teaching effectiveness. Encourage collaborative evaluations where english teachers receive feedback from their peers, administrators, and students.

Innovative Professional Development Formats ($\top_4$):

Introduce alternative professional development formats, such as workshops, webinars, and online courses, to cater to diverse learning preferences. Provide english teachers with opportunities to attend conferences, engage in action research, or participate in collaborative projects. Foster a culture of continuous improvement by integrating professional development into regular team meetings and planning sessions.

We have a collection of alternatives denoted as $\top = \{\top_1, \top_2, \top_3, \top_4\}$,. We also have a set of attributes denoted as $\yen$=$\{\yen_1, \yen_2, \yen_3, \yen_4\}$. We have experts weight vector $\breve{\Omega} = \{0.47, 0.38, 0.15\}$.

Step 1 Decision matrices by the expert1, expert2 and expert3 in Table I, II and III respectively.

| $\top_2$ | $((0.2339, 0.2635), (0.6709, 0.7816), (0.6712, 0.7530))$ |
| $\top_3$ | $((0.3383, 0.3321), (0.6880, 0.6895), (0.7455, 0.7540))$ |
| $\top_4$ | $((0.3428, 0.2096), (0.6584, 0.8620), (0.7375, 0.7384))$ |
| $\pounds_{\diamond_{ij}}$ | $\yen_4$ |
| $\top_1$ | $((0.1753, 0.2204), (0.8740, 0.8363), (0.9219, 0.8234))$ |
| $\top_2$ | $((0.1694, 0.2060), (0.8003, 0.7974), (0.8306, 0.7959))$ |
| $\top_3$ | $((0.2396, 0.1579), (0.7423, 0.7678), (0.7856, 0.8363))$ |
| $\top_4$ | $((0.1481, 0.1427), (0.8570, 0.7856), (0.7905, 0.8892))$ |

Step 6 The ideal and anti ideal solution are estimated in Table VIII and in Table IX respectively.

TABLE VIII. THE IDEAL SOLUTION

| $\pounds_{\diamond_{ij}}$ | $\yen_1$ |
|---|---|
| $t^+$ | $((0.3312, 0.2025), (0.8135, 0.8046), (0.7884, 0.8446))$ |
| $\pounds_{\diamond_{ij}}$ | $\yen_2$ |
| $t^+$ | $((0.3194, 0.2913), (0.7769, 0.8019), (0.8223, 0.8640))$ |
| $\pounds_{\diamond_{ij}}$ | $\yen_3$ |
| $t^+$ | $((0.3428, 0.4745), (0.8182, 0.8366), (0.7661, 0.8256))$ |
| $\pounds_{\diamond_{ij}}$ | $\yen_4$ |
| $t^+$ | $((0.2396, 0.2204), (0.7729, 0.7958), (0.81170.8209))$ |

TABLE IX. THE ANTI IDEAL SOLUTION

| $\pounds_{\diamond_{ij}}$ | $\yen_1$ |
|---|---|
| $t^-$ | $((0.1632, 0.1577), (0.8135, 0.8046), (0.8648, 0.9051))$ |
| $\pounds_{\diamond_{ij}}$ | $\yen_2$ |
| $t^-$ | $((0.2533, 0.2388), (0.7769, 0.8019), (0.8459, 0.9008))$ |
| $\pounds_{\diamond_{ij}}$ | $\yen_3$ |
| $t^-$ | $((0.2339, 0.2096), (0.8182, 0.8366), (0.8685, 0.8732))$ |
| $\pounds_{\diamond_{ij}}$ | $\yen_4$ |
| $t^-$ | $((0.1481, 0.1427), (0.7729, 0.7958), (0.9321, 0.9034))$ |

Step 7 The distance between weighted normalized decision matrix and Ideal solution $d_{ij}^+$ and weighted normalized decision matrix and Anti Ideal solution $d_{ij}^+$ in Table X and in Table XI respectively.

TABLE X. DISTANCE BETWEEN WEIGHTED NORMALIZED DECISION MATRIX AND IDEAL SOLUTION $d_{ij}^+$

| $\pounds_{\diamond_{ij}}$ | $\yen_1$ | $\yen_2$ | $\yen_3$ | $\yen_4$ |
|---|---|---|---|---|
| $\top_1$ | 0.11615 | 0.10829 | 0.02665 | 0.19177 |
| $\top_2$ | 0.08473 | 0.02366 | 0.14285 | 0.07344 |
| $\top_3$ | 0.06940 | 0.07461 | 0.13644 | 0.03276 |
| $\top_4$ | 0.13238 | 0.06862 | 0.16539 | 0.12292 |

TABLE XI. DISTANCE BETWEEN WEIGHTED NORMALIZED DECISION MATRIX AND ANTI IDEAL SOLUTION $d_{ij}^-$

| $\pounds_{\diamond_{ij}}$ | $\yen_1$ | $\yen_2$ | $\yen_3$ | $\yen_4$ |
|---|---|---|---|---|
| $\top_1$ | 0.05398 | 0.11034 | 0.16539 | 0.15820 |
| $\top_2$ | 0.08419 | 0.04679 | 0.06313 | 0.15684 |
| $\top_3$ | 0.11092 | 0.07864 | 0.06500 | 0.14756 |
| $\top_4$ | 0.12889 | 0.05455 | 0.08152 | 0.14160 |

Step 8 The degree of deviation of every option from ideal and anti ideal solution are given in Table XII

TABLE XII. DEGREE OF DEVIATION OF EVERY OPTION FROM IDEAL AND ANTI IDEAL SOLUTION

| | $\mathfrak{S}_\mathfrak{i}^+$ | $\mathfrak{S}_\mathfrak{i}^-$ |
|---|---|---|
| $\top_1$ | 0.44285 | 0.48791 |
| $\top_2$ | 0.32469 | 0.35094 |
| $\top_3$ | 0.31321 | 0.40212 |
| $\top_4$ | 0.48930 | 0.40657 |
| $\mathfrak{S}_\diamond$ | 0.31321 | 0.48791 |

Step 9 The utility function of each alternative is computed In Table XIII

TABLE XIII. The Utility Function of Each Alternative

| | $K_i^+$ | $K_i^-$ |
|---|---|---|
| $\top_1$ | 0.70726 | 1.00000 |
| $\top_2$ | 0.96466 | 0.71928 |
| $\top_3$ | 1.00000 | 0.82417 |
| $\top_4$ | 0.64012 | 0.83330 |

Step 10 The average departure of the options is computed In Table XIV

TABLE XIV. The Average Departure of the Options $Q_i$

| $Q_i$ |
|---|
| 0.85363 |
| 0.84197 |
| 0.91208 |
| 0.73671 |

Step 11 Ranking all possibilities in descending order in Table XV.

TABLE XV. Ranking of Numerical Problem

| method | scoring |
|---|---|
| CRADIAS Method | $\top_3 \geq \top_1 \geq \top_2 \geq \top_4$ |

As a result, we determine that option $\top_3$ is the best optimal solution. The graphical representation of CRADIAS method given in Fig. 2

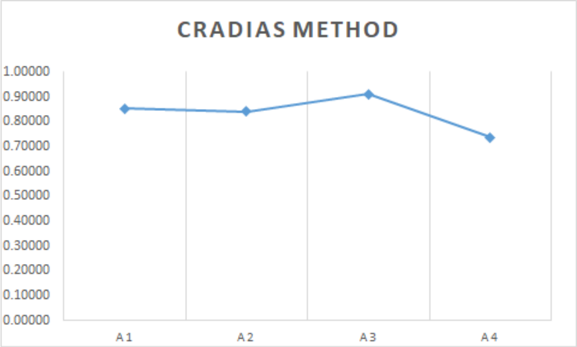

Fig. 2. Graphical Representation of Ranking

## V. Comparison Analysis

In this section, we compare the CRADIAS method to the developed MAGDM technique, highlighting the advantages of the established methodology. The characteristics of the CRADIAS method provided in this study are compared to the MARCOS method [39]. We demonstrate how the suggested approach efficiently solves real-life decision-making problems (DMPs) with uncertainty through this extensive comparison, stressing its efficacy and robustness.

### A. *MARCOS approach for* $SF\acute{Z}N$

**Algorithm**

1) Decision matrices by the experts.
2) Using aggregation operators to to aggregate all individuals spherical fuzzy $\breve{z}$-numbers decision matrices into collective spherical fuzzy $\breve{z}$-numbers decision matrix $\pounds_{\diamond_{ij}} = [\pounds_{\diamond_{ij}}]_{m\times n}$
3) The attribute weights are calculated by CRITRIC method. calculate attributes weights by using following equation: Compute the score values of decision matrix.

$$\Im(\pounds_{\diamond_{ij}}) = \frac{2+((\epsilon_{ij})(\tau_{\epsilon_{ij}}))-((\nu_{ij})(\tau_{\nu_{ij}}))-((\ni_{ij})(\tau_{\ni_{ij}}))}{3} \quad \forall i,j. \; .$$

$$\overbrace{\Im(\pounds_{\diamond_{ij}})} = \begin{cases} \frac{\Im(\pounds_{\diamond_{ij}}) \; - \; \Im(\pounds_{\diamond_{ij}})^-}{\Im(\pounds_{\diamond_{ij}})^+ \; - \; \Im(\pounds_{\diamond_{ij}})^-}, & j \in \mathrm{R_b}. \\ \\ \frac{\Im(\pounds_{\diamond_{ij}})^+ \; - \Im(\pounds_{\diamond_{ij}})}{\Im(\pounds_{\diamond_{ij}})^+ \; - \; \Im(\pounds_{\diamond_{ij}})^-}, & j \in \mathrm{R_c}. \end{cases}$$

where $\mathrm{R_b}$ and $\mathrm{R_c}$ are the benefit and cost type of criteria sets respectively. $\Im(\pounds_{\diamond_{ij}})^- = min_i \Im(\pounds_{\diamond_{ij}})$ and $\Im(\pounds_{\diamond_{ij}})^+ = max_i \Im(\pounds_{\diamond_{ij}})$

Calculate the standard deviation by using the following equation:

$$\S_j = \sqrt{\frac{\sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{ij}})} - \overline{\Im(\pounds_{\diamond_{ij}})}\right)^2}{m}}.$$

Where $\overline{\Im(\pounds_{\diamond_{ij}})} = \frac{\overbrace{\Im(\pounds_{\diamond_{ij}})}}{m}$.

Calculate the correlation between criteria pairs by using the following equation:

$$\Upsilon_{jl} = \frac{\sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{ij}})} - \overline{\Im(\pounds_{\diamond_{ij}})}\right)\left(\overbrace{\Im(\pounds_{\diamond_{i}l})} - \overline{\Im(\pounds_{\diamond_{i}l})}\right)}{\sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{ij}})} - \overline{\Im(\pounds_{\diamond_{ij}})}\right)^2 \sum_{i=1}^{n}\left(\overbrace{\Im(\pounds_{\diamond_{i}l})} - \overline{\Im(\pounds_{\diamond_{i}l})}\right)^2}.$$

Calculate each criterion's information amount using the formula below:

$$\Gamma_j = \sum_{l=1}^{n}(1 - \Upsilon_{jl})$$

Calculated the weight of each attribute b using following equation:

$$\breve{\Omega} = \frac{\Gamma_j}{\sum_{j=1}^{n}\Gamma_j}$$

4) Normalize the decision matrices.
Normalize by using following equation:

$$\pounds_{\diamond_{ij}} = \begin{cases} \pounds_{\diamond_{ij}} = \\ \Big\{(\epsilon_{ij}, \tau_{\epsilon_{ij}}), (\nu_{ij}, \tau_{\nu_{ij}}), (\ni_{ij}, \tau_{\ni_{ij}})\Big\}, & j \in \mathrm{R_b}, \\ {\pounds_{\diamond_{ij}}}^{c} = \\ \Big\{(\ni_{ij}, \tau_{\ni_{ij}}), (\nu_{ij}, \tau_{\nu_{ij}}), (\epsilon_{ij}, \tau_{\epsilon_{ig}})\Big\}, & j \in \mathrm{R_c}, \end{cases}$$

where $\mathrm{R_b}$ and $\mathrm{R_c}$ are the benefit and cost type of criteria set respectively.

5) The positive ideal solution (PIS) $P_j^+$ and negative ideal solution (NIS) $N_j^-$

$$P_j^+ = \left\{ \begin{array}{l} (\max_{i=1,\dots m}\epsilon_j, \max_{i=1,\dots m} \tau_{\epsilon_j}), \\ (\min_{i=1,\dots m} \nu_j, \min_{i=1,\dots m} \tau_{\nu_{ij}}), \\ (\min_{i=1,\dots m} \ni_{ij}, \min_{i=1,\dots m} \tau_{\ni_{ij}}) \end{array} \right\}.$$

$$N_j^- = \left\{ \begin{array}{l} (\min_{i=1,\dots m}\epsilon_j, \min_{i=1,\dots m} \tau_{\epsilon_j}), \\ (\min_{i=1,\dots m} \nu_j, \min_{i=1,\dots m} \tau_{\nu_{ij}}), \\ (\max_{i=1,\dots m} \ni_{ij}, \max_{i=1,\dots m} \tau_{\ni_{ij}}) \end{array} \right\}.$$

6) Calculate the distance between normalized decision matrix and PIS $\ddot{d}_{ij}^+$ and NIS $\ddot{d}_{ij}^-$ by using following equations:

$$\ddot{d}_i^+ = (\breve{\pounds}_{\diamond_{ij}}, P_j^+)$$

$$\ddot{d}_i^- = d(\breve{\pounds}_{\diamond_{ij}}, N_j^-)$$

where,

$$d(\breve{\pounds}_{\diamond_{ij}}, P_j^+) = \left\{ \begin{array}{l} \Big(\Big((\epsilon_{ij}.\tau_{\epsilon_{ij}}) - (\epsilon_j^+.\tau_{\epsilon_j}^+)\Big)^2 + \\ \Big((\nu_{ij}.\tau_{\nu_{ij}}) - (\nu_j^+.\tau_{\nu_j}^+)\Big)^2 + \\ \Big((\ni_{ij}.\tau_{\ni_{ij}}) - (\ni_j^+.\tau_{\ni_j}^+)\Big)^2\Big)^{\frac{1}{2}} \end{array} \right\}.$$

$$d(\breve{\pounds}_{\diamond_{ij}}, N_j^-) = \left\{ \begin{array}{c} \Big(\Big((\epsilon_{ij}.\tau_{\epsilon_{ij}}) - (\epsilon_j^-.\tau_{\epsilon_j}^-)\Big)^2 + \\ \Big((\nu_{ij}.\tau_{\nu_{ij}}) - (\nu_j^-.\tau_{\nu_j}^-)\Big)^2 + \\ \Big((\ni_{ij}.\tau_{\ni_{ij}}) - (\ni_j^-.\tau_{\ni_j}^-)\Big)^2\Big)^2\Big)^{\frac{1}{2}} \end{array} \right\}.$$

7) Calculate the closeness coefficient. Utilizing $\ddot{d}_{ij}^+$ and $\ddot{d}_{ij}^-$, determine the closeness coefficient as follows:

$$\mathfrak{C}ij = \frac{\ddot{d}_{ij}^-}{\ddot{d}_{ij}^+ + \ddot{d}_{ij}^-}.$$

8) Calculate the extended decision matrix. Make the extended decision matrix by insertion of $\mathfrak{C}_{ij}$ , and the anti-ideal ($\mathfrak{A}^- = \{\mathfrak{C}i1^-, \mathfrak{C}i2^-, ..., \mathfrak{C}in^-\}$) and ideal ($\mathfrak{A}^+ = \{\mathfrak{C}ij^+; j = 1, 2, ..., n\}$) solution.

$$\mathfrak{A} = \begin{pmatrix} \mathfrak{C}i1^- & \mathfrak{C}i2^- & \dots & \mathfrak{C}_{in}^- \\ \mathfrak{C}11 & \mathfrak{C}12 & \dots & \mathfrak{C}_{1n} \\ \mathfrak{C}21 & \mathfrak{C}22 & \dots & \mathfrak{C}_{2n} \\ \vdots & \vdots & \dots & \vdots \\ \mathfrak{C}m1 & \mathfrak{C}m2 & \dots & \mathfrak{C}_{mn} \\ \mathfrak{C}i1^+ & \mathfrak{C}i2^+ & \dots & \mathfrak{C}_{in}^+ \end{pmatrix}$$

Here

For benefit type criteria

$$\mathfrak{C}ij^- = min\mathfrak{C}ij$$

and

$$\mathfrak{C}ij^+ = max\mathfrak{C}ij$$

For cost type criteria

$$\mathfrak{C}ij^- = max\mathfrak{C}ij$$

and

$$\mathfrak{C}ij^+ = min\mathfrak{C}ij$$

9) Convert the extended decision matrix $\mathfrak{A}$ into normalized form $E = [n_{ij}]_{(m+2)\times n}$,based on the following equation:

For benefit type criteria

$$n_{ij} = \frac{\mathfrak{C}ij}{\mathfrak{C}ij^+}$$

For cost type criteria

$$n_{ij} = \frac{\mathfrak{C}ij^+}{\mathfrak{C}ij}$$

where, $\pounds_{\diamond_{ij}}$ and $\mathfrak{C}ij^+$ are the elements in the E matrix.

10) Calculate the weighted decision matrix. Build up the final weighted decision matrix $F = [f_{ij}]_{(m+2)\times n}$ by the following equation

$$f_{ij} = n_{ij} \times \breve{\Omega}_j$$

where, $n_{ij}$ is an element of the matrix $E^{'}$ and $\breve{\Omega}_j$ is the weight of jth criteria.

11) Determine the utility degree of alternatives $\mathfrak{U}_i$ by employing following equations:

$$\mathfrak{U}i^- = \frac{\mathfrak{S}i}{\mathfrak{S}^-},$$

$$\mathfrak{U}i^+ = \frac{\mathfrak{S}i}{\mathfrak{S}^+},$$

where, $\mathfrak{S}i = \sum j = 1^n f_{(i+1)j} (i = 1, 2, ..., m)$, $\mathfrak{S}^- = \sum_{j=1}^{n} f_{1j}$ and $\mathfrak{S}^+ = \sum_{j=1}^{n} f_{(m+2)j}$.

12) Compute the utility function of alternatives $F(\mathfrak{U}_i)$ based on the following equation:

$$F(\mathfrak{U}i) = \frac{\mathfrak{U}i^+ + \mathfrak{U}i^-}{1 + \frac{1-F(\mathfrak{U}i^+)}{F(\mathfrak{U}i^+)} + \frac{1-F(\mathfrak{U}i^-)}{F(\mathfrak{U}_i^-)}},$$

where the utility function with respect to the ideal $F(\mathfrak{U}i^+)$ and anti-ideal $F(\mathfrak{U}i^-)$ are given, respectively, by the following formulas:

$$F(\mathfrak{U}i^+) = \frac{\mathfrak{U}i^-}{\mathfrak{U}i^+ + \mathfrak{U}i^-},$$

$$F(\mathfrak{U}i^{-}) = \frac{\mathfrak{U}i^{+}}{\mathfrak{U}i^{+} + \mathfrak{U}i^{-}}.$$

13) Rank all alternatives in descending order and choose the best one.

| $\top_3$ | 0.65825 | 0.55173 | 0.47135 | 0.79136 |
| $\top_4$ | 0.47799 | 0.44527 | 0.31079 | 0.55153 |
| $\top_i^{+}$ | 0.65825 | 0.55423 | 0.89171 | 0.79136 |

Step 9 The normalized extended decision matrix are given in Table XXII.

TABLE XXII. Normalized Extended Decision Matrix

| $\pounds_{\diamond_{ij}}$ | $¥_1$ | $¥_2$ | $¥_3$ | $¥_4$ |
|---|---|---|---|---|
| $\top_i^-$ | 0.59576 | 0.80340 | 0.28391 | 0.60303 |
| $\top_1$ | 0.63106 | 0.91017 | 1.00000 | 0.60303 |
| $\top_2$ | 0.59576 | 1.00000 | 0.28391 | 0.92753 |
| $\top_3$ | 1.00000 | 0.99549 | 0.52859 | 1.00000 |
| $\top_4$ | 0.72616 | 0.80340 | 0.34854 | 0.69694 |
| $\top_i^+$ | 1.00000 | 1.000007 | 1.00000 | 1.00000 |

Step 10 The weighted normalized of extended decision matrix are given in Table XXIII.

TABLE XXIII. Weighted Normalized of Extended Decision Matrix

| $\pounds_{\diamond_{ij}}$ | $¥_1$ | $¥_2$ | $¥_3$ | $¥_4$ |
|---|---|---|---|---|
| $\top_i^-$ | 0.10426 | 0.20724 | 0.10352 | 0.12207 |
| $\top_1$ | 0.11044 | 0.23478 | 0.36461 | 0.12207 |
| $\top_2$ | 0.10426 | 0.25795 | 0.10352 | 0.18777 |
| $\top_3$ | 0.17501 | 0.25679 | 0.19273 | 0.20244 |
| $\top_4$ | 0.12708 | 0.20724 | 0.12708 | 0.14108 |
| $\top_i^+$ | 0.17501 | 0.25795 | 0.36461 | 0.20244 |

Step 11 The utility degree of alternatives $\mathfrak{U}_i^-$ and $\mathfrak{U}_i^+$ are given in Table XXIV.

TABLE XXIV. Utility Degree of Alternatives

| $\mathfrak{U}_i^-$ | $\mathfrak{U}_i^+$ |
|---|---|
| 1.54890 | 0.83190 |
| 1.21673 | 0.65350 |
| 1.53969 | 0.82696 |
| 1.12175 | 0.60248 |

Step 12 The utility function of alternatives $F(\mathfrak{U}_i)$ are given in Table XXV.

TABLE XXV. Utility Function of Alternatives

| $F(\mathfrak{U}_i)$ |
|---|
| 0.69628 |
| 0.55023 |
| 0.70045 |
| 0.50728 |

Step 13 Ranking all possibilities in descending order are given in Table XXVI .

TABLE XXVI. Ranking of all Possibilities

| method | scoring |
|---|---|
| MARCOS Method | $\top_3 \geq \top_1 \geq \top_2 \geq \top_4$ |

Ranking of comparison between CRADIAS method and MARCOS method are given in Table XXVII.

TABLE XXVII. Ranking of Comparison between CRADIAS Method and MARCOS Method

| sr. | methods | scoring |
|---|---|---|
| 1 | CRADIAS method | $\top_3 \geq \top_1 \geq \top_2 \geq \top_4$ |
| 2 | MARCOS method | $\top_3 \geq \top_1 \geq \top_2 \geq \top_4$ |

Graphical Representation of comparison between CRADIAS and MARCOS method Ranking in Fig. 4.

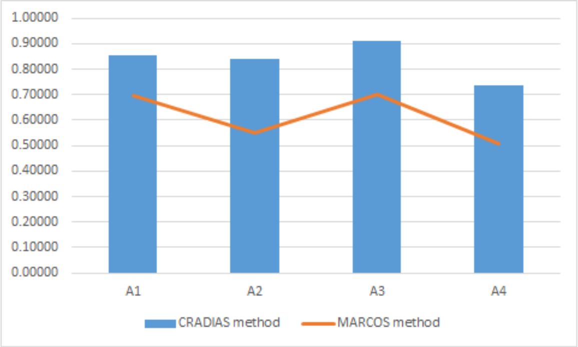

Fig. 4. Graphical Representation of Comparison between $SF\acute{Z}N_{SW}$ and MARCOS Method Ranking

## VI. Discussion

An experiment was conducted in the scenario of spherical fuzzy Z-numbers to assess the performance of the proposed algorithms with respect to existing metrics. All tactics eventually lead to the same optimal option, despite some variations in the ranking. A detailed comparison of rankings and graphical representations for the MARCOS approach and CRADIAS inside the $SF\breve{Z}N$ environment can be seen in Table XXVII and Fig. 4. The major objective of this study was to ascertain which method of decision-making was more effective in this specific circumstance. Throughout the investigation, it was found that the ranking order of the alternatives can exhibit slight variations based on the aggregating methods used. However, the optimal course of action was consistently determined by each strategy. Consequently, $\Im(\top_3)$ emerges as the optimal substitute option. The power and reliability of the recommended algorithms are demonstrated by the striking consistency in selecting the optimal solution. The fact that, despite minor ranking discrepancies, every participant chose the same optimal solution suggests how effective the recommended technique is in resolving issues brought on by spherical fuzzy $\breve{Z}$-numbers.

## VII. Conclusion

This work attempts to offer basic operating principles for Spherical Fuzzy Z-numbers ($SF\breve{Z}N$) utilizing the CRADIAS technique. We address the inherent complexity of Multiple

Attributes Group Decision Making (MAGDM) scenarios by combining the strategies of these suggested operators in a novel decision-making approach. This innovative method adds a layer to the decision-making process that enables the assessment of both positive and negative factors. In summary, the empirical findings of our research demonstrate that the approach presented here is the most useful and realistic way to solve MAGDM difficulties. Following a thorough examination of situations related to the assessment of english teaching performance in a secondary school setting and comparisons with the MARCOS method, the recommended $SF\breve{Z}N$ Operators have been shown to be viable and valid. Furthermore, our work supports its results with a rigorous mathematical example. Ultimately, our findings demonstrate that the approach outlined in this paper is the most practical and effective means of resolving MAGDM issues. Further research endeavors will concentrate on developing innovative methods of decision-making that are particular to the $SF\breve{Z}N$ context. The ELECTRE technique, EDAS, TOPSIS, and other methods will be combined in these approaches to increase the effectiveness of decision-making.

Faculty of Science and Engineering, Waseda University, Tokyo, Japan[4]

***Abstract*—Resource Public Key Infrastructure (RPKI) is a solution to mitigate the security issues faced by inter-domain routing. Within the RPKI framework, Route Origin Authorization (ROA) plays a crucial role as an RPKI object. ROA allows address space holders to place a single IP address prefix or multiple IP address prefixes in it. However, this feature has introduced security risks during the global deployment of RPKI. In this study, we analyze the current status of ROA issuance and discuss the impact of using two ROA issuance policies on RPKI security and synchronization efficiency. Based on the aforementioned work, recommendations are proposed for the utilization of ROA issuance policies.**

***Keywords*—BGP; RPKI; route origin authorization; inter-domain routing security; computer network protocols; routing**

## I. Introduction

The Border Gateway Protocol (BGP) [1] is one of the most vital protocols on the Internet, responsible for the exchange routing and reachability information among autonomous systems (AS) on the Internet. However, the design of BGP neglected security considerations and the decentralized nature of the Internet, consequently giving rise to numerous security issues. Among these, BGP route hijacking poses the most severe risk, capable of triggering a cascade of catastrophic consequences such as data breaches, network outages, and malicious attacks [2]. To mitigate the issue of BGP route hijacking, the Internet Engineering Task Force (IETF) Secure Inter-Domain Routing (SIDR) working group has devised RPKI and consistently refined it.

RPKI is rooted in the concept of cryptographically verifying BGP update messages [3]. RPKI utilizes digital signatures to authorize and allocate Internet Number Resources (INR) [4], and verifies BGP update messages by using cryptographical RKPI objects. Much research has been conducted on enhancing the RPKI during the process of global deployment. In terms of the trust model, in 2016, Hari et al. [5] proposed a basic framework for decentralized internet infrastructure based on blockchain. This framework abstracts the allocation of IP address prefixes and the mapping relationship of IP address prefixes and AS Numbers (ASN) as transactions on the blockchain. By leveraging the distributed and tamper-resistant properties of the blockchain [6], preventing malicious operations and reducing the centralization of authority in the existing RPKI trust model. In terms of potential attack risks, Hlavacek et al. [7] explored the dependency of RPKI on DNS components and proposed that disruptions to DNS resolvers can lead to RPKI failures. Additionally, Hlavacek et al. [8] introduced a downgrade attack on RPKI and analyzed the potential damage caused by such attacks in existing RPKI deployment environments, providing defense recommendations based on these analyses. In terms of ROA security, Gilad et al. [9] conducted research on the improper use of the maxLength field in ROA, which poses security risks to RPKI, and provided configuration recommendations for the maxLength field.

This study focuses on ROA security. ROA is the most prevalent object in RPKI. The eContent structure of ROA includes a version field, an asID field, and an ipAddrBlocks field [10]. The version field defaults to zero. The asID field contains a single AS number, authorized by address space owners as the origin for IP address prefixes. The ipAddrBlocks field contains a list of one or more IP address prefixes that will be announced, allowing address space owners to place one or more IP address prefixes in ROA. However, when placing multiple IP address prefixes in ROAs, there is a security issue where INRs are unexpectedly validated as invalid, thereby diminishing the reliability of RPKI. In this study, we found this security issue arises only when ROA overclaims. Through further analysis, we attributed this security issue to the fate-sharing nature of ROA with multiple prefixes. In contrast, the absence of the fate-sharing nature in ROA with a single prefix avoids this security issue. Additionally, we identified two scenarios triggering this security issue through experiments. Then we analyzed the current ROA situation and found that many address space holders choose to use the issuance policy of ROA with multiple prefixes. This choice poses security risks to the current RPKI production environments. But compared to ROA with a single prefix, ROA with multiple prefixes offers the advantage of reducing ROA data volume. Requiring using the issuance policy of ROA with a single prefix in the RPKI production environment would impact the synchronization efficiency of RPKI. To evaluate this impact, we conducted experiments to compare the synchronization times under two different ROA issuance policies. The experimental results indicate that the increased synchronization time resulting from using the issuance policy of ROA with a single prefix is acceptable. Through the aforementioned works, we provided recommendations for using the issuance policy of ROA with a single prefix as the preferred option, and promoted the formulation of IETF Request for Comments (RFC) 9455 [11], enhancing the security of the RPKI.

This paper is organized as follows: Section II introduces the overview of the RPKI as the foundation for understanding this paper, Section III presents the analysis of the current ROA situation, Section IV describes security issues arising from ROA with multiple prefixes overclaiming, Section V shows our evaluation of the impact on synchronization efficiency in the current RPKI production environment when using the issuance policy of ROA with a single prefix, Section VI concludes our work.

## II. Overview of RPKI

The RPKI system is primarily comprised of a certificate issuance system, a certificate storage system, and a certificate synchronization and verification mechanism. As illustrated in Fig. 1, the certificate issuance system allocates INRs through issuing certificates, followed by storing certificates in the certificate storage system. RPKI Relying Party(RP) synchronizes and verifies RPKI certificates and signature objects, and then provides the verification result to BGP routers for filtering purposes.

### *A. Issuance System*

The certificate issuance system adopts a hierarchical certificate model that aligns with the allocation architecture of INR. At the top level, the Internet Assigned Numbers Authority (IANA) allocates INRs to the RIRs, which manage and allocate address spaces within their respective regions. RIRs allocate their INRs to the National Internet Registries (NIR), the Local Internet Registries (LIR), or the Internet Service Providers (ISP), who allocate INRs downstream to smaller network operators.

RPKI employs five independent RIRs as the trust anchors (TAs), which are AfriNIC, APNIC, ARIN, LACNIC, and RIPE NCC. RPKI is deployed through either the hosted model or the delegated model [12]. With the hosted model, RIR bears the responsibility of maintaining RPKI and providing CA service. This allows address space holders to focus on creating and maintaining ROAs. With the delegated model, address space holders are obliged to operate their CAs to create and maintain ROAs. Such a model affords address space holders autonomy in managing their IP address resources, reducing their reliance on RIR.

CA is an entity that is responsible for issuing CA certificate and end-entity (EE) certificate. The allocation of INR between CAs requires the parent CA to generate and sign a CA certificate for the child CA. After establishing a relationship between the parent CA and the child CA, the child CA is required to periodically request the parent CA to update the CA certificate to maintain the validity of the certificate chain. Krill [13], which is a widely used CA software, implements this mechanism by setting the request periodic interval to ten minutes. When CA allocates IP address prefixes to AS, CA needs to generate an EE certificate for AS. Once generated, the EE certificate is required to sign the ROA content that has been encapsulated using the Cryptographic Message Syntax (CMS) format [14]. The EE certificate and ROA have a one-to-one correspondence relationship. To simplify ROA issuance and revocation processes, the EE certificate is embedded in the corresponding ROA.

### *B. Storage System*

RPKI storage system is comprised of multiple repository publication points, CAs store their CA certificates, ROAs, and Certificate Revocation Lists (CRLs) in their respective repository publication points. The repository publication point establishes a manifest [15] based on the stored files. Manifest is beneficial for detecting replay attacks and unauthorized in-flight modification or deletion of signed objects. Upon authorization of INRs is modified by CA, a real-time message will be promptly dispatched to notify its repository publication point to update RPKI objects.

In the RPKI storage system, the repository publication points are interconnected via two fields in the CA certificate, namely Subject Information Access (SIA) and Authority Information Access (AIA) [16]. The SIA field records the repository publication point address of CA, thereby facilitating the search for certificates issued by CA. Meanwhile, the AIA field records the repository publication point address of the parent CA, thereby enabling the retrieval of certificates issued by the parent CA. By utilizing the two aforementioned fields, it is theoretically feasible to systematically traverse the entire RPKI repository system.

The storage system supports data synchronization by means of both the RPKI Repository Delta Protocol (RRDP) [17] and rsync [18]. Considering the broad support for rsync across multiple operating systems, the SIDR working group chose to utilize rsync as the synchronization protocol for RPKI during its initial design. This choice promotes the widespread adoption and deployment of RPKI. Although rsync has implemented the incremental synchronization mechanism to reduce synchronized data, this approach is in high demand on computational resources. Hence, the SIDR working group devised RRDP as a substitute for rsync [19]. By utilizing storing space to decrease the demand for computational resources, RRDP requires that every repository publication point maintains updated files, documenting all modified operations (for example, updated manifests and CRLs, newly issued certificates, or ROAs) along with their corresponding timestamps in the repository publication point.

### *C. Synchronization and Verification Mechanism*

RP is a critical component in the RPKI synchronization and validation mechanism. RP uses Trust Anchor Locators (TALs) to retrieve the CA certificates and public keys of each TA. The corresponding repository publication point address is obtained from the SIA field in the CA certificate. Afterward, RP synchronizes RPKI objects from the repository publication points of TAs by using either RRDP or rsync, with RRDP being the preferred synchronization option, and continues to synchronize repository publication points of the child CAs downwards. After synchronizing RPKI objects to the local cache, RP validates them by verifying each object along the certificate chain from top to bottom. Following this, RP parses the mapping relationships of IP address prefixes and ASN recorded in valid ROAs to generate a route filtering table. By default, common RP software typically synchronizes and validates at intervals of one hour or less [20].

The BGP router in AS utilizes the RPKI to Router (RTR) [21] protocol to regularly fetch the route filtering table from

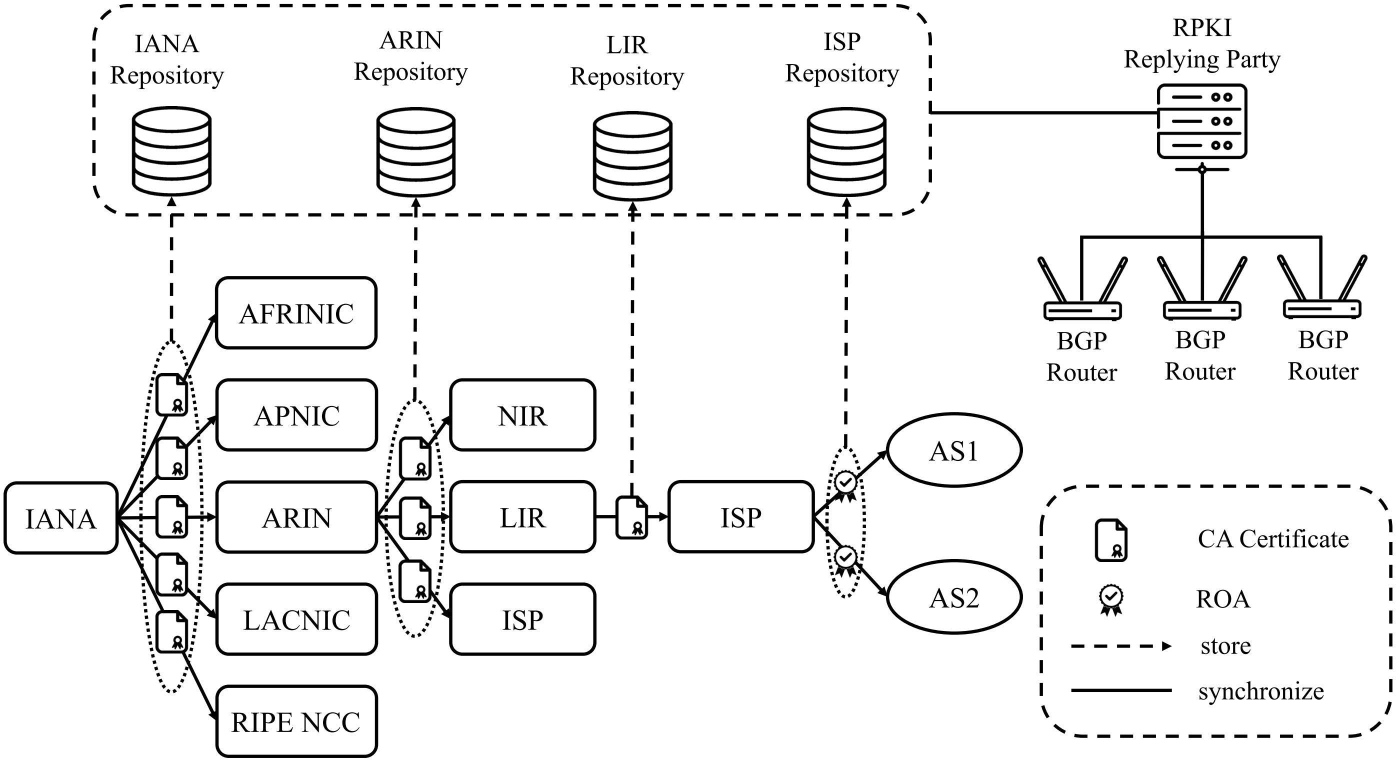

Fig. 1. RPKI system. The certificate issuance system is displayed below, the certificate storage system is shown above, and the certificate synchronization and verification mechanism is presented on the right side.

TABLE I. The Relationship between VRPs and the Validity of Routes

| IP address prefix of route | VRP match ASN of route | VRP mismatch ASN of route |
|---|---|---|
| Not covered by VRP | NotFound | NotFound |
| Covered by VRP | Valid | Invalid |

RP. BGP router utilizes the route filtering table to perform route origin validation (ROV) [22] on the received BGP announcements, thereby sieving out invalid BGP routes. The relationship between the Validated ROA Payloads (VRPs) [23] in the route filtering table and the validity of the routes in BGP announcements is shown in Table I.

Covered by the IP address prefix of VRP refers to the length of the IP address prefix in VRP is shorter than that in route, and all the bits specified by the IP address prefix length of VRP are identical between VRP and route. Valid routes are accepted by the BGP router while invalid ones are rejected. The routes with the verification status of NotFound are accepted by default. BGP router administrator retains the ability to adjust the acceptance of routes with the verification status of NotFound in accordance with individual needs and preferences.

## III. ROA Analysis

In this section, we made the following analysis to elucidate the current ROA situation. The data utilized for this analysis was provided by RIPE NCC and Internet Multifeed Co. [24], up until February 25th, 2023.

TABLE II. The Number of Global ROA

| ROA type | Quantity |
|---|---|
| Total ROA | 139484 |
| ROA with a single prefix | 110944 |
| ROA with multiple prefixes | 28540 |

TABLE III. The Number of Global IP Address Prefix

| ROA type | Quantity |
|---|---|
| Total ROA | 404101 |
| ROA with multiple prefixes | 293157 |

As shown in Table II, approximately 139484 ROA objects were globally issued. Further analysis reveals that around 110944 (79.54% of all ROA objects) ROAs contain a single IP address prefix, while the remaining 28540 (20.46% of all ROA objects) ROAs contain multiple IP address prefixes. Calculating the number of IP address prefixes within all ROAs with multiple IP prefixes, the statistical results are presented in Table III. Among 28,540 ROAs contain two or more IP address prefixes with a total of 293,157 IP address prefixes. Notably, despite the greater number of ROAs with a single prefix, the IP address prefixes contained in ROAs with multiple prefixes constitute 72.55% of the total IP address prefixes.

TABLE IV. The Average Size of Each ROA in Five Types of ROAs

| The number of IP address prefix in ROA | average size (bytes) |
|---|---|
| 1 | 1999 |
| 2-10 | 1915 |
| 11-50 | 2157 |
| 51-100 | 2785 |
| >100 | 5677 |

TABLE V. The Number of ROA and IP Prefix Addresses Issued with Two Policies Among Five RIRs

| RIR | ROAs with a single prefix | ROAs with multiple prefixes | IP address prefixes in ROAs with multiple prefixes |
|---|---|---|---|
| AfriNIC | 2999 | 319 | 1562 |
| ARIN | 55943 | 2629 | 16166 |
| APNIC | 16543 | 6810 | 88166 |
| LACNIC | 15318 | 2081 | 16398 |
| RIPE NCC | 20141 | 16701 | 170865 |

Additionally, ROAs with multiple prefixes have been further categorized into four types based on the number of IP address prefixes contained in them: those containing 2-10, 11-50, 51-100, or more than 100 IP address prefixes. These categories of ROAs were analyzed alongside ROAs with a single prefix.

Table IV demonstrates that ROAs containing more than 100 IP address prefixes are, on average, only 2.8 times larger than ROAs containing one or two to ten IP address prefixes. It illustrates the effective reduction of both the quantity and size of ROA achieved by placing multiple IP address prefixes into one ROA.

Furthermore, Table V shows an analysis of ROA data in five RIRs. The quantity of ROAs with a single prefix is more than ROAs with multiple prefixes within each RIR. However, different RIRs have different ROA issuance policies. In AfriNIC and ARIN, the majority of IP address prefixes are issued via ROAs with a single prefix. The situation is reversed while in APNIC and RIPE NCC. Especially in RIPE NCC, the number of ROAs containing two or more IP address prefixes closely approximates ROAs containing only one single IP address prefix. In LACNIC, the number of IP address prefixes in both types of ROA is almost evenly divided.

## IV. Security Risk of Overclaiming

This section introduces the existing mitigation measures for the security risk of overclaiming and their shortcomings, then outlines two scenarios that using the issuance policy of ROA with multiple prefixes leads to INRs being unexpectedly validated as invalid due to overclaiming, and finally describes the adverse effects on routing security, and proposes mitigation strategies.

### *A. Shortcomings of Existing Mitigation Measure*

The initial version of the certificate validation procedure requires that any certificate containing INR not held in the issuing certificate will be verified as invalid. The certificate signed by an invalid certificate is also verified as invalid. When the parent CA transfers or reclaims INRs, the CA certificate of the child CA will not refresh at once, causing the child CA to overclaim the transferred or reclaimed INRs. Consequently, any CA certificates or ROAs issued by the child CA will be verified as invalid before the CA certificate of the child CA is updated, irrespective of whether they contain transferred or reclaimed INRs.

To mitigate potential adverse effects on routing security, the IETF SIDR working group modified the certificate verification algorithm [25]. By using the modified algorithm, certificates and ROAs that do not contain transferred or reclaimed INRs are verified as valid. This modification effectively mitigates the issue of downstream certificate becoming invalid due to the issuing certificate being overclaimed. With the modified algorithm, utilizing the issuance policy of ROA with a single prefix, ROA overclaiming would only affect itself. However, when utilizing the issuance policy of ROA with multiple prefixes, even if ROA overclaims only one transferred or reclaimed INR, all INRs contained in the ROA will be verified as invalid due to the fate-sharing nature. This will cause the BGP router to filter routes inaccurately.

### *B. Parent CA and Child CA Deploy Repository Publication Points on Different Servers*

As illustrated in Fig. 2, the parent CA initially allocated 192.168.1.0/24 and 192.168.2. 0/24 to the child CA. The child CA allocated IP address prefixes to AS65000 and AS65001 by issuing two ROAs: one containing 192.168.1.128/25 and 192.168.2.128/25, authorizing AS65000 as the origin; the other containing 192.168.2.0/25, authorizing AS65001 as the origin. The parent CA and child CA deployed repository publication points on different servers.

After a period of operation, the parent CA reclaimed 192.168.1.0/24 from the child CA. Subsequently, the child CA sent a request to the parent CA to update its CA certificate. Upon receiving this request, the parent CA notified the repository publication point I to update the CA certificate of the child CA and returned a response to notify the child CA that the update had been completed. The child CA received the response and notified the repository publication point II to update ROAs.

If the repository publication point is working, as the response to the update notification, the repository publication point II will revoke ROAs and generate ROAs that do not contain any IP address prefixes in the range of 192.168.1.0/24. However, due to a malfunction in the publication program, the repository publication point II could not update the ROAs. When RP attempted to synchronize data from the repository publication point II, it discovered that the RRDP service provided by the publication program was not working. Therefore, RP switched to utilizing rsync to synchronize data from the repository publication point II. During validating the RPKI objects, RP identified that 192.168.1.128/25 contained in 65000.roa was not held in the CA certificate of the child CA. Consequently, 65000.roa was validated as invalid. As a result, the route that announced AS65000 as the origin of 192.168.2.128/25 would be validated as NotFound or invalid.

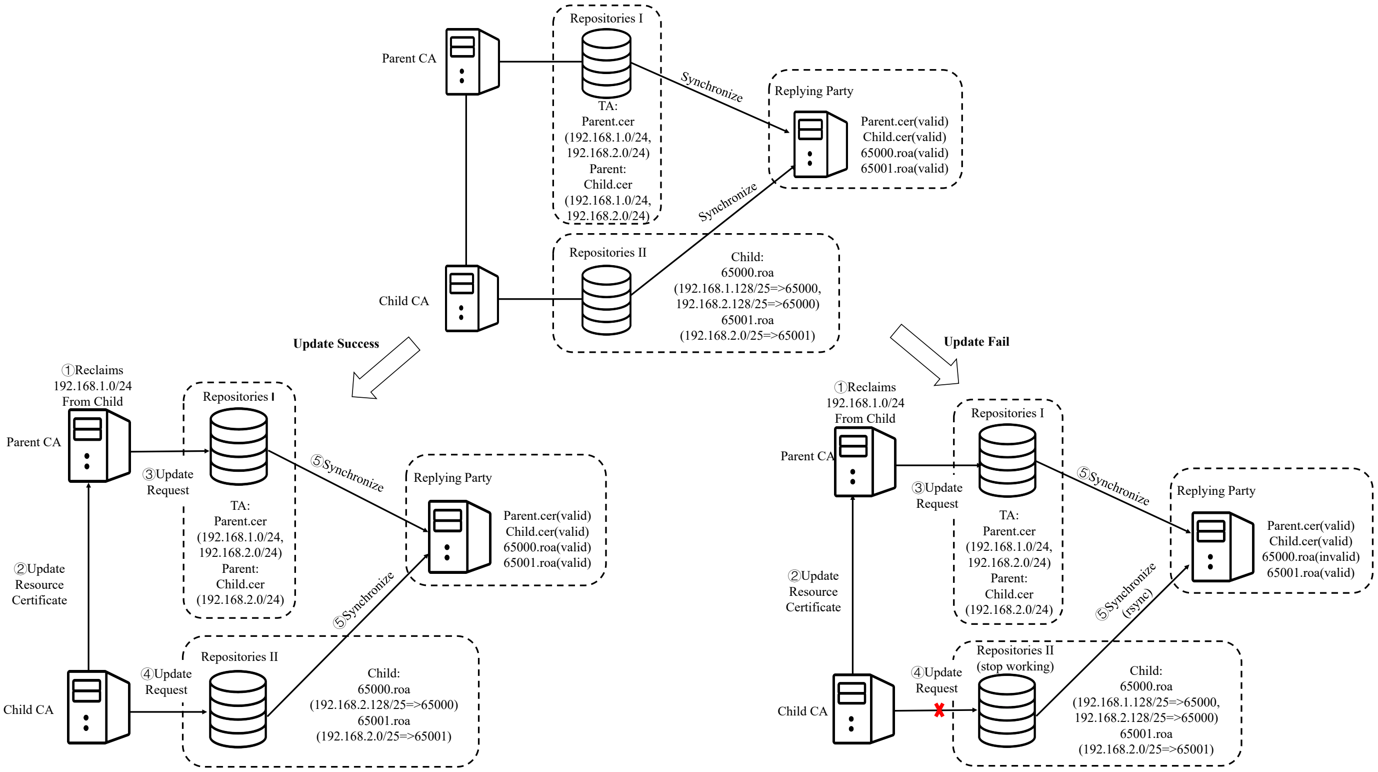

Fig. 2. When the repository publication points deploy on different servers, different results caused by publication program is working or malfunctioned during updating.

### C. Update Latency Between Parent CA and Child CA

As shown in Fig. 3, the initial state mirrors that of Fig. 2, but both the parent CA and the child CA deployed the repository publication points on the same server. After a period of operation, 192.168.1.0/24 held by the parent CA was reclaimed. Following updating the CA certificate of the parent CA, 192.168.1.0/24 was not contained in the CA certificate. However, because the child CA has not updated its CA certificate, the CA certificate still contained 192.168.1.0/24 and the 65000.roa issued by it also contained 192.168.1.0/24. Until the child CA periodically sends the certificate update request, the parent CA updates the CA certificate of the child CA and the child CA updates the ROAs issued by it.

During update latency, if RP synchronizes the data from the repository publication points, the 65000.roa will be validated as invalid due to containing 192.168.1.128/25, which is not held by the CA certificate of the parent CA. This would cause the route that announced AS65000 as the origin of 192.168.2.128/25 to be validated as NotFound or invalid.

### D. Security Risk and Mitigation Strategies

In the scenarios described in Sections IV.B and IV.C, the invalidation of 65000.roa would result in the absence of the VRP “192.168.2.128/24=>65000” from the VRP set acquired by the BGP router from the RP. When the BGP router receives a BGP announcement “192.168.2.128/24 originate from AS65000”, if there exists a VRP whose prefix covers 192.168.2.128/24 in the VRP set, such as “192.168.0.0/16=>65002”, the BGP router will validate this BGP announcement as invalid and rejected it. When traffic with a destination address within the 192.168.2.128/24 range passes through the BGP router, it will be forwarded to AS65002. Such route leakage will lead to severe performance degradation or even network outage [26]. If there is no existing VRP whose prefix covers 192.168.2.128/24 in the VRP set, the BGP router will validate this BGP announcement as NotFound and retain it. In this scenario, the 192.168.2.128/24 has lost the protection of RPKI, allowing malicious AS to launch BGP hijacking by crafting specific BGP announcements to steal traffic.

Both scenarios can be mitigated by eliminating the fate-sharing nature by adopting the issuance policy of ROA with a single prefix. Overclaiming triggered by the scenario described in section IV.B is rarely, because it is caused by software malfunctions. The scenario described in section IV.C may occur each time INRs from the child CA are reclaimed. In this scenario, except for adopting the issuance policy of ROA with a single prefix, the risk of overclaiming can be mitigated by promptly notifying the administrators of the child CA to manually update the CA certificate. However, because this requirement is difficult to accomplish, the existing CA software provides the periodical certificate update service. In addition, when the resources are reclaimed due to expiration without the awareness of administrators, manual and prompt update of CA certificates is impossible. Evidently, adopting the issuance policy of ROA with a single prefix emerges as the simplest and most efficacious method.

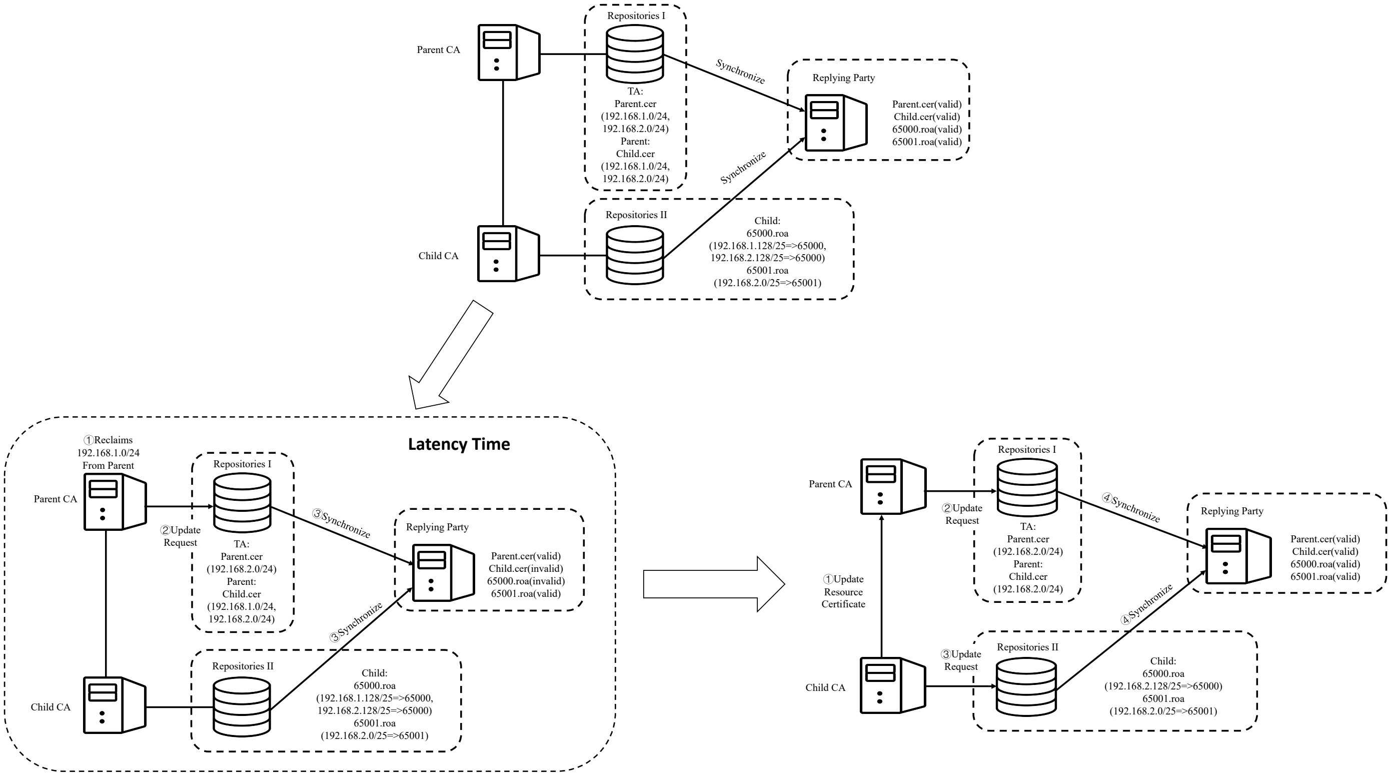

Fig. 3. When the resource of the parent CA change, the change of ROAs verification status during and after latency time for update.

## V. Synchronization Efficiency

As shown in Table IV, it can be concluded that when the INR quantity is the same, using the issuance policy of ROA with multiple prefixes can significantly reduce the data size of ROA. The data size will affect the efficiency of the process of RP synchronizing data from the repository publication point. This section analyzes the impact of using two different ROA issuance policies on the efficiency of initial synchronization and incremental synchronization to discuss the feasibility of requiring the use of the issuance policy of ROA with a single prefix in the RPKI production environment.

### A. Initial Synchronization

The initial synchronization refers to the synchronization that takes place when the local cache of RP is empty. In the course of RP operation, the transmission data volume during initial synchronization is the largest. The experiments were conducted to compare the synchronization efficiency of using two extreme ROA issuance policies. One policy involves placing only one IP address prefix in an ROA, while the other policy involves placing all IP address prefixes originating from the same AS in an ROA.

Two IP address prefix distribution schemes were considered for the experiments: the randomized distribution of IP address prefixes and the distribution of IP address prefixes from five currently operational RIRs. The randomized IP address prefix distribution is discreteness, but different address space holders have distinct tendencies of issuance policy in the current production environment as mentioned in section III. The randomized IP address prefix distribution is unable to simulate these tendencies. The distribution of IP address prefixes from five currently operational RIRs provides both discreteness and reflects the distinct tendencies of issuance policy of different address space holders in the current production environment. Utilizing the distribution of IP address prefixes from five currently operational RIRs as a sample makes experimental data more practical and representative of the current production environment. By using this sample, the impact of synchronization efficiency can be evaluated in the current production environment when all ROAs with multiple prefixes are transformed into ROAs with a single prefix.

Due to the potential for interference when using public IP address for experiments, the decision was made to choose the largest available private IP address prefix 10.0.0.0/8 in IPv4 for experiments. Similarly, the decision was determined to choose the testing IP address prefix of 2001:db8::/32 in IPv6 as advised by Krill for experiments. For IPv4 address prefixes, a right-shift operation was applied to the IP addresses by 8 bits, and the IP addresses prefix length was increased by 8. This benefited to map the modified IP address prefixes to 10.0.0.0/8 (e.g., 165.98.219.0/24 was modified to 10.165.98.219/32). For IPv6 address prefixes, a right-shift operation was applied to the IP addresses by 32 bits, and the IP addresses prefix length was increased by 32. By doing so, the modified IP address prefixes were able to map to 2001:db8::/32 (e.g., 2407:9e40::/32 was modified to 2001:db8:2407:9e40::/64). By selecting these two IP addresses and adopting these mapping operations, the IP address prefixes can be retained as much as possible.

The number of lost INRs does not exceed 0.46% of the

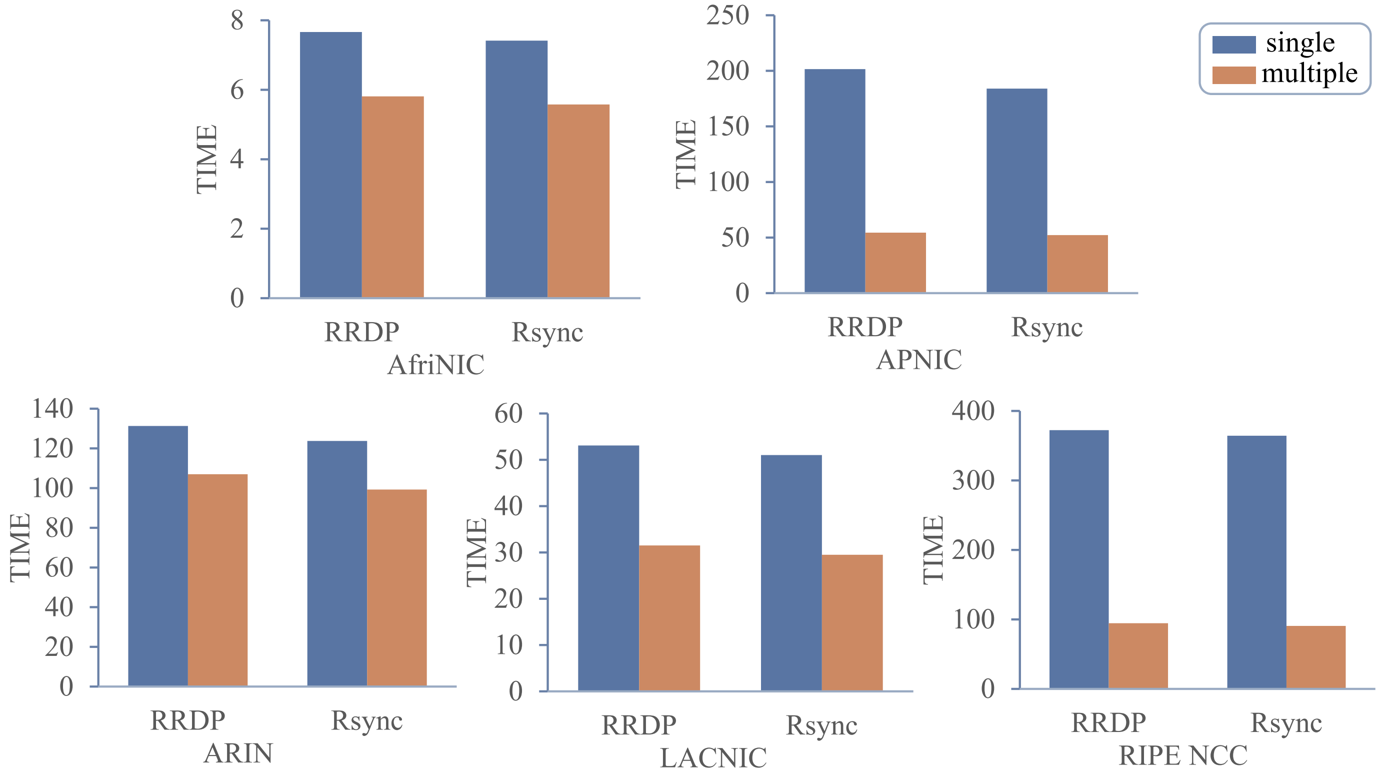

Fig. 4. The experiment results. The five histograms display the synchronization time of samples from five RIRs, using RRDP and Rsync under two different ROA issuance policies. The synchronization time is shown in seconds.

total quantity during the mapping process. In the lost INRs, the length of IPv4 prefix exceeds 24, and the length of IPv6 prefix exceeds 96. Approximately 38.5% of lost INRs are placed in ROAs with a single prefix in the current production environment. The remaining lost INRs are placed in ROAs with multiple prefixes in the current production environment, with an average of 3.7 INRs contained per ROA. When using the issuance policy of ROA with a single prefix, the lost INRs lead to a reduction of approximately 0.46% in synchronization time. While using the issuance policy of ROA with multiple prefixes, the lost INRs lead to a reduction of approximately 0.25% in synchronization time. These tiny errors do not impact the experimental conclusions.

The experiments used two servers, each equipped with 8 cores and 8GB of RAM. Krill software was selected to run the CA, and Routinator [27] was chosen to run the RP. One server was dedicated to running Krill to issue RPKI objects, while another server was utilized to run Routinator to synchronize data. TA issued multiple child CAs through the hosted model based on the number of IP address prefixes in each sample and allocated 10.0.0.0/8 and 2001:db8::/32 to each child CA. Each child CA managed a similar number of INRs. Following each completion of the initial synchronization, the local cache of RP was cleared and the next initial synchronization started. This step was repeated 30 times in each experiment sample of each ROA issuing policy. The synchronization efficiency comparison between two ROA issuing policies is predicated on the mean synchronization time of these 30 tests.

The experimental results are illustrated in Fig. 4, indicating that using the issuance policy of ROA with multiple prefixes leads to an enhancement in synchronization efficiency. The improvement of synchronization efficiency of two RIRs, AfriNIC and ARIN, is not significant. In contrast, the other two RIRs, APNIC and RIPE, show a marked improvement. It should be pointed out that even in RIPE NCC, which issues the greatest number of IP address prefixes, using the issuance policy of ROA with a single prefix does not lead to the initial synchronization time exceeding 7 minutes. The synchronization time of no more than 7 minutes for the initial deployment of RP is acceptable.

### B. Incremental Synchronization

The synchronization except for initial synchronization was defined as incremental synchronization. Following the initial synchronization, RP periodically synchronizes updated files from the repository publication point at intervals no longer than one hour. Unlike the case in initial synchronization, using the issuance policy of ROA with multiple prefixes does not necessarily result in decreasing the transmission data volume in incremental synchronization.

In two distinct scenarios, using the issuance policy of ROA with a single prefix potentially decreases the transmission data volume. One situation is that only deletions are made to IP address prefixes in the incremental synchronization interval. In this scenario, adopting the issuance policy of ROA with a single prefix needs not to synchronize ROAs, while adopting the issuance policy of ROA with multiple prefixes needs to synchronize an entire ROA. Another scenario is when there is a set of a large number of IP address prefixes originating from the same AS and a few operations (additions or deletions of IP address prefixes) made to this set in the incremental synchronization interval. When using the issuance policy of ROA with a single prefix, the ROAs containing the added IP address prefixes are required to be retransmitted. While using the issuance policy of ROA with multiple prefixes, all the IP address prefixes in the set are contained in an ROA. This ROA is required to be retransmitted. In this scenario, the size of the ROA with multiple prefixes may be larger than the total size of the few retransmission ROAs with a single prefix.

The above situations are not uncommon in production environments, thus utilizing ROA with multiple prefixes does not significantly enhance the efficiency of incremental synchronization.

## VI. Conclusions

According to sections III, IV, and V, both the issuance policy of ROA with a single prefix and multiple prefixes possess distinct merits. The former provides greater flexibility and avoids the risk of overclaiming, thereby ensuring stable and valid route announcements. The latter reduces the quantity and size of ROAs, thereby augmenting synchronization efficiency.

Despite the obvious impact on the efficiency of initial synchronization caused by using the issuance policy of ROA with a single prefix in APNIC and RPIE NCC, it is worth noting that RP requires only one initial synchronization. Incremental synchronizations are frequent but the transmission data volume is small, hence exerting an inconspicuous influence on synchronization efficiency. Therefore, it is feasible to use the issuance policy of ROA with a single prefix in existing production environments. Above all, the fundamental purpose of RPKI is to ensure the security of BGP and its ability to provide the BGP router with accurate guidance regarding route filtering is vital. The validity of ROA assumes a pivotal role in this regard. It is deemed acceptable to compromise a certain degree of efficiency in order to ensure the validity of ROA.

In the current RPKI deployment environment, placing only one IP address prefix in ROA should be the preferred option in general situations. If the address space holder insists on placing multiple IP address prefixes into one ROA, the stability of INRs should be evaluated. The INRs that will not be revoked for a long time should be placed in the ROAs with multiple prefixes, while the unstable INRs should be individually placed in the ROAs with a single prefix. However, evaluating the stability of INRs cannot entirely avoid the security risks of overclaiming. Address space holders need to be aware of and assume the security risks by using the ROA with multiple prefixes.

Certainly, like RFC 9455 is a best current practice, the preferred option of ROA issuance policy may change with the ongoing refinement of RPKI. For instance, designing a mechanism that the parent CA proactive notifies the child CA when it reclaims INRs from the child CA can avoid the security risks of overclaiming in the scenario described in Section IV.C. However, the design, standardization, and deployment of such a mechanism take a considerable amount of time. Or using post-quantum cryptography [28]–[30] to protect the security of RPKI. Prior to the deployment of other effective mitigation measures, it is recommended to use the issuance policy of ROA with a single prefix.

## Acknowledgment

We would like to thank our supervisors, Zhiwei Yan and Guanggang Geng, for their unwavering guidance and support throughout the course of this research. Thanks to the IETF SIDR Operations working group, which provided valuable expertise and assistance throughout the course of this research; and thanks to the RIPE NCC for sharing the ROA statistic.

# Scientometric Analysis and Knowledge Mapping of Cybersecurity

Fahad Alqurashi, Istiak Ahmad
Department of Computer Science-Faculty of Computing and Information Technology,
King Abdulaziz University, Jeddah 21589, Saudi Arabia

***Abstract*—Cybersecurity research includes several areas, such as authentication, software and hardware vulnerabilities, and defences against cyberattacks. However, only a limited number of cybersecurity experts have a comprehensive understanding of all aspects of this sector. Hence, it is vital to possess an impartial comprehension of the prevailing patterns in cybersecurity research. Scientometric analysis and knowledge mapping may effectively detect cybersecurity research trends, significant studies, and emerging technologies within this particular context. The main aim of this research is to comprehend the developmental trend of the academic literature about the concepts of "malware detection" and 'cybersecurity'. We collected 9,967 publications from January 2019 to December 2023 and used the Citespace tool for scientometric analysis. This study found six co-citation clusters,namely malware classification, evading malware classifier, android malware detection, IoT network, CNN, and ransomeware families. Additionally, this study discovered that the top contributing countries are the USA, China, and India based on the citation count, and the Chinese Academy of Science, the University of California, and the University of Texas are the top contributing institutions based on the frequency of the publications.**

***Keywords*—Cybersecurity; cyber threats; scientometric analysis; bibliomatic analysis**

## I. Introduction

The Cybercrime in Australia series [1] is intended to shed light on the victimisation and damages caused by cybercrime among computer users in Australia. The data originates from a survey conducted in early 2023, which included 13,887 individuals who use computers. Before the survey, 27% of participants reported encountering online abuse, 22% encountered malware, 20% faced stolen identities, and 8% fell victim to scams and fraud. Cybersecurity research encompasses a variety of domains, including authentication, software and hardware vulnerabilities, and defences against cyberattacks. However, only a small proportion of cybersecurity professionals have a complete comprehension of all facets of this industry. As a consequence, it is of the utmost importance to develop an objective understanding of the prevalent trends in the field of cybersecurity research. Scientometric analysis and knowledge mapping have the potential to successfully identify patterns, major studies, and new technologies in cybersecurity, transportation [2], health, etc., using different sources such as research articles and newspapers [3], [4]. Researchers, experts, and authorities have to comprehend malware detection technologies and their evolution in cybersecurity. The conceptual structure and dynamic growth of cybersecurity research can be shown by applying these bibliometric approaches to the vast malware detection literature. This method emphasises the most significant contributions and the multidisciplinary links that develop malware detection techniques. Since online hazards have increased dramatically, virus detection technologies are essential for digital security. As malware uses polymorphism and metamorphism to avoid detection, the cybersecurity sector has developed new detection methods. This ongoing arms race between threat actors and defenders requires a thorough examination of research and technological trends. Scientists may categorise malware detection literature by methodology, application fields, and efficacy using scientometric analysis. This study gives a macro picture of the research area, directing future research and technology implementation. Knowledge mapping in malware detection and cybersecurity provides a visual and analytical approach for navigating this field's vast information landscape. It helps explain essential ideas, research links, emerging topics, and technology. Stakeholders may identify prominent research fronts and scientific discourse development using co-citation analysis, co-authorship networks, and keyword co-occurrence mapping. This comprehensive picture helps identify knowledge gaps and encourages collaboration, guiding global cybersecurity efforts towards more robust and adaptable malware detection techniques. This project uses scientometric analysis and knowledge mapping to lay the groundwork for cyber security breakthroughs and safe digital environments for future generations.

*a) The Aim and Objectives:* The main aim of this research is to comprehend the developmental trend of the academic literature about the concepts of "malware detection" and 'cybersecurity'. This scientometric research aims to analyse the development trend of academic literature specifically focused on ”malware detection” and ’cybersecurity’.

- To comprehend the collaboration pattern and analyse the research domain.
- To discover the citation trends from 2019 to 2023.
- To discover the countries, institutions, and keywords involved in the domain of malware detection and cybersecurity.

The remainder of the paper is organised as follows: Section II discusses the similar studies and establishes the research gap. Section III discusses the methodology, including the dataset (Section III-A) and scientometric analysis (Section III-B). Section IV discusses the research outcome. Section V concludes by discussing future work.

## II. Literature Review

The quantitative analytics discipline of scientometrics is used to determine and evaluate the volume of research conducted in any given field. In the scientific community, researchers disseminate their findings via a variety of publishing methods. There are several reseach work has been done on scientometric analysis. Raj et al. [5] employed scientometric analysis to discover the knowledge of collaborations, authorship, citations, countrywise, etc. They collected 2720 articles on "cybersecurity" from 2001 to 2018. In another research, [6] focused on Indian authors publications on "cybersecurity" to get knowledge of research trends, collaborating countries, institutions, and top-cited articles. Makawana and Rutvij [7] performed a bibliometric analysis of 149 research articles from 2015 to 2016. Bolbot et al. [8] proposed research direction in maritime cybersecurity by employing meta-analysis (PRISMA) and systematic reviews. The findings demonstrated that Norway, the UK, the USA, and France are the leading nations in maritime cybersecurity. Omote et al. [9] conducted a scientometric analysis using a scienctometric analysis tool named e-CSTI to examine data on science, technology, and innovation in cyber security research. In this research, authors collected data between 2010 and 2019 and discovered that the USA and China emphasise different research areas. In order to provide an in-depth understanding of the present status of medical device cybersecurity research, this study [10] has identified notable authors, organisations, and journal publishers, as well as significant concepts, approaches, and innovations that are often addressed in relation to medical devices. In order to provide an in-depth understanding of the present status of medical device cybersecurity research, this study has identified notable authors, organisations, and journal publishers, as well as significant concepts, approaches, and innovations that are often addressed in relation to medical devices. The study's findings reveal that the most highly contributing country is the USA, and the technology hubs are the UK and India.

The literature review shows that the existing research focused on limited research articles on cybersecurity that were published before 2020. Additionally, there are some works on specific regions or domains. In this study, we collected a total of 9,967 publications from January 2019 to December 2023 and employed scientometric analysis to understand the citation process, calculate the effect of the study, and describe the creation and development of knowledge on a particular research subject.

## III. Methodology

### A. Dataset

*a) Query:* The following query is used to collect dataset from WoS: ALL=("malware") OR ALL=("malware detection") OR ALL=("android Malware") OR ALL=("cyber security") OR ALL=("cyber threats") OR ALL=("cyber attacks") OR ALL=(Cyber-Attack) OR ALL=(RANSOMWARE) OR ALL=(CYBERSECURITY).

We apply several filtering approach to get more specific output of searching. For example, this study only select five-years documents (2019 - 2024) and choose document type as proceeding paper and article, that is written in English language. Furthermore, the filtering criteria only include limited WoS categories, such as Computer Science Information Systems, Computer Science Artificial Intelligence, Computer Science Software Engineering, Computer Science Theory Method, Telecommunications, and Computer Science Interdisciplinary Applications, and research areas, for example, Computer Science, and Telecommunications.

TABLE I. Dataset Analyzing Report

| **WoS Categories** | | **Document Types** | |
|---|---|---|---|
| Computer Science Information Systems | 5,790 | Proceeding paper | 5,907 |
| Computer Science Theory Method | 4,823 | Article | 4,118 |
| Computer Science Artificial Intelligence | 2,162 | **Countries** | |
| Computer Science Software Engineering | 1,852 | USA | 2,458 |
| Telecommunications | 1,816 | China | 1,668 |
| Computer Science Interdisciplinary App. | 1,575 | India | 828 |
| **Research Areas** | | England | 695 |
| Computer Science | 9,448 | Germany | 540 |
| Telecommunications | 1,816 | Australia | 506 |

This study collected a total of 9,967 Publications, where those publications 62,377 times total cited and 52,546 times without self-citation. The total citing articles are 37,384 and without self-citation are 33,747 with H-Index equal to 82.

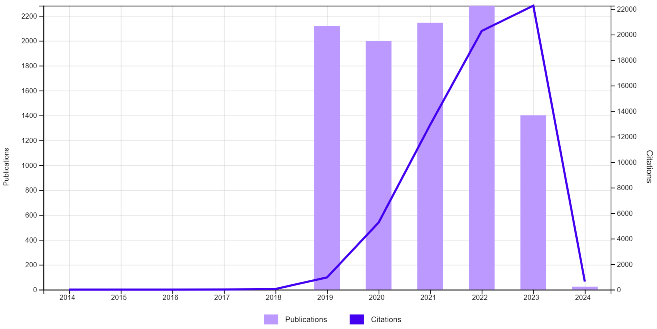

Fig. 1. Articles citation report generated from WoS.

Fig. 1 depicts the citation report of the collected 5-years dataset from Web of Science. The details of the dataset is listed in Table I.

### B. Scientometric Analysis

The quantitative investigation of scientific research is referred to as scientometrics. Using extensive datasets of research publications, it allows for the understanding of the citation process, calculates the effect of the study, and describes the creation and development of knowledge on a particular research subject. While it is still possible to miss literary concepts in traditional investigations, scientometric approaches allow academics to analyse a significant quantity of bibliometric data and identify systematic conclusions connected to literature. This investigation employed CiteSpace [11], a Java-based programme that analyses and visualises co-citation networks, for scientometric analysis. The purpose of the tool is to pinpoint turning points and new trends in a certain field. It provides unique benefits for presenting and evaluating scientific data to enable more accurate interpretation of earlier research by painstakingly creating a multitude of easily understood visualisations that may help reveal the implications hidden in a vast body of knowledge. Some importance terms used in scientometric analysis are co-citation analysis, Burst Strength, Burst Begin-End, Degree, Centrality and Sigma.

In the network generated by CiteSpace, two quantifiable markers may be used to identify important nodes: the burst strength and betweenness centrality. The proportion of the shortest path between two clusters to the total of these shortest routes is used to calculate node betweenness centrality.

$$Centrality(node_x) = \sum_{x \neq y \neq z} \frac{\gamma_{yz}(x)}{\gamma_{yz}} \tag{1}$$

In Eq. 1, $\gamma_{yz}(x)$ represents the count of pathways that go via node x, whereas $\gamma_{yz}$ represents the count of the shortest routes linking node y and node z. The burst identification technique was used to identify sudden fluctuations in citations at certain time periods. The process of calculating citation bursting strength begins with acquiring and importing pertinent bibliometric information, then implements Kleinberg's method to analyse the citation timeline for every document inside the collection. Citation burst strength is determined by statistically evaluating the increase in citation frequency within a certain time period in comparison to periods with no significant increase. An article with a significant burst strength demonstrates a notable rise in its citation rate, indicating an enhanced level of impact or significance during the burst timeframe. The citation degree is calculated by calculating the number of linkages a node has with adjacent nodes in the network. A larger citation degree shows more direct citations, signifying more impact or significance on the subject. Conversely, Sigma is computed by multiplying the number of citations by betweenness centrality, which expresses the frequency at which a node acts as a link between other nodes. Papers with high sigma values are often both highly cited and influential in bridging various disciplines or concepts within the academic field.

In addition, CiteSpace provides scientometric analysis that includes an investigation of countries, organisations, and the co-occurrence of keywords.

## IV. Results and Discussion

Cluster analysis is a prevalent approach to finding hidden contextual patterns in knowledge discovery. Through the use of cluster analysis, an extensive repository of data from research is divided into discrete units according to the relative strength of word correlation. This facilitates the identification of research themes, patterns, and their connections within a certain field of study. In this study, six co-citation clusters were identified using the log-likelihood ratio (LLR) technique. This was possible since the clusters created by LLR had excellent quality, with high intra-class and low inter-class similarity. Additionally, based on the uniqueness and coverage of each cluster, LLR chooses a label based on the keywords of the texts cited in each cluster. Cluster labelling quality is determined by the variety, depth, and breadth of terms formed from keywords in articles. The label supplied for each cluster identifies the focus of that cluster. Fig. 2 shows the cluster analysis using co-citation analysis, demonstrating the timeline of each cluster. We discovered six clusters including malware classification (ClusterID=0), evading malware classifier (clusterID=1), android malware detection (clusterID=2), iot network (clusterID=3), convolutional neural network (clusterID=4), and ransomware families (clusterID=5).

### A. *Cluster Analysis*

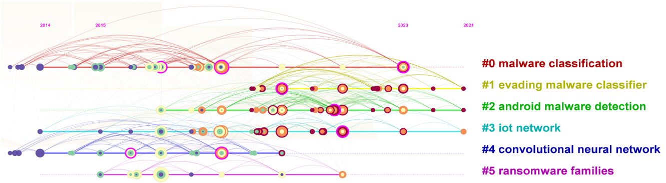

Fig. 2. Cluster analysis.

Table II shows the cluster network summary by listing the top 20 research publications sorted by burst strength. The list includes all details, such as, publication year, burst strength, burst begin-end, degree, centrality, sigma, frequency, and cluster ID for each publication.

TABLE II. Cluster Network Summary

| Ref. | Pub. Year | Burst Strength | Burst Begin-End | Degree | Cent. | Sigma | Freq. | CID |
|---|---|---|---|---|---|---|---|---|
| [12] | 2015 | 13.02 | 2019 - 2020 | 19 | 0.06 | 2.04 | 42 | 0 |
| [13] | 2015 | 11.45 | 2019 - 2020 | 13 | 0.03 | 1.4 | 37 | 0 |
| [14] | 2020 | 9.75 | 2021 - 2023 | 17 | 0.02 | 1.17 | 42 | 2 |
| [15] | 2018 | 8.57 | 2021 - 2023 | 3 | 0 | 1.01 | 94 | 3 |
| [16] | 2017 | 8.29 | 2020 - 2021 | 12 | 0.03 | 1.32 | 33 | 0 |
| [17] | 2016 | 8.04 | 2020 - 2021 | 2 | 0.01 | 1.04 | 32 | 5 |
| [18] | 2015 | 7.7 | 2019 - 2020 | 4 | 0 | 1 | 25 | 5 |
| [19] | 2019 | 7.64 | 2021 - 2023 | 10 | 0.06 | 1.51 | 33 | 5 |
| [20] | 2017 | 7.39 | 2019 - 2020 | 11 | 0.01 | 1.07 | 24 | 4 |
| [21] | 2015 | 7.39 | 2019 - 2020 | 9 | 0.01 | 1.07 | 24 | 4 |
| [22] | 2016 | 7.31 | 2019 - 2021 | 6 | 0.02 | 1.16 | 121 | 5 |
| [23] | 2019 | 6.68 | 2021 - 2023 | 24 | 0.06 | 1.52 | 74 | 2 |
| [24] | 2018 | 4.93 | 2020 - 2021 | 21 | 0.06 | 1.3 | 53 | 2 |
| [25] | 2019 | 4.8 | 2021 - 2023 | 23 | 0.11 | 1.65 | 57 | 2 |
| [26] | 2016 | 4.79 | 2019 - 2021 | 9 | 0.08 | 1.47 | 80 | 3 |
| [27] | 2019 | 4.76 | 2021 - 2023 | 21 | 0.09 | 1.48 | 58 | 1 |
| [28] | 2020 | 4.6 | 2021 - 2023 | 9 | 0.01 | 1.07 | 56 | 1 |
| [29] | 2019 | 4.51 | 2021 - 2023 | 18 | 0.02 | 1.1 | 55 | 2 |
| [30] | 2016 | 3.93 | 2019 - 2020 | 15 | 0.06 | 1.24 | 49 | 0 |
| [31] | 2016 | 3.21 | 2020 - 2021 | 8 | 0.04 | 1.14 | 49 | 5 |

#### 1) *Malware classification and evading malware classifier:*

*a) Malware Variations:* Malware can be classified into several types, including worms, spyware, viruses, trojans, bots, rootkits, ransomware, scareware, and so on.

Worms use software and operating system flaws to propagate to other machines. They do not need to connect to a programme like viruses. Worms may overburden web servers, steal data, install backdoors, and more. Worms' speed and autonomy make them hazardous, causing internet interruptions and severe financial harm to afflicted organisations and individuals. Spyware secretly tracks users' internet activities, keystrokes (keyloggers), and financial data. It may be installed without the user's knowledge via free software downloads or malicious websites. Identity theft and unauthorised access to personal and financial data may result from spyware, which slows system performance and internet connections.

When run, viruses change other computer programmes and implant their own code. Infected systems may malfunction, lose data, and operate poorly. Email attachments, compromised software programmes, and file downloads distribute viruses, which need human input to activate their destructive activities.

Trojans, or Trojan horses, deceive users. They frequently seem like respectable applications but do bad things when run. Trojans, unlike viruses and worms, do not multiply but may provide paths for other malware to steal data or create a zombie machine under an attacker's control. Trojans may gain unauthorised access to systems, stealing data, compromising privacy, and installing further software.

Computer programmes called bots automate jobs. However, malicious bots are used to take control of a computer and employ it in a botnet. DDoS assaults, spamming, phishing, and cryptocurrency mining are all possible with botnets. Botnet machines may be located worldwide, making attacks hard to track. Rootkits stealthily obtain root or administrative access to a computer without users or security software noticing. Rootkits may intercept and modify system operations to mask their presence and other malicious actions, making detection and removal difficult. Rootkits let attackers steal data, monitor user activities, and remotely control a machine.

Ransomware encrypts a victim's data or locks them out of their machine and demands a fee to decode or unlock. Phishing emails, fraudulent ads, and software weaknesses disseminate it. Ransomware may cause considerable data loss, financial harm, and operational interruption until the ransom is paid or files are recovered from backups. Scareware tricks users into thinking their computer has a virus or other major problem to get them to buy needless or hazardous software. It usually appears as pop-up advertising or antivirus software-like security notifications. Scareware may cost money and install spyware or other malware if the user buys it or removes the phoney risks it claims to have found.

*b) Types of Malware Detection:* The top cited papers for malware detection and classification are [32], [27], [33], [34], [28].

Signature-based Detection: This approach is one of the simplest and traditional techniques for detecting malware. Antivirus software conducts scans on files, executable programmes, and system locations, and then compares them with a database in order to identify any matches. The signature-based approach detects distinct character sequences inside the binary code. Each time a novel kind of malware is released, anti-malware companies must acquire a sample of the new virus, scrutinise it, generate fresh signatures, and distribute them to their customers. Conventionally, domain experts are responsible for manually creating, updating, and distributing the signature bases. This technique is often recognised as being time-consuming and requiring a significant amount of labour. This kind of detection strategy reduces the responsiveness of anti-malware software programmes to emerging threats. It has the potential to enable some malware samples to evade detection and remain undiscovered for an extended time.

Heuristic-based Detection: This approach uses algorithms to analyse the behaviour and features of programmes to discover suspected malware based on abnormal patterns or behaviours. This approach goes beyond signature matching; instead, it examines the code's structure for any unusual traits that might point to a danger, including the inclusion of code that is often used to take advantage of vulnerabilities. By concentrating on characteristics shared by malicious software, heuristic detection may detect newly created or altered malware, although it may produce more false positives than signature-based detection.

Behavior-Based Detection: This approach keeps a check on how software behaves naturally inside the system, rather than employing malware fingerprints to identify threats ahead of time. This method monitors how an application accesses network resources, user data, system files, and processes and checks for malicious activity such as unapproved changes, eavesdropping, or data exfiltration. It can successfully detect polymorphic and previously undiscovered malware that would elude signature-based techniques since it analyses behaviours in real-time. Its emphasis on behaviour, meanwhile, may result in false alerts should benign programmes exhibit anomalous behaviour.

Anomaly-Based Detection: Providing a baseline of typical network or system activity, anomaly-based detection then keeps monitoring for variations from this baseline. Significant discrepancies might be a sign that malware is present. This technique is very helpful in detecting complex assaults and zero-day threats, but it may produce incorrect results if the baseline is not well established.

Sandbox Detection: Malicious programs are run in a virtual environment called a "sandbox" that is isolated from the primary system in sandbox detection. This keeps the system safe while enabling the programme to execute and display its behaviour. Sandboxing works well against malware that may avoid identification by detecting it during analysis or by postponing execution.

Cloud-based Detection: The process of detecting malware now follows a client-server approach using a cloud-based architecture. This involves preventing the execution of unauthorised software programmes listed in a blacklist and verifying the legitimacy of software programmes listed in a whitelist at the user's end. Additionally, any unknown files are analysed at the server side and the results are promptly communicated to the clients. The grey list comprises unfamiliar software files, which may be either harmless or dangerous. Historically, the grey list was either rejected or verified manually by experts in malware analysis. Due to advancements in malware authoring and creation methods, the quantity of file samples on the grey list is consistently growing. As an example, the grey list produced by either Kingsoft or Comodo Cloud Security centre often includes over 500,000 file samples on a daily basis [Ye 2010]. Therefore, it is essential to create intelligent methods to enhance the efficiency and effectiveness of malware detection on the server side of the cloud.

Hybrid Detection Methods: Hybrid methodologies integrate many detection methods to enhance the overall effectiveness of malware detection and minimise the occurrence of false positives. For instance, antivirus software may use a combination of signature-based and behavior-based detection methods to provide extensive safeguarding against both recognised and unrecognised hazards.

Feature Analysis: Static analysis examines PE files without running them. Static analysis targets binary or source codes. If a PE file is compressed using third-party tools like UPX or ASPack Shell, it must be decompressed first. To decompile Windows executables, employ disassembler and memory dumper tools. Memory dumper tools extract protected main memory codes and save them to a file. A memory dump is important for examining packed executables that are hard to deconstruct. Unpacking and decrypting the executable reveals static analysis patterns such Windows API calls, byte n-grams, strings, opcodes, and control flow graphs. Feature extraction is achieved via dynamic analysis methods, such as profiling and debugging, by analyzing the PE files being executed (on a physical or virtual CPU). To do dynamic analysis, a variety of methods may be used, including function parameter analysis, function call monitoring, information flow tracking, and instruction traces.

*2) Android malware detection and convolutional neural network:* The rapid proliferation of Android malware, its ability to evade detection, and the possible loss of enormous amounts of data assets held on Android devices make Android malware detection and categorization an issue involving big data. Applying deep learning to Android malware detection appears to be a logical and intuitive decision. Nevertheless, scholars and practitioners encounter several obstacles, including the selection of a deep learning architecture, the extraction of features, the evaluation of efficacy, and the acquisition of sufficient high-quality data. This research discovered the top cited papers for android malware detection based on the Co-citation network are [35], [36], multimodal technique [23], significant permission identification [37], intrusion detection dataset [15], Google Playstore Android dataset named Andro-Zoo [38], and so on.

Fully Connected Network (FCN) [39] has been used in several Android malware detection approaches. The FCN analyzed the AndroidManifest.xml and classes.dex files to extract information such as needed permissions, contextual details, and API calls, which were then used to characterize the Android programs. The activation function employed in the hidden layers is the Parametric Rectified Linear Unit function, as it is very efficient and allows for dynamic modification. In the output layer, Softmax is employed as an activation function.

Convolutional Neural Network (CNN) [36] is employed to identify Android malware in raw opcode sequences. First, the application for Android was disassembled, and its opcode sequences were retrieved for analysis. An opcode embedding layer received one-hot vectors of opcode instructions. The embedding layer enabled the CNN network to gather opcode semantics. Abstract characteristics were extracted using convolution layers. Moreover, a max-pooling layer after each convolution layer selected the most appropriate malware-detecting opcode sequence. The app's maliciousness was determined via a fully linked hidden layer before the output layer. Through cooperative training, the CNN network learned malware patterns from raw opcode sequences without employing any handcrafted features.

Long Short-Term Memory (LSTM) and Recurrent Neural Network (RNN) [40] can acquire semantic knowledge and connections within sequential data, enabling them to process sequential opcode or bytecode. Xin et al. [41] presented DroidDeep, a DBN-based tool for Android malware detection. It uses approximately 32,000 layers AndroidManifest.xml and classes.dex features. These features include app permissions, activities, components, permissions used, and requests to sensitive APIs. DroidDeep prepares string properties for processing by one-hot encoding them as numerical vectors. The DroidDeep DBN architecture uses unsupervised pre-training to find high-level feature representations and supervised fine-tuning via back-propagation to improve detection. These learnt characteristics are used to train an SVM classifier to detect malware. DroidDeep excels in malware detection with 99.4% accuracy, making it ideal for real-world applications. The stacked Auto-Encoder (AE) in Deep4MalDroid [42] analysed the graph-based characteristics to identify the Android malware.

*3) IoT Network:* The top cited research papers discovered by this study are [43] and [44]. The first paper discussed Advanced Persistent Threats (APT) detection-related challenges and unsolved issues using ML. Hackers target Internet of Things (IoT) systems for a variety of reasons, including disclosing, shifting, disabling, copying, or obtaining unauthorised access to or using an asset without authorization. The second paper discussed DDoS in the IoT. A Denial-of-Service (DoS) attack is one instance when an attacker uses an authorised host network to transmit a large number of packets to the victim to overwhelm them with messages. On the other hand, port scanning assaults take place when a hacker finds an open port that might be used to launch an attack. As a result, hackers are able to get comprehensive information about the network, such as MAC and Internet Protocol (IP) addresses. The most used datasets for IoT-based threat detection are N-BaIoT [45], Bot-IoT [46], ToN-IoT [47], and Edge-IIoTset [48].

*4) Ransomware families:* Ransomware is a kind of malware that is used as a means of extortion. Ransomware is a kind of malicious software that covertly infiltrates a victim's system and promptly demands payment in exchange for decrypting the encrypted data [31], [49]. The majority of ransomware families exhibit the following features: device lockout, data deletion and stealing, encryption, and delivering alarming notifications. Ransomware families include Cryptolocker, CryptoWall, CTB-Locker, CrypVault, CoinVault, Filecoder, TeslaCrypt, Tox crypto, VirLock, Reveton, Tobfy, and Urausy.

### *B. Country Analysis*

Fig. 3 shows the node-line country network, in which each node is a country and the line indicates the cooperative links between nations. The amount of articles determines the node's size of the country.

Table III shows the country network summary by listing the top 10 countries sorted by four categories: citation count, degree, centrality, and sigma. The highest-rated countries based on citation counts are the USA (2019), China (1417), India (694), England (523), Australia (416), and so on. Based on degrees, the top countries are England (39), the USA (30), the Netherlands (NL) (29), Belgium (28), France (27), and so on. England and Wales are the highest-rated countries based on centrality and sigma, respectively.

### *C. Institution Analysis*

Fig. 4 shows the node-line institution network, in which each node is a institution and the line indicates the cooperative links between institutions. The amount of articles determines the node's size of the institution.

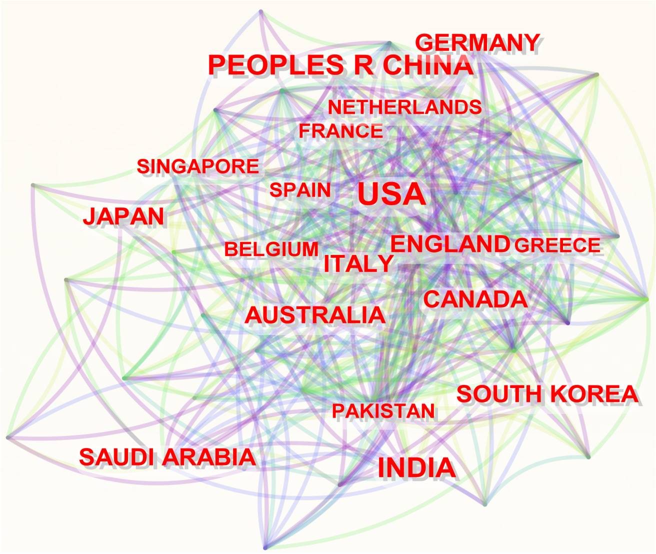

Fig. 3. Country analysis.

TABLE III. Country Network Summary

| Citation Count | | Degree | | Centrality | | Sigma | |
|---|---|---|---|---|---|---|---|
| USA | 1979 | England | 39 | England | 0.16 | Wales | 1.01 |
| China | 1417 | USA | 30 | USA | 0.08 | USA | 1.00 |
| India | 694 | NL | 29 | France | 0.08 | England | 1.00 |
| England | 523 | Belgium | 28 | NL | 0.07 | France | 1.00 |
| Australia | 416 | France | 27 | Australia | 0.07 | Australia | 1.00 |
| Germany | 416 | Sweden | 26 | Italy | 0.06 | NL | 1.00 |
| Italy | 363 | Italy | 25 | UAE | 0.06 | Italy | 1.00 |
| South Korea | 285 | Spain | 25 | Singapore | 0.06 | UAE | 1.00 |
| Saudi Arabia | 269 | Pakistan | 25 | Belgium | 0.05 | Singapore | 1.00 |
| Canada | 268 | UAE | 25 | Spain | 0.05 | Belgium | 1.00 |

Fig. 4. Institution analysis.

Table IV shows the institution network summary by listing the top 10 institutions sorted by two categories: frequency, and burst-strength. The top-rated institutions based on frequency are Chinese Academy of Sciences (194), University of California (147), University of Texas (127), and so on. Based on burst strength, the highest institutions are University of California Berkeley (11.14), Fraunhofer Gesellschaft (7.63), IMT - Institut Mines-Telecom (7.04), University of North Carolina (5.76), KU Leuven (5.21), and so on.

TABLE IV. Top Institution Network Summary

| Frequency-based | | Burst Strength-based | |
|---|---|---|---|
| Chinese Academy of Sciences | 194 | University of California Berkeley | 11. 14 |
| University of California | 147 | Fraunhofer Gesellschaft | 7.63 |
| University of Chinese Academy of Sciences | 130 | IMT - Institut Mines-Telecom | 7.04 |
| University of Texas | 127 | University of North Carolina | 5.76 |
| State University of Florida | 124 | KU Leuven | 5.21 |
| Institute of Information Engineering | 109 | IIT | 4.64 |
| Ben Gurion University | 109 | Texas A&M University | 4.35 |
| National Institute of Technology | 104 | University of Illinois | 2.91 |
| University of Georgia | 86 | University of Illinois Urbana-Champaign | 1.41 |
| Nanyang Technological University | 84 | National University of Singapore | 0.97 |

### D. Keywords Analysis

Fig. 5 depicts the keyword co-occurrence network. Keywords are concise and indicative synopses of the content of research studies. Keyword co-occurrence networks may be used to identify the current most prevalent topics in the area of knowledge during a certain time period. The node's size is determined by how often it uses the keywords.

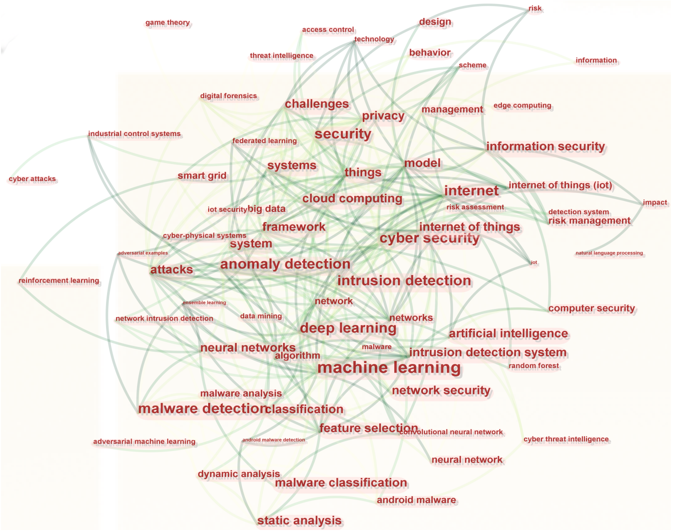

Fig. 5. Keywords analysis.

Table V shows the most frequent terms with frequency from 2019 to 2023. some keywords, such as, federated learning (16), risk (15), ensemble learning (12), adversial examples (12), iot (11), and NLP (11) are mostly used in 2023. The top keywords in 2022 are desgn (40), cyber-physical systems (33), CNN (24), reinforecemnt learning (22), scheme (19), and random forest (18). In 2029, the most frequent used keywords are intrusion detection (369), machine learning (852), deep learning (476), information security (131), cloud computing (111), feature selection (121), static analysis (120), dynamic analysis (60), android malware (48), and data mining (15).

TABLE V. KEYWORD NETWORK SUMMARY

| Year | Keywords with Frequency |
|---|---|
| 2023 | federated learning (16), risk (15), ensemble learning (12), adversial examples (12), iot (11), NLP (11) |
| 2022 | desgn (40), cyber-physical systems (33), CNN (24), reinforecemnt learning (22), scheme (19), random forest (18) |
| 2021 | network (74), algorithm (63), risk management (34), industrial control system (26), network intrusion detection (18), adversial machine learning (15) |
| 2020 | internet of things (99), digital forensics (15), behavior (39), malware (18), computer security (35), cyber threat intelligence (19), information (16) |
| 2019 | intrusion detection (369), machine learning (852), deep learning (476), information security (131), cloud computing (111), feature selection (121), static analysis (120), dynamic analysis (60), android malware (48), data mining (15) |

## V. CONCLUSION

Cybersecurity is a crucial study issue that is garnering significant attention across all sectors. Mapping cybersecurity research is crucial to assess the level of preparation in cybersecurity skills and identify areas that need improvement. This study aims to discover research needs and peaks in the fields of cyber security, malware detection, and android malware detection. This study performs a scientometric analysis and knowledge mapping of cybersecurity-related papers that were published over the last five years. We collected 9.967 research articles from WoS (see Section III-A). After that, scientometric analysis is performed to analyse research domain patterns, related research knowledge, which is referred to as clusters in this study, and keywords, and finally, discover the most contributing countries and institutions. This study found six clusters: cluster ID=0 for malware classification; cluster ID=1 for evading malware classifier; cluster ID=2 for android malware detection; cluster ID=3 for iot networks; cluster ID=4 for convolutional neural networks; and cluster ID=5 for ransomware families. The United States, China, and India are the top three contributors in terms of citation count. The Chinese Academy of Science, the University of California, and the University of Texas are the top contributing institutions over the last five years. Future work may include analysing the complete literature and comparing the findings to those from the top-ranked journals.

## ACKNOWLEDGMENT

The authors acknowledge with thanks the technical and financial support from the Deanship of Scientific Research (DSR) at the King Abdulaziz University (KAU), Jeddah, Saudi Arabia, under Grant No. (IFPIP: 1353-611-1443).

***Abstract*—In recent years, particularly with the Ethereum blockchain's advent, smart contracts have gained significant interest as a means of regulating exchanges among multiple parties via code. This surge has prompted the emergence of various smart contract (SC) programming languages, each possessing distinct philosophies, grammatical structures, and components. Consequently, developers are increasingly involved in SC programming. However, these languages are platform specific, implying that a transition to another platform necessitates the use of different languages. Additionally, developers require a certain level of control over SCs to address encountered bugs and ensure maintenance. To address these developer-centric challenges, this paper presents SCEditor, a novel Eclipse Sirius-based prototype editor designed for the visualization, design, and creation of SCs. The editor proposes a means of standardizing the usage of SC programming languages through the incorporation of graphical syntax and a metamodel conforming to Model-Driven Engineering (MDE) principles and SC construction rules to generate an abstract SC model. The efficacy of this editor is demonstrated through testing on a voting SC written in Vyper and Solidity languages. Furthermore, the editor holds potential for future exploitation in model transformation and code generation for various SC languages.**

***Keywords*—Blockchain; Metamodel; Model-driven Engineering (MDE); Smart Contract (SC); SC Programming**

## I. Introduction

In 1994, SC started as a concept of formalizing and securing relationships over networks [1]. SCs are self-executing applications, representing a key technology of a decentralized system based on Blockchain platforms [2].

The integration of SCs across various sectors has been extensively explored and advocated for within academic literature. These contracts, enabled by blockchain technology, offer versatile applications with significant implications. They enhance security, trust, and efficiency in diverse domains such as healthcare [3], [4], banking and finance [5], IoT [6], secure data sharing [7], supply chain [8], business [9], [10], education [11], software development methodologies [12], [13], security risk management [14], [15], and legal frameworks [16].

Studies emphasize SCs' pivotal role in reshaping traditional business models [9], democratizing software development through accessible methodologies [12], [10], [13], fortifying security frameworks against vulnerabilities [14], [15], and promising enhanced security and efficiency in education systems [11]. Additionally, the evolution of SCs into self-enforcing entities, known as smart legal contracts, marks a transformative shift in contractual agreements [16].

This widespread impact affirms their integral role in shaping the future landscape of multiple domains. The substantial interest in SCs has led to the creation of various development languages aimed at facilitating their programming and mitigating potential issues related to their maintenance and control.

Solidity and Vyper are the two most popular and widely used languages in SC programming. Solidity is object-oriented and considered the primary language for Ethereum and other private Blockchain-based platforms. Vyper, on the other hand, has a clear and straightforward compilation code, it is a Pythonic programming language characterized by strong typing. Furthermore, Vyper purposefully includes less functionality than Solidity in an effort to make contracts more secure and simpler to audit [17].

Despite recent advancements in the SC programming languages, they still have a lot of problems to overcome, and several concerns continue to undermine their adoption. For example, Vyper does not support Inheritance, Inline Assembly, Function and Operator Overloading, Recurring Calls, etc [18], [19]. A significant challenge that developers encounter in the Ethereum platform is the dilemma of deploying code to a system that is immutable while the development platform itself continues to evolve. You cannot just easily upgrade or change your SCs. You must be ready to take proper actions to solve occurring problems, from migrating users, apps, and funds to deploying the SC.

To produce a SC with one of these two widely used languages, it will take time learning as well as coding. Also, developers need to have certain control over the SC, so in case of a hard fork. To tackle this problem effectively, developers can promptly and appropriately respond by taking necessary measures. Therefore, to enhance the definition and development of SCs, it is preferable to raise the level of abstraction and offer a contract modeling mechanism independently of any specific language [20].

In recent years, the exploration of Model-Driven Engineering (MDE) as a means to abstractly model smart contracts has garnered significant attention among researchers. While the State-Machine model, UML Class Diagram, and Business Process Model and Notation (BPMN) have been central to many of these studies, there remains a minority that explores the model-driven development process. In this paper, we introduce SCEditor, a prototype model-driven tool developed using Eclipse Sirius, and based on an abstract metamodel. It aims to standardize the modeling of smart contracts by leveraging MDE principles.

The primary objective of the proposed tool is to streamline development processes and make more efficient the design, visualisation and generation of SCs. This work also discusses the common SC programming languages, picking the most used ones, comparing them, and deducing common components to extract an abstract metamodel. The latter is used to instantiate models including structural and functional aspects, establishing a complete representation of SCs. The key benefit of the SCEditor is that offers a range of SC components in a user-friendly graphical syntax. This facilitates the creation of platform-independent SC models, simplifies platform migration, allows adaptation to various SC languages, and ensures ongoing control over them. To test the validity of the proposed editor, a voting SC application was designed, found in the documentation of both Vyper and Solidity.

The paper has the following structure: Section II reviews innovative and recent academic approaches for SC development based on Metamodeling. Section III gives an overview of SCs as well as MDA-based tools, whereas Section IV presents the proposed approach by describing the metamodel definition process and explaining in detail the implementation process of the SCEditor. Section V presents the chosen use case to verify the validity and effectiveness of the proposed method and emphasize the findings. In Section VI we discuss the obtained results and position our proposal against the studied approaches. Finally, Section VII summarizes the main findings and proposes some suggestions for future directions.

## II. Related Work

Several studies have been conducted regarding SC programming and MDE. Most of them are based on state-machine or BPMN, and few on model-driven development process [20]. Most of the existing approaches focus on the behavioral aspect of SCs and employ both BPMN and UML statechart models for modeling business processes [21], [22], [23], [24].

During our research, we initially came across Lorikeet [23], which exploits BPMN models and fungible/non-fungible registry data schemas to create standardized ERC-20/ERC-721 compliant asset registry SCs. Lorikeet's BPMN Modeler is developed using the bpmn-js modeling library, which is licensed to bpmn.io, a division of Camunda. This led us to explore another tool called Caterpillar, also developed by the same author. Caterpillar makes use of Camunda, an open-source platform for workflow and decision automation. One notable advantage of Camunda is its upgradability and its adherence to industry standards such as the Case Management Model and Notation (CMMN) and the Decision Model and Notation (DMN), as defined by the Object Management Group (OMG).

Another approach based on BPMN entitled BlockME was presented by [21]. It focuses on creating a business process based on BPMN 2.0 which has the ability to integrate with the Blockchain Access Layer (BAL), which serves as a middleware facilitating communication between external applications and open blockchain systems, allowing for transaction exchange.

In study [22], the authors have specified a visual domain-specific language (DSL) obtained from a UML class diagram, and this method uses a collection of BPMN and DEMO (DMN) models for the design of the process. The proposed approach presents a metamodel for designing a SC, which is simply a class diagram that incorporates various SC concepts.

A Model Driven Architecture (MDA) based approach was proposed by [25], to define legal SCs. It consists of the definition of the UML class diagram which describes legal SC components like legal states, data sources, action, etc. The added value of this approach is the comparison of current modeling languages for the creation of legal SCs in light of the suggested unified model.

iContractML 2.0 [26] is a framework that allows the creation of SCs using MDE. The proposed tool focuses on using a reference UML class diagram to model SCs graphically. However, the tool does not fully support the functional aspect, as it provides templates only for some of the commonly used basic functions.

The study used the Model-driven Architecture [27], employing the UML class and state-chart diagrams to model the structural and functional aspects of SCs. The modeling process involved a series of transformations, including model-to-model (M2M) and model-to-text (M2T) transformations, which converted the Solidity PSM model into code.

The study in [28] introduces a model-driven framework that automates the storage of domain-specific data on the Ethereum blockchain platform. It achieves this by utilizing Ecore model instances. The framework generates Solidity SCs by employing model-to-model and model-to-text transformations through the use of Acceleo. To evaluate the approach, the persons-movies dataset was utilized within the Ganache environment.

## III. Background and Motivation

### A. Smart Contract Programming Languages

Ethereum, the blockchain-based platform, is considered as a reliable technology with integrity characterized by the decentralized execution of processing in SC format [29]. It has become the most popular platform for both deploying and storing SCs in a public distributed database [30]. It was not until the advent of Ethereum that the concept of SCs was implemented, even though it had been around for years. The first idea was born in 1994 by Nick Szabo [31]. A SC is an autonomous computer application that runs without the need for validation by stakeholders. SCs are exploited to make transactions. Therefore, if a transaction attempts to perform more transactions than the gas spent allows, an exception is thrown, and the transaction is cancelled. Of course, the gas represents the fee that is paid before executing the SC by the caller with the Ethereum currency ETH.

For SCs development, Solidity is frequently employed, being the foremost choice due to its widespread popularity. In addition to Solidity, several other SC programming languages are utilized, such as Vyper, Mandala and Obsidian [32]. Each of these languages takes different approaches to enhance existing development tools.

As shown in Table I, we have compiled a comprehensive list of most of the SCs programming languages, organized them based on their respective dates of creation, and evaluated them against the following set of characteristics:

- Paradigm: This is a technique used to group programming languages based on their characteristics. Multiple paradigms can be used to categorize languages.
- Level: Programming languages can be distinguished into two levels: High and Low. The major distinction between them is that high-level languages are simpler for programmers to comprehend, interpret, and compile than low-level languages. Unlike humans, machines can easily and quickly understand low-level languages.
- Targeted platform: This defines the platform on which the language runs.

TABLE I. SC LANGUAGES DESCRIPTION

| SC Programming languages | Paradigm | Level | Targeted Platform |
|---|---|---|---|
| LLL [33] | functional | low-level | Ethereum |
| Serpent [34] | procedural | low-level | Ethereum |
| Solidity [35] | object-oriented | high-level | Ethereum |
| Vyper [36] | procedural | low-level | Ethereum |
| Bamboo [37] | procedural | high-level | Ethereum |
| Obsidian [38] | state-oriented | - | Hyperledger Fabric |
| Rholang [39] | concurrent | - | RChain cooperative |
| Michelson [40] | stack-based | high-level | Tezos blockchain |
| Plutus [41] | functional | - | Cardano blockchain |
| Sophia [42] | functional | - | Æternity blockchain |
| Mandala [43] | - | high-level | - |
| Flint [44] | contract-oriented | high-level | Ethereum |
| Scilla [45] | functional | intermediate-level | Zilliqa |

The choice of SC programming languages is limited to two, a deliberate decision prompted by various factors. Some languages are still in the development process, others do not provide well-informed documentation, and some are no longer used by developers. The selection process focused on identifying the most widely utilized and well-documented programming languages, to afford the maximum characteristics of comparison. Consequently, the chosen languages are Solidity and Vyper.

Through an analysis of both shared and distinct features, we delineate the disparities between the selected languages at two distinct levels: conceptual and syntactical. At a conceptual level, a prominent disparity between Solidity and Vyper lies in their handling of root element. Notably, a single Solidity file can encompass multiple SCs, whereas with Vyper, each SC necessitates its own separate file. In terms of syntax, Solidity draws inspiration from JavaScript, while Vyper is inspired by Python syntax (Indentation, constructor, etc).

### B. MDA Based Tools

*1) The MDA Architecture:* MDA, which stands for Model Driven Architecture, is a specific vision of MDE defined by the OMG group. MDE is a powerful approach that exploits models as central artifacts to streamline the software and systems development process. It is considered a methodology for improving the quality, efficiency, and maintainability of software and systems by focusing on abstract representations of system structure, behavior, and functionality. When used effectively, MDE can lead to improved productivity, higher-quality software, and greater adaptability to changing requirements and technological platforms. Therefore, MDA can be seen as a subset of MDE, which represents an architecture for designing, visualizing, developing, transforming, and storing software models that the machine can understand, and develop independently of the implementation technologies by separating technical constraints from functional ones [46].

As depicted in Fig. 1, the OMG group proposes the MDA and turns it into a realizable engineering framework for use in the system/software design process. This approach advocates the exploitation of models as operational elements participating in the production and implementation of software. Consequently, the model serves as input for a transformation engine, which generates some or all of the desired software. Models are instances of the concepts defined by the metamodel, and a metamodel, in turn, defines the structure and rules that govern the construction of models in a particular domain. Metaclasses, on the other hand, are used to define the types of elements in a metamodel. The MDA approach requires the production of computation-independent models (CIM) which are transformed into platform-independent models (PIM) and subsequently into platform-specific models (PSM). Several tools and graphical editors have been created based on the principles of MDA to design models and facilitate the implementation of model transformations. One notable example is Eclipse Sirius.

*2) Eclipse sirius:* Sirius, developed by the Eclipse Foundation, is an open-source project that offers a flexible workbench for model-based architecture engineering. This workbench can be customized to suit specific requirements and needs. Sirius gives developers the ability to create a fully rich graphical editor containing all the components needed to design the domain model, from tables, trees, nodes, edges, colors, shapes, etc. It also offers the possibility to deploy the editor on the Web [47].

By leveraging Sirius, developers can implement the MDA principles by creating graphical editors. These editors can provide a visual representation of the models, allowing users to create, edit, and validate them. Additionally, Sirius can be combined with other OMG standards to define transformation rules and generate code from the models, aligning with the code generation aspect of MDA.

From the perspective of specifiers and developers, Sirius enables the capability to define workbenches that incorporate various editors such as diagrams, tables, or trees. It allows for seamless integration and deployment of these customized environments within Eclipse IDE or RCP applications. Additionally, existing environments can be further customized through specialization and extension. From an end-user perspective, Sirius provides feature-rich and specialized modeling editors that facilitate the design of models. It ensures synchronization between different editors, enabling a cohesive and efficient modeling experience.

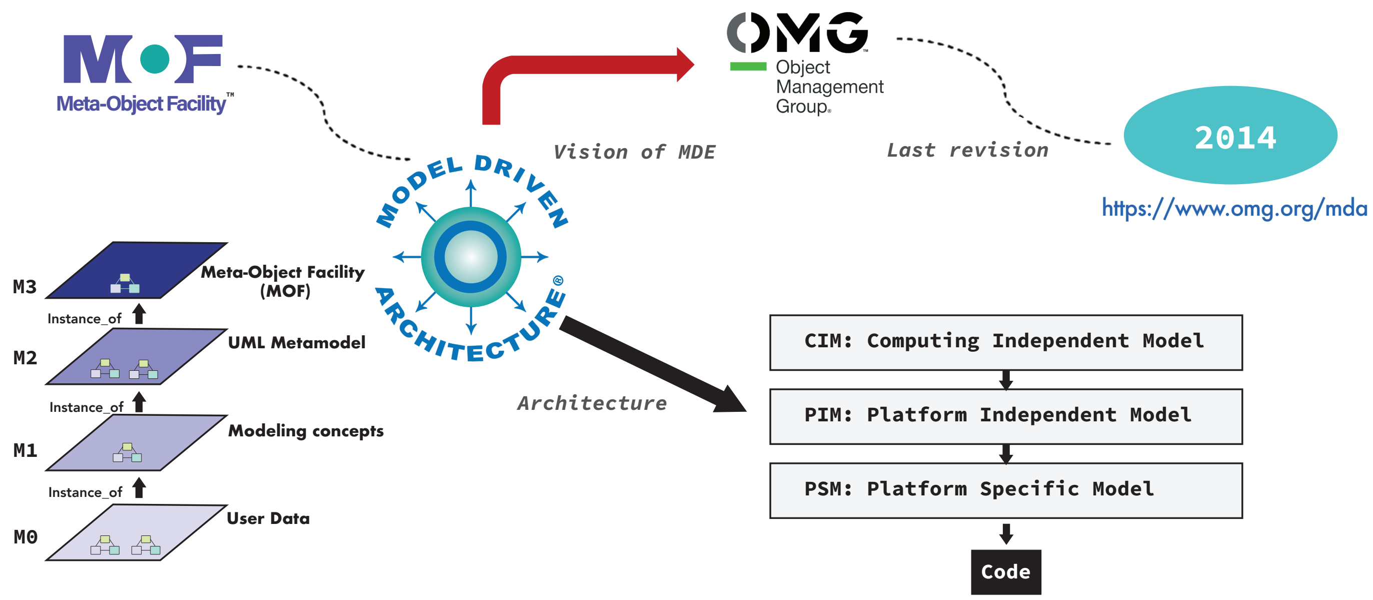

Fig. 1. The MDA framework.

## IV. The Proposed Approach

In this section, we explain the proposed approach for the elaboration of the SCEditor. To begin with, we started with the creation of an abstract representation of the SC components, then, suggested a graphical representation for each one of them. Finally, we used the metamodel in the Sirius Eclipse project to elaborate a prototype of the SCEditor.

### A. Metamodel Definition

The creation of the metamodel was done using Eclipse Modeling Framework (EMF) [48], which is an open-source technology in model-based software development. It is a comprehensive abstraction for describing, creating, and working with structured data.

The construction of the proposed metamodel was based on gathering a set of concepts used in the composition of SCs. These concepts were collected from both the literature describing SCs and the studied languages. There were continuous updates to the metamodel as we encountered new references, and while creating model instances that covered most of the SC elements.

In our endeavor to present a comprehensive yet digestible depiction of a the metamodel, we employed segmentation, dividing it into distinct structural and functional components. This segmentation aimed to enhance clarity and facilitate a more focused analysis. However, this division led to the exclusion of some relationships bridging the structural and functional aspects.

Fig. 2 illustrates the structural aspect of the metamodel. This segmented representation aims to provide a detailed breakdown of the structural aspect, showcasing the various metaclasses and their interrelations within the metamodel. it's important to note that due to the complexity and size constraints, certain interrelationships with the functional aspects have been omitted to maintain readability and visual clarity.

Fig. 3 presents the functional aspect of the segmented metamodel, focusing on the dynamic behavior and interactions between system components. This depiction emphasizes the operational aspects, illustrating Statements, Expressions and interactions between the identified elements within the function Body. The functional representation aims to elucidate the operational flow and functionalities. While this view provides insights into the functional dynamics, it may lack some structural context crucial for a complete understanding of the system.

The classes illustrated in Fig. 2 and Fig. 3 encompass both the structural and functional facets of the SC. Within the structural realm, delineating the program's foundational architecture, reside classes such as "Struct," "Interface," "Variable," "Modifier, "Function," "Event, and "Type" Conversely, the functional aspect characterizes the SC's operational behavior, incorporating the abstract classes "Statement" and "Expression" and their respective derived subclasses. Elaboration on the intricate relationships among these classes is provided in the next section.

### B. SCEditor

SCEditor is a graphical editor for SCs design, visualization, and generation. The proposed editor is a high-level tool that provides a set of SC elements in a comprehensive graphical representation, making it easy for the users to create platform-independent models of SCs, facilitate platform migration, enable adaptation to different SC languages, and maintain a certain control over them through time.

SCEditor is based on the eclipse project "Sirius". It relies on creating model instances of a given SC conform to the

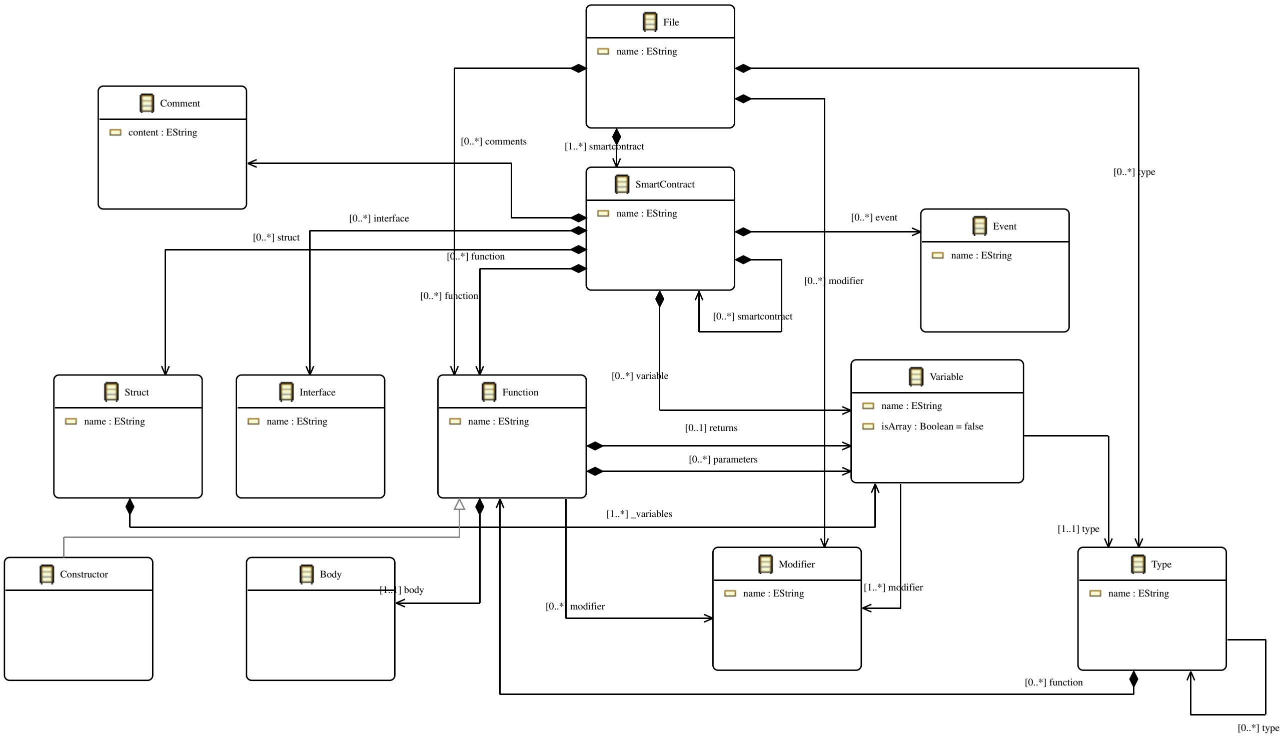

Fig. 2. Metamodel strcutural metaclasses.

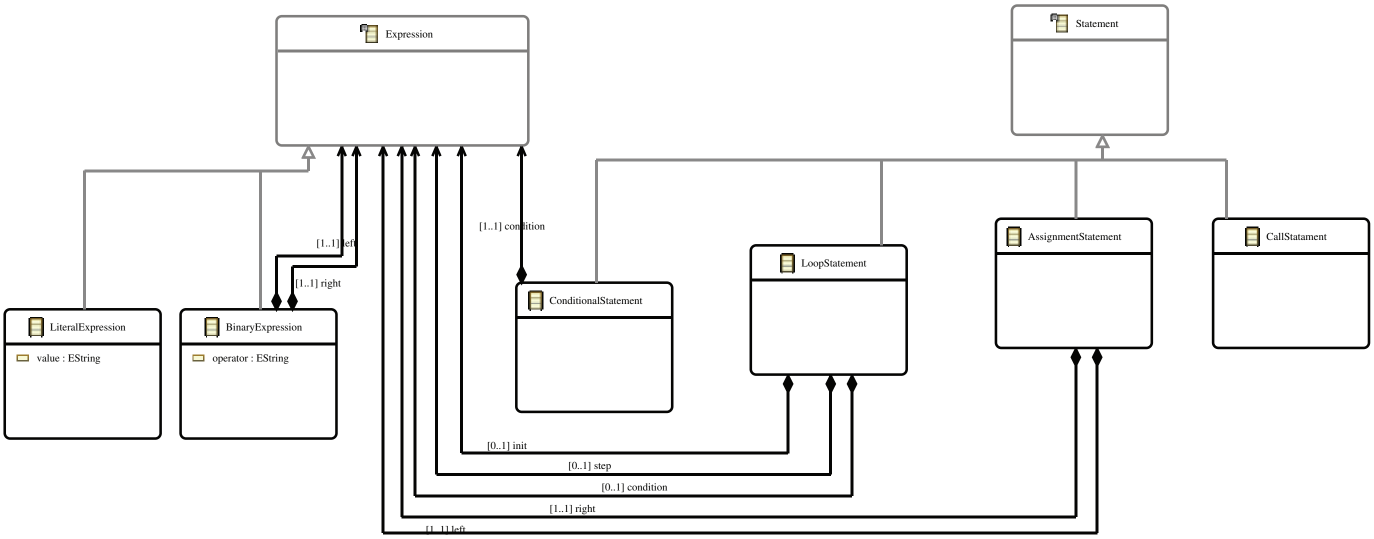

Fig. 3. Metamodel functional metaclasses.

SC metamodel. The creation of the model consists of using the elements provided in the palette of the editor. The editor relies on two diagrams: the Smart Contract Diagram (SCD) which contains elements needed for the representation of the structural aspect, and the Function Diagram (FD) composed of elements describing the functional aspect of the SC metamodel.

*1) Smart contract diagram:* The structural and static aspect plays an integral role in storing, managing, and manipulating data and transactions within a SC. In this section we present SCD which is a graphical representation comprising various structural nodes. it describes the static aspect of a given SC. Its visual representation aids in comprehension, enabling developers to grasp the composition and structure of the SC.

At the outset, the design of the SC model begins with the creation of the SCD, the latter represents the top layer of the model. These elements are categorized and found in the palette (see Fig. 4(a)).

The SCEditor comprises two palettes: one dedicated to the SCD (see Fig. 4(a)), and the other specifically designed for the FD (see Fig. 4(b)), the latter will be elaborated upon in the following section. These palettes encompass tools divided into four categories:

- Contract Tools: It contains the main elements of a SC, such as Contract, Function, and Struct.
- Statement Tools: It contains all statement elements like AssignmentStatement, CallStatement, etc.
- Expression Tools: It contains all expression elements, like LiteralExpression, ValueExpression, etc.
- Function Tools: It contains the variables used as Parameter or Return variables.

Table II presents the components of the SCD, accompanied by their respective palette icons and graphical representations.

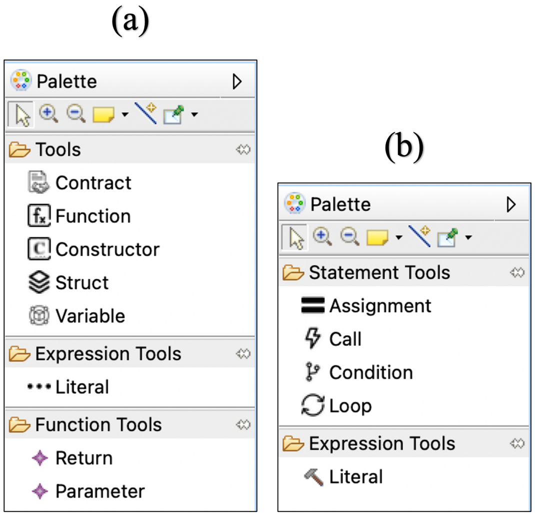

Fig. 4. SCD and FD palettes.

Contract, Struct, and Function elements are represented as containers. The reason behind is that these elements can contain other components. "Contract" represents the container that will include all the necessary elements to design the SC structure and logic. It is composed of one or many Struct, Function, or Variable. The "Struct" element defines a custom type and contains one or many "Variable". The latter constitutes a value stored in the SC storage. Finally, the representation of the "Variable" element is defined by a node.

When representing the logic of the SC, we faced many challenges. The first one was the creation a comprehensive set of components (Statement, Expression) to illustrate the functional aspect of the SC model. The second one was related to the representation of these components which was excessively growing as the body of the function expanded, leading to an overcrowded diagram. To solve these issues, a "Function Diagram" was defined, thus having only the visualization of the functions on the SCD, and when explored, it leads to a specific FD representation.

TABLE II. SCD ELEMENTS

| Element | Palette icon | Graphical Representation |
|---|---|---|
| Contract | | Container |
| Struct | | Container |
| Variable | | Node |
| Function | fx | Container |

*2) Function diagram:* The Function Diagram is a visual representation that depicts the structure and relationships of statements within a "Function" element.

The FD serves as a valuable tool to express the logic of a function and to improve the readability of the SCD. The numerous elements required for the representation of the function body is mitigated by encapsulating them in the "Function" node.

To create an FD, we first need to declare a "Function" element in the SCD, then, by double-clicking the latter we navigate into the FD workbench that contains a dedicated palette shown in Fig. 4(b). This palette is composed of "Statement" and "Expression" child metaclasses required to design the function body. These elements are described in Table III with their graphical representation.

When choosing a type of "Statement", the editor will create a container composed of the nodes required for the composition of the selected element. For example, the creation of an "AssignmentStatement" implicates the construction of two nested nodes, the first is the left "Expression" that will be assigned the value of the second one, which is the right "Expression". The CallStatement allows the call of any defined function in the "File" element. As for the "LoopStatement", it is used when an iteration is needed. The construction of this element implicates the creation of three nodes: "initial" which describes the initial state of the iteration, "condition" which indicates the condition to stop the iteration, and "step" which represents the iteration step. For expressing a series of "Statement" conditioned by a "Condition" node, we use "ConditionalStatement". Finally, we have the "Expression" child metaclasses which consist of "LiteralExpression" that contains an expression value, and, "BinaryExpression" which is used to compare, increment, or decrement a certain expression.

It is important to note that besides the nodes contained in "LoopStatment" and "ConditionalStatement", these elements need to have a body that contains their logic. Similarly, we can define an FD to describe these statements' bodies.

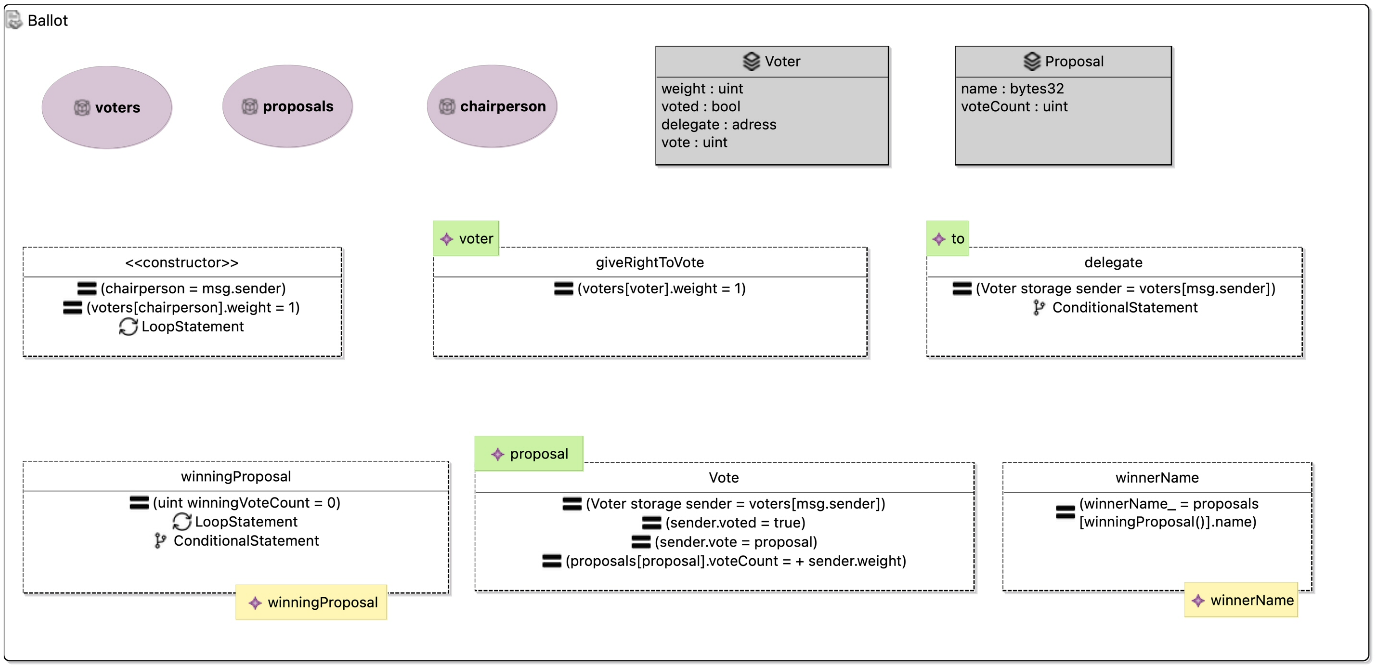

Fig. 5. SCD representation of the Ballot SC.

TABLE III. FD ELEMENTS

| Element | Palette icon | Graphical representation |
|---|---|---|
| AssignmentStatement | 〓 | Container |
| CallStatement | ⚡ | Container |
| LoopStatement | ⟳ | Container |
| ConditionalStatement | ⑂ | Container |
| LiteralExpression | ••• | Container |

## V. RESULTS

### A. Case Study

Voting is a delicate, precise, and open procedure process, it requires a certain degree of security and privacy. The issue with most of the voting applications is that they have several design problems [49]. They are centralized by design and proprietary, which implies that the code base, database, system outputs, and monitoring tools are all under the simultaneous control of one supplier. Such centralized systems struggle to gain the credibility needed by voters and election organizers due to the absence of an open-source, independently verifiable output.

Given this, blockchain technologies can be very helpful for this process as they offer open-source, peer-reviewed software that is ubiquitous, secure, and efficient, preserving the ballots' confidentiality, enabling free, impartial audits of the results, lowering the level of confidence required from the organizers [49], [50].

In this light, we choose to work with a basic example of a voting application to validate the applicability of our approach. The case study represents a voting SC that will be used as a reference to create a model based on the metamodel. The latter is found in the documentation of the studied languages [51], [52]. The SC will create one contract per ballot, and then the chairperson - who is the creator of the contract - will grant the right to vote to each individual by his address. These individuals will then choose to vote themselves or delegate their vote to another person they trust. Finally, after the voting process is done, we will get the proposal with the largest number of votes.

The selected SC highlights numerous features of the SC languages, implying a test of the proposed metamodel's validity. To make it short, we focused only on code segments implemented in Solidity [51] and Vyper [52]. This decision was made due to existence of most elements required for constructing a SC, encompassing SC and variable declarations, structures, constructors, and more.

Analyzing code from both Solidity and Vyper reveals common elements such as variables, loops, conditional statements, and functions. Both languages share fundamental constructs for control flow and data types, despite syntax variations.The common elements found in codes are as follows:

- **Ballot contract**: It refers to the voting SC. In Vyper, it is represented by the filename itself.
- **Voter structure**: It contains information about the voter defined by the following variables:
    - **weight**: It is accumulated by delegation.
    - **voted**: True/false, depends if the person has voted or not.
    - **delegate**: The address of the person to whom the right to vote has been delegated.
    - **vote**: Index of the voted proposal.
- **Proposal structure**: it can be created by users. It has the following variables:

  - ○ **name**: Name of the proposal.
  - ○ **voteCount**: Number of votes.

- **chairperson variable**: The creator of the contract.
- **giveRightToVote** function: It gives a voter the right to vote, it can be called only by ‘chairperson‘.
- **delegate function**: It delegates vote to the voter ‘to‘.
- **winningProposal function**: It returns the proposal with the largest number of votes.

### B. Design and Implementation

In this section, we will provide an example of an SCD, an FD, and the resulting model.

At the outset of creating a new diagram, the workbench automatically positions itself within the root file which contains one or multiple SCs. The illustrated palette in Fig. 4(a), provides the necessary elements to create a Contract, Struct, Function, or Variable.

The user initiates by selecting the desired item and clicking on the workspace, triggering the display of a graphical representation of the corresponding element. Subsequently, the user is asked to enter the properties of the created element. Once completed, the user can proceed to define the description of the functions, this can be achieved by double-clicking the function element on the SCD. This action generates new workspace and palette enabling the user to define the body of the function

Fig. 5 illustrates the SCD of the case study. First, we find the name of the SC on the top left of the container. The three purple elliptic nodes represent the voters, proposals, and chairperson variables. Right next to them, we can find the Voter and Proposal Struct illustrated by a gray container containing the dedicated variables. The constructor and functions of the SC are represented by dashed white containers including in the body the logic defined by the Function Diagram. The green-bordered nodes found on top of the functions represent the input parameters, while the yellow-bordered ones represent the return value of the function.

For example, the “winningProposal” function shown in Fig. 5, has five statements varying from AssignmentStatment, LoopStatement, and ConditonalStatement. These statements are ordered according to the execution order declared in the Function Diagram in Fig. 6.

Fig. 7 represents an ecore viewpoint of the resulting model. The instance output is an XML Metadata Interchange (XMI) format, which is an OMG standard for the representation of object-oriented information in XML format. It is important to highlight how easy it is for the user to use the XMI model for other Model-driven related purposes such as M2M or M2T transformations.

The components depicted Fig. 7(a) directly correlate to the specific elements established within the SCD. Furthermore, Fig. 7(b) serves as an illustration of the structure of the Voter “Struct” element. Additionally, Fig. 7(c) elucidates the composition of the “winningProposal” function, showcasing its internal body structure and the variable returned by this function.

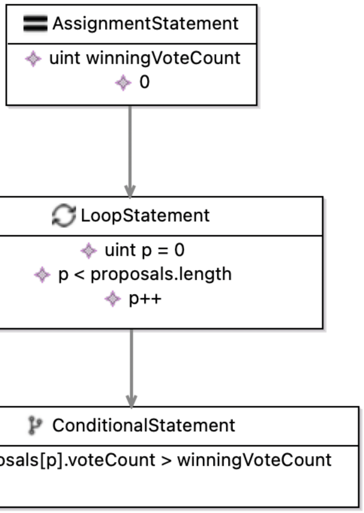

Fig. 6. FD representation of the winningProposal function.

## VI. Discussion

The primary objective of this research endeavors to construct a structured graphical representation for SCs, founded upon an abstract metamodel developed in adherence to MDE standards. The methodology adopted for this endeavor involves the construction of a metamodel, predicated on an in-depth analysis of programming languages used for SCs, aiming to offer a broader, more generalized, and abstract delineation. This approach facilitates a platform-independent depiction of SC definitions, emphasizing the comprehensive portrayal of both structural and behavioral facets intrinsic to SCs. The core focus of this representation lies in encapsulating the intricacies inherent in the structural and operational dimensions of SCs.

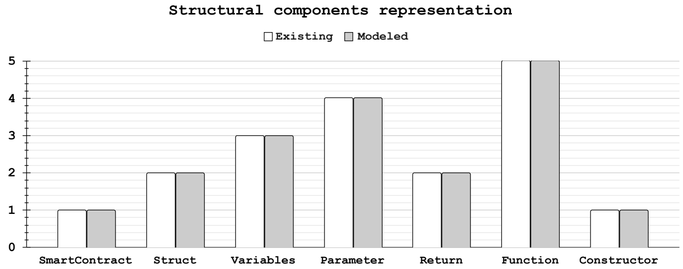

Fig. 8. Structural representation comparison between existing SC code and elements modeled within the SCEditor modeled elements.

Fig. 8 displays a bar graph contrasting existing elements in white with modeled components in gray. The white bars indicate the count of elements found within the codebase, including classes, structs, variables, parameters, returns, functions, and constructors. Conversely, the gray bars represent the number of these code elements visually depicted in the diagram. This visual comparison reveals that all structural components were successfully represented.

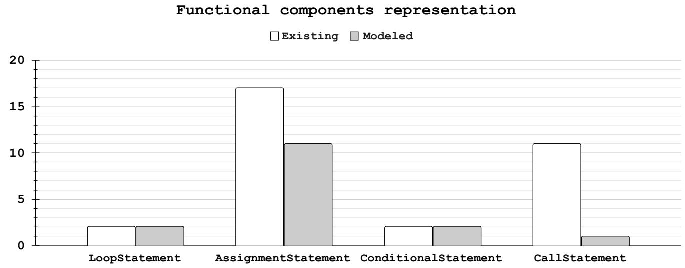

Fig. 9. Functional representation comparison between existing SC code and elements modeled within the SCEditor modeled elements.

In Fig. 9, it is evident that only 50% of the behavioral components were represented in the model, predominantly comprising function bodies, resulting in a cumulative representation of 68% for all components. This comparison underscores notable disparities; for instance, out of the 17 existing AssignmentStatements, only 11 were visually represented. Similarly, among the 11 CallStatements, merely one was visually modeled.

Several limitations were encountered concerning the representation of the behavioral aspect (FD). Specifically, the complexity of FD elements increased as the statements became progressively more intricate. Although the representation remained feasible, the growing number of components resulted in an overcrowded diagram. Regarding the structural aspect, users are required to define the types and built-in functions they intend to employ while constructing the SCD and FD. Additionally, the absence of test and exception handling functions (e.g., assert, require, etc.) is notable. Further work and validation are necessary to incorporate these functionalities at the abstract level alongside other features.

After examining various modeling approaches highlighted in the related work section, a key observation emerged regarding the predominant use of BPMN. Many methodologies for representing business processes rely on BPMN, an officially recognized standard by the OMG. However, while BPMN adeptly illustrates data flow and connections between data artifacts and activities, it isn't explicitly designed as a data flow language. Furthermore, this specification does not cover the operational simulation, monitoring, or deployment of business processes.

Other modeling approaches offer capabilities similar to those of our proposal [26], [27], [28]. It can be argued that these approaches are restricted in their scope as they do not include all the structural and dynamic components of the SC. However, they can only present the structural aspect of the SC leaving the functional one to the user in the manual definition.

In comparison with these approaches, the SCEditor presents a broad and abstract representation of the SC, as the user can define both the structural and functional aspects of the SC.

## VII. Conclusion

This work presents the SCEditor, a prototype model-driven tool based on an abstract representation designed to standardize modeling SCs using MDE. The development of this graphical editor utilized Eclipse Sirius in conjunction with a metamodel definition formulated from derived rules originating from Solidity and Vyper languages.

The primary objectives of this proposed tool encompass streamlining and enhancing the efficiency of SC design and modeling processes, to meet the needs for developing large-scale SCs.Additionally, it aims to consolidate the similarities across various SC programming languages while identifying and addressing disparities between them, ultimately proposing a unified model.

We conducted a validation of our graphical editor by subjecting it to a voting SC example sourced from Solidity and Vyper documentations. The graphical editor effectively modeled a majority of the SC components, encompassing both its structural and functional elements. This abstract representation of SCs holds promise for future utilization in generating customized code for various blockchain programming languages

Our forthcoming efforts will center on model transformations to target additional blockchain platforms. This approach will enable us to propose more abstract models that adhere to the distinct rules of each platform. Subsequently, we intend to conduct a usability test aimed at addressing challenges associated with the abstraction of the metamodel.
