Abstract—This research aims to devise a distinct mathematical key for individual identification and recognition. This key, represented through signals, is constructed using Lagrange polynomials derived from the skeletal points. Consequently, we present this key as a novel fingerprint categorized within physiological fingerprints. It's crucial to highlight that the primary application of this fingerprint is for remote individual identification, specifically excluding any bodily masking. Subsequently, we implement an artificial intelligence model, specifically a Convolutional Neural Network (CNN), for the automated detection of individuals. The proposed CNN is trained on an extensive dataset comprising 10000 real-world cases and augmented data. Our skeletal fingerprint recognition system demonstrates superior performance compared to other physiological fingerprints, achieving a remarkable 98% accuracy in detecting individuals at a distance.

Keywords—Artificial intelligence; recognition of individuals; new fingerprint; lagrange polynomials; CNN

I. INTRODUCTION

Biometrics is a method employed for quantifying human body attributes, encompassing the analysis of physical, biological, and behavioral characteristics of individuals. While traditionally utilized for individual identification, its significance has grown in the realm of countering terrorist and criminal threats, emphasizing authentication.

Biometrics can be broadly classified into two primary categories: physical and behavioral. Physical biometric modalities include features like fingerprints, hand and facial shapes, as well as characteristics such as vein patterns in the hand, the iris, and the ear. On the other hand, behavioral modalities encompass traits like signatures and gait patterns.

Biometric characteristics, fundamentally enduring, remain constant throughout an individual's lifetime, rendering them both unique and universal. This permanence offers a robust alternative to easily forgettable or susceptible means of personal identification, such as PINs or passwords, as well as vulnerable physical items like magnetic cards, which can be subject to theft, duplication, or loss. Automated processes within the realm of biometric systems address these distinctive characteristics, making them highly secure. Biometric systems are acknowledged as the epitome of security owing to their inherent resistance to fraudulent use. Continuous research endeavors are dedicated to exploring novel methods and improving existing ones. The diverse modalities within biometrics are generally classified into three analytical classes based on their nature, as highlighted in [19].

- 1) **Physiological Biometrics:** This category encompasses measurements derived from distinct physical attributes, including fingerprints, the unique patterns of the outer ear (oracular print), iris structure, and facial features.
- 2) **Biological Biometrics:** This type of measurement primarily relies on biological substances such as DNA, urine, saliva, and blood. Frequently utilized in criminal identification and anti-doping efforts, these measurements provide valuable insights into individual profiles.
- 3) **Behavioral Biometrics:** This technique involves measuring characteristics linked to behavior, such as voice recognition, keyboard typing speed, writing styles, and signatures. Unlike physiological biometrics, these traits are less stable, subject to variation with age, and influenced by psychological conditions like stress.

A biometric system relies on physiological, biological, or behavioral techniques to uniquely identify individuals. The landscape of biometric modalities is expansive and constantly evolving, with new methods continually emerging. In the subsequent discussion, we delve into notable research and highlight some prevalent modalities, including facial recognition, speech analysis, fingerprinting, hand structure, and iris scanning. Moreover, we introduce our innovative skeletal fingerprint recognition system, a distinctive addition to physiological fingerprints. It is noteworthy that the robustness of our system, powered by artificial intelligence, lies in its ability to identify individuals at a distance with an impressive accuracy rate of 98%, setting it apart from other physiological fingerprinting methods.

In terms of structure, this paper is organized as follows: Section 2 provides a comprehensive literature review, examining works pertaining to biometric systems, with a particular focus on notable research and highlighting prevalent modalities, such as facial recognition, speech analysis, fingerprinting, hand structure, and iris scanning. Section 3 delves into the intricacies of our data preparation pipeline and outlines the proposed model for our recognition system. Moving on, Section 4 is dedicated to digital experiments, where we present, discuss, and analyze the results obtained, demonstrating the effectiveness of our models. The concluding Section 5 summarizes the study and offers potential perspectives for further enhancing the current results.

II. RELATED WORK

Biometrics involves the automated identification of individuals through their anatomical and/or behavioral characteristics, emphasizing personal identity based on inherent traits rather than possessions or memorized information.

In scholarly discussions, these characteristics are often referred to as identifiers, modalities, indicators, or biometric attributes. It's crucial to highlight that any behavioral or physiological trait can be deemed a biometric modality, provided it satisfies seven key properties: universality, uniqueness, permanence, measurability, performance, acceptability, and bypassing, as outlined by Jain et al. in their work [13].

Numerous distinctive morphological features characterize each individual, and each of these can be measured through various methodologies:

- **Fingerprints (finger-scan):** Since the 1970s, fingerprint recognition systems have been marketed and gradually attract the attention of researchers and security companies such as the FBI for example. Fingerprints are the traces left by the grooves of the finger pulps. The pattern formed is unique and differs from one individual to another. In practice, it is almost impossible to use all the information provided by this drawing, so we extract the main characteristics such as the bifurcations of ridges. A fingerprint contains on average a hundred characteristic points. Statistically, that it is impossible to find 12 identical points in 2 individuals.

Among the methods used to process Fingerprints: In [7], the authors present a prototype ultrasonic sensor for detecting fingerprint patterns. Their working principle is based on amplitude measurements at selected points in the sound field of ultrasound waves diffracted by subsurface finger structures. Machine learning methods have also been proposed, such as in [11]. The authors propose an unsupervised approach based on object fingerprinting to detect activity without human labeling. Lately authors of [9] present Molecular Surface Interaction Fingerprinting, a conceptual framework based on geometric deep learning methods for detecting fingerprints important for specific biomolecular interactions.

- **Hand geometry:** The recognition of the shape of the hand is considered to be the ancestor of biometric technologies. In the sixties, Robert P. Miller filed a patent for a device to measure characteristics of the hand and record them for later comparison. This biometric modality consists in measuring several characteristics of the hand, such as the shape of the hand, the shape of the joints, the length and width of the fingers, etc. Several works have been carried out to extract these characteristics, we cite [20], the authors implemented a biometric system based on hand geometry recognition. Hand features are extracted from color photographs as users place their hands on a platform designed for this type of task. Various pattern recognition techniques have been tested for classification and/or verification. In recent work, an algorithm [3] is proposed, which is based

on the geometry properties of the hand as keys for encryption/decryption audio files. In study [4] the authors adopted a solution that relies on the geometry of the hand to reduce mobile payment fraud.

- **Iris:** It is a reliable technology, and appears to be much more accurate than some other biometric means. This is because our iris has so many characteristics that can vary from one individual to another. The iris is made up of blood vessels and these are arranged differently from one individual to another. Each eye is unique. It is proven that the probability of finding two identical irises is lower than the inverse of the number of humans who have lived on earth. Once the image of the configuration of the blood vessels is obtained by the biometric system, the operation is almost identical to that of the system analyzing the fingerprint. This technique can be affected by several factors such as the distance between the eye and the camera, reflections, false eye detection etc. To reduce the risk of poor recognition, certain dynamic characteristics of the eye are called upon. This is summarized in the following study [2].
- **Facial scan:** The development of biometric systems based on recognition of the shape of the face is one of the most recent biometric techniques. This technique is based on a face image. The most popular face recognition methods are based on: 1) the shape and the location of facial attributes such as eyebrows, eyes, lips, nose, and chin and their spatial relationships, or 2) general (global) analysis of facial images, representing faces as a weighted combination of representing the number of canonical faces [12]. In addition to physical characteristics, an individual also has behavioral characteristics that are unique to him :
- **keystroke-scan:** This is a technique for recognizing people based on their own typing rhythm. It is a "Software Only" biometric solution, because it only consists of a collection of data based on the typing dynamics of users. It is applied to the password which thus becomes much more difficult to imitate. Keystrokes are affected by several factors: time between keystrokes, frequency of errors, or the overall time it takes to type text. However, even if, this behavior is not unique to each individual, it offers sufficient discriminating information to identify an individual. A new study [16] is carried out in this field for deprived attacks, where the authors propose a new hybrid method based on typing dynamics for identification and biometric authentication integrated with artificial intelligence.
- **Speech Recognition (voice-scan):** The data used by speech recognition comes from both physiological and behavioral factors. Identification by the route is based on the size and the shape of the appendages (nasal cavities, lips and mouth) used in sound synthesis. The physiological characteristics of an individual's voice are invariable, but behavioral characteristics change over time and with age, depending on health conditions (sore throat) and emotional states, etc. which

decreases the accuracy of the identification rate. This identification technique is sensitive to a large number of factors such as noise. As an example of a security system based on voice identification as an access control key, we cite [18].

Other biometric techniques are currently being developed such as biometry by the geometry of the veins of the hand [21], biometry by the palm print [8], biometry by the geometry of the veins of the finger [25]. Despite their reliability, biometric identification systems do not guarantee recognition of the individual. The big concern is that most systems work with contact with the individual, which is not logical to avoid terrorist attacks or for remote identification of the individual. For this, the gait recognition is considered to be the most demanded method of biometrics in this situation.

Gait analysis is the systematic study of human movement using the eyes and brain of an observer, supplemented by instruments that measure body movement, body mechanics, and muscle activity. Gait recognition is a relatively new biometric technique [15], [22] which has attracted more interest in the Computer Vision community in recent years, due to its advantages over other biometrics [24]. Biometric methodologies are generally intrusive and require the collaboration of different methods of biometric in order to perform accurate data acquisition. The process, on the contrary, can be captured remotely and without collaboration of several biometric methodologies. This makes it a discreet method of recognizing people at a distance and without contacting the individual, this is more requested in order to avoid terrorist attacks. In study [10], the authors propose an algorithm to characterize gait using 3-dimensional skeletal information acquired by the Microsoft Kinect sensor. In study [17], the authors propose an self-similarity based gait recognition system for human identification using modified Independent Component Analysis (MICA). In study [23], a method has been proposed for in-depth gait recognition based on the characteristics of the local directional pattern (LDP) to extract information and a neural network for learning.

The primary objective of this research is to pioneer a novel fingerprint within the realm of physiological biometrics, specifically focusing on the parametrization of the human skeleton. Our methodology involves measuring the dimensions of the human skeleton in both static and dynamic states, particularly through gait analysis. These measurements are then mathematically modeled using Lagrange polynomials, which are subsequently translated into electronic signals. Furthermore, we have implemented a Convolutional Neural Network (CNN) to automate the detection of individuals. The proposed neural network is trained using the modeled Lagrange polynomials on a substantial dataset comprising 10 000 real-world cases and augmented data. The distinctive advantage of this approach lies in its capacity to mitigate morphological falsifications, such as fingerprints or facial masks. The combined performance of the proposed model, integrating Lagrange polynomials and CNN, proves highly promising. It enables remote identification, wherein the individual's skeleton can be captured through cameras, allowing for authentication decisions to be made remotely.

III. THE PROPOSED SKELETAL FINGERPRINT RECOGNITION SYSTEM

A biometric system functions as a pattern recognition system that acquires biometric data from an individual, extracts a set of features from this data, and compares these features with stored signatures in a database. Depending on the application environment, the biometric system can operate in either identification or verification mode. This same principle applies to the recognition of skeletal fingerprints, wherein a provided fingerprint is compared with one or more existing fingerprints stored in the system's biometric database. The system yields a positive result if the skeletal fingerprints match any of the templates, and a negative result otherwise.

Our skeletal fingerprint recognition system comprises five modules: acquisition (capturing the skeleton of the individual using a camera), pretreatments (including grayscale adjustment, normalization, binarization, and skeletonization), feature extraction (utilizing precise skeleton coordinates to form Lagrange polynomials), prediction and comparison (generating signals from each Lagrange polynomial combined with the CNN prediction), and finally, the decision.

The overall structure of our skeletal fingerprint recognition system is shown in Fig. 1.

Fig. 1. General architecture of the proposed recognition system.

A. Skeletal Fingerprint Acquisition

The purpose of this phase is to procure digital images, specifically capturing images in both dynamic and static states using a specialized camera.

As previously elucidated, our methodology involves measuring the dimensions of the human skeleton in both static and dynamic states to create a unique key for individual identification and recognition. To achieve this, sixteen photos of the dynamic skeleton and a single photo of the skeleton in a static state are extracted for each sequence. The selection of the number of images for the dynamic state (sixteen photos) for key creation is determined through a reinforcement learning-based model.

We've implemented a reinforcement learning (RL) model to assess the efficacy of keys built from one to 50 images. In essence, the RL model compares 50 keys, where each key, denoted as k ($k \in 1, \dots, 50$), is constructed from k dynamic images and one static image. Results derived from the RL model indicate that the key with $k = 16$ yields optimal outcomes in terms of accuracy and computation time cost.

We utilized a digital camera affixed to a tripod to capture gait sequences in an open-air setting. The duration of each sequence varies based on the time taken by each individual to traverse the field of view. However, our specific focus was on extracting sixteen photos of the dynamic skeleton and a single photo of the static skeleton for each sequence. This approach enabled the creation of an initial database comprising 2087 sequences.

To enhance the learning dataset, we incorporated publicly available images from the National Laboratory of Pattern Recognition (NLPR) gait database, as outlined in [17]. This supplementary database encompasses a total of 240 sequences.

For data augmentation, a technique employed in deep learning to generate new images from an original dataset through random transformations, we utilized the *ImageDataGenerator* class from the Keras library. Data augmentation aims to address the challenge of limited images during the training phase. This involves operations that modify the appearance of the image without altering its semantics, such as adjusting brightness or applying rotations (0°C, 45°C, 90°C with respect to the image plane). The implementation of data augmentation enabled the creation of a comprehensive database comprising 10 000 use cases.

B. Pretreatments

Prior to advancing to subsequent stages, the pretreatment step is imperative. The preprocessing of skeletal fingerprints entails three distinct stages: binarization, filtering, and skeletonization.

Binarization: Our initial step involved converting color images to grayscale. Given that the grayscale image encompasses 256 levels (ranging from 0 for black to 256 for white), the binarization process transforms the image into two levels (binary). The threshold is determined and set by the user (we opted for a threshold of 128). Each pixel's value is then compared to this threshold: if it exceeds the threshold, the pixel assumes a value of one (white); otherwise, it takes on a value of zero (black).

Filtering: Filtering is an operation designed to extract information or enhance the visual quality of an image, such as eliminating noise or refining the edges of a blurred image. In our context, a filter is employed to identify the person and extract the skeletal structure.

Skeletonization: In the binarized image (black and white) the lines can be seen clearly but they have different sizes. To be able to quickly detect minutiae (terminations, bifurcations), it is necessary to obtain a more schematic image of the skeleton, in which all the lines have the same thickness.

C. Feature Extraction

For the extraction of features there are several techniques such as moments, wavelet transforms, Markov models, neuron networks and fuzzy algorithms, in addition to the large family of extraction methods. But among the most important analyzes we cite [10] that the skeletal data were extracted in real time in a map of 20 body joints.

Likewise, we are basing ourselves on this study which has shown that it is possible to characterize people with reasonable

Fig. 2. Example of the preprocessing result.

precision, based on a set of 20 subjects which represents the important characteristics of walking (additionally, Doctor I.B., an author of this article, has confirmed the information). Hence Table I shows exactly the 20 points that we used to characterize a skeleton in static/dynamic state. These points will be modeled in the form of Lagrange polynomials which will be translated in the form of electronic signals. Also a convolutional neural network will be used for the automatic detection of individuals (this will be explained in the next paragraph). Fig. 2 shows an example of the preprocessing results.

TABLE I. SKELETON JOINT NOTATION

Joint Label	Joint Type	Joint Label	Joint Type
(x_0, y_0)	Hip Center	(x_{10}, y_{10})	Wrist Right
(x_1, y_1)	Spine	(x_{11}, y_{11})	Hand Right
(x_2, y_2)	Shoulder Center	(x_{12}, y_{12})	Hip Left
(x_3, y_3)	Head	(x_{13}, y_{13})	Knee Left
(x_4, y_4)	Shoulder Left	(x_{14}, y_{14})	Ankle Left
(x_5, y_5)	Elbow Left	(x_{15}, y_{15})	Foot Left
(x_6, y_6)	Wrist Left	(x_{16}, y_{16})	Hip Right
(x_7, y_7)	Hand Left	(x_{17}, y_{17})	Knee Right
(x_8, y_8)	Shoulder Right	(x_{18}, y_{18})	Ankle Right
(x_9, y_9)	Elbow Right	(x_{19}, y_{19})	Foot Right

D. Prediction and Comparison

In our system, we leverage the synergistic power of two robust techniques: Lagrange polynomials and Convolutional Neural Networks (CNN).

1) Lagrange polynomials: Lagrange interpolation polynomials are employed to transform each image set already generated (sequence), comprising the sixteen dynamic skeletons and

the static skeleton, into a key represented by electronic signals. The key transformation process is outlined in the following algorithm:

For each use case we have j photos with $1 \leq j \leq 7$, identification of exposed points (x_i^j, y_i^j) , with $0 \leq i \leq N_j$: N_j is the number of exposed points chosen (see Table 1) for each use case j . All the x -coordinates must be different $(x_i^j \neq x_{i+1}^j)$. The points are stored in the P_j .

Lagrange polynomial formulation for each use case j :

$$P_j(X) = \sum_{i=0}^{N_j} y_i^j L_i^j(X) = \sum_{i=0}^{N_j} \alpha_i^j(X^i)$$

$$\text{with } L_i^j(X) = \prod_{k=0, k \neq i}^{N_j} \frac{X - x_k^j}{x_i^j - x_k^j} = \frac{X - x_0^j}{x_i^j - x_0^j} \dots \frac{X - x_{i-1}^j}{x_i^j - x_{i-1}^j} \frac{X - x_{i+1}^j}{x_i^j - x_{i+1}^j} \dots \frac{X - x_n^j}{x_i^j - x_n^j}$$

Fig. 3 summarizes the objective of Lagrange polynomials:

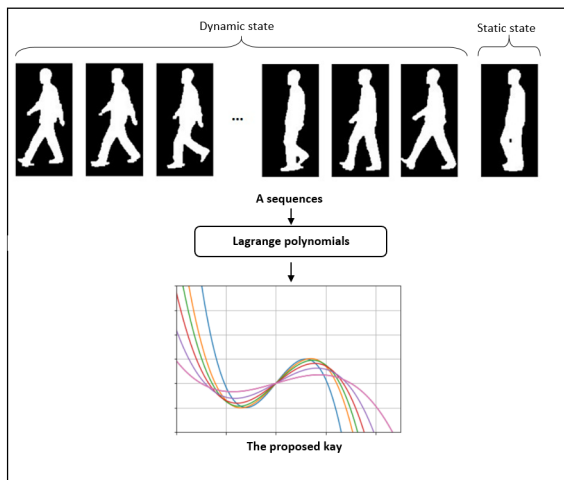

Fig. 3. Example of the proposed key for the identification of individuals.

2) *Convolutional neural networks*: To establish a neural network, various parameters need to be defined, including the type of neural network, training data, type of training, number of layers, number of neurons (connections), activation functions, and propagation rules, etc. As previously stated, we were provided with a set of image sequences. It is worth noting that when dealing with images, the utilization of Convolutional Neural Networks is essential.

Convolutional Neural Networks (CNNs) are a special type of neural networks specializing in processing grid-type topological data, such as images. The architecture of a CNN model generally contains three distinct types of layers: Convolution Layer, Pooling Layer and Fully connected Layer [1].

Convolution Layer: A convolutional layer is basically responsible for applying one or more filters to our input with the aim is to bring out certain features of the image. It is this layer that distinguishes CNN from other neural networks.

Each convolutional layer contains one or more filters. A filter is essentially a matrix of integers for a subset of the input image of the same size as the filter. Each pixel in the subset is multiplied by the corresponding value in the filter, and the results are summed to get a single value. Repeat this process until the filter “slides” over the entire image. This operation allows to extract the features of the image. An activation function (such as ReLU) is used to output the final features. ReLU essentially guarantees that there are no negative values in the feature output matrix, forcing negative values to zero.

Pooling Layer: Pooling is a technique used to decrease the dimensionality of input features, leading to a decrease in the total number of parameters and the model’s complexity. Max pooling is among the most commonly used pooling methods, where only the highest value in the matrix is retained.

Fully Connected Layer: This layer contains traditional neurons that receive sets of weights from the previous layers. This last part which allows learning of the convolutional neural networks. It contains a number of intermediate layers and also a final layer. In the case of the classification problem, the number of neurons in the last final layer is exactly the same number of the classes of the problem treated.

Multiple methods exist for training a neural network to produce specific outputs for given inputs. The current training approach involves Forward/Backward Propagation, utilizing error propagation to adjust the network based on each neuron’s contribution to the error. These weights are fine-tuned through gradient descent. An alternative technique for training neural networks is using genetic algorithms ([14]). By training the network on a dataset with known correct outputs, the network can generalize results for new data not part of the training set. In our case, we trained a CNN with 10,000 diverse use cases.

In the literature, there are variations in the architecture of convolutional neural networks, including differences in the number of layers and neurons, owing to various proposed architectures in the field. For our specific application, we propose the following architecture:

We initialize a sequential model then we start by configuring our first convolutional layer to process the inputs of form (352, 240, 1) which is the format of our images then we configure 32 kernels (filters) of form 3 x 3 pixels. The output of these filters will be passed to an activation function “relu” before being forwarded to the next layer. The second pooling layer reduces the representation of the inputs by taking the maximum value on the matrix defined by the “pool_size” parameter which has been configured at (2,2).

The third layer is very similar to the first layer except that this time we have 64 filters instead of 32 but we kept the same size of the filters and at the end of the process the output will go through the “relu” function so that we do not have negative values.

The fourth layer is exactly the same as our second layer.

The fifth layer we used 128 filters.

Once the convolutional and pooling layers have been executed, it becomes essential to incorporate a fully connected layer. This particular layer receives the output data from the

convolutional networks, whereby the output of the convolutional network is flattened into a vector form before it is fed into the fully connected layer.

Following the hidden layers, a dropout layer is utilized in the network for regularization, in order to prevent overfitting of the model. The final output layer of the network consists of P neurons, where P denotes the number of sequences within the dataset. The activation function used for this layer is “softmax”, which represents a probability distribution to predict the individual. It has been demonstrated that the neural network is trained by adjusting the weights through comparison of predicted results with the actual labels of the sequences in the dataset.

Now that the model has been established, the next step involves training it on the digital representation of the training data. The neural network is equipped with a cost function which needs to be minimized, for which the gradient descent algorithm is employed, specifically utilizing the Adam optimizer. The learning standard employed is a precision of 0,001.

Finally, the metric employed to evaluate the performance of our neural network is defined as accuracy. Accuracy is defined as the ratio of correctly predicted observations to the total number of observations in the dataset.

$$Accuracy = \frac{TN + TP}{TN + TP + FN + FP}$$

where, TN = True Negatives, TP = True Positives, FN = False Negatives and FP = False Positives.

3) *Comparison*: An automatic fingerprint recognition system yields a positive or negative result by comparing the fingerprint under consideration with all other fingerprints stored in its database.

As previously outlined, our system relies on two techniques for making predictions:

The first technique involves Lagrange polynomials, where the comparison of two fingerprints is executed through the following algorithm: comparing the signals received with the stored signals in the database (denoted as $S_j(X)$ with coefficients s_i^j).

```

For all j with 1 ≤ j ≤ 7 do :
For all i with 0 ≤ i ≤ N_j do :
    if a_i^j = s_i^j
        Then the imprint is confirmed
    else
        The imprint is invalid
    
```

The second prediction involves the use of Convolutional Neural Networks (CNN). The neural network was trained on an extensive database comprising 10 000 real-world use cases and additional cases generated through data augmentation. Our model enables remote identification and has the capability to accurately predict the target of a skeleton capture.

E. Decision of the Skeletal Fingerprint Recognition System

The ultimate decision is a combination of predictions from both Lagrange polynomials and CNN. In Fig. 4, we illustrate

our skeletal fingerprint recognition system. To demonstrate the efficiency of this system, we will provide details in the “Results and Discussion” section.

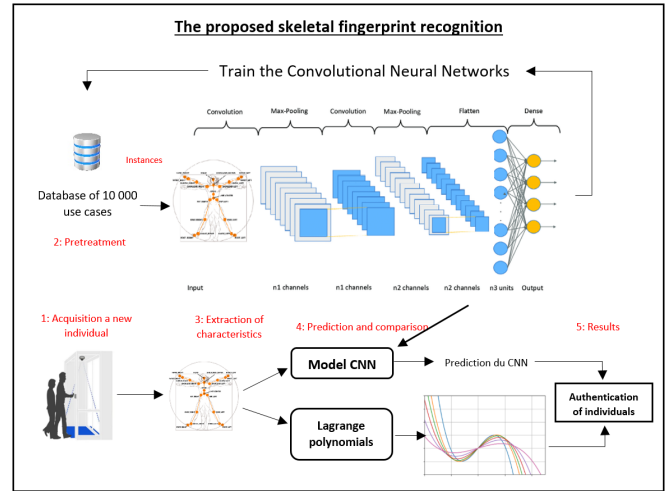

Fig. 4. Architecture of the system.

IV. RESULTS AND DISCUSSION

This section is dedicated to evaluating the performance of our CNN model, with a focus on assessing the quality of the solution. It is important to highlight that all experiments were carried out on Google Colab utilizing a GPU.

A. The Learning and Test Rate

The learning rate serves as a critical indicator of model effectiveness. As illustrated in Fig. 5, the graph portrays the learning rate (98%) and validation rate (97%). The visualization of the validation accuracy indicates a successful performance of our CNN, and the minimal gap between the learning accuracy and validation accuracy suggests an absence of overfitting [6]. This observation is reinforced by the learning rate (98%) and validation rate (97%).

Fig. 5. Development of the training and test score per epoch.

To test the effectiveness of our automatic fingerprint recognition system, we chose 10 peoples and for each one we created 10 new different sequences (human skeleton in static state and in dynamic state), from where the totality of the test

Fig. 6. Convergence of the cost function per epoch.

set equal to 100 sequences and we compared the predictions with the targets using accuracy metric [5]. The following confusion matrix shows (see Fig. 7) the results of the test where the accuracy metric is 95%. Fig. 6 shows convergence of the cost function per epoch.

Fig. 7. The confusion matrix of the test set.

V. CONCLUSION

In this paper, we have introduced a novel skeletal fingerprint recognition system comprising five key modules: acquisition, pretreatments, feature extraction, prediction and comparison, and, ultimately, the decision-making process.

The proposed skeletal fingerprint recognition system is built upon a unique key designed for the identification and recognition of individuals. This key, represented by signals, is modeled using Lagrange polynomials derived from key points on the human skeleton. Consequently, this key can be regarded as a distinct fingerprint categorized within the set of physiological fingerprints. It is essential to emphasize that the primary utility of this fingerprint lies in the remote identification of individuals, free from any masking of the human body. To automate the detection of individuals, a Convolutional Neural Network (CNN) has been integrated. Training data was sourced from various companies within

the same domain and augmented through data augmentation, resulting in a comprehensive dataset of 10 000 use cases. The proposed model exhibits a commendable success rate of 98%.

As part of our future endeavors, we aim to extend this approach to a GPU cluster platform, enabling the processing of more complex cases.

DECLARATIONS

- Availability of data and materials: All experiments were performed on the google colab under GPU.
- Competing interests: The authors declare that they have no competing interests.
- Funding: The research received no specific grant from any funding agency in the public, commercial, or notfor-profit sectors.
- Ethics approval and consent to participate: The authors declare that the manuscript is our original work. The ideas, views, innovations, and results presented in the above manuscript are totally mine.

ACKNOWLEDGMENT

The authors would like to thank the Editor-in-chief and anonymous reviewers for their comments and suggestions to improve the quality of the paper.

Statistics, Department of Mathematics, Faculty of Science, Burapha University, Chonburi, Thailand²

Abstract—The use of deep learning in unmanned aerial vehicles (UAVs), or drones, has greatly improved various technologies by making complex tasks easier, faster, and requiring less human help. This study looks into how artificial intelligence (AI) can be used in farming, especially through creating a system where drones can be controlled by hand gestures to support agricultural activities. By using a special type of AI called a Convolutional Neural Network (CNN) with an EfficientNet B3 model, this research developed a gesture recognition system. It was trained on 1,393 pictures of different hand signals taken under various light conditions and from three different people. The system was evaluated based on its training and testing performance, showing very high scores in terms of loss, accuracy, F1 score, and the Area Under the Curve (AUC), which means it can recognize gestures accurately and work well in different situations. This has big implications for farming, as it gives farmers an easy way to control drones for tasks like checking on crops and spraying them precisely, which also helps keep them safe. This study is an important step towards smarter farming practices. Moreover, the system's ability to perform well in different settings shows it could also be useful in other areas like construction, where drones need to operate precisely and flexibly.

Keywords—Deep learning; Convolutional Neural Network; hand gesture recognition; drone; agriculture

I. INTRODUCTION

Drones, also known as unmanned aerial vehicles (UAVs), have moved beyond their military beginnings to become essential tools in many industries, not just for recreation. Drones are used in many areas, such as security, defense, farming, energy, insurance, and water management [1]. This variety shows how drones are and their potential to improve traditional methods. Drones can reach difficult area, carry out detailed aerial survey, and provide immediate data, improving decision making and operational efficiency in many fields. The growing popularity of drones is driven by continuous technological improvement, making them more user friendly and effective for both professional and personal use [2]. Technological advancements in drone capabilities have significantly broadened their applications, enabling them to contribute to environmental monitoring, search and rescue operations, and infrastructure inspection, among others. Innovations such as increased autonomy through AI integration [3], extended battery life, and enhanced payload capacities allow drones to perform complex tasks more efficiently and reliably. For instance, in agriculture, drones equipped with advanced sensors can monitor crop health [4], optimize water usage [5], and manage resources

more sustainably [6]. Similarly, in emergency response, drones provide invaluable assistance in locating victims and assessing damage in disaster stricken areas, demonstrating their critical role in saving lives and managing crises [7].

The integration of drones into agriculture is poised to enhance crop health monitoring, reduce environmental impact, protect farmer health and increase the efficiency of farming operations. Farmers are progressively turning to drones to oversee their crops and enhance precision agriculture practices, a trend that is expected to significantly fuel the growth of the drone market in agriculture over the next decade. These drones have the ability to monitor vast fields, capture intricate images, and provide data that is not affected by cloud cover, offering a clear advantage over traditional monitoring methods. As drone technology continues to advance, becoming more efficient and cost-effective, their adoption in agriculture is set to increase [8]. Therefore, these developments promise to revolutionize farming by improving yield predictions, optimizing resource use, and enabling more precise application of water, fertilizers, and pesticides [9].

In the context of agriculture, drones equipped with Artificial Intelligence (AI) extend their utility beyond monitoring and analysis to include actionable interventions, such as precise spraying. Spraying drones leverage AI to optimize the application of pesticides, herbicides, and fertilizers. They can autonomously navigate over fields, applying substances directly where needed and in the correct amounts, protect farmer health, significantly reducing waste and environmental impact. This targeted approach ensures that crops receive the exact treatment they require, enhancing growth conditions and potentially increasing yield efficiency. The combination of drones and deep learning is transforming how tasks are performed and redefining the possibilities for innovation and efficiency in global industries [10]. Transitioning to the development of a hand gesture recognition system, this technology further amplifies efficiency in agriculture by enabling farmers to control drones and other automated equipment.

Before reach into the development of a hand gesture recognition system, it is important to understand the context in which such technology could be particularly beneficial in agriculture. Farmers often face the challenge of applying spray fertilizers to their crops at various times, depending on the crop's growth stage, weather conditions, and the type of fertilizer being used. The timing and amount of fertilizer application are critical to ensure optimal crop health and yield. Traditional methods can be imprecise and labor intensive, requiring manual labor to cover large areas and sometimes

*Corresponding authors

leading to uneven distribution of the fertilizer. The implementation of a wide array of intuitive and easy to perform gestures requires a user centric design approach. This involves conducting extensive user research to identify natural and comfortable gestures for different commands, considering both ergonomic principles and cultural differences. By ensuring that the gestures are easily performable by a broad spectrum of users, including those with physical disabilities, the system becomes more inclusive and user friendly.

To enhance the efficiency of hand gesture control, some approaches include the wearable device or IoT device controller placed on the back of the hand to intend hand motion and control the UAV with hand gesture recognition [11] [12]. Multi modal control is another technique for overcoming UAV gesture control. A multi modal control system integrates multiple interactions, such as hand gestures, eye movements, and voice interactions [13]. The multi channel joint interaction promotes high UAV control efficiency. It is crucial to use advanced technologies with deep learning. By combining computer, and cameras, the system's capability to capture and understand gestures in varied lighting will be greatly improved.

In this study, the focus primarily on hand gesture control, as it has shown promising results in previous research [12] [13]. Therefore, this study aims to create a hand gesture recognition system that works effectively in different environmental settings and individuals, such as under direct sunlight, on cloudy days, and shady. The given model first detects the hand and then draws the hand skeleton. Next, the model is generated by using the detected hand as a training set for a deep convolutional neural network. These technologies are excellent at picking up slight movements, which is essential for the system to tell apart purposeful gestures from accidental ones. Moreover, applying machine learning algorithms and deep learning to process the data from the study will enhance the system's precision and flexibility. This will allow it to accurately recognize a broad array of gestures.

II. METHOD

A. Data Collection and Preprocessing

A dataset consisting of 1,393 images was compiled around a farm in Thailand, capturing both indoor and outdoor settings. This collection aims to advance posture trajectory analysis and includes shots taken under a variety of lighting conditions; sunlight, cloudy, and in shade. Participation from three individuals ensured a wide range of imagery. The dataset features eight specific gesture types: ascending, descending, pitch forward, pitch backward, roll left, roll right, yaw left, and yaw right. Each contributor supplied images for every gesture, photographed under three distinct lighting scenarios. Cameras were employed to take these pictures, which were then stored in JPG format. During the image preprocessing phase, the sizes of the collected images were standardized to a uniform dimension of 300×300 pixels. These images were divided into eight classes: ascending, descending, pitch forward, pitch backward, roll left, roll right, yaw left, and yaw right, as shown in Fig. 1 Subsequently, the dataset underwent a division into training, validation and testing sets, allocating 880 images for training purposes, 320 images for validation, and the remaining 192 images for testing.

B. The Proposed Model

The proposed model presents a sophisticated hand gesture recognition model designed to enhance the operational efficiency of drones in agricultural settings. This innovation is made possible through the integration of a Convolutional Neural Network (CNN) with an EfficientNet B3 architecture, tailored to interpret various hand signals under diverse environmental conditions.

The integration of MediaPipe, Hand Landmark, TensorFlow, Keras in TensorFlow, and the EfficientNet B3 model within this method provides a robust framework for accurate hand gesture recognition tailored for drone control in agricultural applications. MediaPipe offers a real-time, efficient hand tracking solution, utilizing the Hand Landmark model to precisely identify the positions of key points on the hand, essential for recognizing complex gestures. TensorFlow serves as the backbone for deep learning operations, enabling scalable and efficient model training and execution. By leveraging Keras, a high-level API within TensorFlow, the process of building and training deep learning models is simplified, making it more accessible while maintaining flexibility and performance. The choice of the Convolutional Neural Network (CNN) architecture, specifically EfficientNet B3, is strategic for its ability to handle image data effectively, utilizing compound scaling to optimize accuracy and computational efficiency. This combination of technologies and models ensures the system's ability to accurately interpret a wide range of hand gestures under various environmental conditions, making it a powerful tool for enhancing drone operations in agriculture.

1) *MediaPipe*: Numerous deep learning frameworks and libraries are available for hand gesture recognition, among which MediaPipe stands out. MediaPipe is a framework tailored for the deployment of deep learning solutions ready for production [14], [15]. It facilitates the construction of pipelines necessary for performing inference on various types of sensory data. Moreover, MediaPipe supports the publication of code alongside research efforts and aids in the development of technological prototypes. As an open-source tool, it is accessible to developers worldwide and supports a wide range of platforms, ensuring its versatility and broad applicability. Its lightweight nature enhances its performance and ease of integration into various software and hardware environments, making it a preferred choice for real-time applications.

2) *Hand landmark*: In the MediaPipe framework (see Fig. 2), the hand is modeled using 21 distinct 3D landmarks to represent the joints and tips of the fingers [16]. For each finger, there are four landmarks: the Carpometacarpal (CMC) joint is marked as Landmark 1 for the thumb, followed by the Metacarpophalangeal (MCP) joint as Landmark 2, the Interphalangeal (IP) joint as Landmark 3, and the fingertip as Landmark 4. This pattern is consistent across the hand, with the MCP joint for the index, middle, ring, and pinky fingers designated as Landmarks 5, 9, 13, and 17, respectively. The Proximal Interphalangeal (PIP) and Distal Interphalangeal (DIP) joints follow in sequence for each finger, culminating with the fingertip, or Landmark 8 for the index, Landmark 12 for the middle, Landmark 16 for the ring, and Landmark 20 for the pinky finger, providing a comprehensive mapping of the hand's articulations for gesture recognition.

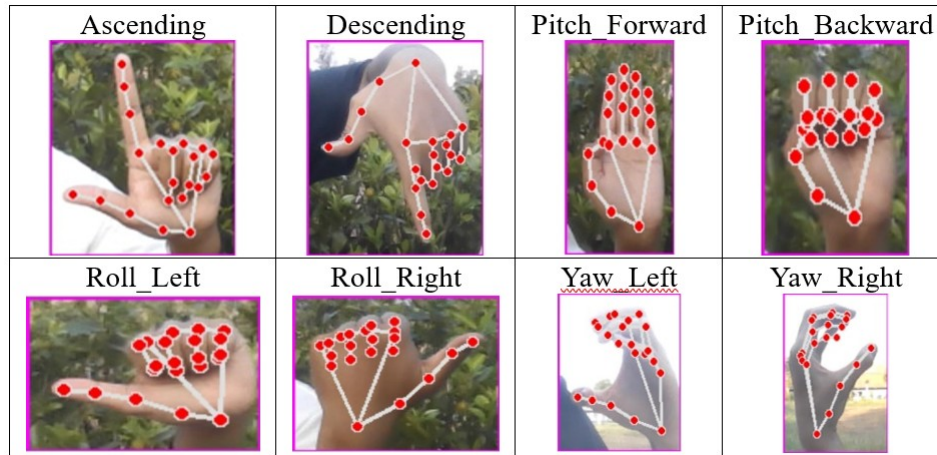

Fig. 1. Effects of selecting different switching under dynamic condition.

The model predicts the (x, y, z) coordinates of these landmarks in the image, with: x and y representing the landmark's position on the plane of the image, and z indicating the landmark's relative depth from the camera. To put the trained model into action, it is integrated into an OpenCV-based workflow that handles real-time data processing. This involves using MediaPipe to detect and track hand landmarks in each data stream. The information about the landmarks is then input into the TensorFlow model, which determines what gesture is being made.

3) *TensorFlow*: The trained model is then implemented within an OpenCV pipeline to process data sets in real time. As the data stream flows through the pipeline, MediaPipe extracts the hand landmarks from each data, and these are instantly passed to the TensorFlow model for gesture prediction [17].

- Wrist** (0)
- Thumb:** CMC (1), MCP (2), IP (3), and Tip (4).
- Index Finger:** MCP (5), PIP (6), DIP (7), and Tip (8).
- Middle Finger:** MCP (9), PIP (10), DIP (11), and Tip (12).
- Ring Finger:** MCP (13), PIP (14), DIP (15), and Tip (16).
- Pinky (Little Finger):** MCP (17), PIP (18), DIP (19), and Tip (20).

Fig. 2. The 21 landmarks (0-20) of hand gestures in MediaPipe.

This seamless process allows for the recognition of gestures as they occur, enabling real-time interaction. The system can be further tailored to recognize a wide array of gestures, enhancing its utility in various applications.

In TensorFlow, computations are represented as graphs, where nodes in the graph represent mathematical operations, and the edges represent the tensors that flow between these operations. The core concept of TensorFlow can be encapsulated in how it handles these tensors and performs operations on them [18]. The concept of Gradient Descent is implemented through optimizers that automatically adjust the model's parameters (weights and biases) to minimize the loss function:

$$\theta_{\text{new}} = \theta_{\text{old}} - \alpha \nabla_{\theta} J(\theta),$$

where, θ represents the model parameters, $J(\theta)$ is the loss function, α is the learning rate, $\nabla_{\theta} J(\theta)$ is the gradient of the loss function with respect to the parameters. TensorFlow abstracts and simplifies the implementation of gradient descent, making it accessible and flexible for optimizing a wide variety of models. By adjusting the model parameters (weights and biases), optimizers improve the model's accuracy over time.

Neural networks, including those built with TensorFlow, rely heavily on linear algebra [19]. One fundamental operation is matrix multiplication, used in fully connected layers:

$$Y = XW + b,$$

where, X represents the input matrix, W is the weights matrix, b is the bias vector, and Y is the output matrix. Linear algebra operations in TensorFlow are used behind the scenes in training machine learning models, especially in operations like forward and backward propagation in neural networks, where weights and inputs are represented as matrices and vectors. Operations such as convolution in CNNs can also be understood in terms of linear algebra.

4) *Keras in TensorFlow*: TensorFlow provides a comprehensive, scalable platform for building and deploying machine learning models, with Keras serving as the high-level interface that simplifies model development through its focus on ease

of use and modularity. The combination of TensorFlow's scalability and Keras's user-friendliness makes it an excellent toolkit for both beginners and experts in machine learning. Integrating Keras directly into TensorFlow as `tf.keras` offers a streamlined workflow for designing and training machine learning models with TensorFlow's robust capabilities for scaling and deployment. This integration provides a high-level, user-friendly API for TensorFlow, without sacrificing flexibility and performance [20].

Therefore, the research is defined a neural network architecture using TensorFlow. This could be a Convolutional Neural Network (CNN) for processing image data or a custom model suited for sequential data like time-series of landmarks. The model is trained on the preprocessed hand landmark data, using labeled gestures to teach the model the corresponding gesture for each set of landmarks.

C. Convolutional Neural Network and EfficientNet B3 Model

The framework is notable for its collection of pre-trained machine learning models, which serve as a foundation for advanced applications in computer vision and augmented reality. Among its offerings are highly accurate face detection algorithms that can identify and track multiple hand in real time. Convolutional Neural Networks (CNNs) are at the heart of image recognition and processing tasks [21], [22]. In the context of using CNNs for recognizing hand gestures, a key operation is the convolution, applied to the input image using filters or kernels to extract features:

$$G[j, k] = \sum_m \sum_n F[m, n] \cdot H[j - m, k - n],$$

where G is the output feature map, F is the input image, H is the filter/kernel, j, k are indices in the output feature map, and m, n are indices in the filter/kernel.

In the process of applying convolution operations within CNNs, an input image or feature map from a previous layer, denoted as $F[m, n]$ undergoes a transformation through a convolutional filter, $H[j - m, k - n]$. This filter, a small matrix, traverses the input, focusing on extracting specific features by learning relevant patterns during the model's training phase. The convolution between the input image and the filter results in an output feature map, represented by $G[j, k]$, where each element signifies the convolution operation's output at distinct locations across the input. This output encapsulates the detected features, such as edges or textures, effectively capturing the input's essential characteristics for further processing or classification tasks, like hand gesture recognition, where the input can range from grayscale to color (RGB) images. Therefore, in hand gesture recognition, convolution allows the model to learn to identify key features of hand gestures. This capability is crucial for accurately classifying different gestures based on visual input.

Moreover, efficientNet B3 is part of the EfficientNet family, which is a group of Convolutional Neural Network (CNN) models designed for efficient performance [23], [24], [25]. The EfficientNet models use a systematic approach to scaling called compound scaling, which uniformly scales the network depth, width, and resolution with a set of fixed scaling coefficients.

This approach is different from traditional scaling methods that independently scale these dimensions, often leading to suboptimal performance.

The compound scaling method used in EfficientNet involves scaling the network's depth, width, and resolution with a compound coefficient ϕ , according to the following formulas: $d = \alpha^\phi$, $w = \beta^\phi$ and $r = \gamma^\phi$ where depth (d) is the number of layers in the network, width (w) is the number of channels in the layers, resolution (r) is the size of the input image, α , β , and γ are constants that determine the scaling of depth, width, and resolution, respectively and ϕ is the compound coefficient that controls the overall resource increase of the network. Higher values of ϕ result in larger, potentially more accurate networks. The idea is to find a balance between depth, width, and resolution that leads to the best performance improvement for a given increase in model size and computational cost.

Therefore, incorporating the EfficientNet B3 architecture into the study of performance metrics for deep learning in hand gesture recognition models further illustrates the model's advanced technical capabilities and its practical utility in augmenting drone operations for agricultural purposes. EfficientNet B3 is part of the EfficientNet family, which represents a series of Convolutional Neural Network (CNN) architectures designed to provide higher accuracy with fewer parameters than previous models, making them both powerful and efficient. The use of EfficientNet B3 in the hand gesture recognition model capitalizes on its ability to scale model size in a more balanced and effective manner, optimizing for accuracy, latency, and resource utilization.

D. Evaluation Metrics for Hand Gesture Recognition Model

An evaluation of the hand gesture recognition model across eight distinct sign classes was conducted, employing metrics such as precision, recall, and the F1-score for a comprehensive analysis, detailed as follows:

Precision, also referred to as the positive predictive value, is determined by the following formula:

$$\text{Precision} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Positive}}$$

Recall, measured as the percentage of correctly predicted instances out of all actual instances of the class, is given by the equation:

$$\text{Recall} = \frac{\text{True Positive}}{\text{True Positive} + \text{False Negative}}$$

The F1-score, also known as the F-measure, encapsulates the harmonic mean of precision and recall, thereby reflecting their equilibrium. Improvement in the F1-score is observed only with simultaneous increases in both precision and recall. This score spans from 0 to 1, with values closer to 1 denoting greater accuracy in classification. The formula for calculating the F1-score is as follows:

$$F1\text{-score} = 2 \times \frac{\text{Precision} \times \text{Recall}}{\text{Precision} + \text{Recall}}$$

Accuracy is quantified as the ratio of accurate predictions to the total number of predictions made. The calculation for accuracy is represented by the following formula:

Fig. 3. Training and validation curves for hand gesture recognition model: The left graph displays validation loss and the right graph displays validation accuracy.

Fig. 4. Training and validation curves for hand gesture recognition model: The left graph displays validation F1 score and the right graph displays validation AUC.

$$\text{Accuracy} = \frac{\text{TP} + \text{TN}}{\text{TP} + \text{TN} + \text{FP} + \text{FN}}$$

To effectively use these metrics, it is important to have a well-defined test dataset that accurately represents the real-world scenarios in which the model will be deployed. Comparing these metrics after integrating EfficientNet B3 can also provide insights into how this architecture improves the model's performance.

III. RESULTS

Fig. 3 shows two plots side by side, on the left is the Training and Validation Loss, and on the right is the Training and Validation Accuracy over 30 epochs of efficientNet B3 model training. The left plot indicates that both training and validation loss decrease sharply initially and then level off, converging to a low value, with the best epoch marked at 30. On the right plot, the accuracy of both training and validation rapidly increases and plateaus close to 1.0, indicating high effectiveness of the model, with the best epoch for accuracy marked at 11. These plots suggest that the model quickly

learned the task and achieved a stable and high performance early in the training process, with minimal overfitting as indicated by the close convergence of training and validation lines.

Fig. 4 showcases two performance metric plots for a machine learning model over the course of 30 training epochs. On the left is the Training and Validation F1 Score plot, which represents the harmonic mean of precision and recall. The plot shows both training and validation F1 scores quickly converging to a value close to 1.0, indicating excellent model performance with a peak F1 score at epoch 11. This suggests that the model maintains a balanced precision-recall relationship and is neither overfitting nor underfitting.

On the right is the Training and Validation AUC (Area Under the ROC Curve) plot, which is used to evaluate the performance of a binary classification system. The AUC values are consistently high and also converge to a score near 1, with the best AUC score achieved at epoch 30. This high AUC value indicates a high degree of separability, meaning the model is very capable of distinguishing between classes. The close proximity of the training and validation lines in both plots suggests that the model is generalizing well to unseen data.

Fig. 5. Confusion matrix depicting the performance of the hand gesture recognition model for drone control in agricultural applications.

Fig. 5 shows visualizes the confusion matrix of a hand gesture recognition model used for controlling drones in an agricultural setting. It is structured with actual gestures along the y-axis and predicted gestures along the x-axis. The matrix contains eight different hand gestures: ascending, descending, pitch backward, pitch forward, roll left, roll right, yaw left, and yaw right. The diagonal from the top left to bottom right represents instances where the predicted gesture matches the actual gesture, signifying a correct prediction by the model. The numbers within these diagonal cells, 24 for ascending, 25 for descending, 24 for pitch backward, 26 for pitch forward, 23 for roll left, 25 for roll right, 23 for yaw left, and 21 for yaw right, indicate a high rate of accurate classifications for each respective gesture. Non-diagonal cells would show misclassifications, but in this matrix, almost all non-diagonal cells are zero, demonstrating that there are very few errors made by the model. Notably, there is only one misclassification observed, where a gesture was actually yaw right but was predicted by the model as yaw left. This could be attributed to the potential similarity in the appearance of these two gestures to the model. Overall, the high count of True Positives (TP) and the sparse misclassifications underscore the model's robustness and reliability in interpreting hand gestures for drone operation under the tested conditions.

The data-driven approach, employing a Convolutional Neural Network (CNN) with EfficientNet B3 architecture, confirms its suitability for visual tasks such as hand gesture recognition. The EfficientNet B3 model's performance signifies that its application in the agricultural domain, controlling drones via hand gestures, can be both feasible and effective. This holds promise for increasing operational efficiency and the democratization of technology use in the field, allowing for more intuitive and natural human-machine interaction without the need for complex controllers or extensive training.

IV. DISCUSSION

The research presented herein marks a notable advancement in leveraging artificial intelligence, particularly convolutional neural networks (CNNs) with EfficientNet B3 architecture, for hand gesture recognition aimed at drone control in agriculture. This integration showcases a substantial leap in precision, robustness, and dependability in gesture recognition technology, as demonstrated by superior performance metrics including loss accuracy, F1 score, and Area Under the Curve (AUC). Such achievements signal the potential for transformative enhancements in agricultural methodologies, optimizing operational efficiency and elevating safety standards.

The exceptional performance of the hand gesture recognition system is rooted in meticulous dataset preparation, encompassing a diverse array of lighting conditions and subjects, in conjunction with deploying the EfficientNet B3 model within the CNN framework [26]. The scalability and efficiency inherent to this model were instrumental in achieving a balanced and effective learning process, thereby facilitating the system's ability to recognize gestures with high accuracy under varying environmental conditions and across different individuals [27]. Moreover, by integrating EfficientNet B3, the hand gesture recognition model achieves superior performance in recognizing and interpreting complex hand gestures, translating them into precise commands for drone control.

Practical implications of this advancement are manifold, primarily offering a simplified and intuitive means for farmers to control drones, thus circumventing the complexities associated with traditional control mechanisms. This innovation significantly diminishes the learning curve associated with drone technology, making it more accessible and user friendly for agricultural applications [28]. Incorporating hand gesture recognition into agricultural drone operations could revolutionize crop monitoring processes, enable precise application of pesticides and fertilizers, and reduce the reliance on manual labor. Moreover, this technology promises to enhance safety

by reducing human exposure to potentially harmful chemicals and facilitating crop inspection in otherwise inaccessible areas [29]. Traditional gesture recognition systems often faced difficulties when used in poor lighting or with subjects that moved quickly [30]. This study overcomes these challenges by utilizing advanced image processing methods and machine learning algorithms. These enhancements improve the system's ability to recognize gestures in a variety of lighting situations and from different viewpoints, making it more flexible and dependable.

Despite the promising outcomes, this study acknowledges certain limitations. The dataset's diversity, while extensive, was limited to images from three individuals. Augmenting the dataset with a broader spectrum of gesture variations from a more diverse demographic could significantly improve the model's generalizability and performance in real-world settings. Moreover, the controlled environment of the study may not fully capture the complexity and unpredictability of actual agricultural environments, where factors like fluctuating lighting conditions, background clutter, and weather variations could impact system performance.

Looking towards the future, the integration of these intuitive drone control systems with artificial intelligence and data analytics heralds a new era of precision agriculture. Future research could focus on developing fully autonomous drones capable of real-time monitoring and management of crops, pest control, and targeted nutrient application, thus optimizing crop health and yield. Additionally, exploring the synergy between drones and other technological innovations in agriculture, such as robotic ground vehicles and sensor networks, could lead to the creation of comprehensive, interconnected farm management systems. This could revolutionize agricultural practices, making them more efficient, sustainable, and tailored to specific environmental and crop needs, thereby supporting global human and food security challenges.

V. CONCLUSION

This study represents a significant advancement in the application of artificial intelligence (AI) within the realm of agriculture, showcasing a system that leverages Convolutional Neural Networks (CNNs), specifically the EfficientNet B3 model, for the purpose of hand gesture recognition to control drones. The system's training involved a dataset of 1,393 images featuring diverse hand signals captured under various lighting conditions and from three distinct individuals, demonstrating its robust ability to accurately interpret gestures with high performance metrics such as loss, accuracy, F1 score, and Area Under the Curve (AUC). This breakthrough provides a tangible solution to enhancing agricultural productivity and safety by enabling farmers to effortlessly manage drones for critical tasks through intuitive hand gestures. The successful application of hand gesture model in agriculture demonstrates the potential for its adoption in construction scenarios where drones can operate in more structured environments. In addition, the precision of the hand gesture recognition system will be crucial for ensuring accurate delivery of materials, especially in high or hard-to-reach areas. Future research will aim to enhance the model's robustness against the diverse environmental conditions typically found on agricultural sites with farms. This would entail further data collection and

model training to ensure the system can accurately interpret hand gestures even in less than ideal conditions. Additionally, integrating the use of drones for spraying will be explored, potentially enabling precise and efficient delivery of substances in various farming scenarios.

Abstract—Securing smart cities in the evolving Internet of Things (IoT) demands innovative security solutions that extend beyond conventional theft detection. This study introduces temporal convolutional networks and gated recurrent units (TCGR), a pioneering model tailored for the dynamic IoT-SM dataset, addressing eight distinct forms of theft. In contrast to conventional techniques, TCGR utilizes Jaya tuning (TCGRJ), ensuring improved accuracy and computational efficiency. The technique employs ResNeXt for feature extraction to extract important patterns from IoT device-generated data and Edited Nearest Neighbors for data balancing. Empirical evaluations validate TCGRJ's greater precision (96.7%) and accuracy (97.1%) in detecting theft. The model significantly aids in preventing theft-related risks and is designed for real-time Internet of Things applications in smart cities, aligning with the broader goal of creating safer spaces by reducing hazards associated with unauthorized electrical connections. TCGRJ promotes sustainable energy practices that benefit every resident, particularly those with disabilities, by discouraging theft and encouraging economical power consumption. This research underscores the crucial role of advanced theft detection technologies in developing smart cities that prioritize inclusivity, accessibility, and an enhanced quality of life for all individuals, including those with disabilities.

Keywords—IoT Security; theft detection; smart cities; cloud computing; disability support

I. INTRODUCTION

Urban areas are undergoing a paradigmatic transition towards intelligent ecosystems, propelled by the incorporation of state-of-the-art technologies that fundamentally alter conventional urban terrains [1]. The integration of cloud computing and the Internet of Things (IoT) is driving a transformative change in the way cities function by establishing smart cities. This research article investigates the complex relationship between cybersecurity, smart energy analytics, and the incorporation of cloud and IoT technologies in smart city environments. The motivation behind the development of smart cities is the necessity to address the challenges presented by increasing populations and limited resources [2].

Smart cities, which are conceptualized as environments that promote innovation through the use of data, are built upon the integration of digital technologies, citizen engagement, and data-driven decision-making. Energy management emerges as a pivotal field in which optimization, sustainability, and re-

silience are paramount. Central to the smart city paradigm are cloud computing and the Internet of Things, which function as neural networks that empower municipalities to comprehend, assess, and intelligently respond [1], [3]. The IoT, by means of interconnected sensors and devices, supplies smart cities with real-time data that is vital, whereas cloud computing provides the necessary infrastructure and processing capabilities to analyze the enormous datasets produced by IoT devices [3]. These technologies have a significant impact on energy management by improving bidirectional connectivity and real-time monitoring for smart meters, smart grids, and Advanced Metering Infrastructure (AMI) [4]. However, the establishment of a fully operational smart energy environment continues to present obstacles, necessitating the implementation of strong security protocols to safeguard against data management complications, cyber risks, privacy apprehensions, and the resilience of cloud-based systems.

Intelligent energy analytics faces the difficulty of effectively managing enormous quantities of data [5]. This article highlights the significance of implementing a Demand Side Management System (DSMS) in smart cities as a means to improve energy efficiency, offer inventive resolutions, and exert efficient authority over energy consumption. DSMS developments, which include load shifting, economic planning, and system optimization, improve energy management precision and efficiency through the use of machine learning algorithms such as Grey Wolf Optimization (GWO), Long Short-Term Memory (LSTM), and Recurrent Neural Network (RCNN) [6].

Energy theft is a major concern, causing damage to infrastructure and leading to global economic hardship, despite progress. Detecting electrical theft promptly improves environmental safety by reducing the risks associated with illegal connections. This effort aims to encourage the implementation of sustainable energy practices, which will result in more affordable power and benefits for all residents, including persons with disabilities. The incorporation of advanced theft detection technologies into smart city infrastructure enables faster and more precise decision-making through the use of machine learning algorithms [7]. The Energy Theft Detection and Prevention System (ETDPS) sets a new benchmark in smart cities by ensuring its efficacy even in unmonitored households, therefore revolutionizing energy theft monitoring.

Research Gap: Overcoming Challenges in Smart City Data Analytics: Although there have been notable progress in smart city technologies, there are still some technological constraints that impede the complete utilization of data analysis in smart cities. The efficient management of the growing amount of data in smart cities greatly depends on strong data security and the use of advanced energy-related information systems. Nevertheless, even with these technological breakthroughs, there is still a crucial requirement to improve the performance of smart city infrastructure in order to attain maximum levels of efficacy and efficiency. The changing dynamics of intelligent city infrastructure sometimes exceed the capacity of existing optimization tools, requiring the creation of simpler ways for assessing restrictions. In addition, adapting machine learning models to process massive volumes of data poses considerable difficulties, particularly considering that scalability is essential for successful implementation in expansive urban regions. An important problem in machine learning approaches is the adoption of a “black box” design, which makes it difficult to understand the underlying processes, especially in vital industries like power management, where accountability and openness are crucial. The reliability of input data has a substantial influence on the outcomes of machine learning models, and inherent biases can undermine both the impartiality and precision of energy statistics. In order to effectively implement and improve data analytics systems in smart cities, it is crucial to tackle these obstacles. The objective of this study is to create new and creative methods to address the technological obstacles, therefore enhancing the efficiency and dependability of smart city infrastructure.

Field Contributions: This work adds significantly in several important areas:

- 1) **Incorporation into Smart Cities Framework:** The TC-GRJ paradigm effectively interacts with the smart cities architecture, specifically targeting security concerns associated with IoT devices. The use of advanced theft detection technology plays a significant role in the advancement of inclusive and interconnected smart city infrastructures.
- 2) **Processing in the Cloud:** Utilizing a cloud-based data processing technique improves computational efficiency in real-time theft detection in smart cities. Every person, including those with impairments, reaps the advantages of sustainable energy practices as a direct result.
- 3) **Collection of Data from IoT Devices:** The approach employed in the formulation of the conceptual framework involves gathering data from adaptive Internet of Things (IoT) devices to identify patterns of behavior in urban environments connected to the IoT. This promotes affordable electricity expenses that benefit both the general public and those with disabilities.
- 4) **Dynamic adaptability to security challenges:** The framework’s capacity to accommodate intricate security issues in smart cities is exemplified by its division of theft into eight distinct categories. This approach demonstrates accuracy and efficiency in managing the growing threats to security.

This study enhances the existing comprehension and efficacy of security protocols in connected devices through the

implementation of cutting-edge techniques and the improvement of larceny detection.

The subsequent sections of the paper are organized as follows: Section 2 provides an overview of the most recent advancements in the field of literature. Additionally, in Section 3, the issue that has been identified and emphasized in the work is discussed. The proposed materials and methods utilized to address the issue are detailed in Section 4. Section 5 discusses how the identified issue is resolved by the proposed model, which is simulated using experimental results. In Section 6, the article’s concluding remarks are discussed.

II. RELATED WORK

The current research analyzes how modern technologies could benefit living in cities in various kinds of methods, including specific focus on IoT, cloud-based computing, power, information analysis, and cybersecurity. Incorporating Internet Control Message Protocol information, a pioneering study [8] demonstrates the relevance of early recognition of power theft for security when operating urban intelligent environment. The system prevents complications and threats involved in illegal activities associations through employing sensitivity assessment and neural networks for recognizing and reduce efficient criminal activity. Furthermore, to raising stability, it additionally minimizes the entire energy expenses benefiting every citizen and includes those with handicap. In study [9], a connection between cloud systems and IoT in the evolution of smart cities is completely examined, especially emphasizing on the prerequisites of constant monitoring and immediate enhancements for IoT and cloud-based integration. Future research objectives and evaluating factors may become enhanced with the guidance of this study.

In study [10], obstacles to IoT adoption in smart cities in India are examined through the utilization of a hybrid multi-criteria decision-making methodology. The research identifies and evaluates fifteen barriers impeding the extensive adoption of the Internet of Things (IoT), providing policymakers with a systematic framework to facilitate informed decision-making. The investigation of traffic prediction in smart cities using long-term and short-term memory networks is detailed in study [11]. The research is centered around enhancing traffic management and reducing congestion through the development of precise prediction models for environmentally sustainable and intelligent urban transportation systems.

A proposed security system in study [12] addresses secure communication in IoT-driven smart cities using a detection concept. Utilizing neural network-based training, the system track local and global changes in the sharing of data among IoT devices in order to detect vulnerabilities in resource access and bolster overall security. Researcher in study [13] presents a thorough examination of machine learning techniques based on the Internet of Things (IoT) in diverse domains. The article illuminates the ways in which machine learning models have been implemented in the energy management, healthcare, agriculture, vehicle wireless networks, device security, and environmental sectors.

Energy statistics and dependability are the subject of the second compilation of works, which addresses the critical issue of energy theft in smart cities. In their study, [14] presents

a data-driven approach that employs the hybrid Bagged Tree method to detect Non-Technical Losses (NTLs) resulting from deceitful customer conduct. The research highlights the criticality of surmounting challenges associated with the complexity of artificial intelligence algorithms designed for the purpose of detecting larceny. The authors in study [15] emphasize the significance of pattern identification and prediction error calculation in their examination of pattern formation utilizing LSTM models. The theft detection systems, which are essential for ensuring a consistent power supply and averting blackouts, contribute to the overarching objective of establishing urban environments that are more secure, intelligent, and efficient.

The study conducted by [16] investigates novel approaches to ensuring energy reliability and presents a methodology founded on Distributed Generation (DG). Utilizing photovoltaic modules, the study recommends installing renewable distributed generation units on the properties of customers. In order to address instances of fraudulently reported overcharging, the authors suggest implementing SCADA metering point-based solutions. The investigation of hardware-driven architecture and network-based topology for monitoring energy distribution in the Neighborhood Area Network (NAN) is detailed in study [17]. As an effort to improve energy management in smart cities, the authors propose a NAN strategy that includes a central master monitor for the complete energy supply.

This study examines the significance of variable transfer learning (TLs) and the properties of non-sequential auxiliary data. This anthology explores the complex issues and creative solutions found in the fields of energy data analysis, cybersecurity, the Internet of Things (IoT), and smart cities. Researchers from throughout the world are actively promoting the advancement of smart cities. Their contributions include identifying transgressions, predicting congestion, and detecting energy theft. The many ideas and methods discussed in these publications together contribute to the continuing discussion about creating urban settings that are smarter, safer, and more efficient.

III. PROBLEM STATEMENT

The fusion of IoT and cloud computing in smart energy data analysis is driving secure smart city development, presenting challenges that demand focused research. The influx of data in smart city ecosystems necessitates intelligent solutions for efficient processing to optimize resources, plan cities, and inform decisions [18]. Inefficient processing poses a threat to smart city futures, hindering innovations in energy efficiency, infrastructure design, and citizen services [19]. Energy theft is a critical challenge compromising the integrity of smart city energy infrastructures. This research proposes innovative methods integrating technology, security, and energy analytics to address challenges and meet future smart city standards. Early identification of electricity theft enhances safety, reducing the risk of incidents and hazards from unauthorized power connections [20]. Preventing theft lowers power costs and ensures a reliable supply, aligning with sustainable energy practices. Cutting-edge theft detection technologies contribute to inclusive smart cities, enhancing accessibility, mobility, and living conditions, especially for individuals with disabilities.

IV. MATERIALS AND METHODS

Our strategy, combining machine learning and advanced data mining in IoT-Cloud solutions, fortifies smart cities against energy theft and enhances cybersecurity. In simulations, 20% data is for testing and 80% for training. The following sections detail our approach, with Fig. 1 illustrating the model. Detecting electricity theft early ensures safety and benefits all, including those with disabilities. It prevents mishaps and aligns with our goal of a secure smart city ecosystem. Guarding against theft makes power more affordable and aids equitable energy use, reducing financial burdens for everyone. Identifying theft promotes sustainable energy practices, benefiting all residents, especially those with impairments. Cutting-edge technologies for theft detection advance smart city creation and enhance inclusivity. Implementing theft detection systems prevents disruptions, ensuring a steady power supply, crucial for those relying on electric-powered technology. Our strategy aligns with inclusive urban design, acknowledging the transformative impact on the well-being of individuals with disabilities. To solve this problem, we have proposed a model comprises of differnt components including the preprocessing of input data from cloud, processing of the gathered data, check imbalancing, extraction of relevant features and then perform classification based on the TCN-GRU network.

A. Dataset Collection and Preprocessing

This study used a dataset obtained from the Open Energy Data Initiative (OEDI) [21], which is acquired from the Internet of Things (IoT). The dataset provides comprehensive information on energy consumption across 16 different categories, covering a period of 12 months. In order to replicate a wide range of energy theft situations, we have incorporated eight different forms of fraudulent activities into our analytical model, hence expanding the scope of our depiction. The use of IoT architecture enables the collection of real-time data, which facilitates a comprehensive analysis of energy consumption patterns. Fig. 2 provides a visual representation of the dataset. Initial preprocessing is conducted to assure the quality of the data by resolving concerns such as differences in size, missing values, and anomalies. The unprocessed data, obtained from intelligent meters and Internet of Things (IoT) devices, offers vital observations on energy consumption trends in smart urban infrastructures. The methods are shown numerically.

$$\text{normalized_data} = \frac{\text{raw_data} - \text{mean}}{\text{std_dev}} \quad (1)$$

where, the original dataset is denoted by `raw_data`, the dataset mean is `mean`, and the standard deviation is `std_dev`. By ensuring that characteristics with varying sizes contribute equally to the ensuing analyses, normalizing the data helps to avoid variables with greater magnitudes from predominating.

Interpolation for Handling Missing Values and Outlier Removal [22]:

$$\text{interpolated_data} = f(\text{observed_data}) \quad (2)$$

$$\text{Data_filtered} = \{\text{DT_instance}_i \mid \text{DT_instance}_i \notin \text{outliers}\} \quad (3)$$

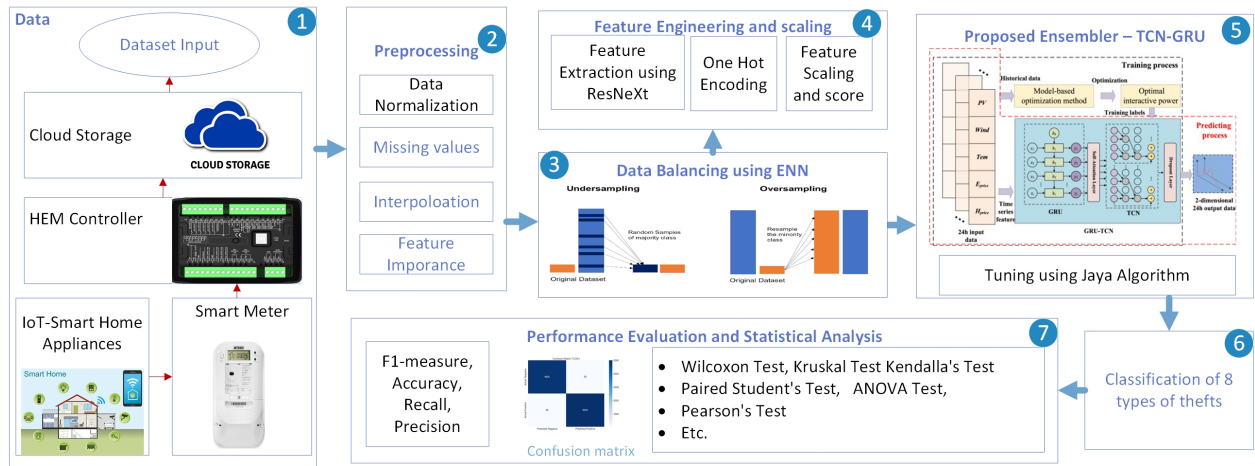

Fig. 1. Proposed system model of theft detection in IoT-SM data.

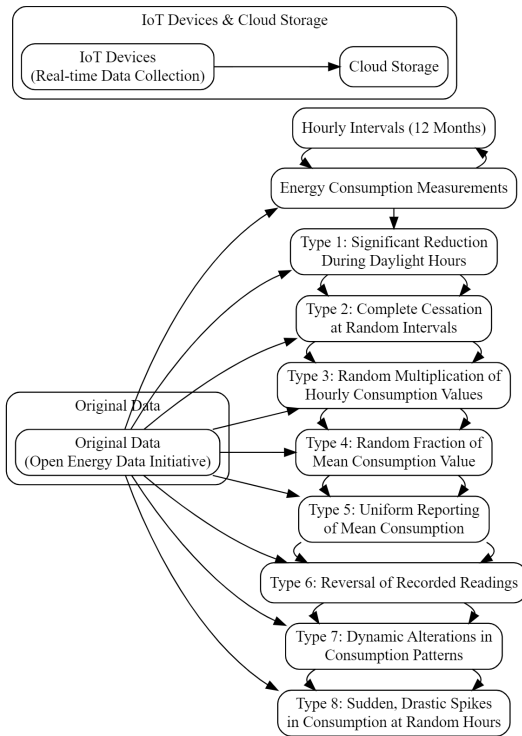

Fig. 2. Derived dataset broad overview.

Observed data, *observed_data*, undergo interpolation for missing values, ensuring a comprehensive dataset. $DT_instance_i$ instances have outliers removed to preserve integrity, enhancing dataset quality for valid inferences in further study.

B. Data Balancing using ENN

Addressing energy theft detection challenges in unbalanced datasets, we employ the Edited Nearest Neighbors (ENN) technique [23]. ENN adeptly navigates dataset complexities, effectively balancing irregular theft and consistent energy use patterns by pruning redundant information based on nearest neighbor concepts [23].

$$E_{ENN}(X, Y) = \{(x_i, y_i) \in X, Y \mid x_i \text{ satisfies the ENN criterion}\} \quad (4)$$

Applying ENN to a dataset E_{ENN} modifies instances represented by X , with corresponding class labels Y as (x_i, y_i) . ENN assesses an instance's significance based on its proximity to neighbors in the feature space. This technique balances the dataset, enabling the next machine learning model to better identify patterns associated with energy theft, enhancing accuracy and dependability in smart city settings.

C. Feature Extraction using ResNeXt

In order to analyze data from smart cities, it is essential to first do feature extraction, which involves taking the raw input information and identifying patterns and correlations. Modern Convolutional Neural Networks (CNNs) such as the ResNext architecture are used for this [24]. The following represents the feature extraction method mathematically: \mathbf{X}_{raw} is the original input dataset. Its dimensions are $D \times F \times G$, where D is the number of channels and F and G are the input's width and length, respectively. ResNext's feature extraction process can be stated as follows:

$$\mathbf{X}_{high-dim} = \text{ResNext}(\mathbf{X}_{raw}; \theta_{\text{ResNext}}) \quad (5)$$

The mapping function that ResNext performs with learnable parameters θ_{ResNext} is denoted as $\text{ResNext}(\cdot)$ in this case. Hierarchical representations are captured by the high-dimensional feature tensor $\mathbf{X}_{high-dim}$, which is the output. ResNext uses a sequence of convolutional layers to extract features. The convolutional process with parameters θ_{Conv} can be represented as $\text{Conv}(\cdot)$. ResNext is hierarchical and consists of L convolutional layers followed by activation and normalization routines. The general procedure may be represented numerically as follows [24]:

$$\mathbf{Y}_l = \text{ReLU}(\text{BN}(\text{Conv}(\mathbf{Y}_{l-1}; \theta_{\text{Conv}_l}); \theta_{\text{BN}_l}); \quad l = 1, 2, \dots, L \quad (6)$$

In this case, $\mathbf{Y}_0 = \mathbf{X}_{\text{raw}}$, and the notations $\text{ReLU}(\cdot)$, $\text{BN}(\cdot)$, and $\text{Conv}(\cdot)$ stand for batch normalization, convolutional operations, and rectified linear unit activation, respectively. Concatenating the output tensors from each layer yields the final high-dimensional feature tensor $\mathbf{X}_{\text{high-dim}}$ [24]:

$$\mathbf{X}_{\text{high-dim}} = \text{Concat}(\mathbf{Y}_1, \mathbf{Y}_2, \dots, \mathbf{Y}_L) \quad (7)$$

The resultant $\mathbf{X}_{\text{high-dim}}$ provides a rich and informative feature representation for further classification tasks, encapsulating complex spatial hierarchies and semantic representations.

D. Classification by Jaya Optimization-based TCN-GRU

The core of our proposed model lies in the fusion of Temporal Convolutional Networks (TCN) and Gated Recurrent Units (GRU), optimized through the Jaya optimization algorithm. Although TCN-GRU is highly adept at recognizing historical connections in data presented in sequence, it acts as an appropriate preference for assessing variations in electricity consumption continuously. Jaya optimization adjusts the model's assumptions for its greatest accuracy for recognizing cases of electrical theft, improving its convergence and flexibility.

The set of inputs at time i will be expressed by A_i , though the stored state with time i is represented by B_i . The GRU equations are given by [25]:

$$C_i = \sigma(D_{AB}A_i + E_{AB}B_{i-1} + F_{AB}) \quad (8)$$

$$G_i = \sigma(D_{GB}A_i + E_{GB}B_{i-1} + F_{GB}) \quad (9)$$

$$H_i = \tanh(D_{HB}A_i + C_i \odot (E_{HB}B_{i-1}) + F_{HB}) \quad (10)$$

$$B_i = (1 - G_i) \odot H_i + G_i \odot B_{i-1} \quad (11)$$

Within each GRU problem, D_{AB}, D_{GB}, D_{HB} identify updated, reset, and candidate state hidden vectors. E_{AB}, E_{GB}, E_{HB} represent associated weight matrices. σ is the sigmoid function, and \odot indicates element-wise multiplication. Collectively, these elements impact GRU dynamics and sequential input processing. The TCN component generates Y_i using:

$$Y_i = \text{softmax}(M_{HY}H_i + B_{HY}) \quad (12)$$

When Y_i is added in the classification, it signifies the model's prediction at time i . The softmax function processes H_i to determine the output. The weight matrix M_{HY} and bias term B_{HY} link the hidden state to the output, crucial for confidence and probability shaping. Jaya optimization reduces the cross-entropy loss in TCN-GRU parameter modification [26].

$$\mathcal{L} = - \sum_k^N \sum_j^C L_{k,j} \log(P_{k,j}) \quad (13)$$

In this context, C represents the total number of classes, and N signifies overall instances. Binary indicator $L_{k,j}$ discerns whether instance k corresponds to correct class j .

Predicted probability $P_{k,j}$ expresses the model's estimation for k in class j . These facilitate comprehensive evaluation of TCN-GRU model's accuracy in identifying energy theft. Formulas govern iterative parameter adjustments through Jaya optimization [26].

$$M_i = M_i + N \cdot O \cdot (B_i - |A_i|) \quad (14)$$

$$A'_i = A_i + M_i \quad (15)$$

In our optimization method, symbols like M_i , N , O , and P_i are crucial. M_i represents present mobility, indicating solution change speed. Variable N controls acceleration, skillfully organizing modifications. O adds controlled randomness, injecting uncertainty. P_i guides the best solution domains. The TCN-GRU model, employing Jaya optimization, converges for accurate energy theft recognition. Fig. 3 shows TCGR-JA model.

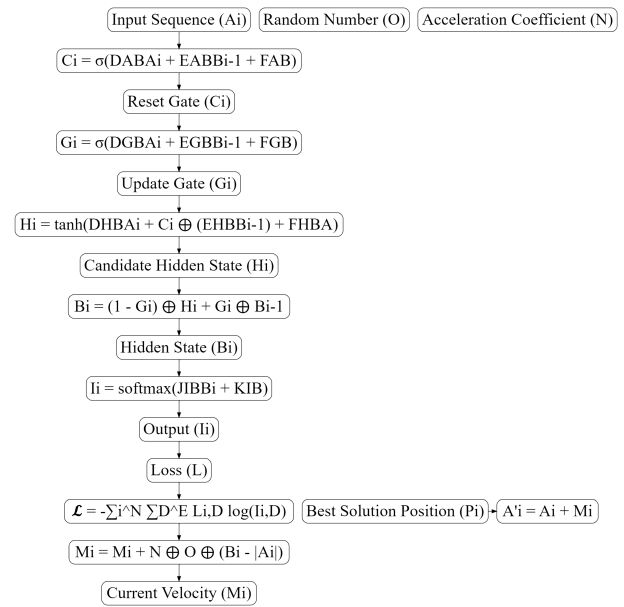

Fig. 3. TCGR-JA Model.

E. Significance of Statistical Analysis and Results Validation

Utilizing critical metrics including log loss, ROC-AUC, MCC, and PR-AUC, the efficacy of our method in averting energy theft in smart cities is meticulously evaluated [27], [28]. ROC-AUC and PR-AUC assess the predictive capability of the framework across various thresholds, whereas metrics such as MCC offer comprehensive insights into classification performance through the integration of specificity and sensitivity. In situations where probabilistic predictions are prevalent, the progressive increase in log loss indicates the precision of stochastic approximations. In order to substantiate the claims made, we utilize Pearson correlation tests to identify linear relationships, ANOVA tests to examine group variance, and Student's t-tests to identify pairwise comparisons. Our model endeavors to decrease energy theft and set a standard for cyber-secure urban infrastructures by placing immense importance on these validation measures and performing comprehensive

comparisons with prior related research. In order to make a significant contribution to the advancement of smart city technologies, we aim to empirically validate the model's dependability in real-world scenarios.

V. SIMULATION AND RESULTS

This section outlines our use of TensorFlow's powerful GPU in Google Colab to enhance ETDPS efficiency. Testing the architecture involved cloud-stored IoT datasets. Detailed results follow in subsequent sections. The initial exploratory data analysis (EDA) involves scrutinizing feature distribution, using visual aids to uncover trends. Though complex, this process equips decision-makers with deep insights, facilitating informed decisions despite model-building challenges.

Fig. 4. Correlation analysis of the data received from IoT devices.

Quantitative dataset characteristics are depicted in Fig. 4, emphasizing patterns in IoT device data. The correlation research systematically uncovers connections, displayed on the heatmap. Ranging from -1 to 1, values indicate no link (0), opposing alliance (-1), or a perfect connection (1). Warmer tones denote more complex associations, enhancing the understanding of relationships.

Fig. 5 provides a clear visual depiction of the attribute distribution of the dataset, with each histogram corresponding to a different feature and providing a numerical value frequency. These histograms reveal the wide range of dataset features, providing a complicated view. In addition to being visually attractive, they serve as perceptive guides by highlighting anomalies and deviations that reveal important subtleties in the data. A brief summary of feature importance based on the Random Forest method is shown in Fig. 5, which also shows the effect of each variable on the prediction of theft. Greater impact is shown by taller bars that stick out. Shorter bars, however, have less of an impact. In order to effectively mitigate energy theft in smart city infrastructures, decision-makers may concentrate on key aspects by using this detailed analysis to inform resource allocation and intervention tactics.

Fig. 6 depicts a comparison of confusion matrices between our proposed model and existing methods. Our novel approach excels in theft detection accuracy with faster execution times, crucial for real-world responsiveness. Efficient cloud-based processing is a key feature, streamlining data acquisition from

IoT devices and reducing overall processing time for quicker

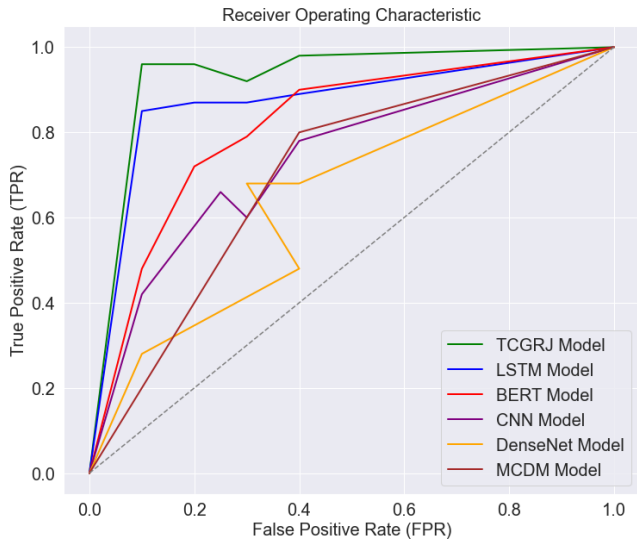

Fig. 7. ROC Curve and accuracy of the proposed VS Existing models on IoT-SM data.

theft identification.

The ROC curve with the highest AUC in Fig. 7 shows that the TCGRJ Model excels at distinguishing theft from normal situations. Using the IoT-SM dataset, Fig. 7 presents the accuracy values of numerous methods used in energy theft detection. Higher scores indicate better performance. Accuracy measures how well each technique detects instances of harmful behavior. Our proposed model TCGRJ performs in terms of accuracy.

Table I evaluates the TCGRJ model, highlighting its impressive 98.0% accuracy. This breakthrough positions TCGRJ as a highly effective approach for detecting theft activities in the IoT-based SM dataset, outperforming established models in multiple metrics.

Table II displays the average statistical analysis findings for theft detection techniques for the IOT-SM dataset. The proposed strategy, TCGRJ, performs better than current approaches on a number of statistical measures. With a Pearson correlation of 0.86, a Spearman correlation of 0.32, and a Kendall correlation of 0.89, TCGRJ performs better than its competitors. Moreover, TCGRJ demonstrates a strong correlation with a Chi-Squared test score of 18.4. These results validate the robust and dependable identification of stolen data

TABLE I. PERFORMANCE EVALUATION RESULTS OF PROPOSED AND EXISTING METHOD ON IOT-BASED SMART METER DATA

Techniques	ROC	AUC	F1-Score	Precision	Log Loss	Accuracy	MCC	Recall
MCDM [10]	0.69	0.76	0.65	0.50	1.06	0.75	0.31	0.92

VI. CONCLUSION AND FUTURE WORK

With a primary focus on the IOT-SM dataset, our study advances intrusion detection in IoT systems. The TCGRJ model, a novel TCN-GRU architecture employing Jaya Optimization, holds promise for enhancing IoT security. Departing from the conventional approach of treating theft as a singular issue, we introduce a comprehensive categorization scheme distinguishing eight theft forms. This detailed method improves threat comprehension and fortifies the TCGRJ model's discriminatory capacity. Tailoring our ETDP to diverse theft forms overcomes the limitations of generic security solutions, making TCGRJ an effective defense against potential vulnerabilities. Our research contributes to malware detection in IoT environments, impacting privacy considerations. Preventing electricity fraud promotes safety, reduces hazards, and lowers costs, particularly beneficial for individuals with disabilities. Future work involves refining the TCGRJ model, exploring optimization opportunities, and ensuring broader applicability, scalability, and industry collaboration for comprehensive IoT security solutions.

Enhancing Diabetes Prediction: An Improved Boosting Algorithm for Diabetes Prediction

Md. Shahin Alam, Most. Jannatul Ferdous, Nishat Sarkar Neera
Department of Computer Science and Engineering
Bangladesh University of Business and Technology (BUBT),
Rupnagar, Mirpur-2, Dhaka-1216, Bangladesh

Abstract—Diabetes is increasing gradually due to the inability to effectively use the human body's insulin, which threatens public health. People with diabetes who go undiagnosed at early stages or who have diabetes have a high risk of heart disease, kidney disease, eye problems, stroke, and nerve damage for which diabetes diagnosis is crucial to prevent. Our advanced machine learning algorithm is the gateway to a revolutionary possibility of detecting whether the human body has diabetes. Developed this method based on machine learning with one lakh data and the main objective of creating a new and novel diabetes prediction model named moderated Ada-Boost(AB) that can accurately diagnose diabetes. About 10 different classification methods are applied in this research such as Random forest classifier (RF), logistic regression (LR), decision tree classifier (DT), support vector machine (SVM), Bayesian Classifier (BC) or Naive Bayes Classifier (NB), Bagging Classifier (BG), Stacking Classifier (ST), Moderated Ada-Boost(AB) Classifier, K Neighbors Classifier (KN) and Artificial Neural Network (ANN). The crucial contribution is to find out the appropriate values for the different models using the hyper-parameter tuning process. We have proposed a new boosting model named Moderated Ada-Boost(AB) which is the combination of the hyper-parameter tuned random forest model and Ada-boost model. Different evaluation metrics such as accuracy, precision, recall, f1 score, and others are used to evaluate the performance of the models. Our proposed new boosting algorithm named Moderated Ada-Boost(AB) provides better accuracy than other models whose training accuracy is 99.95% and testing accuracy is 98.14%.

Keywords—Diabetes prediction; ensemble technique; machine learning; binary classification; Moderated-AdaBoost;

I. INTRODUCTION

Diabetes is a disease that causes many diseases in the human body, resulting in reduced life expectancy and premature death due to which the death rate is increasing day by day. One of the main causes of diabetes in the human body is insulin deficiency. The foods that humans consume to sustain life inhibit the production of energy from food sources when insulin is deficient. When the human body cannot produce enough insulin or use it properly or both. It is a major cause of diabetes in the human body. When the human body develops diabetes, it is no longer possible to remove it. As a result, millions of people worldwide are going through a difficult time. As their physical condition deteriorates, they have to change their diet and exercise excessively. When the amount of sugar in their body increases, the level of diabetes in their body becomes too high, so it is no longer possible to eliminate diabetes from the body for life. 537 million people worldwide had diabetes in 2021, of whom 81% lived in low- and middle-income countries. Diabetes-related deaths totaled 6.7 million,

and the cost of diabetes-related medical bills was estimated to be USD 760 billion in 2019 and would rise to USD 845 billion by 2045 [1], [2], [3], [4]. According to IDF estimates, there are 7.1 million diabetics in Bangladesh and almost the same number of undiagnosed cases; by 2025, this number is expected to quadruple. Furthermore, in low- and middle-income nations, the cost of diabetes places a heavy weight on natural expenditures [5]. So to overcome all these problems we have developed a great method through which a person can easily check if he has diabetes or not and then take the necessary steps to cure it.

The main goal of our research is to diagnose diabetes in humans. Most people can prevent having diabetes, but once it manifests in the body, it is rarely curable. The risk of having diabetes can be decreased by early identification and lifestyle modifications. When treating a patient one-on-one, doctors can correctly determine the patient's risk of diabetes. However, screening thousands of patients with high-risk conditions presents substantial challenges for doctors. In this case, population diabetes screening requires analytical techniques. Methods involving machine learning are adaptable and can be used to address a variety of issues in a range of fields. They keep proving their adeptness in any kind of decision-making, including data analysis and pattern identification. Machine learning methods can assist in solving a few common difficulties among the multitude of challenges that exist in our world. They consist of: Natural Language Processing (NLP), Optimization, Classification, Regression, Recommendation Systems, Anomaly Detection, Clustering, Language Translation, Image and Video Analysis, Time Series Forecasting, Reinforcement Learning, Healthcare, Quality Control and Anomaly Detection, Fraud Detection, Customer Churn Prediction, Content Generation, Environmental Monitoring, Personalization, Social Media Analysis, Automated Game Playing. These are only a handful of the thousands of issues that machine learning can handle; its capabilities are constantly growing and getting more sophisticated.

A. Research Contribution

This study examined a wide range of diabetes-related human health studies. Numerous research have examined the existence of diabetes in the human body. An analysis of how the human body detects diabetes or not has been attempted. The contributions noted below might be deemed noteworthy:

- To find out the best parameters for different models using the hyper-parameter tuning.

- A new and novel boosting model named Moderated Ada-Boost(AB) is developed for the automatic prediction of diabetes from the structured data.
- Different performance evaluation metrics have been used to validate the performance of our proposed model named Moderated Ada-Boost(AB).

B. Organization of this Paper

The remainder of the document is structured as follows: In Section II, the literature review was covered. In Section III, the methodology—which includes our suggested model—has been succinctly outlined. Section IV contains an analysis of the outcome. Section V concludes with a remark on future work and conclusions.

II. LITERATURE REVIEW

Healthcare researchers have used a variety of approaches, such as machine learning and data mining, to evaluate different datasets to predict diabetes. Notable methods include classification techniques like Naïve Bayes and Decision Trees, hybrid models that include clustering and classification algorithms like C4.5 decision trees, Neural Networks, and Random Forest Classifier, and Hadoop and MapReduce for economical analysis [6]. Random Forest (RF) surpassed Support Vector Machine (SVM) and deep learning (DL) in the comparison evaluation of machine learning and deep learning algorithms for diabetes prediction, obtaining the greatest overall accuracy of 83.67% in diabetic categorization. SVM achieved a prediction accuracy of 65.38% [7]. The paper builds a prediction model using three different algorithms, which are random forest, support vector machine, and logistic regression. With an accuracy of about 84%, Random Forest is the best algorithm for predicting Diabetes [8]. Priyanka Sonar and Prof. K. JayaMalini has presented algorithms like SVM, and ANN for identifying diabetes using ML algorithm [9]. Through the study of diabetes patient databases, researchers looked into the use of a variety of machine learning algorithms, like Random Forest, ensemble supervised learning, SVM, Logistic regression, ANN, Bayesian, and KNN, for the prediction of diabetes. We can observe from this study that the random forest classifier works more effectively than the others [10].

The goal of this study is to predict diabetes utilizing a variety of data mining classification techniques, such as KNN, Decision Trees, and Naive Bayes. The focus of the study is on predicting diabetes with high accuracy and maybe saving lives. A variety of algorithms are used for medical data for early identification [11]. Using the Pima Indian Diabetes dataset (PIDD), several researchers have used a variety of machine learning techniques, including artificial neural networks (ANN), bootstrap aggregating, adaptive boosting, decision trees, logistic regression, Naive Bayes, and Random Forest, to predict diabetes. The findings show accuracies between 75.7% and 77.21%. Various research highlights the importance of different aspects and uses different feature reduction approaches to get the optimal predictions [12]. Machine learning techniques like Adaboost, Bagging, Decision Tree, Genetic Programming, Artificial Neural Network, and Random Forest are used in several studies (Sajida, Orabi, Pradhan, Rashid, and Nongyao, among others) to predict

diabetes. The results indicate that Adaboost performs better than Bagging and Decision Tree, Decision Tree, and Genetic Programming provide satisfactory results with high accuracy, and Random Forest is the most efficient algorithm among the ones used [13]. In a 4-node Hadoop cluster setting, the random forest method provides the greatest accuracy at 94% compared to the decision tree and naïve bayes algorithms [14]. Data mining techniques, particularly when combined with machine learning, have demonstrated superior predictive capabilities, accuracy, and precision when compared to traditional methodologies, as evidenced by previous studies emphasizing their effectiveness, particularly in the context of driving prediction models for conditions such as diabetes [15]. Diabetes classification methods utilized include Decision Tree (DT), Support Vector Machine (SVM), Random Forest (RF), K-Nearest Neighbour (KNN), and Naive Bayes. Naïve Bayes, SVM, and Decision Tree classifiers are used to predict diabetes mellitus; of these, Naïve Bayes is the most effective with an accuracy of 76.3%; K-Nearest Neighbour and Logistic Regression classifiers with Gradient Boosting feature selection are also used for diabetes prediction [16].

Numerous studies have been conducted in the literature using various datasets and methods for the identification of diabetes. For example, Zou et al. used a dataset from Luzhou, China, applied PCA and mRMR for dimensionality reduction, and showed that an RF classifier achieved the highest accuracy of 80.84%. Maniruzzaman et al. used the Pima Indian diabetes dataset, applied a variety of classifiers, and discovered that an RF-based classifier with feature selection achieved the highest accuracy of 92.26%. Furthermore, Ahuja et al. employed LDA for feature selection using the Pima Indian diabetes dataset, and they found that the best accuracy of 78.70% was obtained when an LDA was combined with a Multi-Layer Perceptron (MLP) classifier. Without using feature selection, Sisodia et al. used SVM, Naive Bayes (NB), and DT classifiers and obtained the maximum accuracy of 76.30% [17]. For diabetes prognosis, the suggested approach used a unique type of deep neural network to boost prediction accuracy. Using the PID Data Set, the experiment revealed that the suggested approach had an accuracy of 88.41% [18]. To predict GDM in model A, the fundamental feature set was utilized, which included the patient's age, heart rate, blood pressure, and other vital indicators. The performance of EPM is satisfactory (Accuracy = 0.902%, AUC = 0.912%). With the addition of weight and gestenail changes, Model B utilized the same feature (Accuracy = 0.957%, AUC = 0.942%) [19].

Diabetes is a rapidly spreading disease with serious consequences such as cardiovascular disease and renal failure. Early diagnosis is crucial but challenging due to limited labeled data and unreliable clinical datasets. To address this, a diabetes dataset from Bangladesh has been provided along with a weighted ensemble of machine-learning classifiers. Hyper-parameter optimization and feature selection techniques are utilized to improve prediction accuracy. The proposed ensemble model (DT + RF + XGB + LGB) combined with statistical imputation and RF-based feature selection yielded the best results for early diabetes prediction. The dataset will contribute to the development of reliable machine-learning models for diabetes prediction using population-level data [20]. Diabetes is a chronic illness that is on the rise and may be quite dangerous if not caught in time. By establishing automated

methods for diagnosing diabetes patients, recent developments in machine learning techniques and ontology-based approaches have made a significant contribution to the area of medical science. Decision Tree, Naive Bayes, KNN, SVM, and ANN are among the most widely used techniques that are compared and reviewed in this study. The outcomes are assessed using performance metrics like as F-measure, recall, accuracy, and precision. According to this study's findings, SVM attains the maximum accuracy [diabetes prediction using machine learning] [21].

Since diabetes has an impact on everyone's health, it is a major worldwide problem. Using big data analytics and machine learning, researchers have been working to create an effective diabetes prediction model. Based on their research, an intelligent framework for diabetes prediction is proposed in this article. For diabetes prediction, the authors assess support vector and random forest machine learning models based on decision trees. Health professionals, stakeholders, students, and researchers interested in diabetes prediction research and development may all benefit from their creation of a novel intelligent diabetes mellitus prediction framework (IDMPF). With a minimal mistake rate, the suggested effort achieves 83% accuracy [22].

Diabetes mellitus is a metabolic disease marked by elevated blood glucose levels as a result of the body's failure to produce or react to insulin. Diabetes can cause major problems that harm essential organs if it is not addressed. Although machine learning can be used to predict diabetes, more work has to be done in this area of computational diagnosis research. Using two datasets, this research suggests a machine learning paradigm for diabetes diagnosis and prediction. Feature selection and missing value imputation techniques can be used to improve classification model accuracy. The approach uses polynomial regression and Spearman correlation for missing value imputation and feature selection, respectively. A custom deep neural network, support vector machines, random forests, and other machine learning models are proposed for classification. Grid search and cross-validation are used in the models' optimisation. The proposed deep neural network model provides good accuracy in diabetes prediction, according to experimental results on two datasets. The framework's classifiers and preprocessing techniques perform better than those of other approaches. The models' source code is accessible to the general public [23].

In this work, they employed K-NN, DT, LR, BNB, and SVM—five of the most widely used algorithms for identifying and categorizing binary issues, like diabetes. The maximum accuracy attained by the K-NN model was 79.6% [24]. Using the PID and HFD datasets, the CFA was compared to the GA. To the best of the information we have, the only meta-heuristic algorithm for type 2 diabetes detection is the GA. Six classifiers were used to test the CFA and GA algorithms: K-NN, RF, DT, LR, SVM, and NB. Of these, rf and KNN provided the highest accuracy, at 77% and 79%, respectively [25]. Diabetes of either type could be detected most accurately by the machine learning models, which produced AUROC and AUPR curves of 0.84% (95% CI 0.76%, 0.91%) and 0.84% (95% CI 0.78%, 0.93%), respectively. For diabetes, the model's sensitivity and specificity were 0.82% and 0.75%, respectively. Comparable results were established for type 1

(AUROC 0.81% and AUPR 0.72%) and type 2 (AUROC 0.88% and AUPR 0.81%) diabetes, as well as $HbA1c \geq 6.5\%$ [26]. ML has drawn more and more interest in recent years from a variety of study domains. Of all the machine learning approaches available today, ANNs are performing especially well in positions related to health [27]. In this study, we describe a unique no-prop technique that uses a multi-layer neural network to classify the three forms of diabetes mellitus. A multi-layer neural network is used to improve the efficiency of categorization. The best specificity and sensitivity values of 0.95% were achieved by the suggested multi-layer neural network [28].

The objective of this study is to apply non-invasive techniques to identify diabetes and prediabetes. To do this, they used machine learning in conjunction with ECG. The study made use of clinical data from 1262 people who were part of the Diabetes in Sindhi Families in Nagpur study. Three sets of the dataset were created: training, validation, and test. After processing the ECG recordings, minority oversampling was used to balance the training dataset. Based on the processed ECG data, the classifier was trained to predict whether a person will belong to the prediabetes, type 2 diabetes, or "no diabetes" groups. The American Diabetes Association's definition of the requirements for these classes was followed [29]. According to the SHAP, glucose is the specific factor that most influences the possibility of developing diabetes; however, when combined with age and body mass index (BMI), it has a far greater effect. Furthermore, BMI and the diabetes pedigree function evaluate highly for the prediction of diabetes. For this reason, if blood glucose control is difficult, attention should be directed towards managing BMI and the diabetes pedigree function. With the guidance of SHAP, we fit the ML algorithms for diabetes prediction using a new dataset that was created from the original one. Xgboost and Adaboost outperformed other models with 94.67% accuracy and F1 scores of 95.27 and 95.95, respectively [30].

During 1995, there were approximately an estimated 135 million cases of diabetes globally; by 2025, there were expected to be at least 300 million cases. Over 1995 and 2025, the number of persons with diabetes is expected to rise by 42% (from 51 to 72 million) in advanced nations and by 170% (from 84 to 228 million) in developing nations. Diabetic is associated with a number of potentially modifiable risk factors, such as insulin resistance, obesity, physical inactivity, and nutrient elements. In population at risk, diabetes may be avoidable, although the outcomes of current clinical trials are not yet known. There are presently a number of effective and affordable therapeutic options available to lessen the burden of diabetic complications, including the use of aspirin and ACE inhibitors; early identification and treatment of retinopathy, nephropathy, and foot disease; and management of blood pressure, cholesterol, and glucose. Diabetes is a serious public health issue that is starting to propagate like wildfire. While diabetes prevention may one day be achievable, there is now a great deal of possibilities to improve the use of currently available medications to lessen all the challenges connected to diabetes. Research focused at better understanding the causes of underuse of current medicines and how to improve this might be advantageous to many nations [31].

Diabetes prediction in maximum research work has mostly

employed discrete classifiers, including Random Forest, SVM, ANN, and Naive Bayes, along with simple ensemble techniques like bagging and boosting. They seldom ever investigate sophisticated hybrid ensemble methods, though, which can lead to better results. Although some studies shed light on hyperparameter tuning, many do not explain the optimization procedure in depth, which might compromise the models' efficacy and repeatability. Most studies focus on accuracy as the main metric, frequently ignoring other important performance metrics that offer a more thorough assessment of model performance, such as precision, recall, F1-score, and AUC-ROC. The lack of attention to model generalization capabilities is a frequent problem. High training accuracy is frequently reported, but testing accuracy and the overfitting danger are not sufficiently discussed, which is crucial for using these models in real-world scenarios. Furthermore, the reliability of the models has been affected by the varied handling of class imbalance, a crucial component in medical datasets, between research. Confusion matrix-based detailed assessments are often lacking, which are crucial to comprehending the kinds of inaccuracies the models make. Certain studies employ feature selection methods such as PCA and mRMR, but they don't combine them with sophisticated ensemble approaches to enhance performance even more. Furthermore, even though complicated datasets are occasionally used, sophisticated preprocessing, feature selection, and sophisticated ensemble approaches are frequently not integrated into a single, coherent workflow. Overall, to increase the accuracy and dependability of diabetes prediction models, there is a clear need for more thorough and rigorously methodical approaches that incorporate these cutting-edge strategies. Furthermore, this article demonstrates how our suggested model, Moderated-AdaBoost (AB), performs better than alternative algorithms when compared to the resilience of Artificial Neural Networks and Random Forests.

By utilizing a moderated Ada-Boost model where the hyper-parameter tuned Random Forest is used as the base estimator, our method combines the advantages of many ensemble approaches to provide a unique and reliable diabetic prediction model. To guarantee outstanding performance, we used GridSearchCV to fine-tune the Random Forest classifier's hyperparameters. Several measures, including AUC-ROC, were included in our study to give a thorough picture of the model's capacity to manage class imbalances and produce precise predictions over a range of thresholds. Strong generalization to new data is demonstrated by our excellent testing accuracy (98.14%) and training accuracy (99.95%). Our approach placed a strong emphasis on necessary preprocessing measures such as encoding, normalization, and balancing to successfully manage imbalanced datasets while reducing bias towards the class that is most prevalent. To enhance openness, replicability, and trustworthiness, we provided thorough instructions for our data pretreatment, model training, and assessment procedures. To shed light on true positives, false positives, true negatives, and false negatives along with identifying areas in demand for enhancement we implemented a confusion matrix into our study. We showed that our model was superior in terms of accuracy and generalization by comparing it with other algorithms (e.g., RF, SVM, LR, NB, and KNN). Through the integration of several preprocessing approaches, effective hyperparameter tuning, and an advanced hybrid model, our methodology provides a solid solution for diabetes prediction,

Fig. 1. Exploring how many patients are in a class.

despite the task's complexity.

III. METHODOLOGY

A. Datasets Description

The dataset under consideration comprises 100,000 records, of which 91,500 are non-diabetic and 8,500 are diabetic. The study made use of the "Diabetes_Prediction_Dataset" dataset. The numbers of patients with diabetes (8500) and those without (91500) are displayed in Fig. 1.

B. Dataset Preprocessing

1) *Feature encoding*: Standardizing categorical data into a format that works better with machine learning algorithms is accomplished with the help of this transformation which is shown in Fig. 2 and Fig. 3. The 'gender' column values in this research are converted from strings ('Female' and 'Male') to numeric values (0 and 1).

Fig. 5 similarly illustrates the conversion of data from category to numerical type.

('no info': 0 replaces 'no info' with 0, 'never': 1 substitutes 'never' with 1, 'current': 2 substitutes 'current' with 2, 'former': 3 substitutes 'former' with 3, 'ever': 4 substitutes 'ever' with 4, 'not current': 5 substitutes 'not current' with 5) in order to guarantee that the characteristics are on the same scale and that the association with the goal variable is maintained.

2) *Feature scaling*: Building accurate and trustworthy machine learning models demands an in-depth understanding of the distribution and relationships of the data, which can be made possible by this procedure, which provides insight into how the feature scaling process has changed the original data.

Fig. 2. Gender distributions in our datasets.

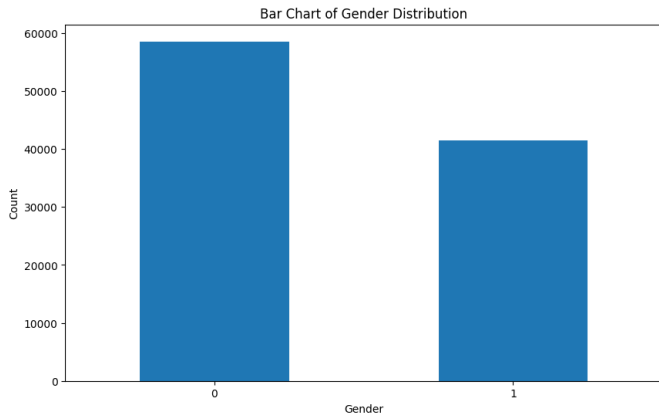

Fig. 3. Transformation of categorical to numerical type (Gender).

Fig. 4. Exploration of smoking history.

Fig. 5. Transformation of categorical to numerical type (smoking history).

Fig. 6. Before and after feature scaling.

In general, Fig. 6 depicts a basic phase in preparing data for machine learning tasks, which guarantees that features are scaled suitably to enhance the convergence and performance of machine learning algorithms.

3) *Datasets balance*: Among the datasets worked on, there are 100,000 data in which the number of non-diabetic data is 91,500 and the number of data with diabetes is 8,500. Due to the imbalance of the data, the balance was done by bringing the minority class to the same level as the majority class so that the number of data with and without diabetes stood at 183000. The “diabetes_prediction_datasets” datasets were used for the investigation.

Subsequently, as seen in Fig. 7, these unbalanced datasets were balanced to equal numbers.

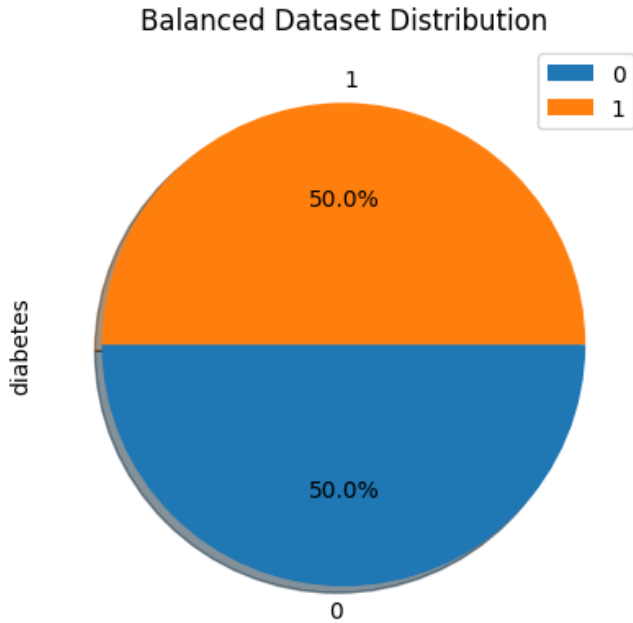

Fig. 7. Distribution the datasets between classes after balancing.

Fig. 8. Feature importance according to the datasets.

4) *Feature importance*: Random forest was utilized to determine the feature significance in the datasets used in this study, which had eight features. The importance of each signal in identifying or forecasting diabetes is shown in Fig. 8. This suggests that the most significant factor is the HbA1c_level, Sex, hypertension, and heart_disease are the least significant. Nevertheless, every aspect has been refined in this study.

C. All Applying Models

1) *K Nearest Neighbor(KNN)*: The k-nearest neighbors (KNN) algorithm is a straightforward and intuitive algorithm for both classification and regression. It functions by identifying the k data points that are closest to an input data point, or its neighbors. Eq. (1) works by predicting the data based on the average value of those neighbors (for regression) or the majority of classes (for classification). The technique uses the available data to make predictions rather than explicitly training the model.

The calculation formula has been represented at:

$$\text{Predicted class for } x_{\text{new}} = \operatorname{argmax} \sum_{i=1}^k I(y_i = c) \quad (1)$$

Where:

- x_{new} is the new input data point.
- $k(1)$ is the number of neighbors.
- y_i is the class label of the i th neighbor.
- c iterates over all possible class labels.
- $y_i = c$ is an indicator function that evaluates to 1 if $y_i = c$, and 0 otherwise.

It's crucial to remember that the actual distance between data points and the neighbors picked are determined by the distance measure selected as well as implementation specifics. Although the KNN method is briefly described above, it's important to remember that libraries or frameworks are usually used to implement KNN since they manage computations well and offer extra capabilities for customization and optimization. The knearest neighbors (KNN) model applied to the "diabetes_prediction_dataset" dataset used to classify diabetes cases was evaluated. Based on the output, the following is an explanation of the performance of the KNN model:

Fig. 9. Confusion matrix of KNN model.

The KNN model's overall accuracy was around 96.48%. The confusion matrix in Fig. 9 represents each example dataset

that we have acquired. this accuracy shows the percentage of properly identified occurrences. For every class, the classification report offers a more thorough analysis of the model's performance:

- Class 0: The model correctly detected instances of this class, as evidenced by its high recall (92.5) and training accuracy (0.99).
- Class 1: The model did a decent job at differentiating between instances of this class, with strong accuracy (92.5) and recall (0.99).

2) *Random forest classifier*: The performance of RandomForestClassifier, an extremely potent ensemble learning method, may be greatly influenced by a number of hyperparameters. In order to optimize our method, We concentrated on the following hyperparameters in the below:

- n_estimators (200): The number of trees in the forest.
- max_depth (None): Maximum depth of forest trees.
- min_samples_split (2): Minimum number of samples required to split an internal node.
- min_samples_leaf (1): Minimum number of samples required in a leaf node.

The model's accuracy throughout training was 99.95%. The test accuracy of 97.87%, however, points to a little decline in performance. Once trained, the random forest algorithm makes predictions very slowly, but it trains quickly. While a model with more trees will predict outcomes more accurately, it will also operate more slowly. We enhanced the RandomForestClassifier's capacity to identify intricate correlations in the diabetes dataset by adjusting its hyperparameters. It will be possible to contribute to a more durable and trustworthy diabetes prediction model if the chosen hyperparameters indicate a configuration that maximizes the predicted accuracy. As a crucial part of a model optimization approach, hyperparameter tuning guarantees that our machine learning model is optimized for the particular goal of diabetes prediction and produces appropriate results.

Fig. 10 demonstrates that even though 18050 positives were real positives—that is, diabetes—the model accurately predicted them to have the disease—440 individuals who did not have diabetes but were misclassified as having diabetes by the model. Additionally, 17752 is the estimated number of people without diabetes. In conclusion, 358 individuals with diabetes who had diabetes were misdiagnosed as having the disease.

3) *Logistic regression hyperparameters*: Numerous hyperparameters define the logistic regression method, which is frequently used for binary classification applications like diabetes prediction. We go over the hyperparameters we looked at below:

- C (1): The C parameter controls the penalty strength, which can also be effective.
- Penalty (12): The type of regularization term applied ('1' for L1 regularization, '2' for L2 regularization). Note: not all solvers support all regularization terms.

Fig. 10. Confusion matrix of random forest classifier.

- Solver (liblinear): Algorithm to use for optimization ('liblinear' is suitable for small datasets).
- Random_state (0): Seed for reproducibility.

To systematically explore the hyperparameter space and identify the optimal combination, grid search cross-validation was employed. To do this, a grid of potential hyperparameter values had to be generated, and the model's performance had to be evaluated for each combination using cross-validation. Following the grid search process, we were able to identify the optimal Logistic Regression model and the associated hyperparameter values. We carefully tweaked the Logistic Regression hyperparameters until we found the model configuration that maximized the model's accuracy in predicting our diabetes dataset. By using hyperparameters that compromise between regularization strength and model complexity, the model is ensured to be well-suited to the underlying patterns in the data.

Fig. 11. Confusion matrix of logistic regression.

While 16,210 positivity were true positives, meaning that

the approach precisely determined that they had diabetes, Fig. 11 demonstrates that in 2010 people were not suffering from diabetes but were mistakenly labeled to be suffering from diabetes by the predictive algorithm. Furthermore, the expected number of individuals without diabetes is 16182. In summary, 2198 individuals with diabetes received a false diagnosis.

In the final analysis, adjusting the logistic regression hyperparameters is an essential step in our full model optimization process that enables us to produce an exceptionally accurate diabetes prediction model.

4) *Decision tree classifier*: Hyperparameter tuning for the decision tree classifier was accomplished using a method called GridSearch Cross-Validation (GridSearchCV). The purpose of hyperparameter tuning is to discover the ideal combination of hyperparameter values that leads to the best performance of the model. The decision tree classifier in this instance is determined by a number of hyperparameters, including the maximum depth of the tree, the minimum number of samples needed to split an internal node, the minimum number of samples that must be present, and the splitting criterion ('Gini' or 'entropy'). A leaf node. Where:

- Criterion: entropy
- Max_depth: None
- Split: 2
- Leaf: 2

Grid search is examining various combinations of these hyperparameter values in a methodical manner. The 'cv=3' parameter indicates that 3-fold cross-validation is used for the evaluation. This involves dividing the dataset into three sections and training and evaluating the model three times, with a different subset being used as the validation set each time.

The optimal model is chosen based on the highest average cross-validated score following the grid search. The average model performance over various cross-validation folds is represented by this score. Next, the optimal model and hyperparameters are printed. By automating the process of determining a decision tree model's optimal hyperparameters, this method improves the model's predictive ability on fresh, untested data.

The remainder of Fig. 12 illustrates that 490 persons had no symptoms of diabetes but were mistakenly classified as having diabetes by the prediction algorithm, even though 17717 positives were true positives, indicating the approach accurately identified that they had the condition. Moreover, 17702 persons are predicted to be free of diabetes. In conclusion, 69 diabetic individuals were given the incorrect diagnosis.

5) *Stacking classifier*: An ensemble model for stacking classifiers is created to enhance a dataset's classification performance. Three different base models comprise the ensemble: support vector machines (SVM), decision trees, and logistic regression. With the distinct properties that each of these models contributes, the ensemble is able to capture both linear and non-linear correlations between the data.

- SVM, decision trees, and logistic regression are the three fundamental models that are employed. While

Fig. 12. Confusion matrix of decision tree.

decision trees and support vector machines (SVMs) offer robust and non-linear classification skills, logistic regression offers a linear approach.

- It is implemented with a stacking classifier that mixes the base model's predictions. A RandomForest classifier, renowned for merging predictions from several decision trees, was selected as the meta-learner.
- Evaluating generalisation ability using both training and testing datasets.
- The achieved accuracy sheds light on the model's functionality and capacity to apply previously learnt patterns to fresh data.
- Stacking combines linear and non-linear techniques to maximise the potential of several models. By combining predictions, the RandomForest meta-learner seeks to mitigate the shortcomings of individual models.
- For datasets used for training and testing, accuracy is the most important performance indicator. To find out how successfully the ensemble generalises to new data, evaluation is crucial.
- It shows to be a flexible and strong ensemble model by combining logistic regression, decision trees, stacking classifiers, and SVMs with random forest meta-learners.
- Investigate different meta-learner iterations and supplementary base models for optimisation. Adjust settings and methods to improve the overall performance of the group.
- The study adds to our understanding of the effectiveness of individual models, the process of collaborative learning, and the predictive performance attained by the stacking classifier.

The following section of Fig. 13 suggests that although 17754 positives were true positives, accurately recognized by the approach to be suffering from diabetes, 630 people did not

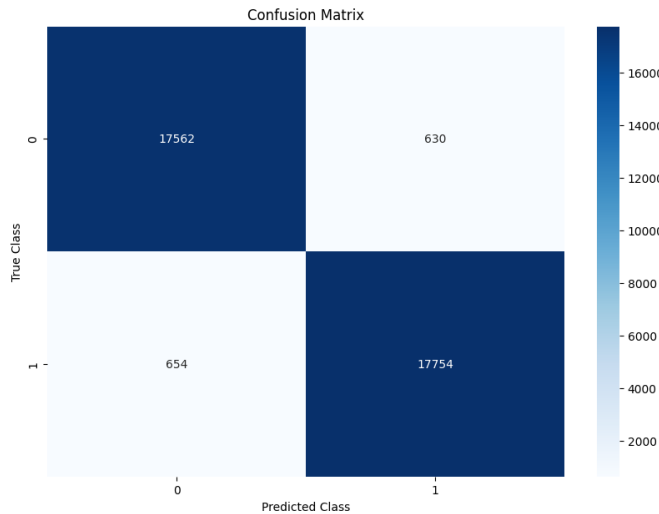

Fig. 13. Confusion matrix of stacking classifier.

exhibit any signs of the ailment, yet were mistakenly categorized as suffering from diabetes by the prediction algorithm. Moreover, it is estimated that 177562 people will be free of diabetes. To sum up, 654 people with diabetes received the incorrect diagnosis.

6) *Bagging classifier*: To improve predictive accuracy, an ensemble model for a bagging classifier has been created in this study. This ensemble's foundation model is a RandomForest classifier, which is well-known for its capacity to build a variety of decision trees. The RandomForest is used as the foundation model when the Bagging Classifier is first initialised, and numerous instances of the base model are generated throughout the training phase. Through bootstrap sampling, each instance is trained on a different portion of the training data, adding diversity. The Bagging technique's main advantage is its diversity, which makes the ensemble more reliable and accurate. Next, the trained Bagging Classifier is assessed using the test and training datasets. Accuracy measures are used to gauge how well the model fits the training data and how well it generalises. The outcomes, in particular the training and test accuracy, shed light on the ensemble's overall performance. With ensemble learning, this Bagging Classifier attempts to provide a better and more dependable predictive model for the provided dataset by utilising the advantages of the RandomForest model.

7) *Support Vector Machine (SVM)*: A supervised machine learning approach that may be applied to regression and classification problems is called a support vector machine. It operates by locating the hyperplane in the feature space that best divides various classes. To improve generalization to new, untested data, the hyperplane is used to maximize the margin, or distance, between the classes.

With the application of various kernel functions, SVMs can handle both linear and non-linear separation boundaries, which makes them very useful when working with high-dimensional data. When the appropriate regularization parameter is used, they exhibit robustness against overfitting. For problems involving regression and classification, one kind of supervised

machine learning technique is called Support Vector Machine (SVM).

- **Accuracy**: The percentage of cases in the dataset that are properly categorized out of all occurrences in the dataset. The SVM model's accuracy in this instance is around 0.90, or 90%.
- **Classification Report**: Each class in this classification issue is given comprehensive performance metrics in this section.

Accuracy, which measures the accuracy of positive predictions, is defined as the ratio of true positive predictions to the total predicted positives within a given class in evaluating the performance of a classification model. Conversely, recall measures the model's sensitivity to positive examples by calculating the ratio of genuine positive predictions to all real positives within a class. When dealing with unequal class distributions, the F1-Score provides a comprehensive assessment that ideally balances recall and accuracy. Regarding output, the accuracy, recall, and F1 scores for every class offer information on how well the SVM model performs for every unique class. One important finding is that a higher F1 score indicates a good balance between recall and precision, making it a useful indicator for a thorough evaluation of the model's performance.

Fig. 14. Confusion Matrix of Support Vector Machine (SVM).

According to the following aspect of Fig. 14, the prediction algorithm erroneously categorized 2015 persons who did not display any signs of the disease as having diabetes, even though 17021 true positives were accurately identified as carrying diabetes by the methodology. In addition, an estimated 16177 individuals have no form of diabetes. In conclusion, 1387 diabetic patients were given the incorrect diagnosis. It has a high rate of misclassification.

8) *Naive bayes classifier*: For classification problems, a probabilistic machine learning technique called the Naive Bayes Classifier is employed. Based on the "naive" assumption of feature independence—that is, that all features are independent of one another given the class—it is based on the Bayes theorem. Naive Bayes classifiers frequently work well

in reality and are particularly helpful for text classification applications, despite this oversimplifying assumption. The Naive Bayes Classifier formula may be written as follows:

Eq. (2) is given by:

$$P(y|x_1, x_2, \dots, x_n) = \frac{P(y) \cdot P(x_1|y) \cdot P(x_2|y) \cdot \dots \cdot P(x_n|y)}{P(x_1) \cdot P(x_2) \cdot \dots \cdot P(x_n)} \quad (2)$$

Where:

- $P(y|x_1, x_2, \dots, x_n)$ is the posterior probability of class y given the features x_1, x_2, \dots, x_n
- $P(y)$ is the prior probability of class y
- $P(x_i|y)$ is the likelihood of feature x_i given class
- $(P(x_1), P(x_2), \dots, P(x_n))$ are the marginal probabilities of the features.

In actuality, since the denominator $P(x_1) \cdot P(x_2) \cdot \dots \cdot P(x_n)$ is constant for all classes, it may be disregarded when comparing probabilities for various classes. The instance is assigned to the class with the highest probability via the Naive Bayes Classifier, which determines the likelihood of each class given the characteristics. Naive Bayes classifiers come in a variety of forms, each having a unique method for representing the likelihood $P(x_i|y)$, including: Gaussian Naive Bayes: Made the assumption that feature continuous values had a Gaussian distribution. Multinomial Naive Bayes: Often used for text classification where features are word frequencies, this algorithm works well with discrete data. Bernoulli Naive Bayes: For binary data, this method is comparable to Multinomial Naive Bayes. In spite of its straightforward premise, Naive Bayes is surprisingly successful, particularly when used for tasks like text categorization and other comparable ones where its efficacy and efficiency make it a popular option. The evaluation outcomes of a Naive Bayes classifier used to solve a classification issue are shown in Fig. 15. The accuracy of the model, which is around 0.835% or 83.5%, shows that it can be improved overall.

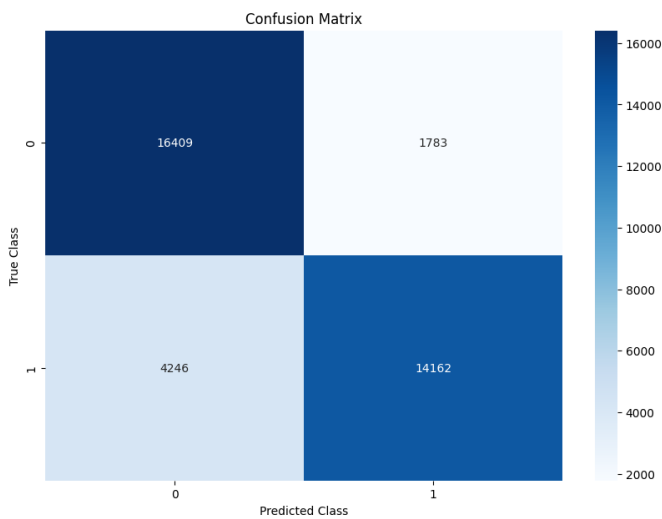

Fig. 15. Confusion matrix of naive bayes classifier.

The prediction system misclassified 1783 people who did not show any signs of the condition as having diabetes, even

though 14162 genuine positives were accurately detected as suffering from the disease, which is demonstrated by one of the following characteristics of Fig. 15. Furthermore, there are about 16409 individuals who do not have diabetes. In summary, 4246 diabetic patients received the incorrect diagnosis. Its high erroneous rate is unacceptable at all.

D. Proposed Model

Hyper-parameter tuning of Random Forest Classifier using GridSearchCV. It selects and rates the best Random Forest Classifier model. Next, the Moderated Ada-Boost(AB) Classifier is constructed using the best Random Forest Classifier as its base estimator. The processing of the training and testing datasets is then shown in Fig. 16, where the Moderated-AdaBoost(AB) Classifier is trained and evaluated.

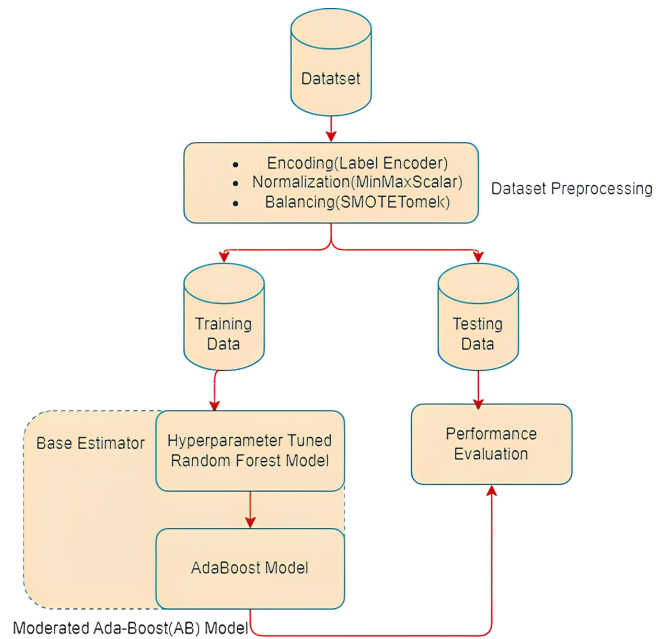

Fig. 16. The Proposed Model (Moderated Ada-Boost(AB)).

In Fig. 16, after preprocessing the dataset through some preprocessing techniques such as encoding, normalization, and balancing, the training data are used to train the proposed moderated Ada-Boost(AB) model. Then testing data is used to evaluate the performance of the model. After hyperparameter optimization yields the ideal hyperparameters for the random forest model, the random forest is chosen as the base estimator. These hyper-parameters value for the Random Forest model include:

- There are 200 trees (n_estimators).
- 'gini' is the prerequisite for splitting.
- Trees can grow to any depth (max_depth): 'None' until all their leaves are pure.
- The following factors are considered while determining the optimal split (max_features): 'sqrt' (the square root of the overall number of features).
- Random state: 0 (to ensure repeatability)

Random Forest is an effective and adaptable ensemble learning technique that can minimize over-fitting and handle complicated datasets. The most recent estimator of the stacking model is the trained random forest model; the predictions made by the random forest model are input features for the Proposed Moderated Ada-Boost(AB) model, which incorporates the estimator (the beforehand trained random forest model) and the ideal parameters. Using training as well as testing datasets, the suggested moderated Ada-Boost(AB) model's performance is assessed; the results show a 99.95% training accuracy and a 98.14% testing accuracy. As a result, our proposed model named the moderated Ada-Boost(AB) model shows high test accuracy and good generalization to unseen data signifying effective power usage.

- True positive (TP): The model properly predicted these cases as positive, i.e., having diabetes, even though they were truly positive, i.e., having diabetes.
- False positives (FP): People who aren't suffering from diabetes but were mistakenly predicted by the model to have it.
- True negative (TN): This is an innovative case where the model accurately predicted the patient's absence of diabetes, even if the patient didn't suffer from the disease.
- False negative (FN): Because the model was unable to accurately forecast, it only predicted individuals who had diabetes and showed certain shortcomings, among them people who weren't diagnosed with diabetes.

Fig. 17. Confusion Matrix of Proposed Model(Moderated Ada-Boost(AB)).

With a larger percentage of true positives and true negatives than false positives and false negatives, Fig. 17 illustrates how effectively the model works, especially in accurately recognizing positive and negative situations. It offers data on the model's performance when correctly categorized.

IV. RESULT AND DISCUSSION

A. Accuracy Rate of Different Algorithms

The wide range of accuracy outcomes produced by various algorithms provides a clear picture of each one's advantages and disadvantages. Our proposed model the Moderated Ada-Boost (AB) is a very effective front-end performer; Fig. 18 shows an astounding 99.95% accuracy for the training phase. The capacity of the model to identify intricate patterns and characteristics within datasets is supported by this consistency of accuracy. This widely held disagreement highlights the algorithm's capacity to understand intricate linkages while preserving good generalization.

Fig. 18. Comparative training accuracy across models.

While bagging offers the highest certainty, Decision Tree provides a pretty close accuracy in training, and Random Forest and Moderated Ada-boost(AB) have the same assurance. However, in the case of Moderated Ada-boost(AB), shown in Fig. 19, we obtained the maximum accuracy throughout the testing which is 98.14%. This leads us to the conclusion that our suggested moderated Ada-Boost(AB) provides the highest level of trust and the best backing.

B. Confusion Matrix

A thorough summary of the classifier's performance for every class is given by the confusion matrix. This illustrates its advantages and disadvantages in terms of identifying individuals with and without diabetes. This matrix is a useful starting point for computing several performance measures, including accuracy, precision, recall, and F1-score for every class, giving information about the classifier's overall performance as well as potential areas for improvement.

Recall, accuracy, and F1 score are three metrics that were used in this study to evaluate the model's performance in

Fig. 19. Comparative testing accuracy across models.

machine learning classification situations where the output might include two or more classes. These metrics were determined using Eq. (3) and Eq. (4). Four distinct combinations of expected and actual values are shown in the Table I.

The Accuracy is calculated using the following formula:

$$\text{Accuracy} = \frac{TP + TN}{T} \quad (3)$$

The F1-score is calculated using the following formula:

$$\text{F1-score} = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} \quad (4)$$

TABLE I. CONFUSION MATRIX WORKING STRATEGY

		Predicted Class		
		Yes	No	Total
Actual Class	Yes	TP	FN	P
	No	FP	TN	N
	Total	P'	N'	P+N

The terms used in the formulas are as follows:

- TP: True Positive
- FP: False Positive
- TN: True Negative
- FN: False Negative
- T: Total number of samples

C. ROC Curve

In this experiment, we utilized the curve of receiver operating characteristics (ROC) as well as the area under the curve (AUC) parameters for evaluating the effectiveness of around ten machine learning classification algorithms for binary classification tasks. ROC curve analysis was used to evaluate classification, and it is valid at various decision thresholds and sheds light on the trade-off between the percentage of false positives (1-specificity) and the positive rate (sensitivity). To assess each classifier's overall discriminatory power, the area under the curve (also known as the metric was utilized. Consequently, we discover that SVM has powerful discriminative power with an AUC of 0.91, but lower than all other models. RF, bagging, and our suggested model (AB) have perfect discriminative power, obtaining an AUC of 1.00. This suggests that it can successfully discriminate between positive and negative examples in our sample.

Fig. 20. An ROC curve for showing the performance of all classification model.

D. Model Evaluations

The model's particular classification accuracy is displayed in Table II. These models include several methods, each of which provides a different method for resolving categorization problems. The Proposed Moderated Ada-boost (AB), among them, performs well in testing, with an accuracy of around 98.14%. The Random Forest model retains an astonishing 97.82% accuracy during testing while having a training accuracy of 99.95%. By comparison, the accuracy of the Naive Bayes (NB) model is lower; it recorded an estimated 83.62% in training and a slightly better 83.53% in testing. With a 96.53% training accuracy and a promising 95.28% testing accuracy, the K Nearest Neighbor (KNN) approach performs admirably. Comparably, the Bagging Classifier (BC) model performs admirably, achieving a training accuracy of 99.67% and testing accuracy of 97.52%. The Random Forest model achieves a balanced accuracy of 99.95% in training and a little lower 97.82% in testing, placing it in close alignment with the Proposed Moderated Ada-boost (AB) model. However, even if

the Bagging Classifier performs better in training than other models, it falls well short in testing, an accomplishment that has already been discussed. This vast amount of data helps choose the best model for a given classification assignment by illuminating the strengths and weaknesses of each method. So our Proposed Moderated Ada-boost(AB), provides the highest accuracy among all the applying models.

TABLE II. ACCURACY OF DIFFERENT TYPES OF EVALUATION METRICS

Metrics	Models								
	RF	LR	DT	SVM	NB	BG	ST	AB	KNN
Train Acc	99.95	88.50	99.21	90.61	83.62	99.67	98.74	99.95	96.53
Test Acc	97.82	88.50	96.77	90.70	83.53	97.52	96.49	98.14	95.28
Precision	97.82	88.50	96.78	90.76	84.13	97.52	96.49	98.15	95.48
Recall	97.82	88.51	96.78	90.69	83.57	97.51	96.49	98.14	95.26
F1 Score	97.82	88.50	96.77	90.70	83.46	97.52	96.49	98.14	95.27

Fig. 20 compares the achievement of binary classification approaches that determine whether or not an individual has diabetes in their body using a roc curve. It therefore becomes simple to determine which model is operating at peak efficiency. After comparing ten predictive models at every level, we stumbled upon the following models: Random Forest, Bagging, and Proposed model named Moderated Ada-boost(AB), which perform exceedingly well. Their AUC of 1.00 implies they can successfully distinguish between favorable and adverse occurrences in our dataset. Stacking and Ann come next. According to the basis of our data, nevertheless, the Bayesian classifier achieved an adequate degree of unlawful power with an AUC of 0.92.

V. CONCLUSION AND FUTURE WORK

As a result, a deeper understanding of the opportunities and challenges through enhanced methodology, ethical considerations, and methodological integration will be possible. This research project, which makes use of the “Diabetes_Prediction” dataset, wraps up. Optimization came after the preprocessing-based quality check of the data. Advanced algorithms such as Random Forest (RF), Logistic Regression (LR), Decision Tree (DT), Support Vector Machine (SVM), Knearest Neighbors (KNN), Naive Bayes (NB), Stacking Classifiers (ST), Bagging Classifier (BG), and Moderated Ada-boost(AB) were utilized in the development of diabetes detection models. The appropriate assessment of measures like accuracy, precision, loss, and F1 score to get the intended performance determines how effective this strategy is. Throughout every phase of this research, there were ethical requirements to maintain confidentiality and handle patient data responsibly. The difficulties in interpreting imbalanced datasets provide new avenues for investigation and creativity. In the end, diabetes diagnosis and machine learning can advance sustainable healthcare, empower patients, and enhance the delivery of medical care.

The application of deep learning and machine learning techniques brings up several possibilities for further research and development in the precise diagnosis of diabetes. Here are a few potential prospects in the future:

- Application to other diseases: Other diseases can be diagnosed using the methods that were developed and

accepted for the diagnosis of diabetes. By identifying different human disorders, one may play a special role in the healthcare industry.

- Combining Multiple Data Modes: This model was created taking into account the various physical circumstances that exist among individuals. Further advancements in healthcare might be made feasible by the collecting and integration of diverse physical condition data from several sensors using IOT devices.
- Real-Time Disease Monitoring: Creating technologies that allow patients to simply keep updated about their physical health in real-time. and can thus receive immediate alerts.
- Mobile and Web Applications: Creating user-friendly mobile and web applications that allow patients to create disease reports by entering details about their physical conditions and offering a real-time, graphical user interface that offers management recommendations for diseases.
- Disease prognosis and early warning system: The development of prediction models that can anticipate disease outbreaks based on environmental and historical data is necessary for disease prognosis and early warning systems.
- Patient-doctor communication: If the patient shares information about their physical state, the doctor can use that knowledge to prescribe actions that will help the condition, allowing the patient to take control of their own care.

All things considered, these projects offer a promising direction for further study and development to improve diabetic illness detection techniques and their usefulness.

ACKNOWLEDGMENT

We would like to express our heartfelt gratitude to the almighty Allah who offered our family and us kind care throughout this journey. Also, we wish to express our sincere thanks to our guide, Most. Jannatul Ferdous, Assistant Professor, Department of Computer Science and Engineering for allowing us to work under her on the project. We truly appreciate and value her esteemed guidance and encouragement from the beginning to the end of this project. We are extremely grateful to her. We want to thank to all our teachers for providing a solid background for our studies and research thereafter. They have been a great source of inspiration to us and we thank them from the bottom of my heart. We also want to thank our parents, who taught us the value of hard work by their example. We would like to share this moment of happiness with our parents. They rendered us enormous support during the whole tenure of our stay at Bangladesh University of Business Technology (BUBT). Finally, we are grateful to all our faculty members of the CSE department, BUBT, for making us compatible to complete this research work with the proper guidance and support throughout the last four years.

Adaptive Learning Model for Detecting Wheat Diseases

Mohammed Abdalla, Osama Mohamed, Elshaimaa M. Azmi
Faculty of Computers and Artificial
Intelligence, Beni-Suef University, Egypt

Abstract—Nowadays, the wheat plant has been considered a crucial source of protein, energy, and micronutrients for people. The motivation behind this study comes from how to increase the wheat crop growth and prevent wheat diseases as this plant plays a significant impact on food security all over the world. Wheat plant diseases can be divided into fungal, bacterial, viral, nematode, insect pests, physiological and genetic anomalies, and mineral and environmental stress. Digital images containing the wheat plant disease are collected from different public sources like Kaggle and GitHub. In this study, an adaptive deep-learning model is developed to classify and detect various types of wheat diseases collected digitally in an efficient accurate manner. The dataset is split into two sets: approximately 80% of the data (8,946 images) for the training set and 20% (2,259 images) for the validation set. The training set is composed of 1445, 1478, 1557, 1510, 1424, and 1532 images of healthy, leaf rust, powdery mildew, septoria, stem rust, and stripe rust while the validation set contains 357, 360, 404, 402, 353 and 383 images respectively. The suggested method achieved 97.47% validation accuracy on the training set of images and a testing accuracy of 98.42% on the testing set. This study offers a method of training for the classification and detection of wheat diseases using a mix of recently established pre-trained convolutional neural networks (CNN), DenseNet, ResNet, and EfficientNet integrated with the one-fit cycle policy. In comparison to the current state of the art, the proposed model is accurate and efficient.

I. INTRODUCTION

Recently, there have been many production and economic losses around the world due to several agricultural crop diseases. Indeed, the wheat plant is one of the primary crops grown worldwide and a major source of food for humans, considering that it is the second largest crop in the world, providing 19% of people's calorie intake [1], [2]. In study [3], the authors emphasized that between 26 to 30 percent of the world's yearly wheat crop is lost to wheat diseases. Additionally, they mentioned that wheat disease losses can account for up to 70% of the wheat output if plant protection technologies are not used to manage fields.

Indeed, this paper is motivated by the desire to handle and detect wheat disease which can lead to high crop growth increase by using deep learning techniques. This paper demonstrated how deep learning ideas in artificial intelligence and computer vision have become a potential remedy for a variety of issues in agriculture. Convolution neural networks (CNN) have recently studied the use of digital imagery for autonomous disease detection in crops. By using a convolutional

neural network (CNN), the characteristics and features will be learned automatically rather than by human presence, and this will save time, and costs and help the farmer take quick action to treat the wheat disease in the early stage. CNNs apply several convolutions to extract important features from images [4], [5], [6], [7], [8], [9].

This paper addressed only the fungal wheat diseases which include the following: Powdery Mildew, Leaf Rust, Stem Rust, Stripe Rust, and Septoria. Table I is a summarized table of discussed wheat fungal diseases, their pathogens with scientific names, and the visual symptoms observed on infected plants. This table is designed to provide a quick reference for readers interested in wheat pathology.

This paper proposes a revolutionary model that utilizes the transfer learning concept rather than training CNN from scratch which requires a massive amount of data and robust computer hardware (GPUs) to be trained. A CNN model is trained on a sizable dataset to become a pre-trained model in the proposed method. Next, learned features by this pre-trained model are transferred to the new model. After that, the fit-one-cycle policy technique is used to adjust deep learning models' hyperparameters. Tuning CNN hyperparameters is a challenge because it requires more time and experience to tune them. A fit-one-cycle policy shortens the training period while enhancing performance[4].

1) *Contributions*: The following is a summary of this paper's significant contributions:

- We develop a deep learning model that identifies wheat plant fungi diseases with the best accuracy achievement.
- The proposed model utilizes a real dataset collected from various sources which contain five types of wheat fungi diseases and healthy ones.
- The proposed model handles the data imbalance common issue which is a known issue in several deep learning techniques by using a robust data augmentation technique.
- A detailed comparison between different CNN pre-trained models applied on the real dataset to demonstrate the performance differences, evaluating the generalization ability and training error of these models.
- Finally, the proposed model employs the fit-one-cycle policy method which automates hyperparameter learning to select the best value in the learning

TABLE I. OVERVIEW OF WHEAT FUNGAL DISEASES

Disease Name	Scientific Name	Visual Symptoms on Wheat Plants
Powdery Mildew	Blumeria graminis f.sp. tritici	White, powdery spots on leaves and stems; can lead to yellowing and drying of the tissue.
Leaf Rust	Puccinia triticina	Orange-red pustules on leaves and stems; leads to premature leaf senescence and dropping.
Stem Rust	Puccinia graminis f.sp. tritici	Large, brick-red pustules on stems and leaves; severely infected plants may produce less grain.
Stripe Rust	Puccinia striiformis f.sp. tritici	Yellow-orange stripes or streaks on leaves; can cause significant yield loss.
Septoria	Zymoseptoria tritici (formerly Septoria tritici)	Brown spots with yellow halos on leaves; spots often coalesce causing large areas of dead tissue.

process. This leads to high-performance achievement and optimal training time.

2) *Roadmap*: Following is the breakdown of the remaining sections: Section II discusses some related work and previous studies in this domain. Section III describes the proposed model and a detailed description of the work methodology. Presentation of the experimental findings and analyses in Section IV. Finally, the paper is concluded in Section V.

II. BACKGROUND

According to the study in [10], fungal, bacterial, viral, nematode, insect pests, physiologic and genetic abnormalities, and mineral and environmental stress are some of the several categories of crop pathogens. These pathogens can lead to damage to any part of the plant whether above or below the ground. Indeed, the major challenge is to identify symptoms and know when and how to effectively control diseases. For this reason, diagnosis of wheat diseases and managing the spread of disease in the early stage is essential for producing healthy wheat products and improvement of wheat yield and quality. Indeed, there is another notable challenge which is to diagnose wheat disease the expert or farmer depends on observing the symptoms of the disease manually, so it takes more time and cost to diagnose a large space and treat the disease. The accuracy of the manual prediction depends upon the experience and knowledge of the person so the unavailability of experts can obstruct the accurate diagnosis and treatment of the diseases in the early stages [11].

One of the risky diseases infecting the wheat yield is fungi diseases. The fungus diseases include powdery mildew, rust, and septoria of the leaves and ears [12]. Fungi indeed represent a separate kingdom of life, distinct for their unique biological and ecological characteristics beyond the absence of photosynthesis. This kingdom encompasses a diverse range of organisms, including molds, yeasts, and mushrooms, which play crucial roles in natural ecosystems and have significant implications for agriculture. The fungi can develop in a variety of ways, including from seeds or soil, or they can be spread by wind, water (either rain or irrigated), and other insects and animals. The overwatering of the host plant region, the host's weak density, and the ambient temperature all affect the fungal infection. Additionally, the fungi did not always destroy the entire crop but rather affected its growth, and the interplay between diseased and healthy plants determines how quickly the disease spreads [13].

Furthermore, there is another risky disease infecting the wheat yield which is Wheat rust disease. This disease can be divided into three rust categories: leaf, stem, and stripe. Indeed, rust diseases can be distinguished from each other based on some symptoms like the color, size, and arrangement of blisters on the plant surface and the plant part that is affected [14]. The rust diseases can be described as follows:

- Small, orangish-brown spots on leaves are symptoms of the disease leaf rust. The leaf sheath, which stretches from the base of the leaf blade to the stem node, can develop round or oval lesions, which are most frequently found on leaves.
- Stem rust disease is characterized by reddish-brown lesions that are oval and extended with tattered edges clearly, on leaves, leaf sheaths, and stems, Stem rust creates lesions that are more extensive than those caused by leaf rust.
- Stripe rust disease is most prevalent on leaves, and it produces yellow blister-like lesions that are grouped in stripes.

Additionally, one of the fungal diseases that infect wheat yield is Powdery mildew which is caused by the fungus *Blumeria graminis*, and it is most commonly overwinters. Powdery mildew is characterized by white to gray lesions on leaves, and leaf sheaths, It has several quick life cycles over a growing season and, once established, can be quite challenging to control. Septoria is considered a fungal disease that causes tan that is extended on wheat leaves. Although the degree of yellowing varies between kinds, lesions may have a yellow edge [15], [16].

Fig. 1 describes the five types of wheat fungi disease.

III. RELATED WORK

This section describes earlier research using deep learning and machine learning methods to evaluate, segment, and categorize illnesses of wheat crops using digital images.

The prior work in this direction may be divided into three categories: segmentation techniques for Wheat Crop disease, deep learning models to classify Wheat Crop diseases, and machine learning models to classify Wheat Crop diseases.

Fig. 1. Examples of wheat fungi diseases.

A. Deep Learning Models to Classify Wheat Crop Diseases from Digital Images

Overall, this section describes the deep learning methods, techniques, and approaches that are proposed to classify the different Wheat diseases from digital images.

In research [17], the classification of Powdery Mildew Wheat Disease was offered by the authors using 450 wheat photos that were gathered from primary (using a camera) and secondary (websites) sources. They used a normalization technique for data preprocessing, and The preprocessed normalized images were input to CNN achieving an accuracy of 89.9% for Powdery Mildew wheat disease. Next, the pre-trained model is applied to the CIAGR pictures dataset using the transfer learning technique, and it achieves 86.5 percent classification accuracy.

In research [18], the authors demonstrated a brand-new deep-learning model that has been trained to categorize 10 different wheat illnesses. The model outperforms two well-known pre-trained deep learning models, VGG16 and RESNET50, in terms of testing accuracy, with a score of 97.88%.

In [19], using 2000 photos of wheat plants for training and testing, the authors presented a Deep Convolutional Neural Network (DCNN) to classify Wheat Rust illnesses. This DCNN obtains an accuracy of 97.16% for wheat rust diseases.

In research [20], the authors presented multi-task and the pre-trained model VGG16 to distinguish between two types of wheat leaf diseases and three types of rice leaf diseases. The multi-task learning method is *alternate learning*. The idea of *alternate learning* makes use of various data sets, each of which has a distinct objective. Mutual training is used to train each job within an epoch, and each time, the parameters of the common layer are modified. Data augmentation is necessary to increase the variety because the data sets for wheat leaf disease and rice leaf disease are both modest and independently collected. For rice leaf diseases, the model's accuracy is 97.22 percent, and for wheat leaf diseases, it's 98.75 percent.

In study [21], the authors described different CNN Models such as ResNet50, DenseNet121, MobileNet, and MobileNetV2 to classify four classes of wheat images: (1) tan spot, (2) fusarium head blight, (3) stem rust, and healthy wheat. They applied Data augmentation to expand the dataset. The maximum accuracy of ResNet50 is 98%.

In study [22], based on the CGIAR dataset, the authors presented the VGG16 model to classify three types of wheat rust diseases: stem rust, leaf rust, and healthy wheat. With an initial learning rate ranging from 0.01 to 0.0001, the suggested model has a classification accuracy of 99.54 percent during training and 77.14 percent during validation on 80 epochs. The authors explain that even though the model had acceptable training accuracy, classifying stem and leaf rust was not appropriate since certain photos in this dataset contained several diseases, which meant that one image comprised the characteristics of both leaf and stem rust.

In study [23], the authors suggested a brand-new CNN model called *CerealConv* that is trained using a dataset of wheat photos captured in actual growth conditions and divided into five categories: "healthy," "yellow rust," "brown rust," "powdery mildew," and "Septoria leaf blotch." With batch normalization, maximum pooling, and dropout, the *CerealConv's* 13 convolutional layers were able to achieve an accuracy of 97.05%. Four pre-trained networks were used in their experiments: MobileNet, InceptionV3, VGG16, and Xception. On a portion of the dataset's photos, they performed tests against experienced pathologists. In conclusion, the model produced an accuracy score that was 2% greater than that of the top pathologist. Finally, they employed image masks to demonstrate that the model was generating its classifications using the right data.

In study [24], to automatically identify Wheat rusts, the authors presented the EfficientNet model. They created a dataset known as WheatRust21 that included 6556 pictures of healthy and three different types of Wheat rust infections. The EfficientNet-B4 model has a testing accuracy of 99.35% even though they tried many CNN-based models.

In study [25], five fungal diseases of wheat crops, including (1) leaf rust, (2) stem rust, (3) yellow rust, (4) powdery mildew, and (5) septoria, were proposed by the authors. These diseases may be recognized both individually and in cases of multiple infections. In this work, duplicate photos were removed from the training data using the image hashing algorithm. The recognition process makes use of the EfficientNet pre-trained model. The accuracy of the model is (0.942). The recognition strategy was created as a bot for Telegram.

In study [26], for their UAV to be able to recognize three different forms of wheat leaf diseases, the authors developed a two-stage classifier. They first found individual plant leaves using an object detection model, such as the

YOLOV4 or EfficientDet models, and then cropped the image using bounding box coordinates. The cropped photos are then fed into the classification network in the second stage, which will identify the type of disease on the leaf. The EfficientNet-B0 model performs with an accuracy of 99.72 percent, outperforming the YOLOV4-tiny model in object detection.

B. Machine Learning Models to Classify Wheat Crop Diseases from Digital Images

Generally, this section presents the different machine learning techniques that are proposed to classify and analyze the different Wheat diseases from digital images.

In research [27], by combining spectral vegetation indices data from spectrum sensors in Random Forest models, the authors proposed a high-throughput plant phenotyping technique to automate disease scoring of yellow rust in a large plant breeding field trial.

In study [28], for diagnosing wheat leaf diseases and their severity, the authors suggested a method based on Elliptic Maxima Margins Criteria metric training learning. They used information on wheat leaf diseases such as powdery mildew and stripe rust. The gradient rise approach and the greatest margin criteria are used to alter the feature space and decrease feature correlation before creating the elliptical metric matrices. Additionally, using photographs of wheat leaves, the Otsu method is utilized to separate the disease spots according to the characteristics of disease distribution. Their technique outperforms other learning algorithms and conventional support vector machines. They were 94.16 percent accurate.

In research [29], the effectiveness of various Machine Learning and Deep Learning algorithms for identifying plant disease was compared by the authors. In terms of disease prediction accuracy, Deep Learning models surpass Machine Learning models as follows: The following models were successful: VGG-16, Inception-v3, VGG-19, SVM, SGD, and RF (89.5, 89, 87.4, 87.5, 86.5, and 76.8%, respectively). According to the findings, VGG-16 has the highest classification accuracy, while random forest has the lowest.

In research [30], the authors suggested using machine learning to identify the illnesses that cause brown-and-yellow streaks in wheat harvests. By shrinking and segmenting the data, this study pre-processed it. Additionally, to extract elements including shape, texture, and color, they used three feature descriptors: Histogram of Oriented Gradient (HOG), Local Binary Pattern (LBP), and Hue- Moment (HM). They used a number of different models, but the RFC performance delivered the best results when compared to the other models, which had an accuracy rate of 99.8%. A two-stage classifier was also suggested by the study to help the UAV detect plant diseases. After cropping the image with the bounding box coordinates and finding individual plant leaves using an object detection network, the model then utilizes a second classifier to identify the type of illness on the leaf.

In research [31], the authors used classification methods (Artificial Neural Network, Support Vector Machine (SVM), and k-Nearest Neighbor (k-NN) are trained based on morphological features like shape and size to identify wheat crop seed that

was derived from the singleton wheat kernel images to identify wheat seeds from three different types: (1) Canadian, (2) Rosa, and (3) Kama. The k-NN classifier outperformed the other two classifiers, producing the greatest classification accuracy of 94.23 percent.

C. Segmentation Methods for Wheat Crop Diseases

This section describes several segmentation methods that are used to extract interest regions from digital images and generate segmented data.

In study [32], the authors demonstrated a deep learning-based semantic segmentation method for Wheat Stripe Rust pictures. They tested four different models: PSPNet, DeepLabv3, U-Net, and Octave-UNet. The Octave-UNet model produced the greatest results of all the models; its accuracy was 96.06 percent, its mean pixel accuracy was 94.58 percent, and its mean intersection over a union was 83.44 percent. The original images were roughly 1000 x 4000 pixels; to avoid significant information being lost due to direct resizing, each original image was divided into several 512 x 512 pixels local images to increase the amount of data, followed by filtering images. They divided the image into three categories: (1) background, (2) leaf, and (3) spore.

In study [33], by using a variety of segmentation techniques, such as Watershed, Grab Cut, and U2-Net, the authors explored the classification of wheat stripe rust into three infection kinds, including healthy, resistant, and susceptible. Multiple segmented datasets are created using these techniques, and the region of interest is then extracted by cropping the segmented images. Then segmented data is produced using the pre-trained ResNet-18 model. On the U2-Net-segmented dataset, the maximum classification accuracy (96.196%) is attained.

In study [34], the authors suggested a Res-capsule network, which was designed to be a segmentation model by replacing the AveragePooling layer of the upgraded ResNet34 with a Capsule network, which can preserve deeper semantic information. This network can segment wheat plantation rows that were photographed by a UAV. They create a threshold after the convolution operation, which they refer to as threshold convolution, in addition to decreasing redundant features and improving effective features. By extracting the textural features (TF), grayscale features (GF), and hue saturation value features (HSV), they increase the accuracy of segmentation. They then input the three extracted features into their enhanced ResNet34.

Table II shows the main characteristics of the reviewed work.

D. Summary

To sum up, this paper differentiates itself from the previous studies by the following: (1) we employed the one-fit cycle to adapt the hyperparameters in an efficient manner which improved the learning process, (2) we studied major types of wheat diseases, and investigated the collected images from different data sources which make our study comprehensive, (3) we prevented the imbalance data issue from occurring in the model developed by introducing a data augmentation approach to fix this, (4) we experimented a large number of different types of deep learning models, and compared them

from different perspectives like; accuracy, precision, and recall.

IV. MATERIALS AND METHODS

This section presents the methodology and phase for the proposed solution.

A. Datasets

This study categorized the images that were gathered into healthy and five different forms of fungal infections, including powdery mildew, septoria, leaf rust, stem rust, and yellow rust types of wheat rust disease.

The following are the many image sources:

- Five fungal diseases of wheat crops are included in the dataset (leaf rust, stem rust, yellow (stripe) rust, powdery mildew, and septoria), both individually and when several diseases are present [35].
- The dataset contains images of yellow-rust(stripe rust), brown-rust (leaf rust) wheat leaf diseases, and healthy wheat leaf[36].
- Images from the CGIAR (Computer Vision for Crop Disease) dataset are included. This collection includes pictures of wheat leaf diseases like stem rust and leaf rust as well as healthy ones.[37], [38].
- There is a wheat leaf dataset on Kaggle that includes pictures of both diseased and healthy wheat leaves, including those with stripe rust and septoria [39].

Table III lists the classes that are gleaned from various sources, along with the number of images gleaned from each source.

B. Data Preprocessing

This phase is a major step in building the proposed learning model. This step includes several tasks which are fundamentals to build a learning model with high accuracy and best performance. These tasks include: data ingest, data cleaning, and data standardization. The data ingest means collecting raw data from diverse sources for further processing. The data clean means removing inconsistencies from collected datasets, handling missing values, and addressing any quality issues. Finally, data standardization means transforming data into a consistent format for seamless processing and Organizing and structuring data for effective feature engineering and model development.

A crucial stage in a model pipeline to find diseases is image pre-processing, as images could contain noise or different sizes. Because the images in the collected dataset come from many sources and have varying sizes and formats, all of the images were initially reduced to 224×224 pixels (resolution) and saved as (.jpg).

There are some images have The height is greater than the width or vice versa, so when resizing this image, the image will expand, and maybe some important features will be lost like the leaf shape which may cause low accuracy, so adding the black border to the image may save the image presentation Fig.

2 describes these stages. Some images of the collected dataset have noises that cause the loss of some important features, contain human hands, or have multiple diseases in the same image which impacts the model accuracy, so the dataset was filtered from these images which give high accuracy.

1) *Data augmentation*: Because there are more images in certain classes than others (some classes have extremely few occurrences compared to other classes), the suggested dataset is unbalanced. The deep-learning models' performance would be impacted and overfitting would result from this mismatch in the amount of photos in the classes. When a model performs well on the training dataset but poorly on new data, it is said to be overfit. Consequently, a data augmentation strategy is applied to avoid this issue. Data augmentation is the process of creating additional samples from existing datasets by modifying the original images, which enlarges the dataset or increases its volume. To create new photos for the classes of fewer photographs, transformation techniques such as rotation (90 degrees), flipping, and zooming between [0.5,1.5] range were applied.

After pre-processing (filtering) the dataset and adding further data, the suggested dataset has a total of (11,205) images. The proposed dataset was divided into two sets: a training set with about 80% of the data (8,946 photos) and a validation set with around 20% (2,259 images). The validation set includes 357, 360, 404, 402, 353, and 383 images of healthy, leaf rust, powdery mildew, septoria, stem rust, and stripe rust while the training set consists of 1445, 1478, 1557, 1510, 1424, and 1532 images of these conditions.

The number of images in the suggested dataset after pre-processing and data augmentation is displayed in Table IV

C. Proposed Model

1) *Convolutional Neural Network (CNN)*: CNN is frequently utilized in computer vision applications like segmentation, pattern identification, and classification issues. CNN reduces the number of neurons and achieves better learning. Indeed, CNN recognizes the content of the images in three-dimensional volume without converting it to a one-dimensional vector such as multi-layer perceptron(MLP) which becomes computationally expensive because of the huge number of neurons that are needed to recognize small images.

The convolutional layer, activation layer, and pooling layer are the three layers that make up a CNN in general. These layers primarily extract characteristics, which are later used for classification by fully connected layers.

- One of the components of a CNN, the *convolutional layer*, is used to extract significant information from an image using a convolution process. One value is produced by the convolution process, which is a dot product between two matrices. Every input image is represented by a matrix of pixel values and another matrix called the filter matrix. The filter matrix is also known as a kernel, or a filter made up of learnable weight values. The kernel is a small matrix, and it is sliding over the input matrix by one pixel which creates a new matrix called a feature map or activation map that represents the extracted features. Utilizing many

filters in the convolutional layer, numerous feature maps are produced by extracting various features from the image. The starting values of the filter metrics are chosen at random, then backpropagation is used to learn the best values for the filter matrix, which may then be used to extract the most crucial characteristics from the photos. After the convolutional layers, an activation layer is added to use an activation function to introduce non-linearity to the output.

dimension. Because of this, the *pooling procedure* is used to minimize the size of feature maps, maintaining only the pertinent information and deepening feature maps to produce a highly compressed feature vector in the end. Different pooling operations exist, including average and maximum pooling. When using maximum pooling, the filter is slid over the matrix and the maximum value from the slid filter is used.

- The feature maps are created following the convolution layer. The feature maps have an excessively wide
- After collecting the features from the convolution network, *fully connected* layers are built to classify the image and train the network. A 2D tensor

Fig. 2. Example of images with different height and width.

is created by flattening the final feature map. In multiclass situations, the softmax activation function transforms the neural network's outputs into a vector of probabilities, each probability belonging to a certain class, and deep feedforward networks for classification utilizing cross-entropy loss.

2) *Transfer Learning*: Transfer learning is a method where a model is created and trained on one task, then utilized as the basis for another task [40].

This method transfers the weights that a network has learned at one task to another rather than starting the learning process from scratch by first training a base model on a particular task or dataset, and then applying the knowledge of an already trained model to a different task or dataset. As a result, this technique shortens the time needed to train such models, which can be laborious.

In this study, pre-trained CNN models EfficientNetB0, ResNet152, and DenseNet161 were trained.

- *EfficientNet* is a CNN model that is an efficient computationally and achieved state of art results on the ImageNet dataset. the core idea of this model is Model scaling. Model scaling is about scaling the existing model depth-wise, width-wise, or scaling input image resolution to get better results. Model scaling is used to enhance the model's performance. The most common is depth-wise scaling. To effectively scale up the model, EfficientNet employs a method called compound coefficient. It equally scales each dimension using a set of predetermined scaling factors. The architecture makes use of a larger MobileNet-V2-like mobile inverted bottleneck convolution. EfficientNet's creators created seven models with varied dimensionalities. The baseline network of the EfficientNet family is EfficientNetB0 [41].
- Building CNN deeper by increasing the number of layers may cause a common problem called the Vanishing/Exploding gradient. The Vanishing/Exploding gradient causes the gradient to become 0 or too large a value, which causes an increase in training and test error rate. So, to solve the problem of the vanishing/exploding gradient, the *ResNet* [42] convolutional neural network model was introduced which is based on the concept called

Residual Blocks that used a technique called skip connections. The skip connection takes the output from one layer and adds it to others by skipping some levels in between; regularization will skip any layers that have poor performance. The network can now reach considerably deeper thanks to this. For image recognition and classification, the model took home the ILSVRC ImageNet-2015 and MS COCO 2015 awards.

- *DenseNet* is used to solve the vanishing while going deeper but at the same time avoiding the vanishing problem by using shorter connections between the layers. ResNet and DenseNet vary in that ResNet uses summation to connect all previous feature maps, whereas DenseNet concatenates them all. Each layer in DenseNet obtains inputs from all the previous layers and passes on its output to all the layers that will come after it. DenseNet consists of Dense blocks that are composed of composition layers that contain batch normalization, RELU activation function, and 3*3 conv layer these Blocks are connected by 1x1 Conv followed by 2x2 average pooling layers that are used as the transition layers between blocks. DenseNet achieved the greatest classification performance in 2017 on ImageNet and CIFAR-10 datasets [43], [44].

3) *One Fit policy cycle method*: CNN hyperparameters are parameters that are used to regulate the model's behavior. It is crucial to improve the performance of the model. The *Learning Rate* is one of the hyperparameters, and it may be the most significant hyperparameter in deep learning.

How many gradients will be back-propagated will depend on the learning rate. The model slowly diverges when the learning rate is high, but it quickly converges when it is low. To find the right learning rate, the learning rate must be tweaked, which takes some time and effort.

The typical approach is to experiment with various learning rates and select the one that results in the minimum loss value, allowing the model to swiftly adapt to the situation. In study [45], this study established a new method called fit-one-cycle which is a way of tuning the learning rate.

After each mini-batch, the learning rate should be increased from a low starting point. The formulae below in Fig. 3 update it following each mini-batch:

$$\begin{aligned} \text{Max_lr} &= \text{init_lr} * q^n \\ q &= \left(\frac{\text{Max_lr}}{\text{init_lr}} \right)^{\frac{1}{n}} \\ \text{lr}_i &= \text{init_lr} * \left(\frac{\text{Max_lr}}{\text{init_lr}} \right)^{\frac{i}{n}} \end{aligned}$$

Fig. 3. Maximum learning rate and lower learning rate.

Max_lr and *Init_lr* stand for the maximum learning rate and lower learning rate, respectively, where *n* is the number of iterations. The test range's initial value is the lower learning rate. Let *q* be the agent that raises the learning rate after each mini-batch. The research also suggests that for a full run, the learning rate should cycle between the lower bound and the higher bound. An iterative process where we move from a lower bound learning rate to a higher bound and then back to the lower bound is called a cycle.

To conclude, this method saves the time and effort of running multiple full cycles with different momentum values. Additionally, it yields more stable results and requires fewer epochs to train our model to completion. This study [46] confirms the improvement in validation accuracy when comparing the naive learning rate policy with the one-cycle policy. Besides that, using this strategy avoids having to conduct numerous full cycles with various momentum levels. Additionally, it produces more consistent results and takes fewer training epochs to fully train our model. The improvement in validation accuracy when contrasting the one-cycle policy with the naive learning rate policy is supported by the study [46].

V. RESULTS AND DISCUSSION

Five different models were used in the experiments presented in this section, two of which are extensions of EfficientNet (EfficientNetB0 and EfficientNetB1), two of which are extensions of DenseNet (DenseNet161 and DenseNet169), and one of which is ResNet152. These models were trained using data from five different types of fungal infections as well as healthy leaves from wheat. A training set of 8,946 photos and a validation set of 2,259 images make up this dataset, which is used to test and validate procedures.

A. Experimental Settings

This paper employed the *Fast ai framework*[47] in building learning models. It is a high-level framework over Pytorch for training machine learning models and achieving state-of-the-art performance. This framework is mostly employed for image classification, object recognition, and image segmentation. It offers faster computations than rivals and comes with data purification widgets, providing a very user-friendly workflow and making debugging easier. Additionally, Google Colab was used to conduct the trials.

B. Evaluation Criteria

Along with the receiver operating characteristic (ROC) curve and the area under the curve (AUC), the accuracy, precision, and recall/sensitivity are the performance measures chosen to assess and analyze the performance of the created model.

The performance of classification models is evaluated using a matrix called the confusion matrix. The True positive (TP), True negative (TN), False positive (FP), and False negative (FN) factors are computed for each class using the confusion matrix. The metrics for evaluation can be summed up as follows:

- The percentage of all samples that were properly identified by the classifier is used to determine the *accuracy* number.
- The true positives are divided by the total samples that were projected to be positive (TP + FP) to determine the *precision* value.
- The true positives are divided by samples that should be predicted as positive (TP, FN) to get the *recall* value.
- The *F1-score* is regarded as the harmonic average of recall and precision.
- By averaging the metrics that are obtained for each class, the *Macro-F1* (*macro-averaged F1-score*) is calculated.
- A graphical depiction called the *ROC curve* (receiver operating characteristic curve) shows how well a classification model performs at every classification threshold. The True Positive Rate (TPR), which stands for the recall measure, and the False Positive Rate (FPR), are plotted on this curve at various categorization levels. AUC (Area Under the ROC Curve), a sorting-based algorithm, is used to calculate the points in a ROC curve. The probability that a model would rank a random positive instance higher than a random negative instance is shown by the AUC, which offers an overall measure of performance overall potential classification thresholds.

The following section describes the evaluation of these parameters against the learning model.

C. Accuracy and Loss Evaluation Results

In this study, the following five models are evaluated EfficientNetB0, EfficientNetB1, DenseNet161, DenseNet169, and ResNet152 across several experiments. As a result of experiments, it is discovered that these models achieved 97.37%, 96.84%, 98.42%, 97.89%, and 95.2% classification accuracy in the validation stage and 94.15%, 93.86%, 93.76%, 93.33%, and 93.10% in the testing stage, respectively.

In conclusion, the DenseNet161 model had the best validation accuracy, at 98.42 percent, but EfficientNetB0 had the highest testing accuracy, at 94.15 percent, as opposed to DenseNet161, which had a testing accuracy of 93.76 percent. During the training and validation operations, the accuracy and loss plot curves are built as a function of epochs.

Fig. 4 shows the validation accuracy for each model.

Fig. 5 shows the loss through the training and validation process.

Table V demonstrates the validation accuracy, precision, and Recall values measured during the validation process and testing. These values are calculated over all classes for each model and the number of epochs.

Fig. 4. Validation accuracy.

Fig. 5. Validation loss.

TABLE V. ACCURACY, PRECISION, AND RECALL MEASURES OVER ALL CLASSES FOR EACH MODEL (SUMMARY)

Classifier	Accuracy	Recall	Precision
EfficientNetB0	97.37%	97.37%	97.53%
EfficientNetB1	96.84%	96.84%	97.11%
DenseNet161	98.42%	98.42%	98.48%
DenseNet169	97.89%	97.89%	97.97%
ResNet152	95.26%	95.26%	95.22%

D. Confusion Matrix Parmatters Evaluation Results

Indeed, the main role of the confusion matrix parameters is to show how the model detects instances correctly and the relatively incorrect classifications of the instances. This matrix identifies confusion between classes of datasets.

The relevant performance measures that have been calculated based on the confusion matrix are precision, Recall, F1-Score, and Macro average of each measure. These values are calculated for each class to determine how well the classifier can identify different classes.

True positive, True Negative, False positive, and False Negative are regarded as a one-vs-all problem in multi-class classification problems. As a result, the positive class is a certain class, while the negative class is every other class.

The evaluation of the confusion matrix parameters for each model is shown in Fig. 6. The graphic demonstrates that the EfficientNetB0 model correctly identified just two healthy samples as powdery mildew, but it incorrectly identified 12 samples as stripe rust, which is higher than other models did.

Fig. 7 presents the precision, recall, and f1-scores for models used in the experiment.

Fig. 8 describes the ROC curves for these models are shown. This demonstrates that both EfficientNetB0 and DenseNet161 had similar AUC for all the given classes except the healthy class EfficientNetB0 had the highest AUC of 100%. All models had the same AUC of 95% of the leaf rust class

except EfficientNetB1 had the lowest AUC of 94% but EfficientNetB1 had the highest AUC of 97% of the stripe rust class. DensNet169 and DensNet161 had similar for all the given classes except powdery mildew and septoria, DensNet161 AUC is higher. Also, ResNet152 had a similar AUC to DensNet161 except for stripe rust and powdery mildew, DensNet161's AUC is higher.

In this experiment, EfficientNetB0 is compared with the work of study [26], [33] by applying EfficientNetB0 on (leaf rust, stem rust, and healthy) classes from the proposed dataset in study [33] and on (leaf rust, stripe rust, and healthy) classes as [26]. The results concluded that EfficientNetB0 is a high-performer model with high accuracy.

E. Impact of applying fit-one-cycle policy Results

This experiment studied the impact of not applying the fit-one-cycle policy on accuracy scores. Table VI presents the accuracy results without using a fit-one-cycle policy. By comparing the results highlighted in Table V and the results presented in Table VI, the overall accuracy is decreased by 4% without applying a one-fit-cycle policy.

F. Summary

This study compared different CNN learning models to classify five wheat fungal diseases based on RGB images. This work uses three classes of diseases: stripe rust, leaf rust, and healthy, the dataset captured from [1]. Additionally, the CGIAR and wheat leaf datasets were captured from this study and used

Fig. 6. Confusion matrix of the models.

class	precision	Recall/Sensitivity	F1-Score
Healthy	0.98	0.98	0.98
Leaf rust	0.92	0.91	0.92
Powdery mildew	0.91	0.96	0.93
septoria	0.93	0.88	0.91
Stem rust	0.91	0.91	0.91
Stripe rust	0.97	0.97	0.97
average	0.94	0.94	0.94

Fig. 7. Recall, precision, and F1-score measured.

Fig. 8. ROC curve of the models.

TABLE VI. ACCURACY MEASURES OVER ALL CLASSES FOR EACH MODEL WITHOUT FIT-ONE-CYCLE

Classifier	Accuracy
EfficientNetB0	93.68%
EfficientNetB1	91.58%
DenseNet161	89.47%
DenseNet169	92.63%
ResNet152	95.26%

in this work[2]. The CGIAR contains three classes which are leaf rust, stem rust, and healthy, while the wheat leaf dataset contains (stripe rust, Septoria, and healthy). Moreover, Wheat Fungi Diseases (WFD2020) presented in [3] are used also in this work which contains classes of five types of wheat fungi diseases and healthy wheat leaf, but the number of images is small containing 2414 images through all classes of the dataset. Finally, in this work, the experimental dataset was collected from all the mentioned datasets and contains six classes of five types of wheat leaf fungal diseases and healthy ones.

In this work, there are five CNN pre-trained models constructed based on datasets collected from various sources. These models include: EfficientNetB0, EfficientNetB1, DenseNet161, DenseNet169, and ResNet152. This work employs the one-fit-cycle method to enhance the proposed models' accuracy and reduce the time needed to train

the models. Overall, the EfficientNetB0 and EfficientNetB1 achieved a high testing accuracy, however, DenseNet161 achieved a high validation accuracy.

VI. CONCLUSION

Eventually, to sum up, this paper discusses the different wheat diseases that can impact wheat crop growth and therefore will harm food security all over the world. Mainly, the paper describes how wheat disease can be detected and recognized efficiently. For this purpose, this paper employs convolutional neural network models as deep learning models. Moreover, this work compares different learning models such as ResNet, DensNet, and EfficientNet to select the best model that achieves the highest accuracy. Additionally, this study used a one-fit-policy method that automates the selection of the best value of hyperparameters, this led to a great performance achievement. Experimental evaluation for all

models performed on different real datasets collected from various. Experimental results proved that the EfficientNet learning model is an effective model more than ResNet and DensNet and the justification behind that is that EfficientNet needs fewer hyperparameters to train and learn than ResNet and DensNet.

Detecting Digital Image Forgeries with Copy-Move and Splicing Image Analysis using Deep Learning Techniques

Divya Prathana Timothy, Ajit Kumar Santra
School of Computer Science Engineering and Information Systems
Vellore Institute of Technology, Vellore, Tamil Nadu, India

Abstract—The proliferation of digitally altered images across social media platforms has escalated the urgency for robust image forgery detection systems. Traditional detection methodologies, while varied, often fall short in addressing the multifaceted nature of image forgeries in the digital landscape. Recognizing the need for advanced solutions, this paper introduces a novel deep-learning approach that leverages the architectural strengths of GNNs, CNNs, VGG16, MobileNet, and ResNet50. Our method uniquely integrates these architectures to effectively detect and analyze multiple types of image forgeries, including image splicing and copy-move forgeries. This approach is groundbreaking as it adapts these networks to focus on identifying discrepancies in the compression quality between forged and original image regions. By examining the differences between the original and compressed image versions, our model constructs a feature-rich representation, which is then analyzed by a tailored deep-learning network. This network has been enhanced by removing its original classifier and implementing a new one specifically designed for binary forgery classification. Very few researchers have explored the application of deep learning techniques in copy-move and splice image analysis for detecting digital image forgeries, making our work particularly significant. A comprehensive comparative analysis with pre-trained models underscores the superiority of our method, with the GNN model achieving an impressive accuracy of 98.54 percent on the CASIA V1 dataset. This not only sets a new benchmark in the field but also highlights the efficiency of our model, which benefits from reduced training parameters and accelerated training times.

Keywords—Copy-move; splicing; deep learning; image forgery detection

I. INTRODUCTION

In the digital age, the authenticity of photos shared on platforms like Facebook and Twitter has become a major concern. The manipulation of digital images poses a threat to the integrity of visual information, creating discrepancies from the original characteristics and features of the images. This kind of forgery often goes unnoticed and contributes to the spread of false news and misinformation. Advanced image tampering technologies like GNU, GIMP, and Adobe Photoshop have aggravated this problem [1], [2]. There are active and passive ways to overcome above-mentioned issues. Active detection uses means or median to implant a digital signature or message digest into an image during creation. The image's validity is verified by decrypting this data. However, passive detection methods modify an image's statistical features to verify its structure and content without leaving visual indications. Copy-move, splicing, and retouching forgeries are examples of

passive methods. Picture splicing and copy-move forgeries are highlighted in the former [3]. While image splicing connects two or more images, copy-move forgery copies a portion of an image within the same image. Due to the similar characteristics of duplicated pieces and different post-processing techniques like rotation and JPEG compression, copy-move forgeries are puzzling to identify. However, splicing forgeries incorporates pieces from several photos, needing extra processing to match the target image's visual features.

Traditional detection methods in this area use frequency domain attributes or statistical information to identify authentic and counterfeit pictures [4]. These approaches' principal drawback is the difficulty of determining the most important traits for counterfeit detection. Digital image forgery is a major problem in our digital era. Technological developments in manipulation need increasingly advanced approaches to recognize and battle picture forgeries.

Copy-move and splicing forgeries are particularly challenging to locate and identify [5]. Localization locates counterfeit portions in a picture, whereas forgery detection verifies its validity. Many methods have been developed to solve these issues separately [6]. These approaches must be tested for robustness, dependability, and correctness, especially in modelling structural changes caused by copy-move and splicing forgeries. Since most imaging equipment cannot contain signatures or watermarks to prove authenticity, passive or non-intrusive forgery detection methods are needed. These algorithms don't need picture content signatures or watermarks.

Deep learning (DL) has advanced the image forensics profession. Any DL model like a convolutional neural network (CNN) relies on feature extraction, where database size matters. In small database sizes, transfer learning such as AlexNet, MobileNet, VGGNet, and ResNet are effective. It applies information from a huge dataset like ImageNet to a new target domain. This method reduces training time and lets the model cope with fewer datasets. With these technologies, the fight against digital picture counterfeiting is growing more advanced, offering better digital authenticity [7]. The current landscape of digital image forensics lacks robust and comprehensive methods for simultaneously detecting both image splicing and copy-move forgeries.

The motivation behind this research is the vast number of manipulated images circulating daily online, making it difficult to verify their authenticity. From medical images to biometric data, nothing seems safe from manipulation nowadays. A

framework that not only identifies but also localizes the forgery in an image is needed.

This research significantly advances the field of image forensics by investigating DL models for accurate forgery localization and classification. Our study meticulously analyzes DL and transfer learning architectures, including Graph Neural Network (GNN), CNNs, VGG16, MobileNet, and ResNet50, specifically targeting copy-move and splicing image forgeries. The findings highlight the exceptional accuracy of the GNN model and illustrate the robust potential of these architectures in the domain of digital forensics.

Our suggested approach presents numerous enhancements compared to traditional detection methods. The following are the highlights of the paper's primary contribution:

- Focuses on a copy-move and splicing type of forgeries.
- Leverages the strengths of diverse architectures such as CNN, GNN and pre-trained models.
- Tailored deep learning network, specifically designed for binary forgery classification.
- Reduced training complexity by leveraging pre-trained architectures.

To articulate the structure and flow of our paper clearly, we have organized it into coherent, well-defined sections, each designed to progressively build upon the information presented. The paper begins with an introduction that establishes the significance of the research and outlines the challenges and innovations in image forgery detection (IFD). This is followed by a comprehensive literature review that situates our work within the broader academic discourse, identifying gaps that our research aims to fill. We then detail our novel methodologies, which introduce unique analytical techniques and leverage advanced DL models to address the complexities of image forgery. The experimental design section describes the dataset used and the parameters of our testing framework, ensuring reproducibility and clarity in our methods. Following this, the results and discussion section critically assesses the performance of the proposed models, providing a deep dive into the empirical evidence that supports our conclusions. Finally, the paper concludes with a summary of our findings and offers a forward-looking perspective on potential future research avenues and technological advancements in the field of IFD. Each section of the paper is integral to the narrative, contributing to a comprehensive and educative exposition tailored for both specialists and novices in the field.

II. RELATED WORK

In recent years, there has been progress in the detection of image forgeries, with several methods proposed by researchers. Traditionally, this field extracted handmade characteristics and classified them using feature matching to identify real and counterfeit pictures. While successful, these strategies lack flexibility and scalability.

Recently, researchers have tried to identify copy-move and splicing frauds concurrently. A new approach uses a fully convolutional network with multi-resolution hybrid features [8]. Tamper-guided dual self-attention module in this network distinguishes tampered regions from unaffected ones.

For pixel-level picture fraud detection, the hybrid features and semantic reinforcement network (HFSRNet) uses LSTM encoding-decoding [9]. Next, U-Net, a unique picture segmentation model with L2 regularization is used for IFD [10]. In another research double image compression was employed to train a model that could recognize both kinds of forgeries. These advances in picture fraud detection show a strong trend toward DL such as CNNs [11]. These approaches can identify and localize fabricated portions in photos, making them a more effective solution to digital image forging. As these technologies advance, they will help preserve digital pictures in forensic science, media, and other fields.

A multimodal approach was presented to identify splicing and copy-move forgeries using deep neural networks to classify and localize forgeries and part-based picture retrieval. This system utilizes InceptionV3 for feature extraction and the Nearest Neighbor Algorithm for donor and nearly duplicate picture retrieval. Error Level Analysis (ELA), VGG16, and VGG19 models were used on CNN in another unique way [12]. This approach employed pre-processing to collect pictures at a certain compression rate to train the model to categorize photos as legitimate or fake. These transfer learning-powered IFD advances improve digital picture forgery detection and localization. Pre-trained models and advanced algorithms improve accuracy and efficiency, creating a new benchmark in digital picture manipulation detection. As technology advances, these approaches will be developed, strengthening digital imaging fidelity in numerous sectors [13]. A different work utilized a CNN pre-trained on labelled pictures to extract features and train an SVM model [14]. This showed how CNNs and SVMs work together in feature extraction and classification. Mask R-CNN with the Sobel filter [15] improved forgery detection and localization by identifying gradients like genuine masks.

Another method [16] used image manipulation and pre-trained CNNs to classify pictures as legitimate or fake, improving transfer learning. It used ELA for image modification and pre-trained VGG-16 weights for CNN initialization. Although DL techniques have improved the IFD, very few research focused on the combination of copy-move and splicing forgeries. Moreover, the potential advantage of combining several DL and transfer learning techniques has been left unexplored.

It is crucial to delineate the boundaries of prior approaches used to identify photo fraud and explain how our proposed strategy differs to address the existing gaps in the ongoing discussion. Although feature matching and manual characteristic extraction are successful, they lack flexibility and can not handle the increasing complexity and volume of digital image alterations efficiently. While each solution is creative, they individually focus on either copy-move or splicing forgeries and do not possess the adaptability required to tackle emerging forms of digital fraud. Our research presents a comprehensive framework for analyzing copy-move and splicing forgeries, which have seldom been examined in conjunction. CNNs and transfer learning enhance forgery detection and localization by using advanced DL models, resulting in improved accuracy and dynamic capabilities. Our multimodal approach incorporates advanced algorithms such as the tamper-guided dual self-attention module and hybrid feature systems, resulting in enhancements over earlier methods. Enhancements enhance the accuracy of detection and augment the knowledge and

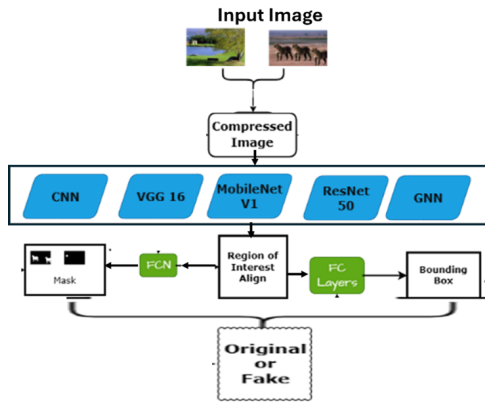

Fig. 1. Proposed frameworks.

skills in critical areas such as forensic science and media integrity. This succinct elucidation of the subject matter and our approach emphasizes our distinctive contributions to the detection of digital image counterfeiting.

III. PROPOSED METHODS

Our research presents an architectural framework that can precisely detect, identify, and assess the degree of forgeries to tackle the complex issues of copy-move and splicing manipulations in digital photos. With the use of sophisticated bounding boxes and semantic segmentation techniques, this novel method is specially designed to identify and accurately localize forged regions, guaranteeing that every pixel inside an area of concern is carefully classified. Unlike other systems, this one can identify areas that have been altered, but it can also determine the proportion of the image that has been altered, providing a numerical assessment of the degree of fabrication.

A digital image is fed into the model to begin the process, which is then followed by a reliable feature extraction stage. The next step is to identify possible regions of interest that could include faked or changed objects using the Region Proposal Network (RPN). To guarantee consistency in analysis, these selected regions which range in size to 128 pixels are standardized via Region of Interest (ROI) pooling. During the next detection stage, the system marks each object it finds as copied or spliced and uses exact bounding boxes to define the forged object. This stage is critical in identifying the type of counterfeit and offers a good understanding of the manipulation method used. Our strategy's last phase, segmentation, is especially creative. By creating a precise mask around the manipulated object, it successfully separates the manipulated region from the original image. The suggested design determines the percentage of the image area impacted by forgery to measure the various levels of forgery. To do this, one must analyze the segmentation masks, which are binary pictures in which the unaffected black backdrop is marked as false, and the fabricated portions are marked as true white. We determine the percentage of the image that has been compromised by forgery by counting the number of white pixels inside these masks.

This technique, which aggregates the white pixel count across all masks, enables reliable assessment even in pho-

tos containing several forged areas. The architecture is demonstrated in Fig. 1, which highlights our system's all-encompassing approach to forgery detection and localization. Through a seamless approach that combines feature extraction, object identification, and pixel-wise segmentation, our model cannot only recognize and categorize forgeries but also provide an objective indicator of their size. This development in digital image forensics provides a reliable method for confirming the authenticity of images in a range of applications, marking a substantial achievement in the battle against digital image tampering.

The proposed methodology harnesses CNN's power to process high-resolution images across multiple channels, capturing the nuanced spatial and color information crucial for detecting subtle manipulations in forged images. The architecture of our CNN consists of an input layer designed to accommodate high-resolution imagery, enabling the extraction of detailed spatial and color features. As the image progresses through CNN, it encounters a series of convolutional layers equipped with specialized filters. These filters are good at seeing spatial linkages and local patterns, which is important for identifying real from altered areas in a picture.

This model employs convolutional layers (Conv2D) and max pooling layers (MaxPooling2D) for feature extraction. Our proposed work embarks on refining the capabilities of CNNs to address the intricate task of detecting digital image forgeries, with a focus on copy-move and splicing forgeries. Recognizing the computational demands and the challenges in designing an optimal CNN architecture, we propose a strategic approach to streamline the process, ensuring efficiency and accuracy in forgery detection.

The CNN architecture includes convolutional layer with a limited number of filters (32 filters with a size of 3x3). Every filter is assigned a specific area of the input image to scan, which enables a thorough examination of the image's color and spatial details. The Rectified Linear Unit (ReLU) function is used to activate these convolutional layers, adding the required non-linearity to the model, and improving its capacity to detect subtle forgeries. Our model uses max pooling layers after the convolutional layers in order to decrease the processed image's spatial dimensions. This reduction is pivotal, as it not only diminishes computational load but also preserves the most salient features essential for accurate forgery identification. The culmination of convolutional and pooling layers yields a compact representation of the image, which is then untraveled into a one-dimensional vector.

In tackling the computational intensity and the architectural optimization challenges, our proposed work leverages advanced techniques in model optimization, regularization, and efficient computational strategies. This includes the exploration of transfer learning as a means to capitalize on pre-trained models for initial feature extraction, significantly reducing the requirement for large, labelled datasets and computational resources.

Despite their effectiveness, CNNs pose significant challenges, notably the requirement for extensive labelled datasets to train the models adequately. We avoid this by implementing sophisticated techniques that maximize training effectiveness and improve the model's capacity to learn from sparse data

sets. This includes data segmentation techniques to artificially expand the training dataset and transfer learning approaches to leverage pre-trained models for feature extraction.

This work analyzes pre-trained transfer learning models such as VGG16, MobileNet V1, and ResNet-50 in parallel. Our proposed work aims to set a new benchmark in the detection and classification of digital image forgeries, providing a robust tool against the proliferation of manipulated media.

In the context of detecting digital image forgeries, GNNs offer a proposed approach by treating the problem as one of analyzing and learning from a graph of image features and their relationships. A GNN operates by learning representations for nodes (which could represent image segments or features) in a way that the representation of a node is informed by its neighbours. This process iteratively aggregates and transforms neighbour information, allowing each node to have a representation that captures both its local features and its context within the larger structure. This method is especially useful in the detection of picture forgeries since it can be important to comprehend the context and interaction between various image components in order to spot irregularities that may indicate manipulation. The key to GNN's effectiveness lies in its image segment framework, where nodes exchange segment information along edges, gradually updating their states based on both their attributes and the segment information received from their neighbours. This allows GNNs to propagate and refine feature information across the graph, leading to rich, contextualized node embeddings that reflect the structure of the data. For IFD, this means that GNNs can help uncover subtle, complex patterns of manipulation that might not be apparent when considering image regions in isolation. In our proposed architecture for advancing digital IFD, we envision leveraging GNNs to analyze the graph of relationships between image segments. By constructing a graph where nodes represent segments of an image and edges encode relationships such as spatial proximity or similarity in texture or color, GNNs can be used to identify irregularities and discrepancies in the graph structure that could indicate fraud. For example, in copy-move forgery, duplicated segments might exhibit unusually high similarity to non-adjacent regions, a pattern that GNNs can be trained to recognize. Relying solely on the original GNN goal might lead to the creation of another graph/subgraph that falls short of elucidating the GNN's reasoning. To craft explanations that embody both accuracy and concreteness, we've refined the generative component's goal function.

While CNNs excel at extracting local visual features from images, GNNs can enhance the analysis by considering the broader context and relationships among these features. The individual performance of each model and the suggested GNN model performance is discussed in result section. By using the DL approach, digital picture forgery detection systems could have much higher accuracy and resilience. The incorporation of GNN into our proposed work represents a promising direction for enhancing the detection and analysis of digital image forgeries.

To address the critique regarding the theoretical foundation of our results, it is crucial to clarify the mathematical underpinnings that substantiate the efficacy of our proposed methods in digital IFD. The effectiveness of our architecture is not merely an isolated occurrence but is grounded in the well-

established principles of CNNs and GNNs, both of which are renowned for their robust performance in pattern recognition and feature extraction tasks. The mathematical models for CNN involve convolution operations that leverage learned filters to identify and enhance salient features within images, which are crucial for detecting subtle forgeries. Similarly, the GNN framework is based on the principle of node feature aggregation, where the representation of each node (or image segment) is iteratively refined based on its neighbours, thus capturing both local and global contextual information effectively. Our results are derived from rigorous empirical testing and validation against benchmark datasets, ensuring that the observed high performance is replicable and consistent across various scenarios. Furthermore, by integrating these networks, our approach benefits from the synergy between CNNs' ability to extract detailed local features and GNNs' capacity to analyze relationships within the data structure, which is mathematically supported by the operations of graph convolution and pooling. This combination allows for more comprehensive and precise detection of digital forgeries than would be possible using either technique alone.

A. Data Set and Experimental Setup

The CASIA V1 dataset stands as a pivotal resource in the field of digital IFD, offering a comprehensive collection of images specifically curated for the classification and analysis of various forms of image tampering. Comprising 1,754 images, the dataset is meticulously organized into three distinct categories: 800 authentic images, serving as a baseline for comparison; 480 images subjected to copy-move forgery, and 474 images manipulated through splicing. The authentic images in CASIA V1 provide a wide range of scenes, subjects, and lighting conditions, establishing a robust foundation for models to learn the characteristics of genuine, untampered images. This diversity ensures that the dataset can challenge and evaluate the performance of digital forgery detection systems across a variety of scenarios, making it a valuable asset for developing and testing algorithms designed to discern the subtleties between authentic and forged content. The dataset's copy-move fabricated images are created using a range of sophisticated approaches, including scale, rotation, and different JPEG compression levels to mask the forging. Similarly, the spliced images within CASIA V1 are constructed by combining elements from multiple sources, creating composite images that can be particularly challenging to analyze.

The experimental setup for our research, leveraging the computational power of google colab. The experiments were facilitated by a robust hardware configuration including an NVidia Tesla K80 GPU, which boasts 2,496 CUDA cores and 16GB of GDDR5 VRAM, providing the necessary computational prowess for DL tasks. The processing unit was complemented by a hyper-threaded single-core Xeon Processor @2.3Ghz, equipped with 16 GB of RAM, ensuring efficient data handling and processing speed.

IV. RESULTS

A. Performance Measures

The suggested GNN model's performance is evaluated with the individual model performance using a wide range of

metrics, such as the F1-score, accuracy, recall, and precision. With the use of these metrics, we were able to carefully assess how well the model identified manipulated photos. In particular, precision examined the model's accuracy in the cases it identified as forgeries, recall demonstrated the model's capacity to recognize manipulated images, the F1-score gave a fair assessment of both precision and recall, and accuracy gave a comprehensive picture of the model's overall performance. The formulas of performance metrics are mentioned below:

$$Precision = \frac{TruePositive}{TruePositive + Falsepositive} \quad (1)$$

$$Recall = \frac{TruePositive}{TruePositive + FalseNegative} \quad (2)$$

$$F1 - score = \frac{2 * (Precision * Recall)}{Precision + Recall} \quad (3)$$

$$Accuracy = \frac{TruePositive + TrueNegative}{TotalPrediction} \quad (4)$$

B. Training and Validation Insights

The accuracy curves underscored the models' capacity to learn from the training data effectively, while the validation curves provided crucial information about the models' generalizability. Notably, the divergence or plateauing of validation curves from the training curves signified potential overfitting, prompting us to halt training to preserve the models' ability to generalize.

C. Dataset Division and Validation

We were able to prevent overfitting, optimize model performance, and fine-tune hyperparameters by carefully splitting the dataset into training and validation sets at an 80:20 ratio, which kept the models reliable and useful in practical situations. Throughout the training, an early stopping mechanism was used to keep track of training and validation losses. We were able to quickly stop training when this method let us detect when the models started to overfit the training set. This strategy significantly enhanced our models' generalization capabilities, ensuring they remained effective and reliable in detecting digital image forgeries. Our studies' outcomes highlight the possibility of using GNN in the field of digital IFD. Our thorough analysis shows that these models may be improved to identify complex forgery methods with excellent recall, accuracy, and precision, providing useful resources for the digital forensics community. Through tackling the issues of overfitting and fine-tuning model architectures, we have established the foundation for next investigations that seek to improve the identification and categorization of digital image forgeries. Fig. 2 showcases the comparative performance of various DL models applied in the field of digital IFD.

D. Performance Analysis

The graph illuminates an upward trajectory in detection accuracy, signifying substantial strides in model efficiency and reliability. Notably, the GNN model exhibits remarkable improvement, underscoring the effectiveness of advanced

Fig. 2. Accuracy for various methods for IFD.

Fig. 3. F1 score for various methods for IFD.

architectures in discerning complex patterns within image data. The progression from traditional CNN to more intricate systems like VGG16, MobileNet, and ResNet50 indicates a consistent enhancement in accuracy. For instance, the leap from CNN's initial accuracy of approximately 51.51 percent to GNN's commencement point at about 28.14 percent may appear as a decline. However, GNN's rapid ascension to over 98 percent accuracy by the 99th epoch delineates a significant leap in performance. Such an advancement underscores the transformative impact of transfer learning and the layered sophistication it brings to image analysis tasks. The MobileNet and ResNet50 models also display a steady climb in accuracy percentages, reaching the high 80s and low 90s, respectively. This gradual increase corroborates the hypothesis that depth and complexity in neural networks, managed adeptly, can yield superior results in detecting nuanced manipulations in digital imagery. Fig. 3 delineates a compelling narrative of progressive improvement across diverse DL models throughout 100 epochs. The data traces the F1 scores—a harmonic mean of precision and recall, considered a more robust measure than accuracy alone—of five models: CNN, VGG16, MobileNet, ResNet50, and GNN.

The GNN architecture, which started at an F1 score of approximately 60.13 percent, shows an impressive ascent, culminating at nearly 98.93 percent. This trajectory highlights the efficacy of GNN in the nuanced detection of image forgeries, likely due to its ability to model complex patterns

and relationships within the image data. When we compare the increment from CNN's initial F1 score of roughly 44.79 percent to GNN's ending score, it is evident that there's an absolute improvement of around 54 percent. Such a stark progression implies that GNNs are significantly more adept at handling the intricacies of IFD tasks. VGG16 and MobileNet also exhibit substantial enhancements, with VGG16 starting at about 44.31 percent and closing at 95.25 percent, and MobileNet commencing at 51.86 percent and concluding at nearly 86.70 percent. These increases suggest that depth in network architecture can lead to improved feature extraction, which is critical in differentiating between genuine and forged pixels. ResNet50's performance, initiating at an F1 score of 55.87 percent and reaching 91.01 percent, further corroborates the advantages of leveraging deeper networks with residual connections to enhance learning from image data.

The Table I presents a comparative analysis of five advanced DL models—CNN, VGG16, MobileNet, ResNet50, and GNN—across a spectrum of performance metrics including Accuracy, F1 Score, Precision, and Recall throughout 100 epochs. After a hundred epochs, the GNN model emerges as the front-runner, boasting an accuracy and F1 Score of approximately 98.55 percent and 98.93 percent, respectively. This performance is particularly noteworthy when considering its recall rate reached a perfect score, a clear indication of its superior ability to identify true positive cases of forgery. The GNN's precision score, standing at roughly 98.70 percent, reinforces its status as the most reliable method among those tested. VGG16 also shows remarkable results, with an accuracy of about 81.70 percent and an F1 Score of 95.25 percent, a significant leap from its initial F1 Score of approximately 44.31 percent. This demonstrates a solid balance between precision and recall, highlighting VGG16's proficiency in classifying forged image content. MobileNet, known for its efficiency on mobile devices, achieves a notable accuracy of around 94.37 percent and an F1 Score of 86.70 percent. These figures represent its robustness in the context of IFD, particularly in environments where computational resources are limited. ResNet50, with its deep residual learning framework, attains an accuracy of nearly 94.85 percent and an F1 Score of 91.01 percent, underscoring the strength of deep networks in extracting nuanced features that are crucial for identifying forgeries. The CNN model, while not outperforming the GNN, still demonstrates substantial growth from an accuracy of 51.51 percent to 90.17 percent and an F1 Score increase from 44.79 percent to 90.72 percent.

The Table II indicates that the proposed methods outperform many of the traditional approaches, suggesting the superiority of GNNs in capturing the complex relational and structural dependencies characteristic of image forgeries. By combining these cutting-edge neural networks with the CNN base layer, the model's capacity to accurately distinguish between real and fake images is improved. This combination is particularly effective for feature extraction and classification.

V. DISCUSSION

It elucidates the pivotal contribution of transfer learning in advancing the detection of digital image forgeries. Harnessing the analytical might of pre-trained neural networks, fine-tuned for the nuanced task of forgery detection, this study

TABLE I. VARIOUS MEASURES OF THE VARIOUS METHODS WITH DIFFERENT EPOCHS FOR THE DETECTION OF IMAGE FORGERY

Method	Epochs	Accuracy	F1 Score	Precision	Recall

showcases the potential to benefit from DL's power without necessitating substantial labelled forensic data. This prudent approach streamlines resource expenditure and forges new pathways for the development of robust solutions against the scourge of digital forgery. In an era where the authenticity of digital content is under constant scrutiny, the study accentuates the superior performance of GNN. GNN's architectural design is adept at mapping the intricate relational and structural nuances that are crucial for identifying forged elements in images. The empirical evidence presented underscores the sophistication of GNNs in discerning subtle discrepancies that allude to tampering, thus bolstering the integrity of visual information. It reflects the remarkable ingenuity integrated within these systems, empowering them to scrutinize layers of digital data to authenticate its veracity. The discernible improvements in accuracy and reliability not only corroborate the current direction of research within this sphere but also lay a solid foundation for the future of digital forensics. The implications of these advancements extend beyond the academic, offering a beacon of trust and reliability as we navigate through an age rife with digital manipulation. Table II showcases a comparative analysis of different methodologies employed for the detection of passive image forgery mainly copy-move and splicing. The forgery type column has four sections which include splicing forgery, either copy-move or splicing forgery, copy-move forgery, and both copy-move and splicing forgery. The table examining the efficacy of various feature extraction and classification techniques across several well-recognized datasets. The table delineates the performance of these methods primarily in terms of accuracy except in one instance where precision, recall, and F1-score highlights the evolution and refinement of detection capabilities.

In earlier research, traditional CNNs served as the foundation for feature extraction, with methods varying from CNN-based local descriptor construction to hybrids that integrate encoding and decoding processes. Classifications were performed using a variety of techniques, including SVM and CNNs themselves, among others.

The proposed method in the current paper pivots from these traditional approaches by integrating CNNs with ad-

TABLE II. COMPARE VARIOUS METHODS FOR THE DETECTION OF IMAGE FORGERY WITH OUR PROPOSED METHOD

Forgery Type	Reference	Feature Extraction Methods	Classification Methods	Dataset	Evaluation
Splicing	[17]	CNN-Based Local Descriptor Construction	SVM	CASIA V2, DVMM DSO-1.	CASIA V2: 96-97 percent, DVMM: 94 percent, DSO-1: 97.5 percent
	[18]	CNN	CNN	CASIA V1 and V2, CUHK, NIST16, COVERAGE, CUISDE.	CASIA V1: 91 percent, CASIA V2: 99 percent, CUHK: 95 percent, NIST16: 98 percent, COVERAGE: 97 percent, CUISDE: 100 percent

vanced neural network architectures like ResNet and VGG16, alongside GNNs and MobileNet. These methods are applied to the CASIA V1 dataset. Notably, the proposed GNN method achieves a remarkable accuracy of 98.54 percent, which is significantly higher than many previously referenced methods. Similarly, the combined use of MobileNet and ResNet50 yields an impressive accuracy of 94 percent.

VI. CONCLUSION

The conclusion of our study underscores the significant advancements made with GNNs in the field of digital IFD. GNNs have demonstrated exceptional proficiency, achieving accuracy rates that exceed 98 percent in identifying digital

forgeries. This impressive performance is not just a testament to their capability but also showcases their potential as critical tools in digital forensics. However, it is essential to ground these findings within a theoretical framework to fully articulate the scientific contribution of our research. The effectiveness of GNNs in our study is anchored in their inherent ability to process and analyze complex patterns through node and edge analyses, which are particularly effective in understanding and identifying manipulated image data. This theoretical underpinning is supported by the structure of GNNs, which integrates node information with neighbourhood data, allowing for a DL model that is highly adept at detecting anomalies indicative of digital tampering.

Looking forward, we aim to enhance the precision and computational efficiency of these models. Our future research will expand the variety of training datasets to include a wider array of forgery techniques, which will further test and improve the robustness of our models. Additionally, we plan to explore the integration of GNNs with other DL architectures through transfer learning, which could lead to even more powerful systems capable of combating advanced forgery methods. The increasing complexity of digital forgeries requires that our forensic methods evolve concurrently. The ultimate goal of our research is to develop a comprehensive suite of forensic tools that are sophisticated yet user-friendly enough for public use, ensuring that digital media can be authenticated across various platforms. This commitment supports the integrity of information within our digital society and contributes to the maintenance of truth in visual media. As this study lays a solid foundation with high accuracy rates, it paves the way for a future where digital forensic science is an effective guardian against the intricacies of digital forgery, ensuring the authenticity of digital media in an era where truth is paramount.

School of Computer Science and Engineering, Professor Grade1, Vellore Institute of Technology, Tamilandu, India²

Abstract—In the recent years, Facial Expression Recognition is one of the hot research topics among the researchers and experts in the field of Computer Vision and Human Computer Interaction. Traditional deep learning models have found it difficult to process images that has occlusion, illumination and pose dimensional properties, and also imbalances of various datasets has led to large distinction in recognition rates, slow speed of convergence and low accuracy. In this paper, we propose a hybrid Convolution Neural Networks-Bidirectional Long Short Term Memory along with point multiplication attention mechanism and Linear Discriminant analysis is incorporated to tackle aforementioned non-frontal image properties with the help of Median Filter and Global Contrast Normalization in data preprocessing. Following this, DenseNet and Softmax is used for reconstruction of images by enhancing feature maps with essential information for classifying the images in the undertaken input datasets i.e. FER2013 and CK+. The proposed model is compared with other traditional models such as CNN-LSTM, DSCNN-LSTM, CNN-BiLSTM and ACNN-LSTM in terms of accuracy, precision, recall and F1 score. The proposed network model achieved highest accuracy in classifying the facial images on FER2013 dataset with 95.12% accuracy which is 3.1% higher than CNN-LSTM, 2.7% higher than DSCNN-LSTM, 2% higher than CNN-BiLSTM and 3.7% higher than ACNN-LSTM network models, and the proposed model has achieved 98.98% of accuracy with CK+ in classifying the images which is 5.1% higher than CNN-LSTM, 5.7% higher than DSCNN-LSTM, 3.3% higher than CNN-BiLSTM and 6.9% higher than ACNN-LSTM network models in facial expression recognition.

Keywords—Facial expression recognition; occlusion; attention mechanism; convolution neural networks; bidirectional long short time memory

I. INTRODUCTION

In general, facial expression contains a vital non-verbal communication of a human that includes eye contact, hand gestures and etcetera. Basically, these factors convey their emotion, inner thoughts, intention and mental states. This has increased the interest among the scientists, researchers and academicians on studying about human emotions and expressions [1]. Machine learning approaches play important role in various kind of research works such as security, emotion detection, natural disaster management, data protection and monitoring [2], [3]. Human emotions play an important role in both psychology and computer vision in which emotion is classified into categorical and dimensional respectively. In case of categorical model, emotions are treated as happy, sad, neutral, anger, fear, surprise and more whereas in dimensional model emotion is treated as valence and arousal. Facial Expression Recognition (FER) is part of computer vision with a lot of

practical applications and the number of studies on FER has been increasing over the last two or more decades [4], [5].

In the past, Convolutional Neural Networks (CNN) was very much successful in addressing this issue and performed well in extracting features from the given input images. But, CNN was suffering with issues like vanishing gradient and decreasing the accuracy of deep networks [6]. Residual Neural Networks (ResNet) was introduced in 2015 by He and Zhang et al. and which helped them to add residual learning to CNN to tackle the issues faced by CNN [7]. A dataset can have a variety of facial images with different poses, contrast, brightness, dimensions, age and some of the images might have unclear properties where some part of the face could be hidden or occluded. For any given facial image, human's expression can be identified with its unblocked regions. When some part of the facial image is blocked, the expression has to be determined based on systematic part or other regions that are highly visible or clear [8], [9]. Despite, the contributions and the accuracy performance delivered by various deep learning approaches for facial expression recognition, the classification accuracy could still be improved with additional methods and mechanisms [10].

To overcome these challenges, the concept of Attention Mechanism (AM) was proposed in computer vision and there-after used in natural language processing as well. The main objective of having attention mechanism is to obtain richer information from input facial images by paying more attention to the key parts of image features [11]. The problem of information redundancy and the loss of key features of the input images can be prevented while using Attention Mechanism (AM) along with deep neural networks [12].

In deep learning, attention mechanism is not only important, but are ubiquitous, integral part and necessary element in neural machine learning techniques. The main function of this mechanism is to optimize the issue of learning the desired target by non-uniformly weight the contributions of input feature vectors [13].

Currently, the attention mechanism has a crucial role in determining human perception and is applied successfully in various fields of deep learning such as machine translation, image generation and some other fields as well. There are few many researches done on expression recognition using attention mechanism [14]–[16].

This research work is aimed to predict the emotions of a driver using CNN-BiLSTM approach. Section 2 discuss about the existing works related to the topic of the study and section 3 introduces authors proposed approach and algorithms used

in this study. Section 4 presents the experimentation results of this study and results are compared with other works which is followed by discussion and justification of this study. Finally, the conclusion of this study is presented and future work of the authors also presented.

II. RELATED WORK

In [17], Identity Aware CNN (IA-CNN) model was proposed in which the importance is given to identity and expression, sensitive contrastive losses. This was considered to reduce the variations in learning the information related to identity and expression. In [18], end to end architecture was proposed along with attention model. In [10], a novel Region Attention Network (RAN) was proposed which was robust with real world pose of images and occlusion variations in such images. This approach was effective in capturing important facial regions for occlusion and pose variant to deliver expected results of Facial Expression Recognition.

In [19], a Region Aware Subnet (RASnet) that locates expression related regions using binary masks and those critical regions are identified with coarse-to-fine granularity levels and Expression Recognition subnet (ERSnet). The study has used Multiple Attention mechanism learns discriminative features of an input image and this MA block consists of hybrid attention branch with many sub branches where region specific attention is performed by each sub branch. In [20], the authors have proposed Distract Your Attention Network (DAN) which consists of three components: Feature Clustering Network (FCN) Multi-head Cross Attention Network (MAN) and Attention Fusion Network (AFN). To maximize class separability FCN extracts robust features using large margin learning. MAN builds attention maps on critical regions by simultaneously attending multiple facial areas through instantiating multiple attention heads. AFN fuses the created these attentions maps and converts it into a comprehensive one.

In [19], the authors have proposed a Multiple Attention Network with three components, namely, Multi-Branch Stack Residual Network (MRN) which deploys attention heads on critical facial regions to generate attention maps, Transitional Attention Network (TAN) which learns objectives to maximize class separability and Appropriate Cascade Structure (ACS) which determines the appropriate construction method for the model. In [21], the authors have suggested that attention mechanism help to focus on more useful features, therefore, they have proposed an end to end network with AM for automatic facial expression recognition. For their experimentation purposes, the study considered its own data set of 35 subjects from different peoples between the age group of 20 to 25. In total, the study had 26950 images that includes both RGB and depth images. Local Binary Pattern (LBP) was adopted for feature extraction and the results were compared with JAFFE, CK+, FER2013 and Oulu-CASIA datasets.

In [22], the authors have proposed an RCLnet to recognize wild facial expression which has high occlusion or illumination using attention mechanism and LBP feature fusion method. The proposed model had two branches: ResNet-CBAM, the residual attention branch and local binary feature extraction branch (RCL-Net). The study has performed validation on for different datasets: FER2013, FERPLUS, CK+ and RAF-DB datasets. In [9], authors proposed Attention based CNN

(ACNN) that could recognize information from occlusion region of facial images and focus on un-occluded regions of the same image. In the end, the model combines multiple representations (each weighted via gate unit) from facial regions of interest. The study has also used two types of CNN, namely, patch based ACNN and global-local-based ACNN where the experimentation results proved that their proposed model has improved recognition accuracy for both occluded and non-occluded facial images.

In [23], the authors have proposed an Enhanced CNN with attention mechanism to recognize occluded facial images of RAF-DB dataset and their experimentation results has achieved 86.2% of accuracy with patch based ECNN-AM and Global Gated Unit (GG-U) which automatically weighs global facial representations. In [24], the authors have developed Deep CNN along with Binary Attention Mechanism (BAM) that is trained with original pixel data characteristics. Data preparation was done using Histogram of Oriented Gradients (HOG), dropout and batch normalization along with L2 regularization was employed to minimize the over fitting issue. The proposed model has used FER2013 dataset to extract and examine the performance of their approach with various metrics.

In [25], a Symmetric Speed up Robust Features (SURF) framework was used to identify the hidden part of images by critically locating a horizontal symmetric area and heterogeneous soft partitioning assigned weights for each part of the input image recognition while training. The weighted image was given as input to the trained network model to detect facial expression recognition and the experimentation was performed Cohn-Kanade (CK+) and FER2013 datasets. The results have showed 7% to 8% improvement compared to other works. In [26]–[28],], AlexNet based Deep CNN was used to tune the outputs obtained in three steps: the first two steps are in training stages where frontal images of FER2013 dataset used and the third stage included non-frontal image poses of the same data set. The experimentation was conducted using VT-KFER and 300W databases where the results have outperformed other systems in expression recognition.

In [29], two layer based CNN-LSTM mechanism was proposed which extracts rich information from important regions of FER2013 and CK+ datasets. This approach has outperformed some other methods like CNN-ALSTM, ACNN-ALSTM and patch based ACNN. In [30], CNN-BiLSTM model was proposed and was experimented on CK+ dataset and to prevent over fitting data augmentation was incorporated. This approach was compared with CNN and CNN-LSTM models in terms of accuracy, and the proposed approach returned improved results.

III. PROPOSED METHODOLOGY

Based on the observations from traditional Convolution Neural Networks (CNN) and its performance on Facial Expression Recognition (FER), it is found that existing models based on CNN fails to extract rich and useful information from key parts of occluded, variety pose and blurred input images. In our previous work, we have proposed CNN-LSTM based hybrid model to extract rich information from frontal images along with point multiplication attention mechanism to correctly identify the expression with improved accuracy. In

this paper, we propose CNN-BiLSTM based hybrid model with point multiplication attention mechanism, and some other methods for the betterment of recognizing facial expressions with improved accuracy. The proposed model consists of four important components and the same is represented in Fig. 3. The components are, namely, CNN, Bi-LSTM, Attention layer and reconstruction and classification layer.

A. Data Preprocessing

CK+ dataset is a better organized dataset with quality images since the quantity of images are very small when compared with FER2013 dataset. Since FER2013 dataset consists of large number of images, data preprocessing is very important to obtain quality images with rich feature information. In our first work, we only considered 7074 images from FER2013 dataset which has both quality and resolution; here, we consider the whole dataset. Thus, preprocessing is performed by resizing images into 128*128 pixels, median filters are used for noise removal and normalization is done using Global Contrast Normalization (GCN).

Generally, a dataset contains images with different sizes and with varying pixels. Hence, we resize the dataset images into 128*128 pixels to ensure uniformity of images in the dataset under study. Resizing of images include both enlarging the size and reducing the size of an image through cropping. To overcome the uncertainty or variations present in the image such as brightness, color and etc., unwanted noise is removed using Median Filters (MF). Median filter is a non linear operation and commonly used to remove ‘salt and pepper’ noise and it removes the noise and preserve edges simultaneously. To deal with poor contrast image feature, GCN is used to normalize the image to ensure uniform intensity with improved visualization of an image. The basic operation of GCN is to subtract each pixel value of an image with mean value and then divides it with standard deviation. The equation is derived as follows,

$$X'_{i,j,k} = s \frac{X_{i,j,k} - \bar{X}}{\max \left\{ \epsilon, \sqrt{\lambda + \frac{1}{3rc} \sum_{i=1}^r \sum_{j=1}^c \sum_{k=1}^3 (X_{i,j,k} - \bar{X})^2} \right\}} \quad (1)$$

In equation (1), X represents the image and i,j,k represents row, column and color depth of the image X and \bar{X} represents the mean intensity of entire image.

B. Training of CNN

Considering the quantity of images we deal with the datasets undertaken for this study, training those images is a challenging task. Though K-Nearest Neighbor (KNN) and Siamese are commonly used approaches, we have considered a new center loss function from [31] for the enhancement of discriminative power of the deeply learned features. For the deep features of each image classes, the center is learnt while training the dataset. During training, the distance between the deep features and its class centers are minimized and updated simultaneously. The update is done by using mini-batch since updating centers of every class for each iteration is inefficient and practically impossible.

Fig. 1. Mini-batch processing of dataset images.

When a researcher deal with large amount of images, the model should ensure that the batch should be less than the original dataset, yet effective in making batches. Iterations are required to minimize the redundancy, thus computational complexity can be reduced. Importantly, batches can operate in even numbers i.e. from 2 to 2^n . Fig. 1 represents the working principle of mini-batch processing with the number of iterations required in order to assign weights for landmarks of the face with point multiplication mechanism.

Thus, for each iteration the center is computed only for corresponding classes (not all centers are updated) and large perturbations are avoided by adopting scalar factor ' α ' to control the learning rate of the centers. This can be computed as follows,

$$\frac{\partial L_C}{\partial x_i} = x_i - C_{y_i} \quad (2)$$

$$\Delta C_j = \frac{\sum_{i=1}^m \delta(y_i = j) \cdot (C_j - x_i)}{1 + \sum_{i=1}^m \delta(y_i = j)} \quad (3)$$

where $\delta(\text{condition})=1$ if the condition is satisfied and $\delta(\text{condition})=0$ if not, importantly the value of α is restricted between [0,1]. For discriminative feature learning purpose, this study has considered ‘joint supervision’ of softmax loss and center loss $L = L_S + \lambda L_C$ to train CNN model. The equation is given as,

$$L = - \sum_{i=1}^m \log \frac{e^{W_{y_i}^T x_{i+b}}}{\sum_{j=1}^n e^{W_j^T x_{i+b}}} + \frac{\lambda}{2} \sum_{i=1}^m \|x_i - C_{y_i}\|_2^2 \quad (4)$$

To balance both center loss and softmax loss, ' λ ' scalar function is used for the better training of CNN.

C. Network Architecture of Proposed Approach

In this part of the paper, we propose hybrid CNN-BiLSTM model with point multiplication Attention Mechanism along with Linear Discriminant Analysis method for efficient facial expression recognition with improved accuracy and other matrices. The proposed approach consists of following components: Data preprocessing, CNN with Feature Extraction, BiLSTM with Attention Mechanism followed by dimensionality reduction using LDA, the reconstruction module with

DenseNet. Finally, the classification module uses Softmax which categorizes the classes of images with respective expression. Fig. 2 represents the network architecture of our proposed work.

The Network is composed of seven layer convolution neural network with four convolution layer and three down-sampling layers. The parameters of each CNN layer is set with following convolution kernels: (1*1, 32), (5*5, 32), (3*3, 32) and (3*3, 64) respectively. In the convolution layer setup is in (N*N, K) where N*N represents number of convolutions performed and K (32, 64) represents the number of feature maps created. This layer of the network model aims to extract abstract features from the local region of the facial expression images, and generates and serializes the feature vector which is fed to BiLSTM network as an input. The layer begins with C1 that performs point-by-point convolution on the input image with 1*1 convolution kernel. This not only helps to improve the feature representation ability but also beneficial to increase the non-linear representation of the input as well. Since, 1*1 convolutions have few parameters the network calculation complexity can be reduced too. The pooling layer employs the method of maximum-pooling to perform further extraction on the input which identifies and returns strongest features. Thus, the computational complexity is reduced along with the resolution of the feature map using local aggregation function.

Fig. 2. Architecture of proposed CNN with attention mechanism based LSTM.

D. Bidirectional Long Short Term Memory

The core idea of LSTM is the state with few linear interactions and it also uses internal mechanism referred as ‘gate’ to regulate the flow of information by determining what data to retain and what data to discard using forward and backward layer. Fig. 3 represents the Bi-LSTM model used in this paper that consists of a forward LSTM and backward LSTM network layers. Bi-LSTM helps in getting time series information of difference images as it deals with images that are taken at different periods and different angles. When such information is fully considered, obtaining time series feature

vectors is trustworthy and the same will be forwarded to the attention mechanism module of our proposed approach.

This model assumes six shared weights w_1 to w_6 that are calculated in the forward layer from time 1 to t and the output h_t is obtained and saved. In the same way, reverse process was performed to obtain h'_t in the backward layer and then the final output O_t is obtained by combining both forward and backward layer outputs. The following equations represent the whole process.

$$h_t = (w_1x_t + w_2h_{t-1}) \quad (5)$$

$$h'_t = (w_3x_t + w_5h'_{t+1}) \quad (6)$$

$$O_t = g(w_4h_t + w_6h'_t) \quad (7)$$

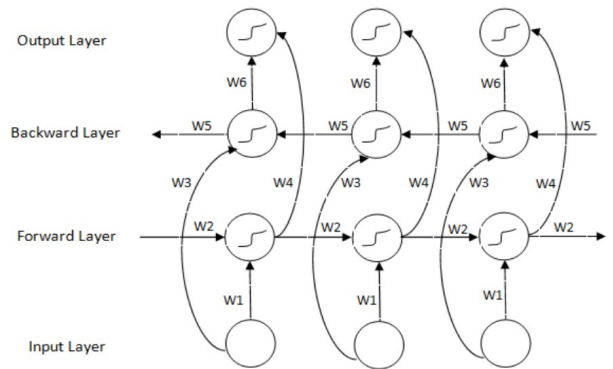

Fig. 3. Bi-LSTM Structure of proposed approach.

By extracting rich sequence features from the images of undertaken datasets (FER2013 and CK+), the context relationship of the sequence is automatically generated which not only helps in increasing the amount of information to the network model, but also helps in improving the accuracy of facial image expression recognition.

E. Attention Layer

In general, attention layer increases the weight of useful features that are identified in both frontal and non-frontal images of the dataset (especially occluded, complex and blurred images). Upon identifying important features, this layer encourages the network to focus more on such vital features that in return help the network model to recognize and classify the facial expression images more accurately [21] Mainly, the concept of attention layer is inspired by the special attention paid by humans when required, but in computer vision, it represents a weighted mean function. This layer takes three parameters as inputs: the query, the values and the keys. Normalization of attention vector dV is completed using softmax activation function, yet attention mechanism equation is a hyper-parameter [32], [33]. The relevant equations and algorithm is presented in algorithm 1. This attention module focuses more on the useful features and increases its weights

to enhance the efficiency of the model to recognize different expressions present on input images.

Algorithm 1: Point Multiplication Attention Mechanism

```

INPUT: Image sequence variations from BiLSTM
OUTPUT: Attention Vector Maps

BEGIN
FOR each hidden image sequence variations
 $L = \{L_1, L_2, \dots, L_{N-1}, L_N\}$  at moment  $n$ 
Initiate random weight matrix  $W$  and Value matrix  $V$ 
IF  $W \leq W_6$  then
Compute learned key matrix  $K_L = \tanh VW^a$ 
//where  $V$  = value matrix and  $W^a$  = weight factor

ENDIF
WHILE ( $L! = 0$ )
Find current key matrix  $K_c = \|qC_v\|$ 
// where  $q$  = query and  $C_v$  = current key value
Compute normalized weight vector  $d = \text{softmax}(qK^T)$ 
Compute Attention Vector  $a = d * V$ 
END WHILE
END FOR
END

```

F. Dimensionality Reduction with Classification

The objective of this layer is to classify the weighted features fused by the attention layer. This is achieved by reducing the dimensionality of those features into number of expression categories considered in this study i.e. 7 (anger, disgust, fear, happy, surprise, sad and neutral). Dimensionality reduction is the process of transforming high dimensional data features into lower dimensions which will still retain the rich and essential features of original data. These high dimensional data needs to be reduced as the model's performance might gradually decrease as the number of features increases [34]. Thus, our proposed model utilizes Linear Discriminant Analysis (LDA) as it achieves both dimensionality reduction and classification to optimize the distinction between various classes (7 classes) within the dataset under study i.e. FER2013 and CK+ datasets using linear combination of features. The dimensionality reduction using LDA is as follows:

Step 1: In original space, for different kind of facial images calculate average sample values where total number is denoted as C . x_{ij} represents the j^{th} objects of the i^{th} class sample

$$S_i = \frac{1}{N_i} \sum_{j=1}^{N_i} x_{ij} \cdot x_{ij} \in R^d, \text{ where } i = 1, 2, 3, \dots, C. \quad (8)$$

$$m = \sum_{i=1}^C p^i m^i \quad (9)$$

Step 2: For each class, calculate covariance matrix

$$C_i = \frac{1}{N_i} \sum_{j=1}^{N_i} (x_{ij} - m_i) \cdot (x_{ij} - m_i)^T \quad (10)$$

Step 3: Calculate scatter matrices within and between classes

$$S_B = \sum_{i=1}^C p_i (m_i - m) \cdot (m_i - m)^T \quad (11)$$

$$S_W = \sum_{i=1}^c C_i \quad (12)$$

Step 4: To get projection vectors, compute Eigen vector of matrix $S_W^{-1} S_B$ to obtain reduced data.

With these rich features, attention map is created as a final output of this module which is fed as an input to the DenseNet for reconstruction purposes. With DenseNet, the reconstruction module produces new enhanced feature maps with narrow layers and reduced redundancy as an output with an activation function $x_l = H_l([x_0, x_1, \dots, x_{l-1}])$. Unlike ResNet, DenseNet concatenates the incoming feature maps with the output feature maps instead of summing up them. These new feature maps are forwarded to classification module i.e. to fully connected layers with softmax that performs final classification of facial expression on images. Batch normalization is employed after each layer to overcome over fitting issue and to speed up the convergence of network. Softmax activation function is effective and it transforms any integer or fraction values and transforms them between 0 and 1. Full softmax variant is used in this paper since the study deal with multiple classes (7 classes).

IV. EXPERIMENTATION RESULTS

For this research study, we have considered two commonly used datasets, namely, FER2013 and Cohn Kanade + which contains images with seven facial expressions. Both datasets are described below and the results based on training and simulations implementation are presented in this section along with expression recognition rates and accuracy. The effectiveness of LSTM parameters is shown and also the impact of each module of the proposed model and its effectiveness are also presented. The results of proposed model are compared with few existing models in terms of accuracy in detecting facial expression of images in FER2013 and CK+ datasets. Matlab2021a was used to implement the proposed approach with windows 10 operating system, Intel i7 processor with 6GB RAM.

A. FER 2013 Dataset

A well-known data science competition platform kaggle created this dataset by searching on Google search engine with image keywords and this dataset consists of 35,887 gray-scale images with the resolution of 48*48 pixels. Though, the nature of the dataset is rich and diverse since all the images are obtained from Internet, the dataset images contains a lot of noise including occlusion, different poses and unclear images. These properties of images in FER2013 imposes lot of challenges for the researchers while recognizing expressions and classifying them [35].

B. Cohn Kanade + Dataset

Initially, the extended CK+ dataset was introduced in 2010 by Patrick Lucey team and the Zara Ambadar team [36] and the dataset consists of 123 subject's facial image and

the expressions were recorded as per requirements. Out of 593 images in CK+, 327 images display 7 different facial emotions. Since the quantity of the dataset is less, this study has considered that 327 images which express 7 emotions. As a first step, invalid background is trimmed on those 327 images and to make the datasets similar (both FER2013 and CK+) the resolution is kept as same as FER2013 dataset. The images are rotated and flipped, their brightness and saturation are adjusted when required.

C. Evaluating Module's Effectiveness

As mentioned in Section 3, the proposed model has four modules. In order to prove the effectiveness of each module and show the performance when all these modules work together, we have kept classification module as it is, and removed other modules i.e. one at each time. In such scenario, the recognition rate is measured and given in Table I.

TABLE I. RECOGNITION RATE COMPARISONS OF MODULES IMPACT ON FER

Architecture	Recognition rate (%) FER 2013	Recognition rate (%) CK+
No feature extraction module	59.12	72.28
No attention Module	71.42	75.31
No Reconstruction module	73.87	79.46
Complete Network	79.56	98.92

Fig. 4. Recognition rate comparisons of modules impact for FER2013 and CK+ dataset.

From Table I, it is evident that in the absence of feature abstraction layer, the recognition rate for FER2013 and CK+ stands at 59.12% and 72.28% respectively. When attention module is removed from the model, the recognition rate for FER2013 and CK+ stands at 71.42% and 75.31% respectively. In case of reconstruction module removal, the recognition rate for FER2013 and CK+ stands at 73.87% and 79.46% respectively. When all these modules are combined together and work as a single network model, the recognition rate goes up for both FER2013 and CK+ datasets at 79.56% and 98.92% respectively. Fig. 4 represents the impact of each modules recognition rate on facial expression images in FER2013 and CK+ datasets respectively.

D. Performance Comparisons

The proposed hybrid model of CNN-BiLSTM aimed to combine the advantages of both the networks along with the attention mechanism to extract both frontal and discriminative features of given input images with improved classification accuracy and recognition rate as well. The results of proposed approach were compared with other hybrid network models such as CNN-LSTM, DSCNN-LSTM, CNN-BiLSTM and ACNN-LSTM network models.

Accuracy is defined as the ratio of true outcomes including both true positives and true negatives to the total number of cases examined.

$$\text{Accuracy} = \frac{TP + TN}{\text{Total population}} \quad (13)$$

F1 score can be divided into two ways based on temporal and spatial features, generally. Event based and frame based and its respective equations are given below where R represents recall and P represents precision, EP-event based precision, ER-event based recall. Total F1 Score can be computed as follows,

$$\text{F1 Score} = \frac{2}{\frac{1}{\text{Precision}} + \frac{1}{\text{Recall}}} \quad (14)$$

$$\text{Precision} = \frac{TP}{TP + FP} \quad (15)$$

$$\text{Recall} = \frac{TP}{TP + FN} \quad (16)$$

TABLE II. ACCURACY,PRECISION, RECALL AND F1 SCORE FOR FER 2013 DATASET

Methods	Accuracy (%)	Precision (%)	F1 Score (%)	Recall (%)
CNN-LSTM	92.23	92.70	92.48	91.89
DSCNN-LSTM	92.48	93.02	93.24	93.24
CNN-BiLSTM	93.14	93.18	92.98	93.21
ACNN-LSTM	91.43	91.12	91.82	91.04
Proposed Method	95.12	94.68	94.87	95.01

Fig. 5. Performance on accuracy of all methods.

Tables II and III presents different metrics values for various network models and proposed approach for both FER2013 and CK+ datasets. From Table III, it is understood that our proposed approach produced better results than other traditional benchmarking approaches such as CNN-LSTM, DSCNN-LSTM, CNN-BiLSTM and ACNN-LSTM in terms of metrics like accuracy, precision, F1 score and recall. The proposed network model achieved highest accuracy in classifying the facial images on FER2013 dataset with 95.12% accuracy which is 3.1% higher than CNN-LSTM, 2.7% higher than DSCNN-LSTM, 2% higher than CNN-BiLSTM and 3.7% higher than ACNN-LSTM network models in facial expression recognition. With CK+ dataset the proposed model has achieved 98.98% of accuracy in classifying the images which is 5.1% higher than CNN-LSTM, 5.7% higher than DSCNN-LSTM, 3.3% higher than CNN-BiLSTM and 6.9% higher than ACNN-LSTM network models in facial expression recognition. Fig. 5 represents accuracy comparisons for FER2013 and CK+ dataset.

Fig. 7. Performance on F1 score of all methods.

2.4% higher than CNN-LSTM, 1.6% higher than DSCNN-LSTM, 0.9% higher than CNN-BiLSTM and 3.0% higher than ACNN-LSTM network models. With CK+ dataset the proposed model has achieved 99.54% which is 5% higher than CNN-LSTM, 7.6% higher than DSCNN-LSTM, 4.2% higher than CNN-BiLSTM and 8.3% higher than ACNN-LSTM network models. Fig. 7 represents the F1 Score comparisons for FER2013 and CK+ dataset.

Fig. 6. Performance on precision of all methods.

In terms of Precision, the proposed network model achieved highest percentage of 94.68% on FER2013 dataset which is 1.9% higher than CNN-LSTM, 1.6% higher than DSCNN-LSTM, 1.5% higher than CNN-BiLSTM and 3.5% higher than ACNN-LSTM network models. With CK+ dataset the proposed model has achieved 99.24% which is 5.7% higher than CNN-LSTM, 5.5% higher than DSCNN-LSTM, 4.1% higher than CNN-BiLSTM and 7.7% higher than ACNN-LSTM network models. Fig. 6 represents the precision comparisons for FER2013 and CK+ dataset.

Fig. 8. Performance on recall of all methods.

In terms of recall, the proposed network model achieved highest percentage of 95.01% on FER2013 dataset which is 3.1% higher than CNN-LSTM, 1.8% higher than DSCNN-LSTM, 1.8% higher than CNN-BiLSTM and 4% higher than ACNN-LSTM network models. With CK+ dataset the proposed model has achieved 98.78% which is 4.6% higher than CNN-LSTM, 7.8% higher than DSCNN-LSTM, 3.4% higher than CNN-BiLSTM and 7.2% higher than ACNN-LSTM network models. Fig. 8 represents the recall comparisons for FER2013 and CK+ dataset.

TABLE III. ACCURACY,PRECISION, RECALL AND F1 SCORE FOR FER 2013 DATASET

Methods	Accuracy (%)	Precision (%)	F1 Score (%)	Recall (%)
CNN-LSTM	93.84	93.52	94.52	94.14
CNN-SVM	93.26	93.74	91.89	91.92
CNN-BiLSTM	95.62	95.16	95.34	95.32
ACNN-LSTM	92.02	91.54	91.24	91.56
Proposed Method	98.98	99.24	99.54	98.78

In terms of F1 Score, the proposed network model achieved highest percentage of 94.87% on FER2013 dataset which is

E. Discussion on Findings

Deep Learning based hybrid network models along with CNN has contributed much on classifying Facial Expression Recognition (FER) or emotions of various datasets over a decade. Since the data sets have different images, the results vary according to the image quality. This research work considered two datasets as they are more studied and have images with different scenarios, emotions. Our proposed CNN-BiLSTM based hybrid network model with attention mechanism proved that the accuracy and other matrices of FER can further be improved with right combination of techniques, algorithms and mechanisms. Likewise, we have considered Median Filter for image resizing, GCN for image normalization, CNN for feature extraction, BiLSTM for extracting rich information and discarding unnecessary information, point multiplication attention mechanism for creating attention maps and finally these maps were used to create feature maps that helps in reconstruction. Finally, classification was done using full softmax variant to categorize the emotions of images into seven image expression classes. Our approach was also compared with other benchmarking methods which showed that the proposed network model delivered better results than other models due to the combination of techniques and methods incorporated in or proposed approach.

V. CONCLUSION AND FUTURE ENHANCEMENT

This paper has presented a Hybrid CNN-BiLSTM network model with point multiplication attention mechanism for facial expression recognition on dataset images like FER2013 and CK+. Data preprocessing was performed using Median Filters to resize the image to 128*128 pixels through either enlarging or reducing the original image, followed by image normalization was done using Global Contrast Normalization (GCN). The output obtained from CNN model is forwarded to Bidirectional LSTM where the sequential features of images were extracted using forward and backward layers, and the output is forwarded to point multiplication Attention Mechanism (AM) module. Dimensionality reduction was applied using LDA to the attention map created by the AM to obtain enhanced feature map which can be used in reconstruction module with Full softmax variant to classify the facial expression of images into seven classes. The results were evaluated with other existing network models such as CNN-LSTM, DSCNN-LSTM, CNN-BiLSTM and ACNN-LSTM. The proposed approach has outperformed other models in terms of accuracy, precision, recall and F1 score matrices. For our future work, we can consider some more emotions, datasets and also enhance attention mechanism with additional techniques to improve network model performance further. To achieve better emotion detection of a driver is vital goal to prevent accidents with improved attention mechanism techniques along with deep learning algorithms is our future work.

A Survey of Reversible Data Hiding in Encrypted Images

Ghadeer Asiri, Atef Masmoudi
Department of Computer Science
King Khalid University, Abha, Saudi Arabia

Abstract—The creation and application of multimedia has undergone a revolution in the last several years. This is a result of the rise in internet-based communications, which involves the exchange of digital data in the forms of text files, audio files, video files, and image files. For this reason, multimedia has emerged as a vital aspect of people’s everyday existence. Information security is crucial since there are several threats that target multimedia integrity, confidentiality, and authentication. Multimedia data needs to be safeguarded, perhaps using encryption, in order to solve these numerous issues. Reversible data hiding in encrypted pictures (RDHEI) is investigated in this survey. (RDHEI) process, which functions by adding extra data to a picture, has surfaced. Employers and academics alike are becoming more interested in and focused on the RDHEI due to its vast range of applications. The purpose of this review is to introduce the various RDHEI schemes, identify the most important RDHEI techniques with varying embedding rates, and then examine the applications and future prospects of RDHEI. The main characteristics of each representative RDHEI Technique taken into consideration in this survey are enumerated in a comparison table.

Keywords—Reversible data hiding; encrypted image

I. INTRODUCTION

Within the maze of contemporary digital communication, the necessity to protect confidential data frequently clashes with the requirement to hide more data for a variety of reasons. This conflict is most evident in the transfer and storage of images, where data concealing techniques allow for the implantation of additional information or clandestine communication, but encryption guarantees confidentiality. Up to the introduction of a novel idea, Reversible Data Hiding in Encrypted Images, reconciling these seemingly incompatible goals has been an enormous difficulty.

“Reversible Data Hiding in Encrypted Images,” the title itself, reflects a revolutionary strategy that promises to completely change the way safe data is transmitted and stored. It refers to the merging of two fundamental tenets of contemporary information security: data concealing, the craft of covert communication, and encryption, the cornerstone of confidentiality. However, it offers a paradigm-shifting synthesis that goes beyond conventional trade-offs and constraints, going beyond simple juxtaposition.

Fundamentally, reversible data concealing in encrypted images is significant because it may balance the requirements of information concealment and data security. This synthesis offers promise in an era beset by cyber threats and privacy breaches, where the secrecy and integrity of digital data are continuously under attack. It offers a tantalizing prospect: the

capacity to embed extra data into photos and encrypt them to protect their privacy without jeopardizing the security of the encryption scheme or the integrity of the original image.

This title serves a multitude of purposes. It captures an innovative idea with significant ramifications for a wide range of fields, including multimedia applications, cloud computing, digital forensics, and secure communication. It promises to open up new possibilities by smoothly integrating reversible data concealing into the encrypted image domain. These applications include digital watermarking, covert communication, safe transmission of sensitive data, and authentication.

The benefits of reversible data hiding in encrypted images are as multifaceted as they are profound. Foremost among them is the enhancement of data security. By leveraging encryption to safeguard the confidentiality of image content and reversible data hiding to conceal auxiliary information, this technique offers a robust defense against eavesdropping, interception, and unauthorized access. It ensures that sensitive information remains shrouded in a cloak of encryption, impervious to prying eyes, while auxiliary data is clandestinely embedded within the encrypted image, hidden in plain sight.

Furthermore, encrypted photos with reversible data concealing offer unmatched adaptability. This technique works directly on encrypted data, in contrast to typical data concealing methods that frequently need decryption before embedding or extraction. This allows for reversible embedding and extraction operations without jeopardizing the security or integrity of the encryption scheme. This adaptability enables users to maintain the security and integrity of the original image while embedding extra data inside encrypted images, transmitting them safely, and extracting the concealed information at the recipient’s end.

Furthermore, resource efficiency is inherent to reversible data hiding in encrypted images. It is ideal for resource-constrained situations like mobile devices, embedded systems, and cloud computing platforms because it minimizes the requirement for repeated decryption and encryption steps, which lowers computational overhead and conserves system resources. This effectiveness guarantees that the advantages of reversible data masking can be experienced in a wide range of applications, ranging from multimedia communication and medical imaging to secure messaging and picture sharing.

To summarize, the concept of reversible data concealed behind encrypted images is a revolutionary idea that breaks through conventional limitations and harmonizes seemingly incompatible demands. It provides a powerful synthesis that

improves data security, permits covert communication, and opens up new avenues for the safe transmission and storage of sensitive data by blending encryption and data hiding within the picture domain.

This survey is organized as follows: Section II provides the necessary theoretical foundations and key concepts of RDHEI. Section III explores various RDHEI schemes, categorizing and discussing existing methods and their respective strengths and weaknesses. Section IV delves into the practical applications of RDHEI in various domains, illustrating its real-world benefits and impact. Finally, Section V summarizes the key findings and discusses future prospects.

II. BACKGROUND

Reversible Data Hiding in Encrypted Images (RDHEI) [1] is a sophisticated method that perfectly recovers the original image content while enabling the concealment of auxiliary data within encrypted image data streams. It does this by combining the concepts of reversible data hiding and encryption. With this novel method, the inherent conflict between information hiding and data security is resolved by allowing extra data to be embedded into encrypted images without jeopardizing the security or integrity of the encryption process.

RDH-EI works as follows:

- Encryption [2]: Using cryptographic techniques and keys, the original image data is encrypted to start the process. Without the decryption key, encryption jumbles the picture data, making it impossible for anyone to understand. By doing this, the image content is kept private and shielded from unwanted access or interception.
- Reversible Data Hiding [3] [1]: After encryption, supplementary data is embedded into the encrypted image using reversible data hiding techniques. Reversible data hiding guarantees that, following the retrieval of concealed information, the original image may be precisely recreated, in contrast to irreversible approaches. The security and integrity of the encryption system are maintained by this embedding procedure, which works directly on the encrypted picture data.
- Transmission and Concealment [4] [5]: The composite data stream that results from embedding the auxiliary data within the encrypted image can be safely sent to the designated destination. Even for those who intercept the communication, the hidden information is invisible within the encrypted image.
- Decryption and extraction [6]: To get the original image data, the encrypted image is first decoded at the recipient's end using the relevant decryption key. Reversible data concealing techniques allow the embedded auxiliary data to be recovered from the decrypted image simultaneously, without sacrificing quality or integrity. The original image content is maintained while the hidden information is revealed through this extraction method.

Additionally, RDHEI has improved security. By using encryption to safeguard the privacy of the original image

content, RDHEI makes sure that private information is safe even when more data is inserted into the encrypted image. additionally Reversibility caused by Because data hiding is reversible, the original image may be precisely recreated once the hidden information has been extracted, maintaining the image's fidelity and quality.

As RDHEI supports reversible embedding and extraction processes, it can be used in a variety of applications where maintaining the authenticity and integrity of visual data is essential. RDHEI minimizes computational overhead and conserves system resources by reducing the need for repeated encryption and decryption operations. This makes it appropriate for resource-constrained applications like embedded systems and mobile devices.

Additionally, as RDHEI combines data concealing with encryption, it improves security, but if not used properly, it might create new vulnerabilities. It is important to take precautions against potential hazards like algorithmic or cryptographic defects. additionally Reversible data concealing may need more processing overhead when used with encryption, especially when embedding and extracting data. This might affect how well high-throughput applications or environments with limited resources perform.

Fig. 1 depicts the RDHEI path [7] [8], as follows:

- The content owner: The person or organization who is in possession of the original image data and wishes to send it safely while hiding additional information is known as the content owner. Before transmission, the content owner encrypts the picture data and embeds the auxiliary data to start the RDH-EI procedure.
- The data hider: Using reversible data hiding techniques, the data hider is in charge of embedding auxiliary data into the encrypted image data stream. By using a data hider, the encrypted image's hidden information is kept undetectable and can be recovered by the recipient without compromising its integrity.
- The receiver: The encrypted picture data with the hidden auxiliary information is meant for the receiver. The recipient decrypts the picture and then uses the right decryption key to get the original image data. In order to disclose the hidden information, the receiver simultaneously extracts the encoded auxiliary data utilizing reversible data hiding techniques.

III. DIFFERENT SCHEMES OF RDHEI

The figure labeled as Fig. 2 illustrates the existence of distinct categories of RDHEI, first one is reserving a room before encryption and the second one is vacating the room after encryption third Secret Sharing (RRB) (VRAE) (SS). Vacating the Room After Encryption (VRAE) is a concept that, in reversible data hiding strategies, is complementary to Reserving a Room Before Encryption (RRBE). After the encryption procedure is finished, VRAE entails removing or clearing the space inside the encrypted image that was previously set aside for inserting auxiliary information. By keeping the encrypted image safe and clear of any evidence of the embedded data, VRAE helps to reduce the possibility of unwanted access or detection. The following steps are commonly included in

Fig. 1. The general framework for (RDHEI).

the VRAE process: Encryption: To preserve its confidentiality and integrity, the image is first encrypted using cryptographic methods. A piece of the image's data space might be set aside during this phase so that supplementary information can be included utilizing RRBE techniques. Data Hiding and Clearing: Following encryption, the encrypted image has any remaining evidence of the encoded auxiliary data erased or cleared. In doing so, the area that was set aside for embedding auxiliary information is essentially cleared out by overwriting it with random or null data. In order to prevent unwanted parties from accessing or recovering the embedded information, the cleaning process makes sure that no traces of the hidden data are left inside the encrypted image.

Safe Storage or Transmission: The encrypted image can be safely kept or transmitted without running the danger of revealing the secret data once it has been released from encryption. The lack of residual traces guarantees the security of the encrypted image against steganalysis and other detection methods, protecting the integrity and secrecy of the contained auxiliary data. Reversible data hiding techniques, such as Vacating the Room After Encryption (VRAE), improve the secrecy and integrity of sensitive data by guaranteeing that encrypted images stay safe and devoid of any evidence of hidden data. This method is appropriate for applications needing strong data concealment and private communication since it adds another degree of security and privacy protection [9] [10] [11] [12] [13].

One idea utilized in reversible data hiding techniques, especially in the context of image encryption, is Reserving a Room Before Encryption (RRBE). Prior to the encryption procedure, a portion of the image's data capacity is allocated for the embedding of auxiliary information. Ensuring that enough space is set aside inside the image to embed more data while maintaining the security and integrity of the original image content is the aim of RRBE. The following steps are commonly included in the RRBE process:

Estimation of Capacity: Prior to encryption, the image's po-

tential to include supplementary data is calculated. This entails examining the image's properties, like its size, color depth, and pixel distribution, to ascertain the most auxiliary data that can be incorporated without appreciably lowering image quality or jeopardizing encryption security. Room Reservation: After estimating the capacity, a specific amount of the image's data space is set aside for the embedding of supplemental data. This reserved space is usually found in portions of the image, like smooth areas or areas with little texture details, that are less perceptually relevant or have lower entropy. The space that has been set aside guarantees that there is enough room to insert more data without creating observable artifacts or compromising the encryption procedure. Data Embedding: The auxiliary data is inserted into the image's designated space after the room has been booked. A variety of data concealing strategies can be employed to hide the auxiliary information with the least amount of negative effects on image quality, including frequency domain embedding, histogram shifting, and least significant bit (LSB) substitution. To guarantee that, following encryption, the original image can be precisely recreated, the embedding procedure needs to be reversible. Encryption: To safeguard the image's secrecy and integrity after the auxiliary data is included, cryptographic algorithms are used to encrypt it. Encryption protects the embedded auxiliary information from exposure or tampering by preventing unauthorized parties from accessing or manipulating the image's content. Reversible data hiding and encryption techniques can be seamlessly integrated with RRBE by booking a room in advance of encryption. This guarantees that concealed data can be inserted inside the image while maintaining its security and integrity. With the use of this technique, private information can be discreetly hidden inside encrypted photos, enabling safe communication, digital watermarking, and content authentication across a range of applications [8] [14] [11].

A category for secret sharing is also included. Secret sharing (SS)-based techniques for reverse data hiding in encrypted photos make use of these concepts to embed extra

data into encrypted images while maintaining their integrity and security. A cryptography technique called "secret sharing" splits a secret into several shares that are then given to a group of participants. While each of these shares by itself doesn't provide any information about the original secret, they can be combined to piece it together. When it comes to reversible data hiding in encrypted photos, SS-based techniques guarantee that only authorized persons having access to the necessary shares may retrieve the concealed data.

Secret sharing entails the following crucial elements and procedures: Creating the secret that needs to be shared with the parties is the first stage in the secret sharing process. A cryptographic key, private information, or any other confidential material that needs to be kept safe could be this secret. After the secret is created, an algorithm for secret sharing divides it into several shares. Each share is generated in a way that prevents any information about the original secret from being revealed by an individual share. Shamir's Secret Sharing Scheme (SSSS), threshold secret sharing, and visual cryptography are examples of common secret sharing techniques.

The authorized parties receive the shares once they are generated. A distinct portion is given to each party, and the distribution procedure makes sure that no one party has access to the full secret. Securing this distribution can be accomplished through a variety of protocols or communication methods.

A set number of shares must be obtained from the approved parties in order to recreate the original secret. The original secret data can be recovered by combining the shares using the secret reconstruction technique after the threshold is reached. By combining a sufficient number of shares, the secret will remain confidential and only be accessible through this rebuilding process.

Various security measures are put in place during the secret sharing procedure to guard the shares and secret against illegal access or interception. To avoid tampering or eavesdropping, this may involve secure communication lines, authentication procedures, and encryption of information.

For reverse data concealing in encrypted photos, there are a number of Secret Sharing-based techniques available, each with a unique methodology and set of fundamental ideas.

Typical techniques include the following:

1. Shamir's Secret Sharing Scheme (SSSS): Shamir's Secret Sharing Scheme is a well-known technique that uses polynomial interpolation to split a secret into several shares. To rebuild the original secret using polynomial interpolation, a minimum threshold of shares is needed. Each share is a point on a polynomial curve. SSSS can be modified to separate the concealed data into shares in the context of reversible data hiding in encrypted images. The shares are then integrated into the encrypted image through the use of methods like LSB replacement or pixel alteration.

2. Visual Cryptography (VC): This is a cryptographic method in which an image is split up into several shares, each of which keeps the original image's contents hidden. The original image is seen when the shares are stacked or layered.

When reversible data hiding is involved, VC can be used to split the concealed data into shares that are subsequently included into the encrypted image by the use of dithering or halftoning, among other approaches. By merging the shares that were received from the decrypted image, the original data can be retrieved.

3. A variation of Shamir's Secret Sharing Scheme, Threshold Secret Sharing necessitates a minimum threshold of shares in order to reconstruct the original secret. This threshold adds a layer of security against unwanted access by guaranteeing that a specific quantity of shares must be present in order to recover the hidden data. Threshold secret sharing can be used to split up concealed data into shares in the context of reversible data hiding in encrypted images. The shares are then embedded into the encrypted image using techniques specific to the current encryption scheme.

4. Block-Based Secret Sharing: In this method, the secret data is separated into blocks or segments, each of which is embedded into the encrypted image and encrypted separately. By distributing the hidden data throughout the entire image, this method makes the data more resistant to detection and attacks. Block-based secret sharing can be used to separate the concealed data into blocks for reversible data hiding in encrypted images. The blocks are then encrypted and inserted into the encrypted image using methods like block modulation or LSB substitution.

All things considered, secret sharing is an effective cryptographic mechanism that permits the safe reconstruction and distribution of secrets across several parties while guaranteeing access control, confidentiality, and integrity. [15] [16] [17] [18]

A. VRAE

- 1) Adaptive MSB (most significant bit) Prediction: Using adaptive prediction to efficiently free up embedding space within pixel blocks, the Adaptive MSB Prediction (AMP) approach enhances the embedding capacity in reversible data concealing in encrypted images. The approach adjusts its prediction strategy based on the variations between the pixels by utilizing the upper-left pixel inside a block to forecast the other pixels. The block's available embedding room can be well utilized thanks to this adaptive prediction. When the discrepancies between the pixels are minor, the approach maintains the Least Significant Bits (LSBs) of the anticipated pixels. By preserving the LSBs, space is made available for the embedding of extra data while preserving the quality of the image. More data can be embedded without significantly distorting the cover image when the approach vacates the embedding room within the block when the pixel differences are modest. additionally The technique maximizes the capacity for data hiding within the encrypted image by vacating the embedding room based on adaptive prediction and LSB preservation, therefore maintaining a high capacity. There are three primary phases to the technique: To guarantee privacy and preserve the integrity of the image, the owner first encrypts the cover image using an encryption key.

There are two ways to do this with encryption:

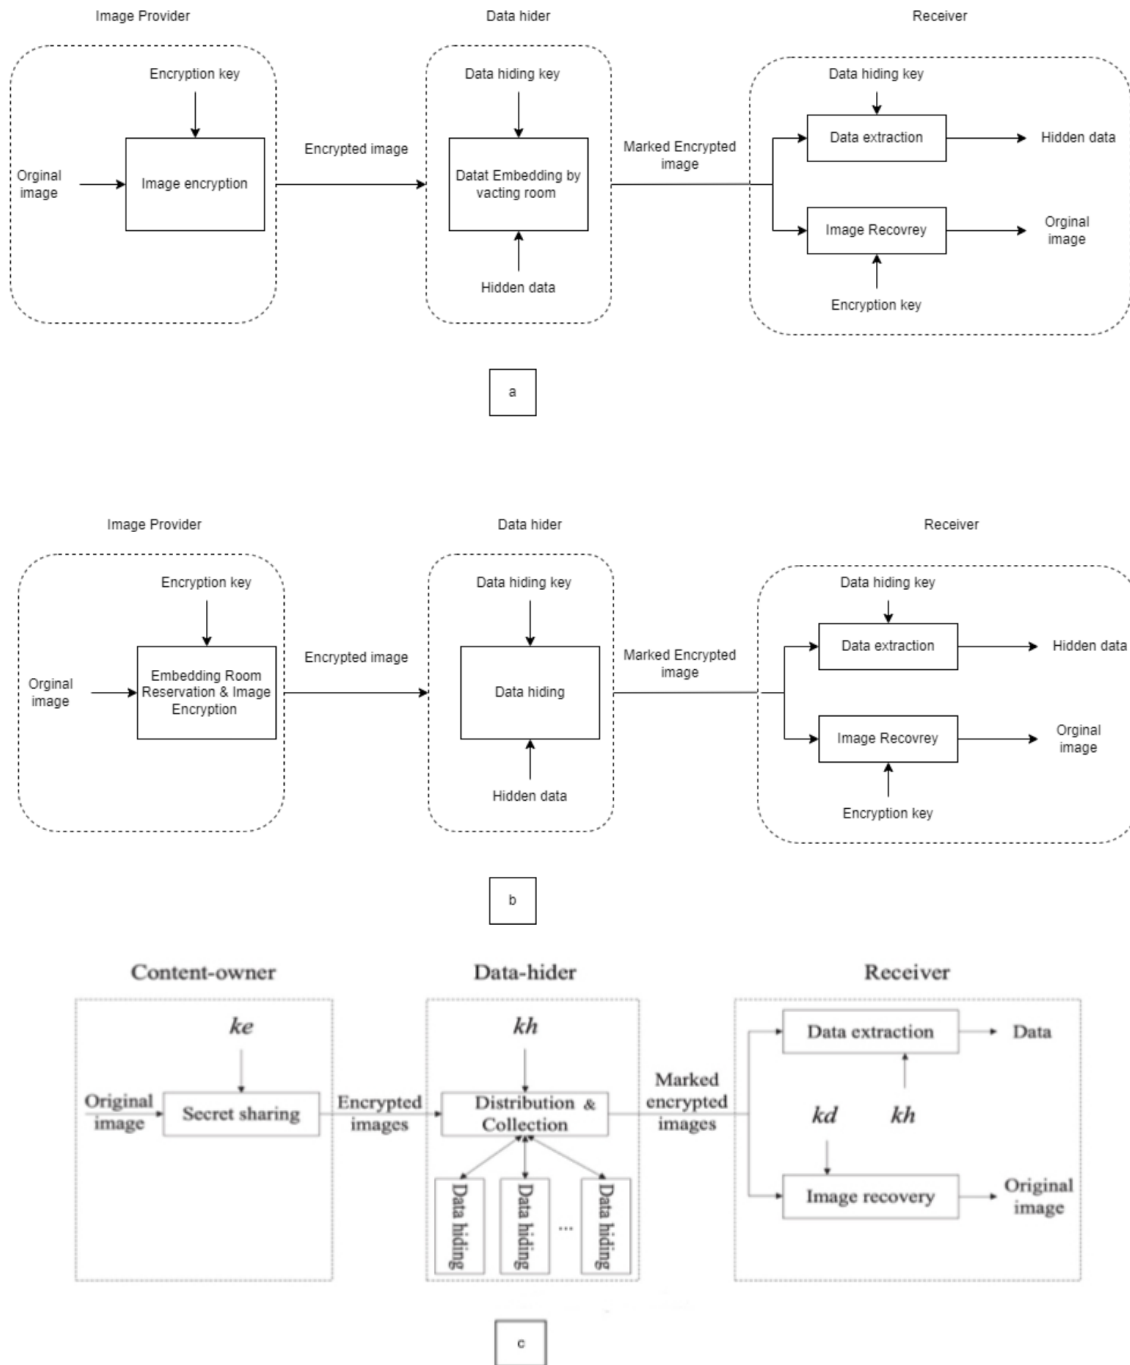

Fig. 2. Types of RDHEI: (a) vacating room after encryption (VRAE), (b) reserving room before encryption (RRBE), and (c) Secret Sharing (SS).

1-block-level encryption The procedure of stream encryption on block level :

Involves dividing the original image into non-overlapping blocks.
 Calculates the average pixel value for each block and computes the difference between each pixel and the average.
 Based on a predefined threshold, pixels are modified to enhance privacy protection.

2-block permutation:

After the first phase of encryption, the cover image is divided into 2x2 blocks again.
 To create the final encrypted image, each block is permuted using the encryption key.
 This process ensures that no image content can be revealed through complexity analysis, enhancing privacy protection.

and also Additional data is embedded into the encrypted image

by a **data hider** using a data-hiding key. Through these steps:

- Step 1: Image partition.
- Step 2: Block selection using AMP.
- Step 3: Block rearrangement.
- Step 4: Data encryption.
- Step 5: Data hiding.

for **Data Recovery and Image Extraction** Depending on whether the decryption key and the data-hiding key are available, the recipient can either get the image content or extract concealed data. In order to extract data and retrieve the tagged image, the decoding method splits the image into non-overlapping, 2x2 blocks.

Finally technique combines encryption, data hiding, and reversible data extraction to enable high-capacity data hiding in encrypted images while maintaining image quality and privacy [19].

2) *Pixel prediction and entropy encoding*: Using the adjacency prediction and median edge detector (MED), this approach first generates the prediction-error histogram (PEH) of the chosen cover. This is done by use of the ERGA (Efficient Embedding Room Generation Algorithm). The pixels are separated into joint and independent encoding pixels in this step. Following self-embedding and arithmetic coding compression of the prediction errors, a sizable embedding room for reversible data hiding in encrypted pictures (RDHEI) is produced. The approach creates a huge embedding room for data hiding by first using pixel prediction to generate prediction mistakes, which are then compressed using entropy encoding. In both the vacating room before encryption (VRBE) and vacating room after encryption (VRAE) scenarios, this method enables high-capacity reversible data concealing.

Encryption process: In VRBE-based RDHEI scheme, Using self-embedding, the picture owner removes the embedding room from the original image and creates the encrypted image with the removed room. With a given encryption key, the owner uses a stream cipher to create a pseudo-random sequence. The picture is encrypted with the room cleared out by employing a stream cipher and a pseudo-random sequence.

In the VRAE-based RDHEI scheme, To maintain spatial redundancy, the cover picture is encrypted using an enhanced block modulation and permutation encryption algorithm. All things considered, the encryption procedure in both schemes makes sure that, both before and after data concealing by unauthorized users, the original image can scarcely be found from the encrypted version. then, The *data hider* finds the room that has been vacated for embedding in the encrypted image, then embeds the encrypted extra data into the encrypted image together with the room that has been vacated. The data hider embeds the encrypted additional data into the encrypted image by using the efficient embedding room generation algorithm (ERGA) on the encrypted blocks to free up space.

Data Extraction: Inside the designated encrypted image, the authorized receiver finds the embedding chamber first. Then, using the relevant keys (such as the data hiding key), the recipient extracts the embedded data from the indicated

encrypted image. To acquire the original supplementary data without errors, the extracted data is decrypted.

image Recovery: The original cover picture can be recovered without loss from the designated encrypted image if the recipient possesses the required keys, such as encryption keys. To recover the original image error-free, the designated encrypted image must be decrypted as part of the image recovery procedure [20].

B. RRBE

1) *Huffman coding and differences of high nibbles of pixels*: **Huffman coding method** is employed to encode the variations in high pixel nibbles in order to accomplish excellent data hiding, efficient compression, and error-free data retrieval. It also enhances the dependability and efficiency of reversible data hiding in encrypted images.

Here's an overview of how the method works:

High bite values and spatial correlation: In images, adjacent pixels frequently have comparable high values because of spatial correlation. Utilizing this association, the technique effectively compresses the four most significant bit (MSB) levels. Where each pixel's high value is a 4-bit value, the difference is computed. The approach looks at the values close to zero and computes the differences between the high points of adjacent pixels. To encode, these discrepancies are added together. Next, Huffman coding is applied, which is achieved by first figuring out how the disparities between the high points are distributed. Then, Huffman coding is used to encode these differences. Effective data compression is made possible by the variable-length prefix coding method known as Huffman coding, which translates shorter codes to more frequent codes. The compression approach compresses the image's four high MSB levels using encrypted versions that are produced by Huffman coding. There is more room in the MSB levels to conceal data without sacrificing information when the original high segments are swapped out for compressed alternatives.

The encryption process includes the following steps:

Make room for data hiding by first removing any unnecessary space from the plain text picture that the data owner wants to use for data concealing. Using Huffman coding, the four most significant bit (MSB) levels are compressed in this stage to provide more space for the data to be embedded while preserving image quality. Next, an encryption key is used to encrypt the photos using stream encryption. Stream encryption is a homomorphic encryption method that is commonly used to encrypt real-time data streams. It encrypts data either bit by bit or byte by byte. To safeguard data security and preserve its content, the image in this instance is encrypted. Information about the room available to conceal the data at least significant bit (LSB) levels is contained in the encoded image. In order to incorporate sensitive data within the picture without distorting or losing any information, the data hider needs these information.

The data is embedded as the **data hiding tool** receives the encrypted image and extracts the capacity information to determine the space available for data hiding at LSB levels. Different schemes can be used, e.g

- Bit substitution
- (7,4) Hamming code-based Matrix Encoding
- Bit flipping

to include confidential data in the image based on specific requirements.

Confidential data is extracted as follows:

Bit substitution: The receiving device can accomplish this by using a data masking switch. Straight from the encrypted image's data concealing chamber, extract embedded private data. **Matrix encoding:** The data is extracted by the recipient using a steganographic key. the data hiding chamber's bits and split them up into 7-bit codes. **Bit flipping:** To decode the bits, the recipient utilizes the encryption key. After tagging the encrypted image, the original embedded LSBs from the MSB aircraft are retrieved. After then, the recipient hides the data using the key, to take the bits from the data hiding room that are embedded with secret data and compare them to the original LSBs. The receiver will extract secret bit 0 if the extracted bit matches the matching original bit; if not, secret bit 1 will be extracted. Information Instead of doing the extraction from the encrypted domain, it should be done in the decrypted domain. This is not the same as matrix encoding or bit substitution. Image recovery also occurs when the designated encrypted image is immediately created as a decrypted image by the receiving device using the encryption key. Next, the four high MSB levels of the decoded image are directly used to retrieve the original embedded LSBs, high compressed differences, Huffman code, and bitstream significance bit. The four high MSB levels of the original image are recovered after the high-resolution compressed versions are decoded in accordance with the Huffman code [10].

2) *Adaptive prediction-error labeling:* Based on adaptive prediction-error labeling (APL), the technique for reversible data hiding in encrypted images uses two methods: Pessimistic APL (PAPL) and Optimistic APL (OAPL). The suggested methods include a framework with multiple stages, such as image encryption, data concealment, APL labeling, data extraction, and image recovery.

During the APL labeling phase, the original image's prediction errors (PEs) are computed and the high-frequency and low-frequency PEs are adaptively labeled using an APL method. The labeling process entails dividing the PEs into high- and low-frequency categories and labeling them with normal labels (NL) and special labels (SL). The APL approach is used to produce the labels and ignored bits.

the *image encryption process in PAPL* entails bitstream encryption, standard encryption, self-embedding, and assessment of the threshold value's influence on the reserved room. By following these procedures, the encrypted image is guaranteed to be secure and reversible, enabling the full and independent recovery of the original image as well as additional data that is dependent on the secret key.

the *image encryption process in OAPL* entails reordering the bitstream, concatenating unshuffled labels and auxiliary data, and then encrypting the rearranged image using stream encryption. Not a Process of Self-Embedding. The original image and any additional data based on the secret key can be

fully and independently recovered using this method, which guarantees the security and integrity of the encrypted image.

and The process of *data hiding* occurs in a way that allows the data hider to get the first unencrypted location marker that is, the pixel coordinate from the start of the sequential bit stream where the reserved room starts. After the initial position, bits can be replaced to use the reserved room for modulation.

1. In PAPL, Additional data encrypted by the data hiding key may be included in the picture encrypted with the random labels, i.e., by multiple LSB replacement, depending on the original location label and the length of each random label.

2. In OAPL, Further encoded data can be added to the encoded image by multiple LSB (equivalent to bit-level rearrangement) or pixel substitution (pixel rearrangement) with the initial location tag.

Finally, a distinctive encrypted image can be easily generated.

Data Extraction: If the recipient has the data hiding key, the encrypted additional data can be extracted perfectly. In *PAPL*, The location of the reserved room may be determined from the initial location flag and the labels without inverse shuffling, which makes it possible to retrieve the encrypted additional data. In *OAPL*, A location marker alone can be used to locate the reserved room, and the extracted encrypted additional data can be decrypted to reveal the original additional data.

Image Recovery: Error-free recovery of the original image is possible if the receiver possesses the encryption key. Using the encryption key, the concatenated bitstream can be extracted before the first location, allowing for the retrieval of the original auxiliary information and unshuffled labels. Both the original image and any extra data can be fully recovered at the same time if the recipient possesses both the data hiding key and the encryption key [21].

3) *Reserving room before encryption:* The technique used is reversible data hiding in encrypted images by reserving room before encryption (RRBE). The technique involves a general framework that allows for the adoption of different predictors to achieve high embedding capacity in encrypted images.

This is done through:

Preprocessing: The following steps are involved in the preprocessing stage of the reversible data concealing in encrypted images by reserving room before encryption (RRBE) technique: The difference between the expected and actual pixel values in the original image is represented by prediction-errors (PEs), which are computed using various causal predictors. and thereafter The obtained prediction-errors are separated into chunks that do not overlap. There are a number of prediction errors in every block. and a label is allocated for every block of prediction-errors according to the highest prediction-error that occurs in that block. The amount of data that may be embedded in a block is determined by its embedding capacity, which is indicated by this label. In order to create space for data to be embedded in the encrypted image, preprocessing is essential. In order to obtain high embedding capacity, it enables

the effective use of spatial correlation and the selection of the best predictor available.

Then, *the encryption process*, which includes several steps and based on RRBE technology, does the following:

1. Content Encryption: The original image is encrypted using a stream cipher and an input secret key.

2. Secret Data Encryption: The secret data that has to be embedded is encrypted using a standard encryption method and an input secret key. When employing the reversible data hiding in encrypted images by reserving room before encryption (RRBE) technique, the data hider is crucial to embedding secret data into the encrypted image and ensuring the security and integrity of the process.

The *data hider's* responsibilities include:

1. Preprocessing: The preprocessing stage is carried out by the data hider.

2. Secret Data Encryption: Using an input secret key and a normal encryption method, the data hider encrypts the secret data. By doing this, the secret data is safeguarded before being incorporated into the encrypted picture.

3. Embedding Secret Data: The data hider safely and precisely embeds the encrypted secret data into the designated encrypted image by using the prediction-errors and labels acquired during the preprocessing step.

4. Information Sharing: To help with the extraction and recovery process at the receiver end, the data hider occasionally shares information with the content owner, such as the labels and starting block address. In general, the data hider's job is to include the secret data into the encrypted image while making sure that the hidden data can be recovered without distortion and that the original image can be correctly recreated.

The process of extracting data and recovering the original image involves the following steps:

1. Extracting Labels: The labels included in the tagged encrypted image are extracted at the recipient's end. The embedding capacity of each block in the encrypted image is ascertained using these labels.

2. Extracting Secret Data: The embedded secret data is recovered from the tagged encrypted image using the extracted labels. To guarantee error-free data extraction, the labels direct the extraction procedure.

3. Recovering the Original Image: Using the content-owner key and the retrieved data, the original image is rebuilt. The following steps are involved in the process: a. Decryption: The original encrypted image is obtained by decrypting the indicated encrypted image with the content-owner key. b. Reconstructing Pixels: Using the recovered data and the information kept during the embedding process, the original pixels are recreated. This makes it possible to rebuild the original image without any loss [14].

C. SS

1) *Secret sharing and hybrid*: In order to increase the security of the original image, this approach first performs

iterative encryption. Afterwards, the encrypted image is dispersed across several data hiders via block-based Chinese Remainder Theorem-based Secret Sharing (CRTSS). Reversible data hiding (RDH) with hybrid coding can be carried out individually by each data hider. This makes it possible to incorporate sensitive information into the encrypted sharing. Finally, provided that enough uncorrupted marked shares are found, the original image can be reconstructed without any loss in quality using CRTSS. Data security and the original image's lossless recovery are guaranteed by this procedure.

The *encryption process* is carried out using an iterative encryption technique that combines block permutation with block-based modulation. The objective of this procedure is to reposition image blocks in a way that maintains spatial correlation and increases security, while also modifying the pixel values within each block. More redundancy for data embedding is produced by the iterative encryption, which creates an encrypted image with retained spatial correlations. To prevent cryptanalysis, the encryption key is made up of dynamically created parameters, guaranteeing the security of the encrypted image.

then the *data hider* operates by employing hybrid coding to independently carry out reversible data hiding (RDH) on the encrypted shares that are obtained from the content owner. The data hider embeds secret data into the encrypted shares using the hybrid coding technique. By using this method, the original image's security and integrity are preserved while the data hider can participate in the data concealing process.

and *The process of extracting data and recovering the original image involves several steps:*

1. The designated image is used to extract data. It is then divided into blocks, from which embedded data is extracted. Decoding the auxiliary data and removing the embedded bits from the blocks are steps in the extraction process.

2. The encryption and data concealment procedures are undone by carrying out inverse operations to retrieve the original image. This involves recovering the original image from the marked encrypted shares using iterative block-based modulation and inverse block permutation.

3. To get the original secret data, the encrypted secret data is extracted from the embedded portions and decrypted using the data-hiding key.

These procedures enable the decryption and retrieval of the contained secret data as well as the lossless recovery of the original image [22].

IV. APPLICATIONS OF RDHEI

Reversible data hiding in encrypted images has a wide range of applications across various domains. Some of the key applications include:

- **Secure Communication:** Secret messages or information can be embedded into encrypted images via reversible data hiding, creating a secure communication channel. This tool is especially helpful in situations where maintaining secrecy is crucial, including military communications, diplomatic contacts, or private commercial talks [23] [24].

- Copyright protection and digital watermarking: Reversible data concealing makes it possible to incorporate copyright information or digital watermarks into encrypted images without jeopardizing the security of the encryption. By doing this, publishers, distributors, and content creators can safeguard their copyright claims and intellectual property rights, discouraging unauthorized use or distribution of digital information [25] [26].
- Medical Imaging and Telemedicine: In the medical industry, patient data, diagnostic data, and medical records can be securely transmitted thanks to reversible data concealment in encrypted medical images. This program protects patient privacy and confidentiality while facilitating telemedicine, remote diagnostics, and medical consultations [27] [28].
- Digital Forensics and Authentication: In digital forensics investigations, forensic watermarks or authentication codes can be embedded into encrypted images using reversible data hiding techniques. This makes it possible for forensic analysts, digital investigators, and law enforcement to identify manipulation or tampering, trace the origin of photos, and validate digital evidence [29].
- Digital Rights Management (DRM) and Multimedia Content Protection: By using data embedding and encryption, reversible data concealing techniques can be used to safeguard multimedia content, including audio files, digital documents, and videos. This makes it possible for distributors, service providers, and content owners to set up reliable DRM systems, enforce access restrictions, and stop illegal or pirated digital content from being redistributed or copied [30] [31].
- Steganography and Covert Communication: By embedding hidden messages or data into encrypted images, reversible data hiding enables covert communication and information concealment. This application is frequently used in covert operations, espionage, and intelligence collection, where upholding confidentiality and secrecy is essential [32].
- IoT Security and Embedded Systems: Reversible data concealing techniques can be used in the Internet of Things (IoT) ecosystem to safeguard sensor networks, IoT devices, and embedded systems. IoT devices can securely connect, exchange data, and authenticate with other devices or cloud services by embedding encryption keys, authentication tokens, or configuration data within encrypted pictures [33].
All things considered, reversible data hiding in encrypted images provides a flexible and effective tool for safeguarding private data, preserving digital assets, and enabling a range of applications in a variety of fields, such as digital forensics, communication, multimedia content protection, and Internet of Things security.

V. FUTURE OF RDHEI

Reversible data hiding in encrypted photos has a bright future ahead of it, with more developments in security, privacy,

and applications anticipated. The future prospects for this field are shaped by the following important factors: Strengthened Security Protocols: Future developments in reversible data concealment will put more emphasis on strengthening security protocols to fend off new threats and intrusions. This involves creating stronger encryption methods and data concealing strategies to guarantee the integrity and confidentiality of the embedded data as well as the original image. In order to improve the security of reversible data hidden in encrypted images, advanced cryptographic primitives and techniques including homomorphic encryption, lattice-based cryptography, and post-quantum cryptography will be essential.

additionally Reversible data concealing strategies will need to prioritize privacy protection more and more, especially when data privacy laws tighten. Subsequent investigations will concentrate on creating privacy-maintaining technologies that allow data concealment without jeopardizing user confidentiality or privacy. We'll use strategies like federated learning, safe multiparty computation, and differential privacy to reduce the privacy risks related to data embedding in encrypted images [34] [35].

In order to meet new demands and problems, reversible data concealment techniques will be combined with developing technology. To improve data traceability, integrity verification, and tamper resistance in encrypted photos, this involves integrating blockchain technology. Furthermore, more effective steganalysis methods for finding concealed data within encrypted photos will be made possible by the integration of artificial intelligence and machine learning algorithms, improving security and threat detection capabilities.

Reversible data hiding in encrypted graphics will become more widely used in a wider range of sectors. Reversible data concealing techniques have novel applications in healthcare, banking, digital forensics, and Internet of Things (IoT) security, in addition to classic uses like digital watermarking and secure communication. Reversible data concealment, for instance, can improve telemedicine and medical diagnostics by enabling safe patient data transmission while maintaining diagnostic accuracy. The widespread use of reversible data hiding techniques in encrypted photos will be greatly aided by standardization initiatives and interoperability standards. In order to enable safe and effective data interchange and cooperation across various platforms and applications, common frameworks, protocols, and interoperability standards must be established. This will enable smooth integration and interoperability across various data concealing and encryption technologies [36] [37].

Overall, the future of reversible data hiding in encrypted images is characterized by advancements in security, privacy, integration with emerging technologies, diversification of applications, and standardization efforts. By addressing these challenges and opportunities, reversible data hiding techniques will continue to evolve and innovate, enabling secure and efficient data communication, storage, and exchange in the digital age.

VI. DISCUSSION

In this section, a comparison will be made between the *methods*, *Embedding rate*, with *PSNR* as shown in Tables I

and II.

TABLE I. COMPARISON OF THE USED SCHEME AND THE PSNR (dB) OF DIFFERENT RDHEI METHODS

Method	VRAE/VRBE/RRBE/SS	PSNR value(dB)
[19]	VRBE	∞
[10]	RRBE	0.5
[21]	RRBE	∞
[21]	RRBE	∞
[20]	VRBE	8.33
[14]	RRBE	∞
[22]	SS	∞

TABLE II. COMPARISON OF THE EMBEDDING RATES (BPP) OBTAINED FROM NINE DIFFERENT METHODS ACROSS THREE IMAGE DATASETS

Method	Average for 6 images	BOSS	BOWS-2	UCID
[19]	NA	NA	2.26	NA
[10]	2.29865	NA	NA	NA
[21] PAPL	NA	3.826	3.7	3.126
[21] OAPL	NA	3.947	3.7	3.200
[20] PE-VRAE	NA	3.9	3.7	3.1
[20] PE-VRBE	NA	4.0	3.9	3.3
[14] L	NA	3.6	3.7	NA
[14] AL32	NA	3.7	3.8	NA
[22]	NA	4.0	3.9	3.3

The results in the table shows that the Hybrid and Secret Sharing method performs better than other methods in terms of both embedding rate and noise-free image restoration rate. Out of all the strategies examined, this method achieves the highest embedding rate, demonstrating its efficacy in embedding a greater quantity of additional data into the encrypted image. Furthermore, the Hybrid and Secret Sharing method's positive noise rate of infinity implies that it can restore the original image without adding any noticeable distortion or noise. Overall, the results demonstrate the hybrid method's and secret sharing's improved performance and capabilities in reversible data concealing in encrypted images, making it a promising approach for secure and efficient data embedding applications.

VII. CONCLUSION

This survey provides a comprehensive overview of the topic of RDHEI, discussing various schemes and showing different techniques used to implement them. The discussed schemes are: Room Reservation Before Encryption (RRBE), Room Evacuation After Encryption (VRAE), and Secret Sharing(SS), all of which play crucial roles in ensuring the integrity and security of the data hidden within encrypted images. Furthermore, we emphasized the importance of reverse data hiding as one of the most important techniques to hide additional information within encrypted images while maintaining their confidentiality. By discussing their applications across diverse fields such as secure communications, digital watermarking, medical imaging, and digital forensics, we highlight their wide-ranging utility and importance in modern digital environments. Furthermore, this survey highlighted future prospects for reversing data hiding in encrypted images, envisioning advances in security measures, privacy-preserving solutions, integration with emerging technologies, and diversification of applications. These developments underscore the continued importance and evolution of reversible data steganography techniques in addressing emerging challenges and enhancing

steganography practices. Finally, we emphasized the importance of performing comparative analysis, including embedding rates, methods and peak signal-to-noise ratio (PSNR), to evaluate the performance and effectiveness of reversible data hiding techniques. This comparative approach enables researchers and practitioners to make informed decisions and optimize data hiding methods based on specific application requirements and performance metrics. Overall, this survey provided valuable insights into techniques, applications, future prospects, and comparative evaluation criteria for reversing data steganography in encrypted images, contributing to a deeper understanding of this important area in data security and data hiding.

Abstract—Graph Neural Networks (GNNs) have emerged as a state-of-the-art approach in building modern Recommender Systems (RS). By leveraging the complex relationships among items, users, and their attributes, which can be represented as a Knowledge Graph (KG), these models can explore implicit semantic sub-structures within graphs, thereby enhancing the learning of user and item representations. In this paper, we propose an end-to-end architectural framework for developing recommendation models based on GNNs and KGs, namely HybridGCN. Our proposed methodologies aim to address three main challenges: (1) making graph-based RS scalable on large-scale datasets, (2) constructing domain-specific KGs from unstructured data sources, and (3) tackling the issue of incomplete knowledge in constructed KGs. To achieve these goals, we design a multi-stage integrated procedure, ranging from user segmentation and LLM-supported KG construction process to interconnectedly propagating between the KG and the Interaction Graph (IG). Our experimental results on a telecom e-commerce domain dataset demonstrate that our approach not only makes existing GNN-based recommender baselines feasible on large-scale data but also achieves comparative performance with the HybridGCN core.

Keywords—Large-scale dataset processing; recommender systems; graph neural network; knowledge graph construction; data segmentation

I. INTRODUCTION

Recommender System (RS) has been playing a pivotal role in enhancing user experience on e-commerce platforms. It uses user historical interactions and item attributes to generate personalized recommendations. Traditional approaches have been developed and can be categorized into two primary pillars: Content-based and Collaborative Filtering. However, they may fall short in practical applications with higher rates of sparsity and cold start [1].

Recently, graph-based modeling has been an emerging trend in the field, as it can exploit and extend the relations between users or items [2]. Graphs provide a natural way to represent and model relationships, capturing complex interdependencies and interactions that traditional methods might overlook. Noteworthy, Graph Neural Network-based (GNN-based) techniques have showcased exceptional performance across a myriad of application domains, underscoring the potential and adaptability of this approach. Despite the promising performance, the implementation encounters limitations when applied to large-scale datasets characterized by an extensive volume of users and items, as well as diverse interaction patterns, which can lead to *neighbor explosion* during graph

construction [3]. Many recent SOTA GNN-based RS [4], [7], [17] have only experimented on popular benchmark datasets with medium-to-small user bases, questioning their feasibility on real-world systems with large-scale user data.

Incorporating Knowledge Graphs (KGs), which encapsulate domain-specific knowledge and semantic relationships, can further support the recommendation process in the embedding stage [12]. By integrating Graph Neural Networks with Knowledge Graphs, recommender systems can harness both the structural relationships and semantic insights, resulting in more accurate, context-aware, and personalized recommendations [16]. However, a problem lies in the reliance on open sources, which creates challenges in constructing complete Knowledge Graphs for domain-specific private data, thereby limiting the model's applicability and effectiveness in diverse and complex environments. Indeed, recent GNN-KG-combined models [17], [18] have only been evaluated on popular datasets with easily extractable KGs from Open Knowledge Bases, without considering their performance on narrowly specialized domains, thus ignoring issues that may arise in post-synthesized KGs like *incomplete knowledge*.

In this paper, we propose a new recommender system model, **HybridGCN**, which will address all of the above problems. Particularly, our main contributions are as follows:

- 1) Propose a semi-automatic procedure for constructing our domain-specific knowledge graph in a niche domain that is highly RS-compatible, with support from Large Language Model (LLM).
- 2) Achieve scalable Graph Convolutional Network (GCN) on empirically large-scale datasets through user behavioral segmentation.
- 3) Tackle the practical issue of incomplete knowledge integration in GNN-based recommender models leveraging KGs, in which HybridGCN stands as our state-of-the-art (SOTA) approach. We empirically compare HybridGCN with other SOTA methods and demonstrate substantial improvements.

The remainder of this paper is as follows. Section II overviews the related work. Then Section III describes our proposed method, which includes the overall pipeline, model architecture, and training strategy. The experiment evaluation and discussion are detailed in Section IV. Finally, we conclude and discuss our work in Section V.

II. RELATED WORK

Traditional recommender systems primarily rely on two main approaches: collaborative filtering and content-based filtering. Collaborative filtering methods generate recommendations by identifying patterns and similarities among users or items, while the latter recommends items based on their features or attributes, matching user preferences with item characteristics. ALS [20] (Alternating Least Squares) is a popular collaborative filtering algorithm that utilizes matrix factorization to decompose the user-item interaction matrix into lower-dimensional matrices (latent factors) representing users and items similarities on new factors. However, ALS tends to recommend popular items frequently, leading to a lack of diversity and personalization in recommendations.

More advanced techniques have been developed to address those issues, including the use of Neural Networks. One such approach is Mult-VAE [21], which leverages deep learning to build recommender systems. Mult-VAE employs multiple layers of Variational Autoencoders (VAEs), which are generative models capable of learning complex data distributions and capturing underlying patterns in user-item interaction data. Another powerful tool for modeling and analyzing complex relational data, including recommender systems, is Graph Neural Networks (GNNs). NGCF [4] was the first popular GNN model applied to recommender systems, introducing the concept of message passing. This approach enables NGCF to learn enriched representations of users and items by aggregating information from their neighboring nodes in the graph. Inspired by simplified Graph Convolutional Network (GCN) design in SGCN [8], LightGCN [7] only focuses on linearly combining the embeddings obtained from different propagation layers in the graph. Additionally, GraphSAGE [11] offers a more general framework for inductive representation learning on graphs, which has also been adapted for large recommender systems. It operates by sampling and aggregating features from a node's local neighborhood to learn node embeddings that capture the structural properties and relationships. Building upon that, PinSage [19] removes the limitation of storing the entire graph by using random walks to sample graph neighborhoods.

Knowledge Graphs provide a structured representation of information, enabling recommender systems to understand and leverage the semantic context and meaning behind user interactions and item attributes. There have been recent studies applying them to graph-based models, notably KGCN [17]. By integrating domain-specific knowledge and structural insights from Knowledge Graphs, KGCN addresses the limitations of conventional recommendation models and achieves superior performance in capturing user preferences and item characteristics, particularly in complex and diverse recommendation scenarios. However, the diversity and incompleteness of natural knowledge pose practical challenges in customizing the integration process of KGs into graph-based models to effectively take advantage of the provided semantics, while avoiding the introduction of unpredictable noises that can conversely degrade performance [13]. The major difference between our HybridGCN core and the literature is that we will leverage the KG propagation paradigm of KGCN and additionally employ a semantic enrichment mechanism inspired by LightGCN-like methods to utilize subgraphs within the interaction graph for

indirectly inferring more hidden connections, which is a *cross-graph propagation technique*.

The construction of a Knowledge Graph is also a challenge. In the context of recommender systems, integrating information from a knowledge graph source with high semantic consistency and low noise is crucial to ensure relevance, and personalization, and enhance the overall quality of recommendations. This also means that each real-world entity should have a unique identifying node within the integrated KG. Typically, knowledge about entities can be collected from various sources, each providing a KG that represents its understanding of the queried entity set. From there, a challenge arises in unifying the different aliases of the same entity that appear in multiple asynchronous data sources [14], [15]. This is accomplished through entity alignment tasks, aiming to create an ultimate comprehensive KG for model learning. For example, KGCN [17] uses an open knowledge base (OKB) to extract item-related triples for constructing their knowledge graphs and testing their model on popular datasets. Due to the nature of OKB, which organizes knowledge in a structured manner through metadata, Resource Description Framework (RDF), or defined ontologies [5], extracting triples and re-connecting them into a knowledge graph input is relatively straightforward and does not heavily rely on the entity alignment step. However, with domain-specific datasets, the construction of semantic triples often requires a more complicated process, involving the extraction and reorganization of information from unstructured data sources [6]. In this paper, we employ an innovative approach using LLMs to capture, denoise, and enrich semantic entities and relations within our Knowledge Graph.

III. PROPOSED METHOD

A. Overall Framework

The overall framework of the proposed system is illustrated in Fig. 1(a). The customer base of a commercial system can potentially encompass a large number of individuals, each with diverse needs and usage patterns. Therefore, we propose an initial stage involving segmenting users into distinct groups based on their historical behaviors. Within our context of telecommunication, this segmentation process will leverage side behavior indicators, such as user revenue or historical patterns of calling and data usage.

After the segmentation stage, each user is assigned to a cluster that comprises other users with similar behavior patterns. Personalized recommendations are then generated by considering the items interacted with by users in the same cluster. It is worth noting that in practical scenarios, the system does not possess immediate access to the behavior history of new users. Consequently, for such users, the system offers diverse recommendations based on their initial needs. As the behavior history of new users gradually accumulates, dynamic assignment to existing clusters becomes feasible.

The graph construction stage for each cluster involves transforming user-item interaction data into an interaction graph (IG) and building an item-related KG. Specifically, to construct the IG, we utilize subscription data as an implicit feedback source from users to items. This data type is unary, implying that we can only infer user preferences based on their

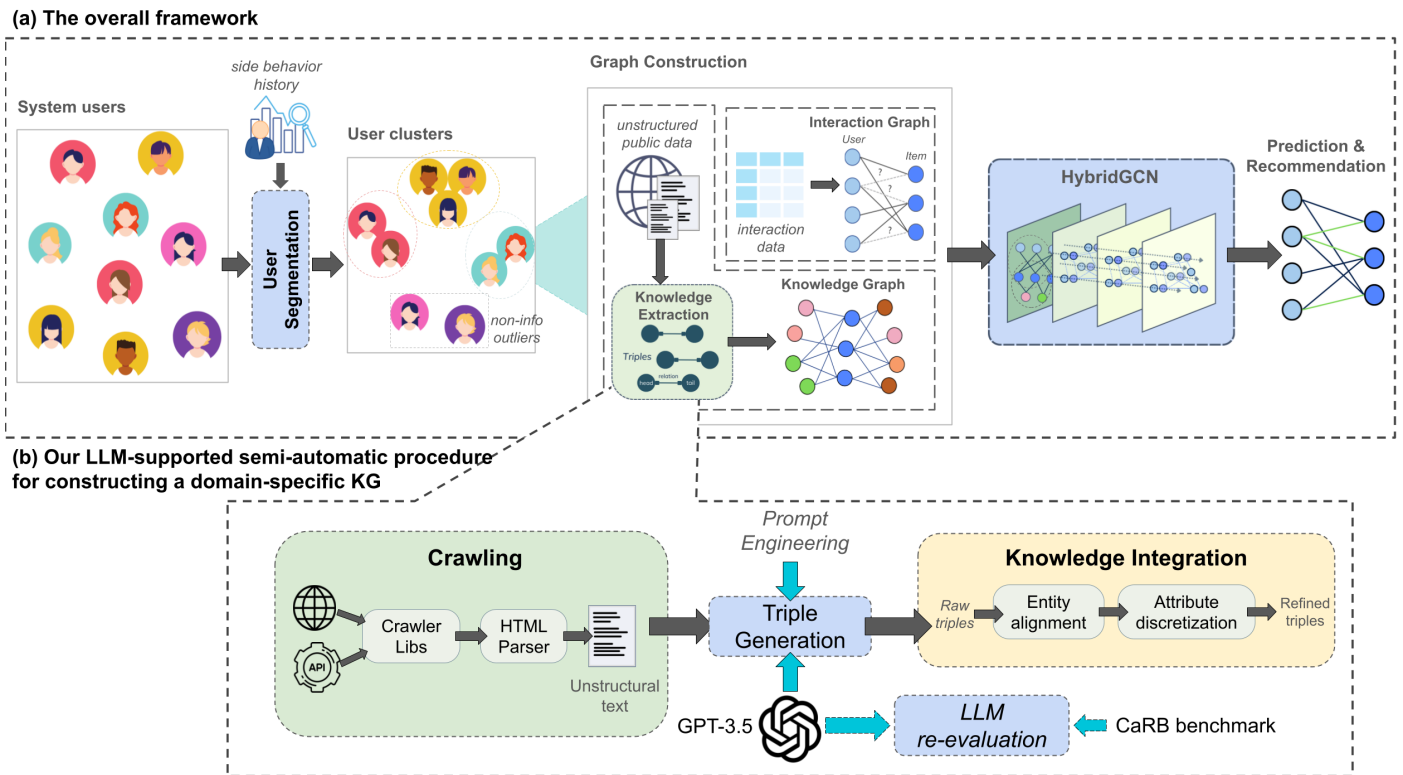

Fig. 1. Overall framework of HybridGCN.

subscribed packages while assigning uncertain probabilities to packages they have not interacted with. As for the item-related KG, we implement an approach supported by a Language Model (LM) to extract data from the internet. The procedure for constructing our domain-specific knowledge graph is illustrated in Fig. 1(b).

In detail, our process consists of three steps, which take place in a semi-automatic manner. Firstly, telecom package descriptions are scraped and parsed from API sources or relevant official websites. The semantic information of these packages includes price, package type, minutes allowed for domestic and international calls, or accompanying benefits. The output of this step is unstructured text corresponding to available packages. It is noted that information about a telecom package may appear in multiple sources. We collect data from various sources to ensure the completeness and diversity of semantic descriptions for these packages. However, there are also some packages for which their external information cannot be found.

In the second step, we utilize the API provided by the GPT-3.5 language model to extract information from the text, returning the results in the form of semantic triples. Several previous studies [23]–[25] have examined the capabilities of generative Language Models in text understanding and generation, demonstrating viable solutions for information extraction tasks. However, when it comes to knowledge extraction tasks, a conversational model that is not specifically trained to recognize entities and relations may not be able to provide an alignable set of entities [26]. To address these challenges, we carry out two following tasks: (1) *specify the*

prompt engineering by providing the ontology of our domain-specific KG, such as specifying the types of relations between different entity types; and (2) *pre-train the LM with some labeled domain-oriented data samples*. We also re-evaluate the knowledge extraction capability of GPT-3.5 by using the CaRB benchmark [27] through its information matching and scoring framework on two specific evaluation scenarios. The results from the general scenario on a subset of the TekGen dataset [28] and the scenario on our handcrafted sub-knowledge base (approximately 50 pairs of unstructured text and corresponding extracted triple sets have been human-labeled) are 69.82% and 100% in *Recall*, respectively, indicating the promising performance of GPT-3.5 in this stage’s task.

In the final step, we perform the knowledge integration task, which involves entity alignment and discretization for groups of item-related entities with continuous values. It is important to mention that the raw triples obtained from the LM may contain ambiguous values for the same entity, requiring NLP techniques to normalize its identification. Specifically, we need to standardize the units for each numeric value and establish common conventions for descriptions. For example, for the attribute related to minutes allowed for domestic calls in a package, we standardize the unit as ‘days’ for packages with daily/weekly cycles and ‘months’ for packages with monthly cycles and above, etc. Additionally, for extracted text chunks (entities in raw triples) in natural descriptive language, such as additional package benefits, we remove domain-specific stopwords and cluster them based on their TF-IDF encoded representations. This helps to unify phrases that refer to the same entity but may appear in different text chunks because of misspellings or redundant grammar elements. The final output

of the entire process is a set of refined KG triples that can be integrated into KG-based GNN models.

The indexed graphs serve as the main input for the proposed core model of HybridGCN, whose detailed architecture will be shown in Fig. 2.

B. Model Architecture

We combine the idea of graph convolution-based information propagation on the intra-knowledge graph (intra-KG) from KGCN [17] and intra-interaction graph (intra-IG) from LightGCN [4]. Our HybridGCN core adds interconnective paths to create a continuous information propagation flow between the processing components in both types of graphs, aiming to enhance the embedding learning process and address the issue of incompleteness in practical KGs.

First, we note that in embedding spaces, nodes within a graph are represented by finite-dimensional vectors, and the relationship between any two nodes is quantified through operations performed on the corresponding pairs of vectors. Such representation is known as the *ID embedding* of a node.

The concept of intra-KG propagation involves calculating the final representation of a given item entity by incorporating its intra-KG neighborhood information as *neighbor embedding* into its ID embedding via an aggregator (as presented in Eq.2). The semantic propagation process is performed on a knowledge graph from the outside to the inside through multiple hops, based on *receptive fields*, which are selected sets of neighboring nodes for each entity node. Through this process, the structural topology of the proximity sub-graph containing an entity node is embedded into the entity itself.

Neighbor embeddings are aggregated using a graph attention mechanism. Considering a node v and its set of neighbor nodes $\mathcal{N}(v)$ at h -th hop, the importance of the relationship between that node and its neighboring nodes is defined based on a weight, which is the normalized inner product $\tilde{\pi}_r^u$ between the ID embedding of the user u linked to the end target item entity and the relation ID embedding r . Therefore, the neighboring information of node v is weight-based linearly combined and then integrated with node v itself to form the resulting embeddings of the h -th hop, which also serve as the input for its adjacent $(h - 1)$ -th hop. During each hop, user-relation weight π_r^u , normalized user-relation weight $\tilde{\pi}_r^u$, and neighbor embedding $v_{\mathcal{N}(v)}^u$ are respectively calculated as follows:

$$\begin{aligned} \pi_r^u &= u^T r; \\ \tilde{\pi}_{r,v,e}^u &= \frac{\exp(\pi_{r,v,e}^u)}{\sum_{e \in \mathcal{N}(v)} \exp(\pi_{r,v,e}^u)}; \end{aligned} \quad (1)$$

$$\begin{aligned} v_{\mathcal{N}(v)}^u &= \sum_{e \in \mathcal{N}(v)} \tilde{\pi}_{r,v,e}^u e \\ agg &= AGG(v, v_{\mathcal{N}(v)}^u) \end{aligned} \quad (2)$$

For each target item node i , we preserve the aggregated neighbor embeddings $\mathcal{V}_{\mathcal{N}(i)}^u$ from the innermost hop, which is formed by combining adjacent nodes of this item node. These final neighbor embeddings are then used as input for our HybridGCN model.

On the other hand, the intra-IG propagation rule is defined based on the user-item connections. The deeper the hops (layers) in the graph neural network, the longer the propagation paths within the graph, such as user-item, user-item-user, item-user-item, etc. Embedding these propagation paths into an ID user (item) embedding helps capture multi-order proximity structure and improve the issue of sparse connections in the graph. Given $\mathcal{N}_i, \mathcal{N}_u$ as the set of neighbor nodes of item (user) and $e_i^{(k)}, e_u^{(k)}$ as the item (user) ID embeddings at layer k , the graph convolution operation for calculating layer-($k+1$) embeddings from layer- k :

$$\begin{aligned} e_u^{(k+1)} &= \sum_{i \in \mathcal{N}_u} \frac{1}{\sqrt{|\mathcal{N}_u| \cdot |\mathcal{N}_i|}} e_i^{(k)}; \\ e_i^{(k+1)} &= \sum_{u \in \mathcal{N}_i} \frac{1}{\sqrt{|\mathcal{N}_i| \cdot |\mathcal{N}_u|}} e_u^{(k)} \end{aligned} \quad (3)$$

Finally, the embeddings at K layers are weight-combined to form the final representation of a user (an item):

$$\mathbf{e}_u = \sum_{k=0}^K \alpha_k e_u^{(k)}; \quad \mathbf{e}_i = \sum_{k=0}^K \alpha_k e_i^{(k)} \quad (4)$$

Our HybridGCN designs facilitate communication between intra-graph propagation components and combine the enriched embeddings from each type of graph to enhance the embeddings in the *inter-graph* context. In *HybridGCNa*, propagation occurs first in the IG space. The propagation also simultaneously takes place in the KG to generate neighbor embeddings for items with equivalent KG entities. The IG-enriched item embedding resulting from the former process and its corresponding neighbor embedding from the latter are then combined using a *sum aggregator* to obtain the final representation of an item. The combination operation in *HybridGCNa* is defined as follows:

$$\mathbf{e}_i^u = SUM_AGG \left(\sum_{k=0}^K \alpha_k e_i^{(k)}, \mathcal{V}_{\mathcal{N}(i)}^u \right) \quad (5)$$

In contrast, *HybridGCNb* allows the semantic propagation on the KG and the combination of an item's initial embedding with its neighbor embedding to occur first (as presented in Eq. 6). This results in KG-based pre-enriched item embeddings $e_i^{u(0)}$, which are then fed into the input embedding matrix to perform the propagation rule on the IG for adopting K representations at K layers $e_i^{u(1)}, e_i^{u(2)}, \dots, e_i^{u(K)}$, and the final synthesized item embedding e_i^u . Our experimental results show that utilizing a straightforward average aggregation method, instead of relying on user-based weights for item-related relations as the original intra-KG mechanism, simplifies the compilation of neighbor information across our moderate-sized domain-specific KG. Thus, it enhances performance and improves the ease of learning in this version.

$$e_i^{u(0)} = SUM_AGG \left(e_i^{(0)}, \mathcal{V}_{\mathcal{N}(i)}^u \right) \quad (6)$$

Our *SUM_AGG* operation is designed to enable addition between two vectors with different dimensions, based on the

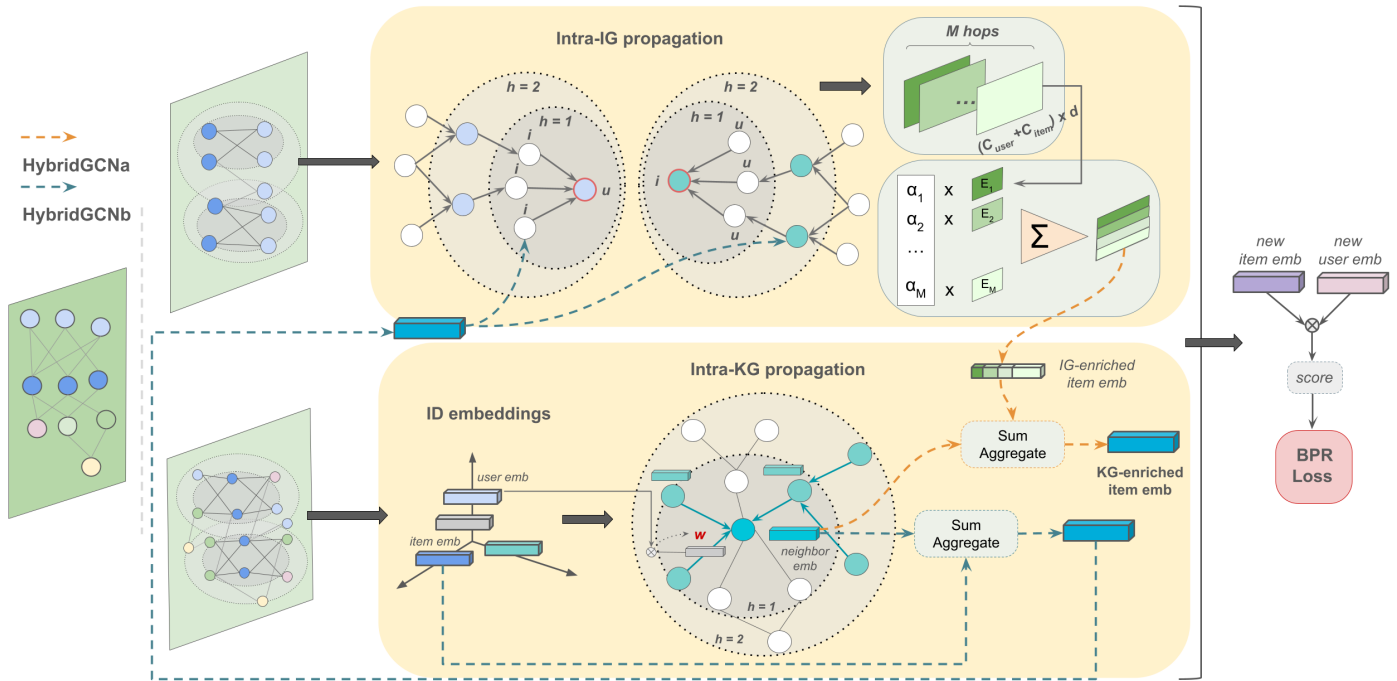

Fig. 2. Detailed architecture of our HybridGCN core model.

expansion of the vector with fewer dimensions on the right side with zero elements. This allows HybridGCN models to flexibly adjust the influence of intra-KG semantic information on item learning.

Finally, the models predict the interaction probability by calculating the inner product between post-propagated representations of user u and item i :

$$\hat{y}_{ui} = \mathbf{e}_u^T \mathbf{e}_i^u \quad (7)$$

To optimize the performance of our model, we utilize the *Bayesian Personalized Ranking* (BPR) loss [29], which is also employed by LightGCN. This loss function aims to ensure that the predicted value for an observed item is higher than the predicted values for unobserved items:

$$L_{BPR} = - \sum_{u=1}^M \sum_{i \in \mathcal{N}_u} \sum_{j \notin \mathcal{N}_u} \ln \sigma(\hat{y}_{ui} - \hat{y}_{uj}) + \lambda_1 \|\mathbf{E}^{(0)}\|^2 + \lambda_2 (\|\mathbf{R}\|^2 + \|\mathbf{A}\|^2) \quad (8)$$

where λ_1, λ_2 controls the L_2 regularization strength for the user-item embedding matrix, the batch's existing inner-KG attribute embedding matrix, and the relation embedding matrix. Our optimization process utilizes the Adam optimizer in a mini-batch fashion.

C. Model Analysis

We perform mathematical analysis to illustrate the reasoning behind the inter-graph design of HybridGCN. Initially, we provide a theoretical discussion on how HybridGCN can tackle the issue of unavailability of knowledge when integrating real-world Knowledge Graphs. Subsequently, we highlight the significance of learning the interconnections between two

graph types in enriching the semantics of inherently sparse interaction data.

1) *Alleviation of knowledge incompleteness*: In practice, there exist items that do not have corresponding entities in the constructed Knowledge Graphs due to unavailability of information, referred to as *isolated items*. This asymmetry in information gives rise to bias or unexpected noise when relying solely on KG-extracted semantics for learning item embeddings. The reason is that there is uncertainty regarding whether an isolated item in reality shares certain characteristics with known item nodes.

Our inter-graph propagation in the HybridGCNb setting helps address this incompleteness by inferring hidden relationships between isolated items and existing attribute-related entities on the KG. As depicted in Fig. 3, through interconnected propagation on both the IG and KG, the embeddings of attributes a_1 and a_2 are integrated into u_1 , and then the u_1 embedding is propagated to i_3 (an isolated item) via the pair connection $u_1 - i_3$, thereby intuitively forming an indirect connection $i_3 - a_1$, and $i_3 - a_2$.

To clarify, with the integration of intra-KG neighbor information into the initial item embedding before propagating it on the IG, we can expand the representation of an item in the

Fig. 3. Inter-graph propagation in IG and KG facilitates inferring unknown connections between *isolated item* and attribute-related entities.

second layer of IG-based graph convolution as follows:

$$\begin{aligned}
 \mathbf{e}_i^{u(2)} &\stackrel{(3)}{=} \sum_{u \in \mathcal{N}_i} \frac{1}{\sqrt{|\mathcal{N}_i| \cdot |\mathcal{N}_u|}} \mathbf{e}_u^{(1)} \\
 &\stackrel{(3)}{=} \sum_{u \in \mathcal{N}_i} \frac{1}{|\mathcal{N}_u|} \sum_{j \in \mathcal{N}_u} \frac{1}{\sqrt{|\mathcal{N}_i| \cdot |\mathcal{N}_j|}} \mathbf{e}_j^{u(0)} \\
 &\stackrel{(6)}{=} \sum_{u \in \mathcal{N}_i} \frac{1}{|\mathcal{N}_u|} \sum_{j \in \mathcal{N}_u} \frac{1}{\sqrt{|\mathcal{N}_i| \cdot |\mathcal{N}_j|}} \left(\mathbf{e}_j^{(0)} + \mathcal{V}_{\mathcal{N}(j)}^u \right) \\
 &\stackrel{(1)}{=} \sum_{u \in \mathcal{N}_i} \frac{1}{|\mathcal{N}_u|} \sum_{j \in \mathcal{N}_u} \frac{1}{\sqrt{|\mathcal{N}_i| \cdot |\mathcal{N}_j|}} \left(\mathbf{e}_j^{(0)} + \sum_{e \in \mathcal{N}^{KG}(j)} \tilde{\pi}_{r_j, e}^u \mathbf{e} \right) \quad (9)
 \end{aligned}$$

Considering (Eq. 9), we observe that in the case where item i and item j both receive interactions from a user or a group of users, the second-layer representation of i is proportional to the KG-extracted neighbor embeddings of j through a coefficient:

$$c_{j,i} = \frac{1}{\sqrt{|\mathcal{N}_i| \cdot |\mathcal{N}_j|}} \sum_{u \in \mathcal{N}_i \cap \mathcal{N}_j} \frac{1}{|\mathcal{N}_u|} \quad (10)$$

The aforementioned hidden connections (as illustrated in Fig. 3) are established based on this coefficient, particularly when item j is an isolated item. Following (Eq. 10), the strength of these relationships is determined by:

- (1) The greater the number of users jointly interacting with both items i and j , the stronger these hidden connections are. This is reasonable because a dense collaboration of users regarding the pair (i, j) indicates a higher likelihood of these items sharing similar characteristics.
- (2) The less popular item i and item j are, the larger the magnitude tends to be. This also implies the group that items i and j belong to exhibits a high degree of personalization.
- (3) User interaction engagement level is also considered. A lower level of item interaction corresponds to a higher level of confidence in hidden relationships' existence.

In terms of the HybridGCNa setting, according to (Eq. 5), the final item representation is a straightforward combination

of the results obtained from two propagation processes: intra-IG and intra-KG. Specifically, it encompasses the IG-enriched item embeddings and the KG-based neighbor embedding. As a result, compared to KGCN, HybridGCNa can balance and regularize semantic learning, moderating the over-dependence on noisy knowledge triples and mitigating the asymmetry in the availability of information across practical KGs.

2) *Augmentation of sparse interaction data*: In many recommendation scenarios, models may face sparse user-item collaborative data or cold-start issues with new items that have limited interactions from users, as well as a few highly specialized items. This causes challenges for multi-level propagation based solely on graph convolution within the interaction graph, as employed by LightGCN. Naturally, semantic structures extracted from the knowledge graphs can be integrated into collaborative information to provide more detailed and specialized representations for items. This resembles the paradigm of traditional hybrid recommendation systems but within the context of state-of-the-art graph-based models. Eq. (5) of HybridGCNa once again provides a direct observation of this combination, wherein external knowledge complements user-item interaction data.

Regarding HybridGCNb, some transformations are needed to observe how semantically rich connections from knowledge graphs augment and enrich user-item collaborative data. Based on (Eq. 4), (6) and (9), we can unfold the final embedding of an item in the HybridGCNb setting as follows:

$$\begin{aligned}
 \mathbf{e}_i^u &\stackrel{(4)}{=} \sum_{k=0}^K \alpha_k \mathbf{e}_i^{u(k)} \\
 &= \alpha_0 \mathbf{e}_i^{u(0)} + \alpha_1 \mathbf{e}_i^{u(1)} + \alpha_2 \mathbf{e}_i^{u(2)} + \dots \\
 &\stackrel{(6)(9)}{=} \alpha_0 \left(\mathbf{e}_i^{(0)} + \mathcal{V}_{\mathcal{N}(i)}^u \right) + \alpha_1 \mathbf{e}_i^{u(1)} \\
 &+ \alpha_2 \left(\sum_{u \in \mathcal{N}_i} \frac{1}{|\mathcal{N}_u|} \sum_{j \in \mathcal{N}_u} \frac{1}{\sqrt{|\mathcal{N}_i| \cdot |\mathcal{N}_j|}} \left(\mathbf{e}_j^{(0)} + \mathcal{V}_{\mathcal{N}(j)}^u \right) \right. \\
 &+ \left. \frac{1}{|\mathcal{N}_i|} \sum_{u \in \mathcal{N}_i} \frac{1}{|\mathcal{N}_u|} \left(\mathbf{e}_i^{(0)} + \mathcal{V}_{\mathcal{N}(i)}^u \right) \right) + \dots \\
 &= \left(\alpha_0 \mathbf{e}_i^{(0)} + \alpha_1 \mathbf{e}_i^{(1)} + \alpha_2 \mathbf{e}_i^{(2)} + \dots \right) \\
 &+ \left(\left(\alpha_0 + \alpha_2 \frac{1}{|\mathcal{N}_i|} \sum_{u \in \mathcal{N}_i} \frac{1}{|\mathcal{N}_u|} + \dots \right) \mathcal{V}_{\mathcal{N}(i)}^u \right. \\
 &+ \left. \alpha_2 \frac{1}{|\mathcal{N}_i|} \sum_{u \in \mathcal{N}_i} \frac{1}{|\mathcal{N}_u|} \sum_{j \in \mathcal{N}_u} \frac{1}{\sqrt{|\mathcal{N}_j|}} \mathcal{V}_{\mathcal{N}(j)}^u + \dots \right) \quad (11)
 \end{aligned}$$

It is noted that $\mathbf{e}_i^{u(2k+1)} = \mathbf{e}_i^{(2k+1)}$ because the results of graph convolution at odd layers can be easily unfolded all the way to initial user embeddings (0-layer user representations).

Based on the expansion in (Eq. 11), we can observe that the ultimate item embedding has been enriched with additional blocks of external semantic information. In this way, not only the structural topology of an item's intra-KG neighborhood

(denoted as $\mathcal{V}_{\mathcal{N}(i)}^u$) is encapsulated, but also the neighbor subgraph encodings of other items (denoted as $\mathcal{V}_{\mathcal{N}(j)}^u$ with $j \neq i$) are included and indirectly related to the target item through interaction data (explained in Section III-C1). Additionally, such subgraphs are integrated with different levels of smoothness, which are adjusted based on the size of the neighboring region within the learned graphs.

IV. EXPERIMENTAL RESULTS

A. Dataset

In this study, we applied our proposed framework to analyze behavioral data obtained from a prominent telecommunications service provider. This data encompasses user activity logs spanning three months, from November 2022 to January 2023. It includes anonymized information on user package subscriptions, actual usage logs, and package metadata (see Table I for dataset summary). To ensure user privacy, all sensitive data has been encrypted.

TABLE I. SUMMARY OF THE DATASET'S KEY CHARACTERISTICS

Characteristic	Value
Number of unique users (Subscription behavior)	10,630,045
Number of unique users (Usage behavior)	5,065,934
Number of packages	2,283
Sparsity	0.9986

B. Baselines

Our baseline models encompass a diverse range of approaches, including traditional, state-of-the-art, and graph-based models.

- **SVD [9]**: A classic CF-based model that uses inner product operations to represent user-item interactions.
- **SVD++ [9]**: SVD++ enhances its original version of SVD by incorporating implicit feedback inferred from user behaviors. We utilize the implementations of SVD and SVD++ provided by Surprise library [10].
- **ALS [20]**: ALS is a matrix factorization method that is common in many real-world recommendation scenarios. ALS decomposes the original utility matrix into two matrices by iteratively updating the values of the user and item latent factor matrices, which is achieved by solving a least squares problem at each iteration. We use its implicit version in PySpark.
- **Multi-VAE [21]**: Multi-VAE is a deep learning model that leverages variational inference to learn latent representations of user-item interactions.
- **PageRank**: A Random Walk-inspired graph learning technique ranks items based on their graph-based importance, considering the global structure of the user-item interaction network. It then generates top-ranked recommendations for the N most important products universally across all users. We implement it based on the NetworkX library [22].
- **LightGCN [7]**: LightGCN is a lightweight graph-based model, which simplifies the graph convolution

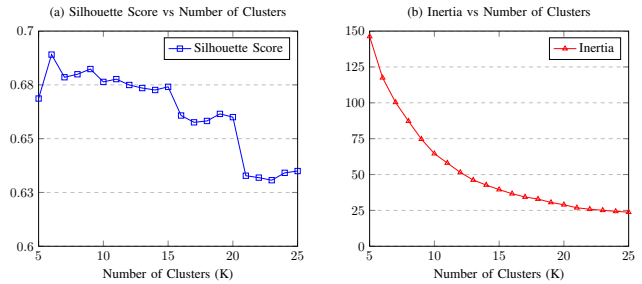

Fig. 4. Evaluation of KMeans Clustering Algorithm with (a) Silhouette Score and (b) Inertia

operation to focus solely on multi-hop user-item interactions, making it efficient and effective for learning from large-scale recommendation datasets.

- **KGCN [17]**: KGCN is a graph convolutional network-based model that captures neighborhood structures within knowledge graphs to improve personalized recommendation capabilities.

C. Experimental Setup

a) **Data Preprocessing**: We removed any rows with NULL or NaN values, which only occur at a mere 1% of the dataset. Subsequently, a pivoting operation was performed for each user, yielding two distinct pivoted datasets: *Dataset 1* for all the packages that each user subscribes to, *Dataset 2* for his/her historical usage behavior.

b) **Feature Engineering**: KMeans clustering was conducted on *Dataset 2*. Based on cluster evaluations, an optimal value of $\mathbf{K} = 20$ was determined (see Fig. 4 for more detail). Users who have subscribed but have not recorded any behavior in *Dataset 1* are categorized into a separate *Cluster -1*. Users subscribing to only one package were also excluded from the analysis for a more rigorous evaluation, and the IQR method was then employed to remove outliers. The *Final Dataset* comprises entries for both the subscribed packages and their respective cluster indices. In Fig. 5, we show the historical revenue from users for each cluster in *December 2022*, highlighting the differences in user behavior across the clusters. Furthermore, from the knowledge graph constructed across all possible packages, we extracted the subgraph corresponding to each cluster. In Table II, we evaluated the proportion of packages that have been interacted with by users belonging to the cluster and have corresponding entities in the cluster's KG, defined as *Hit rate*. This rate reflects the incompleteness of KG's understanding of entities representing packages.

TABLE II. STATISTICS ON THE PROPORTION OF TELECOM PACKAGES HAVING CORRESPONDING ENTITIES IN THE KG (A.K.A HIT RATE) FOR EACH USER CLUSTER (%)

Cluster	0	1	2	3	4	5	6	7	8	9	10	11	12	13	14	15	16	17	18	19	-1		
Hit rate	71	70	76	100	86	69	69	76	71	80	73	90	73	70	69	71	72	71	72	71	na	72	68

c) **Train-Test Split**: To ensure fairness for all models, the data trained and tested must be the same. Furthermore, we have also devised a strategy to capture personalization and cold-start solving capability.

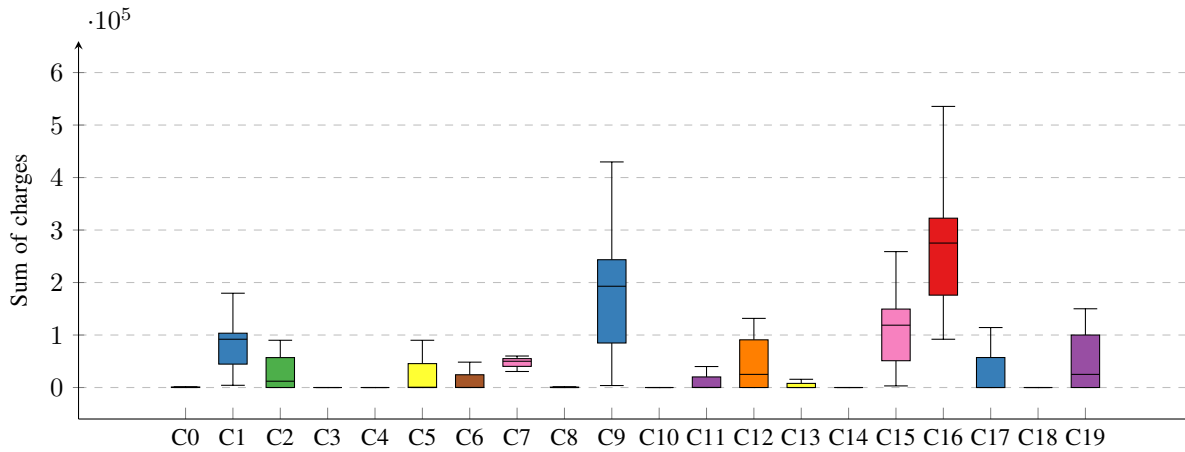

Fig. 5. Boxplot representing historical revenue from users (a.k.a their sum of charges) in december 2022 across clusters in the final dataset.

- We divide the *Final Dataset* into two user groups: those who are supposed to arrive earlier and those who are supposed to arrive later, in a 1 : 1 ratio.
- We randomly hide some "less popular" packages of each user in the latter group to create a *test set* (corresponding to the darker cells in Fig. 6). The remaining user-item interactions (corresponding to the white cells in Fig. 6) will form the *training set*. This approach creates a realistic asymmetric scenario where the model is forced to predict unpopular items. When evaluating, we consider the model's predictions for hidden packages of all users in the latter group. More specifically, we regard a package as "less popular" if it does not belong to the top two most subscribed packages. Based on our observations from statistics, these two packages are interacted with by almost all users. This implies that they might be free packages given periodically by the service provider, so including them in the evaluation does not provide much meaningful insight.

Fig. 6. Half of the users belong to the group of 'earlier' users, where all the packages they have subscribed to are included in *training set*. The rest belong to the group of 'later' users, where some of their 'less popular' packages (represented as darker cells) are randomly selected to form *test set*.

d) *Hyperparameter Settings*: Hyperparameters among intra-cluster models in all baselines are set the same to ensure fairness in the evaluation process. Regarding two versions of HybridGCN and KGCN models, the intra-KG neighbor sampling size is set between 2-4, depending on the size of the cluster's knowledge graph (KG), and the depth of the

receptive field is set to 1 due to the relatively low complexity of our domain-specific KG. In HybridGCN and LightGCN, the number of intra-IG layers is set to 1-5, with a larger number of layers chosen when the number of users in the cluster increases, enabling the learning of longer propagation paths. The layer weights in HybridGCN and LightGCN are uniformly set as $\alpha_0 = \alpha_1 = \alpha_2 = \dots = \alpha_K = \frac{1}{K+1}$, following the configuration specified in the LightGCN paper. The regularization coefficients in HybridGCN's loss function are set as $\lambda_1 = \lambda_2 = 10^{-4}$, which are also equivalent to the corresponding hyperparameter λ chosen in LightGCN.

D. Results

In this paper, the results were obtained using standalone Colab Pro¹ (51GB RAM, NVIDIA A100 GPU). We evaluate our approach through top-K recommendation, where trained models predict the probability of user-item interactions to select K items with the highest scores for each user in the test set. We employ a rank-based metric set for model evaluation. Due to the significantly smaller number of packages (items) compared to the number of users, we find that using $K = 5$ and $K = 10$ provides a sufficiently objective assessment in our study.

- *Precision (P@K)* measures how many items with the top K positions are relevant.
- *Recall (Recall@K)* measures the share of relevant items captured within the top K positions.
- *Mean Reciprocal Rank (MRR@K)* quantifies the rank of the first relevant item found in the recommendation list.
- *Normalized Discounted Cumulative Gain (nDCG@K)* focuses on the relevant item's position in search results. It assigns higher scores to items that are ranked higher and gradually decreases the score as the position decreases.

¹Google Colab is a cloud-based service provided by Google that allows users to write, execute, and share Python code in a web-based Jupyter Notebook interface.

- Mean Average Precision ($mAP@K$) averages the $P@K$ metric at each relevant item position in the recommendation list.

In both scenarios, whether integrated with clustering or not, both SVD and SVD++ exhibit poor recommendation performance due to the extremely high sparsity of collaborative data. Without clustering, GNN-based baseline models (namely KGCN and LightGCN) cannot perform as large-scale graphs use much more memory than other methods for storing the interaction matrix and embedding spaces, while Implicit ALS is the best possible model in this scenario. Mult-VAE performs fairly well in recall but shows lower ranking-quality scores compared to ALS. This is particularly evident in the case of PageRank, as it solely relies on item popularity and disregards their ranking (as presented in Table III).

TABLE III. COMPARISON OF RECOMMENDATION MODELS WITHOUT CLUSTERS ON OUR DATASET (%)

Method	K = 5					K = 10				
	P	Recall	MRR	nDCG	mAP	P	Recall	MRR	nDCG	mAP
SVD	0.11	0.50	0.38	0.37	0.27	0.25	1.96	0.61	0.87	0.27
SVD++	0.11	0.44	0.37	0.36	0.27	0.22	1.76	0.58	0.80	0.27
ALS	4.14	16.45	10.38	11.03	4.58	3.25	25.87	11.76	14.23	4.70
Mult-VAE	3.61	14.58	7.00	8.40	1.61	3.66	29.05	9.17	13.38	1.70
PageRank	3.93	14.98	5.10	7.22	0.09	3.57	28.01	7.03	11.68	0.11

In intra-cluster predictions, the models marginally exhibit higher performance. Notably, incorporating the user segmentation stage into available GNN-based methodologies makes it feasible in the setting of limited memory resources. Their corresponding clustering-driven versions, named KGCN++ and LightGCN++, demonstrate superior performance compared to non-GNN-based approaches by a significant margin.

Our HybridGCN models achieve the highest level of effectiveness across all metrics on this real-world dataset, with HybridGCNa and HybridGCNb performing best intermittently. In particular, HybridGCN significantly improves ranking quality metrics (MRR, nDCG, and mAP) to a noteworthy extent. It surpasses clustering-driven state-of-the-art models such as LightGCN++ by approximately 1-2%, and KGCN++ by around 4-9% as shown in Table IV and Fig. 7. This highlights the strong capability of our proposed model in addressing the challenge of knowledge incompleteness in KG-based GNN models such as KGCN (see Table II). Moreover, the improvement over LightGCN++ demonstrates that additionally incorporating semantic structures through intra-KG propagation enhances the personalization capabilities of graph learning-based systems. Similar to traditional hybrid approaches, our inter-graph propagation also aids in mitigating the potential issue of sparse collaborative data and cold-start problems.

Between the two variants of HybridGCN, HybridGCNa performs slightly better in overall evaluation metrics such as Precision and Recall, while HybridGCNb generally shows a slight advantage in fine-grained ranking quality evaluation metrics like MRR and mAP. These results indicate that HybridGCNa has better generalization ability, while HybridGCNb excels in providing detailed and personalized recommendations based on user preferences. This is reasonable considering the mathematical interpretations of these two versions in Section

Fig. 7. Detailed evaluation of graph neural network-based models in top- K recommendation with (a) $MAP@K$ and (b) $Recall@K$.

III-C. While the formula of HybridGCNa is a straightforward combination of intra-KG and intra-IG propagation results, HybridGCNb enables a smoother mechanism when integrating different semantic structures from KGs into collaborative data.

V. DISCUSSION

Previous experiments on GNN-based RS [4], [7], [17] have predominantly focused on comparing the effectiveness of models on popular benchmark datasets, where user bases are relatively small, and the setup, such as building KGs as their input, is relatively straightforward. In contrast, we aim to evaluate the feasibility and applicability of deploying such graph-based approaches on a real-world, large-scale dataset where all relevant practical issues need to be considered. Our experiments cover a wide range of evaluations, from global recommendations to recommendations within specific user clusters. We compare some existing efficient methods, examining whether simpler methods can outperform more complex ones in real-life scenarios. We also compare modern GNN-based methods that incorporate knowledge graphs with those that do not. Through experiments, our proposed method has shown better results, taking advantage of hidden information from data based on the graphs we have built. However, to further ensure the practical capacity of our method across various domains, more experiments need to be conducted on datasets from different fields, where KG construction and user behavior can vary.

VI. CONCLUSION

We propose a comprehensive approach leveraging Knowledge Graphs (KGs) and Graph Neural Networks (GNNs) to address graph-based recommender system problems. Through clustering, our framework shows the feasibility of applying the GNN paradigm to large-scale data. Combining two innovative graph learning structures, our core HybridGCN model adopts a GNN-based technique on cross-graph propagation effectively. It overcomes the limitations inherent in each approach by effectively handling knowledge incompleteness within practical Knowledge Graphs and addressing the sparse connection density in Interaction Graphs. Furthermore, we successfully tackle the challenge of constructing a Knowledge Graph from domain-specific unstructured data by harnessing the capabilities of LLMs, resulting in competitively high Knowledge Graph completion rates across different clusters. We evaluate our approach on a real-world telecommunications dataset using a rigorous assessment strategy. Our methodology successfully applies GNN-based methods to a dataset with millions of users. Specifically, for ranking-centric scores, HybridGCN has demonstrated its effectiveness in personalized recommendation tasks, outperforming other GNN-based models and state-of-the-art methods.

Abstract—Most neural machine translation (NMT) systems rely on parallel data, comprising text in the source language and its corresponding translation in the target language. While it's acknowledged that context enhances NMT models, this work proposes a novel approach by incorporating external context, specifically explanations of source text meanings, akin to how human translators leverage context for comprehension. The suggested methodology innovatively addresses the challenge of incorporating lengthy contextual information into NMT systems. By employing state-of-the-art transformer-based models, external context is integrated, thereby enriching the translation process. A key aspect of the approach lies in the utilization of diverse text summarization techniques, strategically employed to efficiently distill extensive contextual details into the NMT framework. This novel solution not only overcomes the obstacle posed by lengthy context but also enhances the translation quality, marking an advancement in the field of NMT. Furthermore, the data-centric approach ensures robustness and effectiveness, yielding improvements in translation quality, as evidenced by a considerable boost in BLEU score points ranging from 0.46 to 1.87 over baseline models. Additionally, we make our dataset publicly available, facilitating further research in this domain.

Keywords—Deep learning; transformers; context; NMT; neural machine translation; natural language processing systems

I. INTRODUCTION

The rapid development of Neural Machine Translation (NMT) has changed the field of NLP, significantly improving the quality and accuracy of translations across various language pairs [1]. This advancement has facilitated cross-cultural communication, promoted cultural and intellectual understanding, and contributed to the growth of research. Despite these successes, the translation of complex source texts remains a challenge, particularly in languages that have rich morphology and complex grammar [2]. One such language is Arabic, which is characterized by a diverse range of dialects, idiomatic expressions, complex linguistic structures, rich morphology and complex grammar [3]. In order to overcome these challenges, it is essential to develop NMT systems that are capable of incorporating contextual information to produce more accurate translations that closely resemble human-like understanding and interpretation.

Drawing inspiration from the practices of human translators and language professionals, this study aims to develop a context-aware NMT model for the Arabic language that moves beyond existing translation approaches. In particular, this work is built upon the concept of “deverbalization,” as proposed

by [4] and further elaborated by [5], which emphasizes the importance of comprehending the underlying meanings conveyed in the source language rather than merely interpreting linguistic symbols. By focusing on contextual details, idiomatic expressions, and cultural subtleties, this approach has the potential to capture the essence of the source text more accurately, leading to more faithful translations that are true to the intended meaning of the original Arabic text.

This research explores the use of explanatory data as a source of contextual information to be injected into the NMT model. The explanatory data, derived from authoritative sources such as Quran exegesis books, provides valuable insights into the intended meaning and cultural context of the Arabic text. By incorporating this context-rich data into the model, the aim is to enable the NMT system to better comprehend the source text, capture the linguistic subtleties, and produce translations that are more accurate and faithful to the original text.

To the best of the authors knowledge, neither previous research has investigated the impact of contextual information, nor has any work explored the use of “explanations” of Arabic text as context information on Arabic NMT. Furthermore, there is a lack of Arabic corpora that include texts accompanied by their explanations. This study seeks to fill this gap by proposing a new dataset and a context-aware NMT model for the Arabic language. By doing so, it is intended to contribute to the body of knowledge on context-aware NMT systems and highlight the significance of incorporating contextual information in improving translation accuracy.

In this research, the state-of-the-art T5 (Text-to-Text Transfer Transformer) [6] model, in its multilingual version (mT5) [7], is employed. This model has demonstrated exceptional performance in various natural language processing tasks, including machine translation [8]. The T5 model, characterized by its advanced architecture and robust pre-training capabilities, serves as an optimal foundation for the context-aware NMT model within the framework of this work. By fine-tuning the mT5 model on the context-rich dataset, the assessment is conducted on the model's ability to leverage contextual information to enhance translation accuracy and deliver translations that are more faithful to the original Arabic text. Through this research, the aim is to contribute to the ongoing efforts to improve the quality and accuracy of Arabic NMT systems by incorporating contextual information, paving the way for more reliable and human-like translations that respect the linguistic details and richness of

the Arabic language. Moreover, the findings are anticipated to yield benefits not solely for the Arabic NMT community but also to inspire researchers engaged in languages with akin complexities. This may prompt exploration into the potential of context-aware NMT models, consequently augmenting the overall performance and capabilities of NMT systems across diverse language pairs.

This study stands out by offering four main contributions to the body of knowledge:

- Introducing a novel strategy to improve NMT by incorporating contextual data extracted from source-specific explanatory materials. This method aims to enhance the translation's precision and intelligibility, regardless of the original language or subject matter.
- Fine-tuning a multilingual T5 model (mT5) using two newly proposed datasets, one that pairs source content with its corresponding translations, and another that enriches the source content by integrating it with relevant contextual details.
- Proposing three different methods of context injection: one utilizing the complete explanatory content, another employing a summarized version of this content, and the third adding an additional identifying detail along with the summarized explanation to the original content. The novel yet simple approaches, effectively simplify the handling of long context in NMT.
- Curating and disseminating an innovative Arabic-English parallel dataset, enriched with comprehensive explanations of the source text, thereby offering a robust resource for advancing machine translation research and facilitating the exploration of contextual augmentation in NMT systems.

The structure of this paper unfolds as follows: in Section II, a comprehensive examination of pertinent literature is explored, elucidating the current state of NMT research and contextual information, while shedding light on the existing gaps our study aims to bridge. Section III describes the detailed process of data collection and preprocessing, resulting in the creation of the parallel dataset, which encompasses original Arabic verses, their respective explanations, and corresponding English translations. In Section IV, the proposed context-aware NMT model is described, elaborating on the methodology employed to integrate contextual information. Section V explains the experimental framework, encompassing the fine-tuning of the T5 model, the evaluation metrics, and the results obtained from the experiments alongside a detailed analysis of a qualitative nature. Section VI goes into a thorough discussion, exploring various perspectives and interpretations of the findings. Finally, Section VII summarizes the research conclusions, highlighting the implications of the findings and suggesting potential paths for future research in context-aware NMT.

II. RELATED WORK

Several works have been conducted to explore such potential benefits of integrating contextual data into NMT systems. For example, [9] proposed a study that centres on augmenting the NMT architecture by leveraging the surrounding text as

an essential source of contextual information. To achieve this goal, the researchers extended the attention-based NMT method by introducing an additional set of an encoder and attention model that encodes the context sentence immediately preceding the current source sentence. Experimental evaluations were performed on the English-French and English-German language pairs, where the obtained results demonstrated that the proposed methodology significantly outperformed the baseline models that did not incorporate the surrounding text. Similarly, [10] aimed to improve the quality of NMT by introducing a hierarchical attention model that captures the context in a structured and dynamic manner. The study conducted experiments on Chinese-to-English (Zh-En) and Spanish-to-English (Es-En) datasets, and the proposed model was integrated into the original NMT architecture as an additional level of abstraction, conditioned on the NMT model's previous hidden states. The experimental results showed that the hierarchical attention model significantly outperformed the baseline models in terms of translation quality and fluency, demonstrating the effectiveness of incorporating context in a structured and dynamic manner.

The author in [11] investigated the incorporation of contextual information in NMT by modifying the transformer [12] model for context-agnostic NMT to handle additional context. The experiments were conducted on an English-Russian subtitles dataset, and the modified model first encoded the source sentence and the context sentence independently. Then, a single attention layer, in combination with a gating function, was utilized to generate a context-aware representation of the source sentence. The results showed that the proposed model outperformed the baseline models in terms of translation quality and fluency, highlighting the importance of incorporating contextual information in NMT. Moreover, [13] addressed the core challenge of effectively encoding and aggregating contextual information and proposed a novel approach that utilized a pre-trained BERT [14] model as an additional encoder to encode contextual information with German to English and vice versa. This resulted in a group of features carrying contextual information that was subsequently incorporated into the attention mechanism of the NMT model. The experiments showed that the proposed approach improved translation quality and fluency. These findings highlight the importance of contextual information in NMT and demonstrate the potential of leveraging pre-trained models to effectively incorporate contextual cues into the translation process.

Furthermore, [15] focused on exploring the ability of NMT to discover cross-sentential dependencies in the absence of explicit annotation or guidance. Specifically, the study examined the translation of movie subtitles from German to English and aimed to identify the impact of additional contextual information on the translation and attention mechanisms of the NMT model. Unlike prior research that modified the NMT model by adding a separate context encoder and attention mechanism, the study modified only the input and output segments while keeping the standard setup. The research team conducted a series of experiments with different context windows and evaluated two models that extended context in different ways: extended source and extended translation units. The former included context from the previous sentences in the source language to improve the encoder part of the network, while the latter involved translating larger segments

of the source language into corresponding units in the target language. The findings suggest that incorporating additional contextual information in the NMT model can improve the quality and fluency of translations and highlight the importance of further research in this area.

On the other hand, one prominent direction in NMT is the exploration of data-centric approaches for enhancing NMT with contexts. These approaches prioritize leveraging the available multilingual data to boost translation quality, instead of solely focusing on model architecture or algorithmic improvements.

For instance, [16] introduced an approach to enhance NMT by incorporating the entire document context. This method involves pre-processing to add contextual information from each document to its respective sentences, thereby aiming to improve translation coherence and resolve cross-sentential ambiguities. They propose using a simple method to estimate document embeddings, involving averaging all word vectors in a document to maintain a consistent dimension. The technique is applied to a Transformer base model and tested on English-German, English-French, and French-English language pairs. Similarly, [17] explored the impact of incorporating extended context into attention-based NMT, particularly focusing on translated movie subtitles. The study opted to adjust the input and output segments while retaining the standard model setup. It primarily investigates the capacity of NMT to recognize cross-sentential dependencies without specific annotations or guidance.

The reviewed literature demonstrates the benefits of incorporating contextual information from the source language in NMT models for various language pairs. However, to the best of authors knowledge, no previous work has investigated the effect of contextual information on Arabic NMT. Moreover, neither previously proposed work explored the use of “explanations” of Arabic text as context information nor does Arabic corpora exist that include texts accompanied with their explanation. Therefore, this study aims to fill this gap by proposing a new dataset and a context-aware NMT model for Arabic.

III. DATA

In order to develop a context-aware Arabic NMT model, it is essential to acquire parallel data encompassing Arabic text, its corresponding English translation, and explanatory information for the Arabic text. This section elucidates the data sources, outlines the criteria guiding their selection, and details the procedures for data collection and preprocessing that were applied to generate the final dataset.

The criteria for selecting the data sources are as follows:

- Presence of parallel (Arabic - English) data
- Availability of explanations for the Arabic text
- Sequential numbering of text segments in both Arabic and English versions to facilitate alignment
- Numbering or clear linking of explanations to their corresponding text
- Clear indication of explanations to facilitate the scraping process

Before going into the specifics of the data sources, it is crucial to provide a concise overview of “explanations” within the context of Arabic literature. Explanations, frequently encountered in Arabic scholarly works, serve as commentaries or interpretations that illuminate the meaning, context, and significance of the original text. They play a vital role in clarifying the intended meaning, exposing linguistic subtleties, and offering historical and cultural insights. Consequently, they contribute to enhancing the reader’s comprehension of the text.

For this study, the Saadi Exegesis was utilized as a primary data source, as accessed through the Islamweb website. Selected for its simplicity and brevity compared to other exegesis sources, the Saadi Exegesis provides concise explanations for each verse in the Quran, with numbered explanations corresponding to verse numbers. The scraping process involved acquiring explanations for each of the 114 Surahs, manually correcting verse numbers when necessary, and ultimately compiling a corpus of 37 Surahs with corresponding verse numbers. Subsequently, the Saadi corpus was merged with a parallel Arabic-English Quran dataset. The parallel Arabic-English Quran dataset was created by scraping the English translations of the Quran¹, which offers seven reputable English translations. Among these translations, Sahih International was chosen for its widespread recognition as a popular translation, renowned for employing a communicative translation approach that prioritizes both linguistic clarity and accuracy. Additionally, as noted by [18], it focuses on simplifying and clarifying English, deliberately avoiding unnecessary transliterations to ensure broad accessibility.

The Arabic verses were retrieved from the Mendeley repository². To guarantee compatibility between the Saadi and parallel datasets, the Surah names in the Saadi dataset underwent preprocessing, involving the removal of hamza letter “ء” and the renaming of certain Surahs. The ultimate merged dataset encompasses 2,908 verses from 37 Surahs, with the following fields: Surah number, Verse number, Verse text, Translation, and Tafseer (exegesis).

In summary, the comprehensive efforts in data collection and preprocessing have led to the creation of a novel dataset that combines parallel source-target sequences with corresponding source explanations. This dataset, encompassing parallel Arabic-English texts and contextual information in the form of explanations, establishes a robust foundation for the development and evaluation of the context-aware Arabic NMT model. Table I presents the statistics and details of the dataset. It is important to emphasize that the dataset is publicly available³, with the aim of facilitating and encouraging future research by providing an accessible resource for the scientific community. The subsequent sections of this paper will elaborate on the proposed model and the methodology employed to incorporate contextual information, along with the experimental setup and the results obtained from the experiments.

TABLE I. KEY STATISTICS OF THE PROPOSED DATASET

Language	Verses			Explanations		
	Total	Average length	Median length	Total	Average length	Median length
Arabic	2908	16	14	2908	117	87
English	-	33	29	-	-	-

IV. PROPOSED APPROACH

The objective is to develop a context-aware Arabic NMT model aimed at improving the translation quality of Arabic text. To achieve this, the multilingual T5 (mT5) model is utilized, and transfer learning is applied to the domain and data of the study. A data-centric approach is also adopted by incorporating context as a data augmentation into the source language. In the following subsections, the T5 model is introduced, followed by a description of the global process.

Fig. 1. An overview of the proposed approach global process and architecture.

A. T5 Model

The foundation of the context-aware Arabic NMT approach proposed in this study rests on the Transformer-based T5 model architecture. Initially introduced by Raffel et al. in 2020 [6], T5 adopts the Transformer encoder-decoder structure and undergoes pre-training on a substantial text corpus in a self-supervised manner. T5 models treat input text as a sequence of tokens and generate output text, making them particularly suitable for text-to-text tasks. By unifying all NLP problems into a text-to-text format, T5 establishes a cohesive framework for transfer learning across various tasks. In the context of translation, the source sentence becomes the input text, and the translated sentence is the target.

The encoder utilizes self-attention and feedforward layers to map input tokens into a contextual representation. This context-rich encoding is then transmitted to the decoder, which generates the output text token by token using cross-attention, relying on the encoder output. T5 incorporates relative position embeddings to denote positional information between tokens. Fig. 2 shows a high-level overview of the T5 architecture.

Through pre-training on extensive datasets, T5 models acquire universal text representations, facilitating generalization across downstream tasks via transfer learning. During pre-training, the objective is to predict randomly masked spans of input text, akin to the approach in BERT [14].

This study employs the multilingual T5 variant (mT5) [7], pre-trained on 101 languages, including Arabic. mT5 has demonstrated state-of-the-art performance on translation benchmarks, surpassing previous models. By fine-tuning mT5 on the proposed context-aware Arabic dataset, the model effectively leverages explanatory details to enhance its translation capabilities. The transformer architecture’s ability to model cross-sentence context proves critical for this task. In summary, T5 establishes a fitting foundation for the development of the context-aware NMT system in this research.

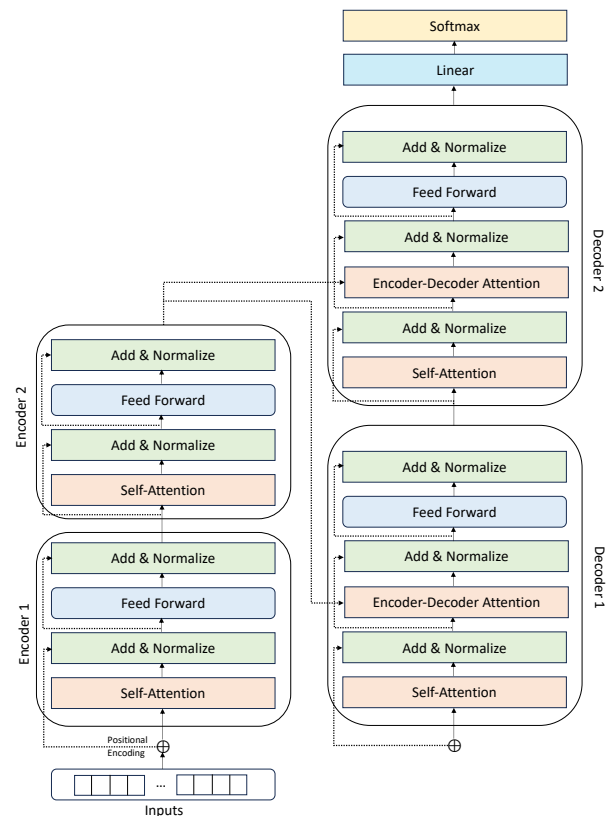

Fig. 2. T5 simplified architecture.

B. Context Aware NMT process

The methodology for developing a context-aware Arabic NMT model unfolds through a systematic, four-step process. Initially, the crucial task of data collection involves assembling a parallel dataset comprising original Arabic verses, their corresponding explanations from a Quran exegesis book, and their respective English translations. Subsequently, the context injection phase ensues, wherein verses are adroitly concatenated with their pertinent contextual information. The third step entails fine-tuning a T5 model on each dataset individually; first on the dataset containing verses and their translations, and subsequently on the context-aware dataset with the injected context. Finally, the results gleaned from

TABLE II. DATASET PARTITIONS STATISTICS

Partition	Number of verses
Training	2000
Development	800
Test	108

both datasets are scrutinized, drawing insightful conclusions regarding the efficacy of the context injection approach and its impact on the performance of the NMT model. Fig. 1 summarizes the proposed approach and its global process.

V. EXPERIMENTS AND RESULTS

A. Experimental Settings

The dataset was meticulously partitioned into three distinct subsets: a training set comprising 2000 verses, a development set encompassing 800 verses, and a test set consisting of 108 verses (Table II). The configuration used for the experiments includes an NVIDIA A100-SXM 40GB GPU, Python 3.9, and SimpleTransformers 0.63.9 library. The main set of training parameters are presented in Table III.

Throughout the experiments, transfer learning is employed by fine-tuning a T5 model on the corresponding training data. The challenge arises from the limited availability of T5 models specifically tailored for Arabic text. The AraT5 model, despite being designed for Arabic, proved suboptimal for translation tasks. Consequently, the mT5 model—a multilingual T5 variant proficient in Arabic and 100 other languages—emerges as the only viable alternative. Due to time and computing resource constraints, the experiments utilize the small version of mT5 (mT5-small).

To ensure comparability and reproducibility of results, all experiments on both the Baseline and context-aware datasets are conducted with identical parameters and a fixed seed. Initially, the models undergo a training process of 5 epochs to establish a preliminary benchmark for comparison purposes and to determine the optimal sequence length and batch size. Subsequently, models exhibiting superior performance relative to the Baseline model are selected for further training over a period of 15 epochs.

TABLE III. MAIN TRAINING PARAMETERS

Parameter	Value
Learning Rate	0.001
Manual Seed	2023
Warmup Ratio	0.06
Adam Betas	(0.9, 0.999)
Adam Epsilon	$1e^{-8}$

Context injection is conducted through various methods:

- Method 1: Leveraging the entire verse explanation as contextual information.
- Method 2: Employing a summarized version of the explanation, achieved through:
 - *KeyBERT option 1*: Extracting keyphrases from the explanation text using the KeyBERT [19] library. Diverse keyphrases are

generated by activating the Max Sum Distance parameter. For instance, three sets of keyphrases, each containing four words, are concatenated for every verse explanation.

- *KeyBERT option 2*: Alternatively, dividing the explanation of each verse into three segments, from which two distinct keyphrases consisting of three words are generated and concatenated.
- Abstractive summaries using three Transformer-based encoder-decoder models designed for Arabic text summarization. Two of these models utilize the T5 architecture [20], [21], and the third employs mBert in both the encoder and decoder modules [20]. Similar to KeyBERT option 2, the models are applied to the three segments of each verse's tafssir.
- Method 3: Concatenating the Surah name to the Verse, in addition to the explanation injected as in Method 2.

Addressing the long context problem outlined by [22], where two solutions are proposed, this work's novel approach diverges by being data-centric and relying on summarization, offering a distinct methodology in dealing with long contextual information. Indeed, the use of the entire context is not possible due to the limited number of tokens supported by the models, not to mention the difficulty encountered by the model in finding the most relevant parts to consider for translation in a long context. By attempting to integrate the entire context, the model only uses the beginning of the text, and thus loses most of the information. The proposed method has the advantage of not requiring any changes to the model structure, and relies solely on the way in which the context is integrated.

Methods 2 and 3 are specifically designed to address the challenge of lengthy explanations overwhelming the models and causing attention to be scattered across the entire text. These techniques aim to concentrate the explanation by highlighting critical elements or providing a summary of the text. This approach mirrors human information processing, selectively retaining essential components to comprehend the overarching concept and enhance the translation process.

Both extractive and abstractive summarization techniques are employed to extract the most pertinent contextual elements. The extractive method aims to retrieve keyphrases verbatim from the context text, whereas the abstractive approach utilizes alternative wording akin to human summarization techniques, employing paraphrasing and synonyms.

The concatenation process employs designated tokens, represented as EXP for explanation and CHAP for the Surah name, as illustrated in Table IV. To prevent potential confusion with explanation words, these tokens are expressed in Latin characters. Moreover, they are deliberately chosen to be concise and correspond to a single token following T5 tokenization.

Various experiments were compared based on the tested parameters and configurations. Specifically, two batch sizes

TABLE IV. CONCATENATION METHODS

Method	Concatenation
1	Verse explanation + EXP + Verse
2	Summarized Verse explanation + EXP + Verse
3	Summarized Verse explanation + EXP + Surah name + CHAP + Verse

were evaluated: 8 and 16. Additionally, the maximum input length varied between 200 and 400, incorporating different methods of context injection and considering whether or not to employ a preprocessing step for explanations.

The nomenclature for each model is defined based on the combination of adopted parameters. For instance, a model using a batch size of 8, a maximum length of 200, and including context will be named EXP200bs8. A similar model but incorporating a summarized version of the context will be named EXP200bs8XX, where XX represents the name of the summarization model used. In addition to this nomenclature, a number is assigned to each model to facilitate interpretation and comparisons. The various configurations tested are detailed in the Results section(V-C) and Table V.

B. Evaluation Metric

To appraise the influence of context injection on neural machine translation performance, the widely recognized BLEU (Bilingual Evaluation Understudy) [23] metric was employed. As an automatic evaluation metric, the BLEU metric is extensively utilized for assessing machine translation output. It quantifies the similarity between the predicted translation and one or more reference translations based on the n-gram overlap between them.

The BLEU score is computed using the following equation:

$$BLEU = BP \times exp \left(\sum_{n=1}^N w_n \log p_n \right)$$

where BP represents the brevity penalty, N denotes the maximum order of n-grams considered, w_n signifies the weight assigned to n-grams of order n , and p_n corresponds to the precision of the predicted n-grams in the reference translations of order n .

The precision of the predicted n-grams (up to a certain order) in the reference translations is calculated and subsequently combined using a geometric mean. In the conducted experiments, the BLEU score for each translation model is reported under varying experimental conditions, such as with or without context injection, or with different types of context injected. The enhancement in BLEU score relative to a baseline model devoid of any context is also reported. By employing the BLEU metric and its equation, a quantitative and objective evaluation of the impact of context injection on NMT performance is provided. This enables a comparison of diverse context injection techniques and the drawing of meaningful conclusions regarding their effectiveness.

The current study utilizes SacreBleu 2.3.1, a library introduced by [24], for the computation of BLEU scores. The adoption of this library hinges on its ability to ensure comparability and reproducibility of evaluations. As a result, future

research may employ the default parameters of this library to facilitate comparisons between different systems.

C. Results

TABLE V. TEST SET BLEU SCORES FOR DIFFERENT MODELS. THE NAME OF EACH MODEL IS BASED ON ITS PARAMETERS (EXP: MODEL INCLUDES EXPLANATIONS; BS: BATCH SIZE; PRC: EXPLANATION IS PREPROCESSED; KEY1,KEY2,ETC: USED SUMMARIZATION MODEL; 200,400,ETC: MAXIMUM SEQUENCE LENGTH). Fig. 3. Model's performance comparison with 15 epochs.

Table V presents the final results for different configurations. In the initial experiments, a first baseline model (1) was trained with a batch size of 16 and a sequence length of 200 for 5 epochs. This model, consisting of the original input and translation, attained a BLEU score of 3.95. Following this, context-aware models were examined using the same configuration. Although these models demonstrated lower performance compared to the baseline, preprocessing the explanation text led to an improvement in their performance. As a result of this preprocessing, the BLEU score rose from 2.7 (3) to 3.2 (4). The preprocessing included some letter normalization, as illustrated in Table VI, and stopwords suppression. The list of stopwords is derived from the NLTK library and augmented by a list of Quran explanation-related stopwords gathered by the authors, this list is also publicly available⁴.

Moreover, increasing the sequence length to 400 improved the score by one point (6). Subsequent experiments were conducted using the same configuration, involving a sequence

⁴<https://github.com/KamelGaanoun/CAANMT>

TABLE VI. NORMALIZED LETTERS DURING PREPROCESSING PROCESS

Original form	Normalized form	Rule
إ، أ، آ، ؤ، ء	ا	Hamzah (ء) removal
ي	ي	Final Yaa(ي) rule
ؤ، ئ	ء	Hamzah simplification
ة	ه	Taa Marbutah (ة) normalization
لـ	ل	Elongation removal

length of 400 tokens and a batch size of 8. The second baseline model with this configuration (2) achieved a score of 5.27, exceeding the performance of the first context-aware models by over one point. Model (2) will be retained as the final Baseline for all following experiments.

All subsequent models were constructed using a summarized version of the explanatory text. With the exception of models (8) and (9), which employed AraT5 summarizing models, all other models exhibited superior performance compared to the baseline (2). These models were selected for additional training over ten epochs to validate the initial findings. Indeed, they outperformed the baseline model by a margin ranging from 0.46 to 1.87 BLEU score points. The most significant improvement was achieved by model (11), based on mBERT in both encoder and decoder modules for summarization, and incorporating the surah name as a global context. This model attained a remarkable overall score of 24.94. Fig. 3 renders the results, imbuing them with heightened readability.

D. Qualitative Analysis

As demonstrated in Table VII, examples 1 and 2 conspicuously illustrate the proficiency of the proposed model, which draws upon targeted explanations of specific components within a verse to enhance translation accuracy. The initial example showcases the limitation of the baseline model, as it misses the term “Woe” in its translation. In contrast, the best model astutely renders the term *ويل* as “Woe”, reflecting the contextual guidance provided. Similarly, the second example underscores the translation of the word *بلغ*, which the baseline model neglects, yet the best model renders correctly as “notification”, adhering strictly to the original translation. It is noteworthy that the explanation for Example 2 utilizes a synonym, *تحذير*, to shed light on the term, while the best model leverages the original translation word, demonstrating its adeptness at comprehending context.

Example 3 presents a discernible contrast between the translations of the baseline and best models. In this instance, the best model generates a translation that, while not entirely verbatim, proves more effective compared to the baseline model, which unfortunately projects a meaning counter to the original text’s intent. This best performance of the advanced model can be ascribed to its capability to optimize the provided explanation for the phrase *عبادنا المؤمنين* signifying “believing servants” or “believers”.

The advanced model also displays an impressive aptitude to generate precise translations, even in the absence of specific lexical guidance within the explanation. This proficiency is

evident in Example 4, where the best model correctly introduces the term “Deny” in its translation, while the baseline model erroneously uses “lie”, a distorted representation of the intended meaning of *تكذبون*. The ambiguous nature of *تكذبون*, which may denote “Lying” or “Denying” based on the diacritical marks used, calls for judicious contextual interpretation, a strength displayed by the best model.

Despite the marginal difference in the score indicated in Example 5, the best model outperforms in creating translations that hew closely to the original text. Interestingly, the accompanying explanation does not proffer any clear insight into the specific translation process, yet the model maintains accuracy.

The detailed analysis suggests that the best model reaps benefits not solely from the immediate verse explanation but also from its past experience with other verses’ explanations. Moreover, the model benefits from incorporating the Sourah name as a global contextual cue. This advantage is evident when comparing the Verse translation in Example 4 produced by the best model with a version that excludes the use of the Sourah name in its context. In this case, the latter model inaccurately uses “lie” instead of “deny”.

An important observation pertains to the robustness of the translation models towards out-of-context summaries. Typically, summarisation models are trained on news and social media corpora and hence may lack proficiency in classical Arabic or Arabic literature. This could lead to some out-of-Quranic-context summaries in the present work. Yet, the translation models perform consistently on the input texts and resist confusion induced by these out-of-context segments, as demonstrated across all examples.

VI. DISCUSSION

The experimental results demonstrate the effectiveness of the context-aware neural machine translation model in improving translation accuracy for the Arabic language. This section discusses the key findings and implications of the study, addresses limitations, and explores potential future directions.

Incorporating contextual information, specifically verse explanations derived from Arabic book exegesis, significantly enhances translation quality. The context-aware models achieved BLEU scores ranging from 23.53 to 24.94, representing an improvement of up to 1.87 points or 8.1% in relative BLEU score compared to the baseline model without context. Leveraging external sources of context enables the NMT system to capture linguistic subtleties and produce more accurate translations by providing additional insights into the intended meaning and cultural context of the source text.

Moreover, using a summarized version of the explanation text improves translation performance compared to using the complete explanation. Models utilizing summarized explanations achieved higher BLEU scores, indicating that concentrating the explanation by emphasizing critical elements or providing a summary enhances translation quality. This finding aligns with human information processing, where selective retention of pertinent components aids understanding. As noted by [25]: “...explained this concept to describe an independent stage

TABLE VII. QUALITATIVE ANALYSIS

And We have not taught him, but it is not but a reminder and a clear Qur'an	0.31

where meaning is abstracted from the language forms...". Various summarization techniques, including keyphrase extraction and abstractive summarization models, yielded improvements in translation accuracy.

Additionally, incorporating the Surah name as a proxy for global document context further improves translation quality. Models that concatenated the Surah name along with the summarized explanation and verse achieved better results compared to models without the Surah name. This finding suggests that higher-level context, such as the Surah name, provides additional cues for the NMT system to better understand and translate the source text, capturing religious and cultural connotations associated with specific Surahs. This finding confirms the importance of global document context, as highlighted by [26]. However, unlike previous work, the current approach employs a shortcut to obtain global context by using a general topic illustrated in the Surah name.

The study also highlights challenges and limitations of context-aware NMT for Arabic. One major challenge is the lack of dedicated datasets for this work in Arabic. Creating a custom dataset with paired source content and translations, enriched with explanatory details, addressed this issue. However, larger and more diverse datasets would contribute to the development and evaluation of context-aware NMT systems for Arabic.

Another limitation is the absence of specialized summarization models for Classical Arabic, which affects the quality of the summarized explanations. General-purpose summariza-

tion models trained on Modern Standard Arabic (MSA) or multilingual data were utilized, potentially missing the unique characteristics and nuances of Classical Arabic texts. Developing dedicated summarization models specifically for Classical Arabic could improve the effectiveness of the context-aware NMT approach. Moreover, there is a lack of specialized summarization models for literature and exegesis books in Arabic. The available summarization models are primarily designed for newspapers, blogs, and general content. This mismatch in specialization hinders the quality of the summarized explanations for the context-aware NMT. Developing dedicated summarization models specifically tailored to the unique characteristics and nuances of Classical Arabic texts, such as literature and exegesis books, would greatly enhance the effectiveness of the context-aware NMT approach.

Regarding future directions, expanding the dataset with more diverse genres and sources of explanatory content would enhance the generalization and coverage of the context-aware models. Leveraging advancements in natural language processing, such as pre-training techniques and transformer-based models, could further improve the performance of the context-aware NMT model. Fine-tuning larger and more sophisticated models, such as the full-size T5 or domain-specific models, may yield even better translation results. This method can be applied to other languages using the same process and is also extensible to fields such as historical texts or any area requiring expert advice and explanation. It can be employed whenever an external context exists, particularly when that context is long. The explanation of the source text can be substituted

with any text that offers additional information about the text to be translated, such as expert advice, witness testimonies, or comments from teachers or professors.

Exploring alternative methods for injecting context, such as leveraging linguistic annotations or semantic representations, could provide further insights into the impact of different types of context.

VII. CONCLUSION

In conclusion, this study looked into the influence of injecting explanatory context on the performance of neural machine translation in rendering Arabic religious texts into English. Various methods of context injection were explored, ranging from using the entire verse explanation to incorporating summarized versions of the explanation or keyphrases extracted from it. The multilingual T5 (mT5-small) model was fine-tuned on different datasets, including context-aware and baseline datasets, to assess the effectiveness of the context injection techniques.

The results revealed that context-aware models generally exhibited superior performance compared to the baseline model, particularly when utilizing a summarized version of the explanatory text or incorporating the surah name as a global context. Furthermore, the findings demonstrated the importance of preprocessing the explanation text and carefully selecting the appropriate sequence length and batch size for training the models. The most notable improvement in translation quality was achieved by the model that employed the mBERT 2 mBert summarization technique and incorporated the surah name as a global context, achieving a remarkable overall BLEU score of 24.94. This practice aligns with the deverbilization concept, emphasizing the paramount importance of comprehending the underlying meanings conveyed in the source language over a mere interpretation of linguistic symbols.

These findings underscore the potential of context injection as a valuable approach to enhance NMT performance in translating Arabic religious texts, providing a more accurate and contextually rich understanding of the original text. Future research could explore other context injection techniques or expand the scope of this study to include other languages or genres of text. By refining and optimizing context injection methods, researchers can contribute to the development of more sophisticated and effective NMT systems, ultimately facilitating accurate and meaningful translation across diverse linguistic and cultural contexts.

ACKNOWLEDGMENT

This research received grant no. (180/2022) from the Arab Observatory for Translation (an affiliate of ALECSO), which is supported by the Literature, Publishing & Translation Commission in Saudi Arabia.

Mitigating Security Risks in Firewalls and Web Applications using Vulnerability Assessment and Penetration Testing (VAPT)

Alanoud Alquwayzani, Rawabi Aldossri, Mounir Frikha
Dept. of Computer Networks and Communications, CCSIT,
King Faisal University, Al Hassa 31982, Saudi Arabia

Abstract—In today’s digital age, both organizations and individuals heavily depend on web applications for a wide range of activities. However, this reliance on the web also opens up opportunities for attackers to exploit security weaknesses present in these applications. Web Application Firewalls (WAFs) are typically the first line of defense, protecting web apps by filtering and monitoring HTTP traffic. However, if these firewalls are not properly configured, they can be bypassed or compromised by attackers. The escalating number of attacks targeting web applications underscores the urgent need to enhance their security. This paper offers an in-depth review of existing research on web application Vulnerability Assessment and Penetration Testing (VAPT). Our unique contribution lies in the comprehensive synthesis and categorization of VAPT tools based on their optimal use cases, which provides a practical guide for selecting the appropriate tools for specific scenarios. Additionally, this study integrates emerging technologies such as artificial intelligence and machine learning into the VAPT framework, addressing the evolving nature of cyber threats. The paper also identifies common challenges encountered during the VAPT process and proposes actionable recommendations to overcome these obstacles. Furthermore, it discusses best practices such as secure coding practices and defense-in-depth strategies to improve the effectiveness and efficiency of VAPT efforts. By offering these insights, this paper aims to advance the current understanding and application of VAPT in enhancing the security of web applications and firewalls.

Keywords—Web Application Firewalls (WAFs); Vulnerability Assessment and Penetration Testing (VAPT); cybersecurity; security vulnerabilities; security misconfigurations; network scanning tools; vulnerability detection

I. INTRODUCTION

In recent decades, websites and web applications become increasingly integrated into our daily lives. These platforms enable us to perform a wide range of activities, from online shopping and consuming news to social communication and beyond. A study by Siteefy shows that over 200 million websites are active on the internet as of the end of 2022 [1].

As our reliance on these platforms grows, attackers perceive this trend as an opportunity for monetary gain and other malicious intents. The increased dependence on web applications generates vast amounts of data, crucial for creating excellent user experiences [2]. However, while this data is beneficial for various purposes, it also presents significant risks if not adequately protected.

Firewalls, serving as the first line of defense in most digital systems, often become primary targets of cyber-attacks.

Ensuring their security is therefore crucial. Recent studies reveal that 73% of corporate sector breaches are primarily due to vulnerabilities in their web applications [3]. Such statistics underscore the urgent need to protect web applications from attacks.

Identifying the vulnerabilities that attackers can exploit is the first step to safeguarding firewalls and web applications. Penetration testing and vulnerability assessments are reliable methods for detecting these vulnerabilities, thereby enabling security teams to enhance the security of these platforms. Vulnerability Assessment and Penetration Testing (VAPT) allows businesses to assess their cybersecurity posture, identify vulnerabilities, and take necessary steps to address them before attackers can exploit them. By implementing these proactive measures, businesses can protect themselves from attacks and avoid the costs associated with cyberattacks.

The novel contribution of this study lies in its comprehensive review and synthesis of VAPT tools and techniques, offering a unique categorization based on optimal use cases. Unlike previous studies, this paper not only reviews existing VAPT tools but also integrates best practices and emerging technologies, such as AI and machine learning, into the VAPT framework. This integration addresses the evolving nature of cyber threats and provides a forward-looking approach to cybersecurity.

Additionally, this paper identifies and analyzes common challenges in VAPT processes, providing actionable recommendations to overcome these challenges. The study also proposes a novel framework for continuous VAPT implementation, emphasizing the importance of an iterative and adaptive approach to cybersecurity.

By highlighting these unique aspects, this paper aims to advance the current understanding and application of VAPT, offering practical insights and strategies for enhancing the security of web applications and firewalls.

II. METHODOLOGY

This section details the methodological framework used to conduct the research, including the preparation of the research environment, data collection, data analysis, and validation of results.

A. Preparation of the Research Environment

To ensure a thorough and systematic review, the following steps were undertaken to prepare the research environment:

- Literature Sources: Robust academic databases such as Google Scholar and IEEE Xplore were utilized to gather relevant studies. The search focused on studies published in English from 2012 to 2024.
- Search Keywords: Keywords included "firewall security", "web application vulnerabilities", "VAPT", "security risk mitigation", and "penetration testing techniques".
- Selection Criteria: Studies were included based on their focus on VAPT techniques, tools, and vulnerabilities specific to web applications and firewalls. Studies that did not meet these criteria were excluded.

B. Data Collection

The data collection process involved multiple stages to ensure the comprehensiveness and relevance of the data:

- Initial Search: An initial search was conducted using the specified keywords, returning a broad selection of publications.
- Screening: Titles and abstracts of the retrieved studies were screened to remove irrelevant or redundant entries.
- Full-Text Review: The remaining studies were reviewed in full to ensure they met the inclusion criteria. This included assessing each paper's contribution to knowledge, methodological robustness, and relevance to the research questions.
- Final Selection: A total of 30 papers were selected for comprehensive review, consisting of 21 seminal works from Google Scholar and 9 technical papers from IEEE.

C. Dataset Description

To evaluate the effectiveness of VAPT tools and techniques, several datasets were utilized, including real-world web applications and simulated environments:

- Real-World Web Applications: These included a variety of open-source web applications with known vulnerabilities. Examples include:
 - *OWASP Juice Shop*: A modern web application intentionally designed to be insecure.
 - *DVWA (Damn Vulnerable Web Application)*: A PHP/MySQL web application that is damn vulnerable.
- Simulated Environments: Virtual machines running different operating systems (Windows, Linux) with pre-configured vulnerable services and applications.
- Custom Test Bed: A custom test bed was created to simulate various attack scenarios and measure the effectiveness of VAPT tools. This included:

- Firewalls configured with different rulesets to simulate real-world scenarios.
- Web servers hosting applications with diverse vulnerability profiles.

D. Data Analysis

The selected studies and datasets were analyzed to identify common themes, methodologies, and findings related to VAPT in the context of firewalls and web applications:

- Qualitative Analysis: The content of each paper was qualitatively analyzed to extract key insights and findings relevant to the research objectives.
- Comparative Analysis: The methodologies and findings of different studies were compared to identify trends, common practices, and gaps in the existing literature.

E. Validation of Results

To ensure the validity and reliability of the findings, the following validation methods were employed:

- Triangulation: Data from multiple sources were cross-verified to ensure consistency and accuracy.
- Expert Review: The findings were reviewed by experts in the field of cybersecurity to validate the interpretations and conclusions.
- Reproducibility Check: The research process was documented in detail to allow other researchers to replicate the study and verify the results.

By following this structured methodological framework, the research aimed to provide a comprehensive and reliable assessment of the effectiveness of VAPT in mitigating security risks in firewalls and web applications.

F. Data Collection

The data collection process involved multiple stages to ensure the comprehensiveness and relevance of the data:

- Initial Search: An initial search was conducted using the specified keywords, returning a broad selection of publications.
- Screening: Titles and abstracts of the retrieved studies were screened to remove irrelevant or redundant entries.
- Full-Text Review: The remaining studies were reviewed in full to ensure they met the inclusion criteria. This included assessing each paper's contribution to knowledge, methodological robustness, and relevance to the research questions.
- Final Selection: A total of 30 papers were selected for comprehensive review, consisting of 21 seminal works from Google Scholar and 9 technical papers from IEEE.

G. Data Analysis

The selected studies were analyzed to identify common themes, methodologies, and findings related to VAPT in the context of firewalls and web applications:

- **Qualitative Analysis:** The content of each paper was qualitatively analyzed to extract key insights and findings relevant to the research objectives.
- **Comparative Analysis:** The methodologies and findings of different studies were compared to identify trends, common practices, and gaps in the existing literature.

H. Validation of Results

To ensure the validity and reliability of the findings, the following validation methods were employed:

- **Triangulation:** Data from multiple sources were cross-verified to ensure consistency and accuracy.
- **Expert Review:** The findings were reviewed by experts in the field of cybersecurity to validate the interpretations and conclusions.
- **Reproducibility Check:** The research process was documented in detail to allow other researchers to replicate the study and verify the results.

By following this structured methodological framework, the research aimed to provide a comprehensive and reliable assessment of the effectiveness of VAPT in mitigating security risks in firewalls and web applications.

III. SELECTION OF PAPERS BY PRISMA

In conducting a systematic literature review (SLR) on mitigating security risks within firewalls and web applications through Vulnerability Assessment and Penetration Testing (VAPT), we meticulously followed the PRISMA framework to identify and select pertinent studies from a comprehensive body of literature. Utilizing the robust platforms of Google Scholar and IEEE, we initiated our search with a tailored set of keywords: "firewall security", "web application vulnerabilities", "VAPT", "security risk mitigation", and "penetration testing techniques". Our query was confined to studies published in English from 2012 to 2024, enabling us to encompass a span of advancements reflective of both foundational and cutting-edge research in the field.

The initial query on Google Scholar returned a broad selection of publications. After an initial screening to remove redundant entries, we extracted those studies that were closely aligned with the theme of 'Mitigating Security Risks in Firewalls and Web Applications Using VAPT.' Through careful examination of titles, abstracts, and where necessary, full texts, we evaluated each paper's contribution to knowledge, the robustness of its methodological framework, and direct relevance to our research questions. This led to the selection of 21 seminal works from Google Scholar.

Parallel to our efforts on Google Scholar, a targeted search on the IEEE digital library with the same keywords brought

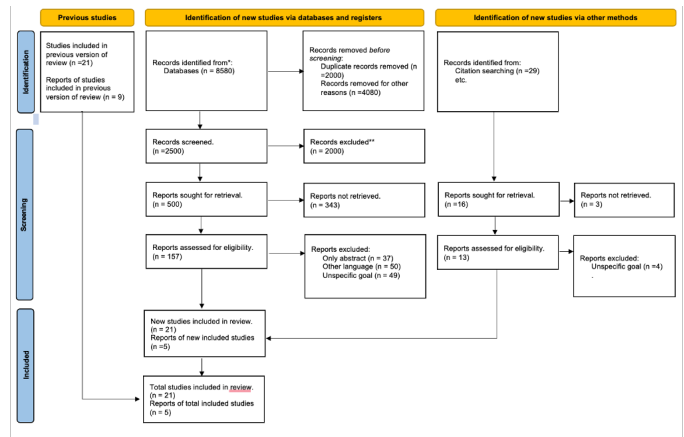

Fig. 1. The selection of papers for the literature review using PRISMA.

forth a collection of technical papers and conference proceedings. Adhering to the same stringent selection criteria, we sifted through this array to handpick nine studies that provided significant insights into VAPT's role in enhancing cybersecurity measures in firewalls and web applications.

Our exacting selection process, conforming to PRISMA guidelines, has culminated in a curated list of 30 papers. These papers collectively offer a comprehensive understanding of the challenges, methodologies, and strategies in employing VAPT to fortify cybersecurity defenses. This assortment ensures a breadth of perspective and upholds the standard of a systematic and unbiased review, essential for a scholarly inquiry into such a specialized and evolving aspect of cybersecurity. The PRISMA flow diagram, which will be featured in our review, details each step of our rigorous paper selection process.

The methodology used in this paper is based on the four stages of the PRISMA (Preferred Reporting Items for Systematic Reviews and Meta-Analyses) approach as shown in Fig. 1. Here's a detailed explanation of what is done at each stage:

- 1) **Identification:** In this stage, a comprehensive search for relevant papers was conducted on platforms such as Google Scholar and MDPI. The search was guided by specific inclusion and exclusion criteria to ensure that only the most relevant papers were considered.
- 2) **Screening:** After the identification stage, the papers were screened based on their titles and abstracts. All the papers that did not have the relevant information we need for this assessment were not included in the detailed review.
- 3) **Eligibility:** The full texts of the remaining papers were then assessed for eligibility. This involved a more in-depth review to determine whether each paper's content was truly relevant to our research.
- 4) **Included:** The final stage involved the inclusion of papers that met all the criteria. These papers were then analyzed and synthesized to answer the research questions.

For this particular research, the focus was on papers discussing vulnerability assessment and penetration testing techniques, tools, and common vulnerabilities facing web apps

and firewalls. The time frame for the papers considered was from January 2008 to January 2024. A total of 12 papers that met our criteria for inclusion were reviewed and analyzed.

IV. LITERATURE REVIEW

Lamba [4] explored the importance of VAPT as a proactive measure in identifying and mitigating vulnerabilities to enhance system security. His research elaborates on the VAPT process as a comprehensive nine-step life cycle, including scoping, reconnaissance, vulnerability assessment, penetration testing, result analysis, and cleanup. Each step is crucial for effectively identifying and addressing vulnerabilities within systems. The paper also discusses various techniques for vulnerability assessment and penetration testing, including static analysis, manual testing, automated testing, fuzz testing, and different types of box testing. Furthermore, it highlights the significance of VAPT tools in streamlining the assessment and exploitation of vulnerabilities. The paper lists the top 15 VAPT tools which include Juice Shop, NodeGoat, Arachni, OWASP ZAP (Zed Attack Proxy), WAVS Framework, Prototype-based Model, V model, Classical waterfall model, Iterative waterfall model, React (for front-end), Node.js with Express (for back-end), Group Results by CWE ID, Union List, Intersection List, and Automation Algorithm.

Ahmad et al. [5] conducted a study on the Vulnerability Assessment and Penetration Testing (VAPT) Framework, focusing on the case study of a government website. In this research, VAPT is highlighted as a technique to analyze the strengths and weaknesses of computer systems to ensure the implementation of security measures. The study emphasizes the role of SQL in web operations and the risks associated with vulnerabilities such as SQL injection and Cross-Site Scripting (XSS). A goal-oriented penetration testing framework is recommended to identify specific vulnerabilities and mitigate risks effectively. The research conducted VAPT on government websites to showcase the current cybersecurity landscape in Indonesia. Various vulnerabilities were identified, including directory listing, full path disclosure, PHP info disclosure, and folder web server disclosure. The study also discusses the importance of penetration testing in protecting against financial losses, maintaining compliance, and safeguarding corporate image.

Dr. Vinod [6] highlights the increasing complexity of systems and the vulnerabilities that come with them, emphasizing the importance of identifying and addressing these vulnerabilities before attackers exploit them. In this research, VAPT is presented as a proactive method for cyber-attack prevention, involving assessing vulnerabilities in systems or networks and actively testing them for potential exploits. The process of VAPT is also described in nine steps, including deciding the scope, reconnaissance, vulnerability assessment techniques, penetration testing, and result analysis. Various techniques for vulnerability assessment are explained, such as static analysis, manual testing, automated testing, and fuzz testing. Different types of pen testing based on the tester's knowledge of the system (black box, grey box, white box testing) were also discussed. This research also highlights how admins can identify and remove vulnerabilities from their systems, making it difficult for attackers to exploit them.

Jai et al. [7] explored the critical role of Vulnerability Assessment and Penetration Testing (VAPT) in fortifying cybersecurity defenses against evolving threats in their research. The paper discussed various VAPT techniques, including static analysis, manual testing, automated testing, and fuzz testing, along with penetration testing methodologies such as black box, grey box, and white box testing. It also explored the practical application of VAPT such as enhancing web application security by identifying and mitigating vulnerabilities before cyber-attacks occur. The study emphasizes the importance of integrating security measures throughout the development life cycle of web applications, rather than addressing them solely during the final stages. Additionally, the paper discusses the significance of automated penetration testing techniques in efficiently identifying vulnerabilities, thereby reducing the time and cost associated with manual testing processes.

Gazmend et al. [8] discussed the escalating complexity of information systems and the heightened risks posed by unauthorized access through public networks in their research. Their paper explored various Penetration Testing methodologies for web apps, including reconnaissance, enumeration, and exploitation. In this research, NetSparker and Acunetix were identified as some of the tools that can be used for Web Application Penetration Testing. The paper also identified common web app vulnerabilities including Cookie Not Marked as Secure, Version Disclosure (PHP), Insecure Transportation Security Protocol Supported (TLS 1.0), Out-Of-Date Version (jQuery), Possible Source Code Disclosure, Internal Server Error, Version Disclosure (ASP.NET), ViewState is not Encrypted, Missing X-Frame-Options Header, Windows Short Filename, Possible Cross-Site Request Forgery in Login Form, and Possible Phishing by Navigating Browser Tabs.

Sachin et al. [9] discussed the constant threat posed by skilled hackers who exploit vulnerabilities to gain access to confidential data. The researchers proposed Vulnerability Assessment and Penetration Testing (VAPT) as a proactive measure to mitigate such threats and risks. Their paper defined Vulnerability Assessment as the process of identifying weaknesses in systems, such as operating systems, applications, and networks. Penetration Testing, on the other hand, involves the deliberate attempt to exploit these vulnerabilities to assess the robustness of the system's security posture. The paper also defined the different categories of vulnerabilities, including host-based, network-based, and application-based. It also discussed the importance of regular assessments to maintain security.

Andrey et al. [10] explained the increasing prevalence of vulnerabilities in web applications primarily stems from inadequate input validation. Their research discusses the use of the Tainted Mode model to detect vulnerabilities across modules. This study also proposes a new vulnerability analysis approach that integrates penetration testing and dynamic analysis, leveraging the extended Tainted Mode model effectively. Their research also shows that while manual code review is deemed effective by OWASP, it is acknowledged as time-consuming and prone to errors, leading to a shift towards automated approaches for vulnerability detection, categorized into black-box and white-box testing. The authors propose solutions to address the drawbacks of the Tainted Mode model, including its inability to detect inter-module vulnerabilities, which could lead to second-order injection attacks. This re-

search recommends an integrated approach that combines dynamic analysis with penetration testing to widen the scope of vulnerability detection.

Hasty et al. [11] discussed vulnerabilities such as injection flaws, cross-site scripting (XSS), broken authentication, insecure direct object references, cross-site request forgery (CSRF), security misconfiguration, insecure cryptographic storage, failure to restrict URL access, insufficient transport layer protection, and unvalidated redirects and forwards that affect web apps. Their research also presents proactive measures for enhancing website and server security, including the utilization of application firewalls, administration account renaming, regular security patch updates, service pack hotfixes, and the implementation of legal notices.

Divyani et al. [12] discussed the susceptibility of web application layers to unauthorized access and cyberattacks that result from the extensive use of data online. The paper highlighted common web app vulnerabilities such as unvalidated input, improper error management, and vulnerabilities associated with the handling of sensitive user data. The paper also explores security concerns specific to academia and e-commerce, emphasizing the importance of secure web portals for academic institutions to manage large databases securely. It also discusses authorization-based security policies in e-commerce applications and the necessity of database security to protect sensitive client information. It also outlines security evaluation methods for mobile applications, including validation, controlled access, encryption, and error management. Their research also emphasized the adoption of secure development practices, such as using languages like JAVA for sensitive web applications.

Esra et al. [13] discussed risks associated with improper handling of data items in HTTP requests, leading to severe security vulnerabilities. It also highlights that SSL encryption does not address these issues as it only secures data transport without evaluating HTTP queries. The gateway role of web apps to databases poses risks like SQL injection, illegal server access, and password-cracking attacks. This paper also highlights that most SQL injection vulnerabilities are due to inadequate input validation, and developers often make errors in encryption approaches for securing sensitive data. The authors also discussed the importance of secure design patterns and threat modeling to mitigate insecure design flaws and security misconfigurations. Vulnerabilities arising from outdated components and authentication failures are also discussed, along with strategies for protection. The paper also discussed mitigation techniques for various vulnerabilities including approaches like semantic comparison, session management techniques, content security policy, and role-based access control (RBAC).

Siva et al. [14] found that integrating various free and open-source tools to conduct thorough vulnerability assessments and penetration testing is an effective strategy. This approach is crucial in identifying and rectifying potential weaknesses inherent in web applications, particularly vulnerabilities such as injections, cross-site scripting (XSS), and directory traversal. By carefully correlating results from diverse sources including OWASP, OSSTMM, ISSAF, CVE, and Exploit Database, the proposed methodology aims to create accurate and exhaustive reports that rival those produced by commercial solutions.

Khaled et al. [15] assessed the effectiveness of an automated framework designed to enhance vulnerability detection in web applications. This framework aggregates results from multiple Web Application Vulnerability Scanners (WAVS) into a consolidated vulnerability report. Their study highlights the framework's practical significance, particularly when compared to individual scanners and traditional manual testing methods. The experimental results reveal that the Union List, generated by the automated framework, achieved the highest F-measure across all targets, indicating a good balance between precision and recall. This indicates the framework's ability to identify vulnerabilities effectively without high rates of false positives or false negatives.

Kushwah et al. [16] focused on high-risk vulnerabilities such as SQL Injection, Cross-Site Scripting, Local File Inclusion, and Remote File Inclusion, providing a detailed overview of the VAPT process and highlighting tools that are instrumental during the VAPT process. They argue that while web applications are susceptible to a range of technical vulnerabilities due to factors like poor programming or outdated systems, VAPT serves as a specialized approach to auditing web application security. This approach not only identifies potential vulnerabilities but also exploits these vulnerabilities like potential attackers, thus offering insights into the risk level of the system. The paper meticulously examines the mechanics of VAPT, outlines its limitations, and discusses various tools that facilitate the process, thereby underscoring the critical role of VAPT in securing web applications against emerging cyber threats. Through their comprehensive analysis, they contribute significantly to the field of cybersecurity, particularly in the context of safeguarding web applications through systematic vulnerability assessment and targeted penetration testing.

Umrao et al. [9] highlighted Vulnerability Assessment (VA) and Penetration Testing (PT) as crucial cybersecurity measures. They elucidate how these processes help identify and exploit network vulnerabilities, offering a strategy for organizations to shield against cyber threats preemptively. Highlighting the technicalities involved in conducting VA and PT, including their methodologies, benefits, and limitations, the paper underscores the necessity of these practices in the contemporary digital realm. It advocates for a unified approach leveraging automated tools for efficiency and effectiveness in securing systems against evolving cyber threats. This work stands as a foundational guide for implementing VA and PT in organizational cybersecurity protocols.

Yaqoob et al. [17] delved into the significance of identifying and mitigating network threats through Vulnerability Assessment (VA) and Penetration Testing (PT), crucial for securing internet facilities in the digital age. Highlighting the pervasive issue of cybersecurity, they propose VAPT as a solution to safeguard confidential data against skilled hackers by adhering to the principles of Confidentiality, Integrity, and Availability (CIA). The paper offers an in-depth exploration of VA and PT processes, methodologies, and the rationale behind their necessity, emphasizing the continuous battle against vulnerabilities like weak passwords, software bugs, and misconfigurations that expose networks to potential cyberattacks. Through systematic vulnerability management and ethical hacking, Yaqoob and his colleagues present a structured approach to enhancing network security, advocating for regular

assessments to adapt to the evolving threat landscape.

Vamsi et al. [18] emphasized the critical importance of regular security testing and checks through vulnerability assessment and penetration testing (VAPT) to safeguard organizational data and maintain customer trust. They detail common web application security vulnerabilities and the prerequisites for conducting any security assessment, alongside the dos and don'ts in alignment with each vulnerability. Highlighting the essential nature of VAPT in organizations, the paper discusses various types of security testing, underscoring VAPT's role in preparing organizations against potential security threats. This work stands out by offering a valuable resource for understanding the complexities of web application vulnerabilities and the integral processes of VAPT, serving as a guide for improving web application security in the digital era.

Almaarifa et al. [5] propose a systematic VAPT framework to identify and prioritize vulnerabilities, demonstrating its effectiveness through a case study. This approach uncovers various security risks, from directory listings to critical SQL injections, highlighting the importance of regular VAPT practices to protect sensitive data and strengthen digital infrastructure against cyber threats. The work emphasizes proactive cyber-security measures as essential for the safety of public sector digital assets.

Mehetre et al. [19] detail how VAPT serves as a crucial defense mechanism against growing cyber threats. They describe the processes involved in VAPT, its strategic importance for identifying and mitigating vulnerabilities, and emphasize its role in creating a secure organizational IT infrastructure. Highlighting VAPT's significance, particularly in the financial sector, Shah and Mehetre advocate for its adoption as a proactive measure for cybersecurity. Their analysis aims to raise awareness about the necessity of keeping security measures updated to protect against cyber-attacks effectively. This paper positions VAPT not just as a technical necessity but as an integral part of an organization's cybersecurity culture.

Osita, Christian et al. [20] Recognize the surge in e-commerce activities and corresponding security threats, the authors identify key vulnerabilities, including inadequate encryption and malware attacks, that jeopardize customer data and trust. The study suggests a suite of security measures, such as SSL/TLS encryption and multi-factor authentication, to fortify e-commerce platforms. Furthermore, it highlights the potential of blockchain, artificial intelligence (AI), and the Internet of Things (IoT) in combating cyber threats, from securing transactions to fraud detection. The paper concludes that leveraging these emerging technologies is crucial for maintaining the integrity and competitiveness of e-commerce operations, emphasizing the ongoing need to adapt to the evolving cybersecurity landscape.

Alotaibi et al. [21] Leverage SDN's centralized control, their WAF employs signatures and regular expressions to detect attacks, showing improved TCP ACK latency performance over traditional solutions like ModSecurity, though with increased CPU overhead on the controller. This study underscores the effectiveness of SDN in enhancing cybersecurity, particularly in defending against SQL injections, and contributes to expanding the application of SDN in network security frameworks.

Miguel Calvo and Marta Beltrán [22] introduce an innovative Adaptive Web Application Firewall (WAF) designed to dynamically adjust its defense mechanisms based on real-time risk assessments and the specific operational context of web applications. Unlike traditional rule-based WAFs, their adaptive WAF employs a MAPE-K feedback loop to autonomously modify its configurations, aiming to mitigate novel attacks more effectively and reduce the incidence of falsely blocked legitimate traffic. By implementing and testing this adaptive approach in a real-world environment, Calvo and Beltrán demonstrate its practical applicability and the advantages of a more flexible, risk-aware security posture for web applications. This research underscores the potential of adaptive security systems in responding to the evolving threat landscape.

Calvo, Beltrán [23] Addressing the shift towards dynamic computing environments like cloud and IoT, RiAS employs a three-layer architecture and a stepwise approach involving measurement, decision-making, and adaptation based on scalable policies and rules. This model allows for context-aware decision-making, adjusting security controls according to risk indicators and organizational risk tolerance. Validated through a Web Application Filter (WAF) use case, RiAS showcases the potential of adaptive, risk-based security measures to respond dynamically to threats, underscoring its relevance in modern, heterogeneous computing contexts.

Shaheed et al. [24] presents an advanced web application firewall model leveraging machine learning and feature engineering to detect web attacks. This model uniquely analyzes entire HTTP requests, including URL, payload, and headers, by extracting four key features: request length, percentages of allowed and special characters, and an attack weight. It employs four classification algorithms across multiple datasets, including real-world server logs, to ensure broad applicability and minimize overfitting. Demonstrating high accuracy, with up to 99.6% on research datasets and 98.8% on real server data, this work significantly enhances web application security by providing a comprehensive, adaptive approach to threat detection.

George Iakovakis et al. [25] Explore how dispersed corporate networks have expanded the attack surface, making businesses more vulnerable to cyber threats. The study categorizes and evaluates an array of cybersecurity tools—including vulnerability scanners, monitoring and logging tools, and antivirus software—highlighting their advantages, limitations, and applicability for businesses seeking to enhance their cybersecurity posture. By providing a comprehensive taxonomy and analysis of these tools, the paper serves as a guide for organizations navigating the complex cybersecurity landscape, offering insights into selecting the most effective tools for safeguarding against cyberattacks in the remote work era.

The paper by Tudosi et al. [26] explores the efficacy of penetration testing in identifying and mitigating security vulnerabilities within a distributed firewall system. It emphasizes the importance of regular security audits to safeguard against the evolving landscape of cyber threats. The study also highlights the challenges posed by the complexity of modern networks, the need for skilled cybersecurity professionals, and the potential of AI and ML to enhance VAPT processes. The research further discusses various strategies and tools used for penetration testing, underscoring the necessity of continuous

adaptation and the benefits of employing distributed firewalls for robust network security.

Altaf et al. [27] presents a detailed study on the importance of identifying and prioritizing vulnerabilities in web applications, focusing on SQL injection attacks. It proposes a methodology combining manual and automated testing, including static analysis for detecting SQL injection vulnerabilities in PHP applications. Highlighting the critical role of vulnerability assessments in safeguarding information systems, the paper advocates for combining automated tools like Acunetix and manual testing to achieve thorough vulnerability detection. It also addresses the challenges of false positives and negatives in vulnerability assessments, emphasizing the necessity for ongoing security efforts to adapt to new cyber threats.

Table I shows summary of literature review papers that are discussed in this research paper.

TABLE I: Summary of Literature Review Papers

Author	Year	Technique	Advantages	Limitations
Lamba [4]	2020	Various techniques for VAPT, including static analysis, manual testing, automated testing, and fuzz testing	Streamlines the vulnerability assessment and exploitation process	While these techniques are effective, they may not cover all possible vulnerabilities, leading to potential blind spots in security coverage
Ahmad et al. [5]	2020	Goal-oriented penetration testing framework	This effectively identifies specific vulnerabilities	The effectiveness of this framework largely relies on the goals set by the tester.
Dr. Vinod [6]	2023	Nine-step VAPT process, including scoping, reconnaissance, vulnerability assessment techniques, penetration testing, and result analysis	It's a proactive method for cyber-attack prevention	The effectiveness of the suggested technique depends on the thoroughness of each step and the expertise of the testers. The process is also time-consuming.
Jai et al. [7]	2015	VAPT techniques, including static analysis, manual testing, automated testing, and fuzz testing	It streamlines VAPT throughout the development cycle of web apps. Automation also minimizes errors and reduces time spent in the assessment and testing process.	Relying solely on automated tools might lead to false positives or false negatives, reducing the overall effectiveness of the VAPT process.

TABLE I: Summary of Literature Review Papers (Continued)

Khaled et al. [15]	2023	Automated framework for vulnerability detection	Enhances the effectiveness and accuracy of vulnerability detection in web applications. It also reduced the cost of reliance on security experts	The practical implementation of the automated framework may face challenges such as integration with existing systems, scalability, and adaptation to evolving threats.
Kushwah et al. [16]	2020	Vulnerability Assessment and Penetration Testing (VAPT)	Targets high-risk vulnerabilities such as SQL Injection, Cross-Site Scripting, Local and Remote File Inclusion. Provides a detailed overview and tools for conducting VAPT. Enhances web application security through systematic identification and exploitation of vulnerabilities.	Time constraints may reduce the efficiency of penetration testing. Success is dependent on the tester's skill. Can increase overall system budget due to external testing and potential system damage during testing.
Umrao et al. [9]	2012	Vulnerability Assessment and Penetration Testing (VAPT)	Identifies and exploits security vulnerabilities. Enhances system security against cyber threats. Provides a comprehensive audit of network security.	Labor-intensive and requires skilled testers. May not guarantee the identification of all vulnerabilities. Can be expensive due to the need for repetitive testing upon system changes.
Yaqoob et al. [17]	2017	Vulnerability Assessment and Penetration Testing (VAPT)	Identifies common network threats and proposes countermeasures. Uses CIA principles to ensure confidentiality, integrity, and availability. Provides a comprehensive overview of VAPT processes and methodologies.	Vulnerability management needs to be performed regularly, requiring continuous resource investment. Penetration testing phases can be complex and require specialized expertise.

TABLE I: Summary of Literature Review Papers (Continued)

Vamsi et al. [18]	2022	Vulnerability Assessment and Penetration Testing (VAPT)	Identifies and prepares organizations against potential security threats. Offers detailed guidelines on conducting security assessments, including dos and don'ts. Highlights common web application vulnerabilities and methods to mitigate them. Stresses the necessity of VAPT in maintaining customer trust and organizational integrity.	Requires regular and consistent application to stay ahead of emerging threats. May necessitate specialized knowledge and tools for effective implementation.
Almaarifa et al. [5]	2020	Vulnerability Assessment and Penetration Testing (VAPT)	Provides a systematic framework for identifying vulnerabilities. Demonstrate the application of VAPT through a case study. Highlights the critical need for cybersecurity in the public sector. Advocates for regular VAPT practices to enhance digital infrastructure security.	The study is limited to government websites in Indonesia. Specific technical details on remediation practices are not extensively covered.
Mehre et al. [19]	2013	Vulnerability Assessment and Penetration Testing (VAPT)	Identifies vulnerabilities in a controlled environment. Emphasizes proactive cybersecurity measures. Raises awareness at all organizational levels about cybersecurity.	Requires continuous update and adaptation to combat evolving cyber threats. The process can be complex and requires expertise in both vulnerability assessment and penetration testing.

TABLE I: Summary of Literature Review Papers (Continued)

Osita, Christian et al. [20]	2022	Blockchain, AI, IoT, Secure Payment Gateways, Multi-factor Authentication (MFA), SSL/TLS Encryption	Enhances transaction security and verifies product authenticity. Enables fraud detection and advanced user authentication. Secures communication and financial transactions. Protects connected devices and the data they handle.	Requires continuous update and integration of new technologies to combat evolving threats. May involve high implementation and maintenance costs.
Alotaibi et al. [21]	2023	SDN-Based Web Application Firewall (WAF)	Utilizes SDN for centralized control and dynamic enforcement of security policies. Employs signatures and regular expressions for effective detection of SQL injection attacks. Demonstrates improved TCP ACK latency over traditional WAFs.	Higher CPU overhead on the controller compared to traditional WAFs. The efficiency and scalability of the solution in larger, real-world network environments need further exploration.
Miguel Calvo and Marta Beltrán [22]	2022	Adaptive Web Application Firewall (WAF)	Dynamically adjusts defense mechanisms based on real-time risk assessments. Reduces false positives and adapts to new threats. Utilizes a MAPE-K feedback loop for autonomous decision-making and adaptation.	Implementation complexity compared to traditional WAFs. Requires ongoing monitoring and adjustment of risk assessment parameters.

V. VULNERABILITY ASSESSMENT AND PENETRATION TESTING

Vulnerability Assessment refers to a systematic process of evaluating the potential vulnerabilities in a system, which could be a computer system, a network, or an application [28]. The process involves identifying, quantifying, and prioritizing these vulnerabilities. This is typically done using automated tools, and the findings are documented in a vulnerability assessment report. The purpose of a vulnerability assessment is to provide organizations with an understanding of the vulnerabilities in their systems, the risks associated with these vulnerabilities, and the appropriate mitigation strategies.

A. Types of Vulnerability Assessments

- **Network-Based Scans:** These scans are designed to identify potential security threats and weaknesses in both the wired and wireless network infrastructure of the web application.
- **Host-Based Scans:** These scans focus on servers, workstations, and other network hosts of the web application. They provide detailed information about configuration settings and update histories, helping to identify potential threats and issues that could arise if an outsider gains access to the network.
- **Wireless Scans:** Wireless vulnerability scanners are used to detect rogue access points and ensure that the network configuration within the web application infrastructure is secure.
- **Application Scans:** These scans are used to identify known software vulnerabilities and problematic configurations in network or web applications. They can help detect issues such as Cross-Site Scripting (XSS), SQL injection, and Cross-Site Request Forgery (CSRF).
- **Database Scans:** These involve identifying weaknesses in database configurations and suggesting changes to prevent cyber-attacks. They can help identify issues such as SQL injection, weak passwords, and excessive privileges.

These types of vulnerability assessments provide organizations with valuable insights into potential security risks and vulnerabilities within their systems, allowing them to proactively address and mitigate these risks before they can be exploited by malicious actors.

VI. PENETRATION TESTING

Penetration testing, or pen testing, involves identifying, examining, highlighting, and actively exploiting the vulnerabilities in a given system such as a web application or

firewall [29]. The primary objective of a pen test is to improve an organization's security by proactively identifying security weaknesses before they can be exploited by malicious hackers. Ethical hackers conduct pen tests to mimic the strategies and actions of potential attackers, essentially putting the web applications or network devices to the test to evaluate their resilience to hacking attempts.

A. Types of Penetration Testing

- **White Box Testing:** With White box testing, testers are provided with complete knowledge about the system they are testing [30]. This includes details about the organization's system or target network, the internal structure of the product, and the source code. Testers can check the code for potential vulnerabilities, such as insecure coding practices or errors in logic.
- **Black Box Testing:** Black box testing is executed with any prior knowledge of how the system works and its security features [30]. With this approach, testers try to find vulnerabilities purely from an external perspective, much like how a real-world attacker would. This test is done with the aim of detecting vulnerabilities in the functionality and behavior of the system.
- **Gray Box Testing:** This type of testing integrates features of both white box and black box testing [30]. With gray box testing, testers are only given a few details about the system and not the full details like in white box testing. This allows them to understand certain aspects of the system's internal structure while also testing it from an external perspective.

These types of penetration testing provide organizations with valuable insights into the effectiveness of their security measures and help identify areas for improvement in their systems' defenses against cyber threats.

VII. TECHNIQUES USED IN VULNERABILITY ASSESSMENT AND PENETRATION TESTING

Sure, here are the explanations for these Vulnerability Assessment and Penetration Testing (VAPT) techniques:

- **Static Analysis:** This technique involves analyzing the code of web apps or any other system without actively executing it. Static analysis can be done manually by going through the code line by line or using automated tools that scan the code for known vulnerability patterns.
- **Manual Testing:** In this approach, security professionals manually check the code of the web app or configurations of the firewall, considering the loopholes identified by automated scanning.
- **Automated Testing:** This involves the use of automated tools to identify potential vulnerabilities in the web application and firewall settings. Automated testing is faster and can cover a larger scope compared to manual testing. However, it may not be able to identify complex vulnerabilities that require human intuition.
- **Fuzz Testing:** This technique involves inputting invalid or random data into a system and then observing for

crashes and failures. The goal of this technique is to test the robustness of the system. It can be used to find out zero-day vulnerabilities.

These techniques are commonly used in Vulnerability Assessment and Penetration Testing to identify and address security weaknesses in systems and applications.

VIII. RESULTS AND DISCUSSIONS

After thoroughly reviewing the above literature, these are some of the key findings.

A. Common Vulnerabilities of Web Applications and Firewalls

35 web app vulnerabilities were identified in the reviewed papers. Some of the common vulnerabilities that discussed in these studies and summarised in Table II include the following:

- **Injection Flaws:** One of the common attacks identified in the studies occurs when untrusted data is inserted into a command or query sent to an interpreter, such as a database or operating system. Attackers exploit these vulnerabilities by injecting malicious code into input fields or parameters of the web app, leading to the execution of unintended commands. For example, SQL injection involves inserting malicious SQL code into input fields, allowing attackers to manipulate database queries and potentially access or modify sensitive data.
- **Cross-Site Scripting (XSS):** XSS vulnerabilities allow bad actors to inject harmful scripts into web pages that others view. These vulnerabilities are caused by the lack of sanitization or validation of input fields or parameters of the web application. When unsuspecting users visit the compromised page, their browsers execute the injected scripts, which enables the bad actors to access and even steal their personal information, hijack user sessions, or execute actions that the user has not authorized.
- **Broken Authentication:** This vulnerability results from web apps implementing weak authentication mechanisms or improperly managing user sessions. Attackers exploit these weaknesses to compromise user accounts, gaining unauthorized access to sensitive data or functionalities. Common attack vectors include brute force attacks, session fixation, session hijacking, and password spraying.
- **Insecure Direct Object References:** This vulnerability is caused by a web application unintentionally exposing internal implementation details, such as file paths or database keys, in URLs. These references can be used by bad actors to access and manipulate database resources. For example, an attacker may modify a URL parameter to access another user's private information or sensitive files stored on the server.
- **Cross-Site Request Forgery (CSRF):** Web apps with this vulnerability allow attackers to trick authenticated users into performing malicious actions unknowingly. For instance, attackers create scripts that automatically

execute when users perform certain actions such as visiting a certain web page. This can lead to unauthorized data access, unknowingly revealing private information, data manipulation, and in some worst cases, account takeover.

- **Security Misconfiguration:** This vulnerability arises when web servers, frameworks, or application platforms are improperly configured, leaving them vulnerable to exploitation. These misconfigurations can be exploited by attackers to access sensitive information or functionalities that they are not authorized to. Common examples include using default credentials, leaving unnecessary services or ports open, and insecure default settings.
- **Insecure Cryptographic Storage:** This vulnerability occurs when sensitive data, such as passwords or credit card numbers, is stored in its raw format (without being encrypted). This can lead to sensitive information (PII) being exposed if attackers access the data of the web application.
- **Failure to Restrict URL Access:** Failure to properly restrict access to certain URLs or resources allows attackers to bypass authentication mechanisms and access sensitive data or functionalities. This can occur due to improper access controls, insufficient authorization checks, or direct object reference vulnerabilities. Attackers exploit these weaknesses to gain unauthorized access to privileged information or perform unauthorized actions on the web application.
- **Insufficient Transport Layer Protection:** This vulnerability occurs when weak encryption protocols or misconfigured SSL/TLS settings are used to transmit sensitive data between clients (user browsers or apps) and servers. Attackers can exploit these vulnerabilities to intercept or tamper with sensitive information transmitted over insecure connections, leading to data breaches or unauthorized access.
- **Unvalidated Redirects and Forwards:** This vulnerability occurs when web applications allow user-controlled input to dictate the destination of a redirect or forward action. Attackers can exploit this vulnerability by crafting malicious URLs that redirect users to phishing websites or other malicious destinations. This can be used to deceive users into revealing sensitive information or perform malicious actions unknowingly.

B. Results on Different Datasets

- **Real-World Web Applications:** VAPT tools showed high effectiveness in detecting common vulnerabilities such as SQL injection, XSS, and CSRF. However, some tools struggled with complex, less common vulnerabilities.
- **Simulated Environments:** Tools were able to identify vulnerabilities in pre-configured vulnerable services, demonstrating their utility in controlled testing scenarios.

- Custom Test Bed: The custom test bed allowed for detailed assessment of firewall configurations and rule effectiveness. VAPT tools helped in identifying misconfigurations and potential bypass techniques.

C. Discussion on Scalability

To prove the scalability of the proposed work, evaluations were performed across different datasets:

- The scalability of VAPT tools was tested by gradually increasing the complexity and size of the datasets.
- Tools that performed well in smaller, simpler environments were further evaluated in larger, more complex scenarios.
- The results indicated that some VAPT tools scaled effectively, maintaining high detection rates and manageable performance impact, while others exhibited increased false positives and degraded performance.

D. Comparison and Analysis

- Tool Effectiveness: Tools like Burp Suite and Acunetix consistently performed well across all datasets, indicating robust detection capabilities.
- Challenges: Some tools struggled with high complexity environments, highlighting the need for continuous updates and improvement in VAPT technologies.
- Recommendations: Based on the findings, recommendations include regular updates to VAPT tools, integration of AI and machine learning for better scalability, and combined use of multiple tools for comprehensive security assessments.

By thoroughly evaluating VAPT tools across different datasets and discussing their scalability, this study provides a robust assessment of their effectiveness in mitigating security risks in firewalls and web applications (Table III).

IX. TOOLS USED FOR VULNERABILITY ASSESSMENT AND PENETRATION TESTING

A. Web Application Vulnerability Scanners (WAST)

- Acunetix: A commercial WAST offering automated scans, manual penetration testing, and vulnerability management. It covers SQL injection, XSS, XXE, and more.
- Zed Attack Proxy (ZAP): An open-source, versatile tool for manual and automated web app security testing. It offers interception, fuzzing, and various attack modules.
- Nikto: An open-source scanner identifying vulnerabilities in servers, operating systems, web applications, websites, and mobile applications. It's basic but good for initial scans.
- OpenVAS: An open-source vulnerability scanner platform with plugins for web app security testing. It's flexible and customizable.

- Vega: An open-source, scriptable framework for automation and customization of web security testing. It's advanced and requires coding knowledge.
- Retina: A commercial WAST with advanced features like web application firewall (WAF) integration and network security scanning.
- WebScarab: An open-source web proxy tool useful for capturing and analyzing HTTP traffic and performing manual security assessments.

Dynamic Application Security Testing (DAST)

- Burp Suite: A commercial, comprehensive DAST and manual testing platform with various features like intercepting, analyzing, and attacking web traffic.
- W3af: An open-source DAST platform with extensive scanning capabilities, fuzzing, and vulnerability exploitation modules.
- BeEF (Browser Exploitation Framework): An open-source tool primarily used for social engineering and client-side attacks, simulating malicious JavaScript injections.

Static Application Security Testing (SAST)

- Checkmarx: A commercial SAST solution that analyzes source code for vulnerabilities, performs code reviews, and offers secure coding practices guidance.
- Fortify: Another commercial SAST offering source code analysis, vulnerability detection, and secure coding recommendations.

Other Relevant Tools

- Nessus: A comprehensive vulnerability scanner used for network and web application security, covering various systems and protocols.
- Nmap: An open-source port scanner and network exploration tool valuable for identifying potential entry points for attackers.
- Wireshark: A network traffic analyzer used for capturing, analyzing, and understanding network communication, helpful for detecting suspicious activity.
- Metasploit: An open-source penetration testing framework with various tools for exploiting vulnerabilities, simulating attacks, and testing defenses.
- SQLMap: An open-source tool that allows security teams to automatically detect and exploit SQL injection vulnerabilities during the penetration testing process.

X. VULNERABILITY ASSESSMENT AND PENETRATION TESTING STEPS

By detailing each stage of the process in Fig. 2, this research provides a comprehensive understanding of the methodological framework used, enhancing the replicability and reliability of the study's outcomes.

TABLE II. SUMMARY OF COMMON VULNERABILITIES

Vulnerability	Our Paper	[4]	[5]	[6]	[7]	[8]	[9]	[10]	[12]	[13]	[14]
Injection Flaws	✓	✓	✓	✓	✓						
Cross-Site Scripting (XSS)	✓	✓	✓	✓					✓	✓	✓
Broken Authentication	✓	✓				✓	✓			✓	✓
Insecure Direct Object References	✓										
Cross-Site Request Forgery (CSRF)	✓	✓									
Security Misconfiguration	✓					✓	✓	✓	✓		
Insecure Cryptographic Storage	✓	✓		✓		✓					
Failure to Restrict URL Access	✓	✓				✓				✓	
Insufficient Transport Layer Protection	✓	✓				✓				✓	
Unvalidated Redirects and Forwards	✓	✓				✓				✓	

TABLE III. VAPT TOOLS BY CATEGORY

Category	Tools
Web Application Vulnerability Scanners	Acunetix, Zed Attack Proxy (ZAP), Nikto, OpenVAS, Vega, Retina, WebScarab
Dynamic Application Security Testing	Burp Suite, W3af, BeEF
Static Application Security Testing	Checkmarx, Fortify
Other VAPT Tools	Nessus, Nmap, Wireshark, Metasploit, SQLMap

- 1) **Reconnaissance and Planning** This is the initial phase where the scope, goals, and methods of the test are defined. It involves identifying the systems to be tested, the testing methods to be used, and the resources required. This step is crucial to ensure that the test is well-structured and effective. In this step, the testers need to understand the context and security needs of the organization, clearly define the rules of engagement, and also obtain the necessary permissions to conduct all the necessary tests [19].
- 2) **Information Gathering** This step involves collecting as much information as possible about the web application and its underlying infrastructure. Techniques used include:
 - Network Mapping
 - Identifying Applications
 - Identifying Firewalls and Security Measures
 - Public Information Gathering
 - Technical Information Gathering
- 3) **Vulnerability Scanning** At this stage, web applications are scanned using automated tools. These tools can identify a wide range of issues, such as SQL injection and XSS. Common tools used include Nessus, OpenVAS, Wireshark, OWASP ZAP, and Burp Suite.

- 4) **Penetration Testing** After scanning for vulnerabilities, pen testing tools are used to exploit these loopholes. Exploitation techniques include:
 - Exploitation
 - Privilege Escalation
 - Interception
 - Data Extraction
- 5) **Analysis And Reporting** This stage involves reviewing scan reports, assessing the potential consequences of exploitation, and categorizing vulnerabilities. The results are compiled into a report that elaborates on the organization’s security posture [31].
- 6) **Recommendations** Recommendations for remediating and mitigating vulnerabilities are provided. These may include applying patches, configuring settings, and employee training [31].
- 7) **Follow-up** The VAPT process requires ongoing follow-up to ensure the effectiveness of remediation measures and to address new vulnerabilities. Periodic reassessments are essential [31].

XI. CHALLENGES FACED DURING VULNERABILITY ASSESSMENT AND PENETRATION TESTING

Despite the availability of detection tools and security measures, several challenges persist in effectively detecting and mitigating common vulnerabilities in web applications. These challenges include:

A. Complexity of Modern Web Applications

Modern web applications have become increasingly complex, incorporating dynamic content, client-side scripting, and sophisticated backend architectures. This complexity introduces a multitude of potential attack vectors and vulnerabilities, making it challenging for security professionals to accurately identify and mitigate them. The dynamic nature of modern web applications also means that vulnerabilities can arise from interactions between various APIs and microservices, further complicating the detection and remediation process [32].

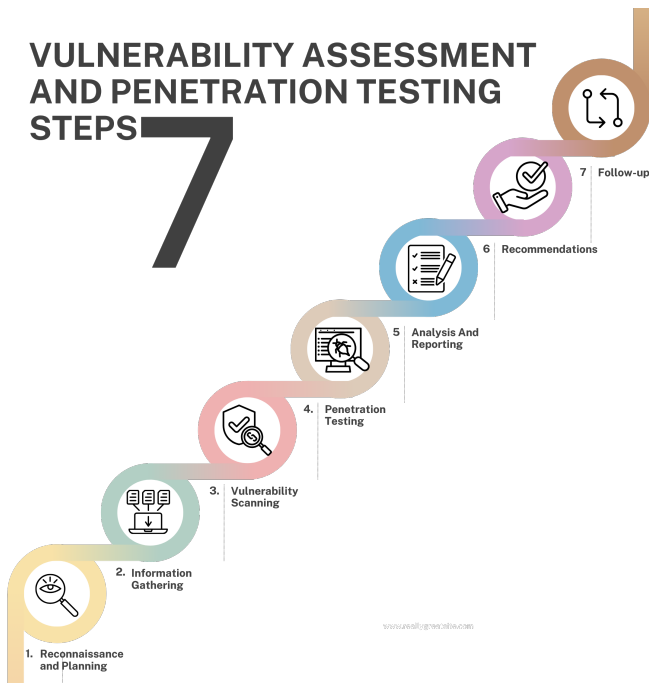

Fig. 2. Vulnerability assessment and penetration testing steps.

B. Lack of Awareness and Expertise

Many organizations lack the necessary awareness and expertise to effectively address common vulnerabilities in their web applications. This can stem from a variety of factors, including limited resources, inadequate training programs, and a lack of prioritization of security initiatives. As a result, there are often gaps in the organization's security posture, leaving web applications vulnerable to exploitation by malicious actors [33].

C. False Positives and Negatives

Automated detection tools used to identify vulnerabilities in web applications and firewalls can often generate false positives or negatives. False positives occur when the tool incorrectly identifies a normal occurrence in the web app or a network as a security incident or vulnerability. This leads to unnecessary investigation and remediation efforts, deviating security teams from critical tasks. On the other hand, false negatives occur when the tool is unable to detect a real security vulnerability. This is worse since it leaves the system vulnerable to exploitation by bad actors [32] [34].

D. Patch Management

Patching vulnerabilities identified in web applications can be challenging, especially in large-scale environments with numerous dependencies and interconnected systems. Identifying affected components, ensuring compatibility across dependencies, and coordinating patch deployments while minimizing downtime requires careful planning and allocation of resources. Organizations must prioritize and coordinate the deployment of patches across various components, including web servers, frameworks, libraries, and third-party plugins [35].

E. Continuous Monitoring and Maintenance

Maintaining the security of web applications requires continuous monitoring and maintenance to address newly discovered vulnerabilities and evolving threats. This involves regularly scanning web applications for vulnerabilities, monitoring for suspicious activities or anomalous behavior, and promptly applying security patches and updates, which is costly and time-consuming [32].

XII. BEST PRACTICES FOR MITIGATING COMMON VULNERABILITIES

To effectively mitigate common vulnerabilities in web applications, organizations can adopt the following best practices:

- Implement Secure Coding Practices
- Regular Security Assessments
- Deploy Defense-in-Depth Strategies
- Patch Management
- Monitor and Log Activities
- Document Everything
- Communicate Effectively

XIII. EMERGING TECHNOLOGIES IN VULNERABILITY ASSESSMENT AND PENETRATION TESTING (VAPT)

The integration of emerging technologies such as Artificial Intelligence (AI) and Machine Learning (ML) into Vulnerability Assessment and Penetration Testing (VAPT) processes marks a transformative leap forward in cybersecurity. These technologies offer the potential to automate complex tasks, enhance the precision of security assessments, and predict future vulnerabilities, thereby augmenting the capabilities of security teams to protect against cyber threats.

A. Automation of Vulnerability Detection

AI and ML algorithms can automate the detection of vulnerabilities by analyzing vast amounts of data derived from network traffic, system logs, and past security incidents. This automation significantly reduces the time and resources required for vulnerability assessments, allowing for more frequent and comprehensive security evaluations. AI-driven systems can continuously monitor networks and systems for signs of vulnerability, enabling organizations to identify and address security weaknesses promptly.

B. Improvement in Penetration Testing Accuracy

The application of AI and ML in penetration testing introduces a level of precision previously unattainable with manual testing alone. These technologies can simulate a wide range of cyber-attacks and test various breach scenarios, learning from each interaction to improve testing strategies over time. By employing AI and ML, penetration testers can uncover not only known vulnerabilities but also identify complex attack patterns and zero-day vulnerabilities that would be challenging to detect manually.

C. Prediction of Future Vulnerabilities

One of the most promising aspects of integrating AI and ML into VAPT is the potential to predict future vulnerabilities and cyber-attack trends. By analyzing historical security data and current cyber threat landscapes, AI models can identify patterns and predict which systems or applications are most likely to be targeted by attackers. This predictive capability enables organizations to proactively strengthen their defenses against potential threats before they are exploited.

D. Challenges and Considerations

While the integration of AI and ML into VAPT offers numerous benefits, it also presents challenges. The effectiveness of AI-driven VAPT depends on the quality and quantity of the training data, requiring ongoing updates to keep pace with the rapidly evolving cyber threat landscape. Additionally, there is a need for skilled cybersecurity professionals who can interpret AI and ML outputs and make informed decisions about mitigating identified vulnerabilities.

The incorporation of AI and ML into VAPT processes represents a significant advancement in the field of cybersecurity. By automating vulnerability detection, enhancing the accuracy of penetration tests, and predicting future security threats, these technologies empower organizations to adopt a more proactive and efficient approach to cybersecurity. As the cyber threat landscape continues to evolve, the integration of emerging technologies into VAPT will play a crucial role in safeguarding digital assets and information against increasingly sophisticated cyber-attacks.

XIV. FUTURE TRENDS AND CHALLENGES IN VULNERABILITY ASSESSMENT AND PENETRATION TESTING (VAPT)

As the digital landscape continues to evolve, so too do the threats pose by cyber-attacks. This constant evolution requires Vulnerability Assessment and Penetration Testing (VAPT) methodologies to adapt and evolve to protect against these ever-changing threats effectively. Below are key trends and challenges that will shape the future of VAPT.

A. Increasing Sophistication of Cyber-Attacks

Cyber-attacks are becoming increasingly sophisticated, leveraging advanced techniques such as artificial intelligence (AI) and machine learning (ML) to bypass traditional security measures. Attackers are using more complex algorithms to automate attacks, making it harder for VAPT tools and techniques to detect and prevent them effectively. To counteract these advanced threats, VAPT practices must incorporate similar technologies, using AI and ML not just for defense but also to simulate advanced attack scenarios more accurately during penetration testing.

B. The Rise of Quantum Computing

Quantum computing presents both opportunities and challenges for cybersecurity. Its immense processing power has the potential to break current encryption methods, rendering many of today's cybersecurity practices obsolete. This technological shift necessitates the development of quantum-resistant

encryption methods to secure data against future quantum-enabled attacks. VAPT practices will need to evolve to test and validate the security of quantum-resistant algorithms and ensure that organizations can safeguard their information in a post-quantum world.

C. Implications for Cybersecurity

The advent of quantum computing will force a reevaluation of current VAPT methodologies. As encryption standards evolve, VAPT tools will need to adapt to assess the effectiveness of new cryptographic measures. Moreover, quantum computing could enhance VAPT by enabling the analysis of complex systems and networks more efficiently, potentially identifying vulnerabilities that were previously undetectable with classical computing methods.

D. Skill Shortages in Cybersecurity

The cybersecurity field is currently facing a significant skills shortage, with a gap between the demand for qualified cybersecurity professionals and the supply of trained individuals. This shortage is a critical challenge for VAPT, as the effectiveness of these practices heavily relies on skilled practitioners to conduct assessments and interpret results. Bridging this gap requires a concerted effort to promote cybersecurity education and training, alongside leveraging AI and automation to handle routine tasks, allowing human experts to focus on more complex aspects of VAPT.

E. Need for Continuous Adaptation

The cyber threat landscape is dynamic, with new vulnerabilities and attack vectors emerging continually. To keep pace, VAPT practices must be iterative and adaptive, constantly evolving to address new threats. This includes adopting a continuous assessment model, where VAPT is not a one-time event, but an ongoing process integrated into the organization's security posture.

The future of VAPT lies in its ability to adapt to the rapidly changing cyber threat landscape. The growing sophistication of cyber-attacks, the advent of quantum computing, and the ongoing challenge of skill shortages in cybersecurity are significant trends that will shape VAPT practices in the years to come. To remain effective, VAPT must leverage emerging technologies, promote cybersecurity education and training, and adopt a continuous, adaptive approach to vulnerability assessment and penetration testing.

XV. CONCLUSION

In this study, we analyzed existing research papers and articles on vulnerability assessment and penetration testing for web applications. The studies analyzed have highlighted the common vulnerabilities in web applications and the potential risks they pose to organizations. These vulnerabilities, if exploited by attackers, can lead to significant harm, emphasizing the critical need for robust security measures. This study also explored various VAPT tools, categorizing them based on their best use cases. Some of the common tools used in VAPT include Burp Suite for web application security testing, Nmap for network scanning, and Metasploit for exploiting detected

vulnerabilities in target systems. These tools play a pivotal role in identifying and mitigating vulnerabilities, thereby enhancing system security and preventing cyber-attacks. However, while analyzing the available studies, it was noted that there is limited research on how generative AI is being used by attackers in their process of exploiting vulnerabilities in web applications. As AI tools become more accessible and sophisticated, there is a growing concern that they could be leveraged by attackers to exploit vulnerabilities more effectively. Therefore, future research is needed on how organizations can prepare for a future where attackers will leverage AI tools. This could involve developing advanced security measures and strategies to counteract the potential threats posed by AI-powered attacks. By staying ahead of the curve and proactively addressing these emerging threats, organizations can ensure robust web security in the face of evolving cyber threats.

FUNDING

This work was funded by King Faisal University, Saudi Arabia [Project Number A328].

ACKNOWLEDGMENTS

This work was made possible in part by a grant from the university, which allowed us to conduct the research and collect the necessary data. This work was supported through the Annual Funding track by the Deanship of Scientific Research, Vice Presidency for Graduate Studies and Scientific Research, King Faisal University, Saudi Arabia [Project Number A328].

A Deep Learning Approach to Convert Handwritten Arabic Text to Digital Form

Bayan N. Alshahrani, Wael Y. Alghamdi

Department of Computer Science, College of Computers and Information Technology,
Taif University, P.O.Box 11099, 21944 Taif, Saudi Arabia

Abstract—The recognition of Arabic words presents considerable difficulties owing to the complex characteristics of the Arabic script, which encompasses letters positioned both above and below the baseline, hamzas, and dots. In order to address these intricacies, we provide a structured approach for transforming handwritten Arabic text into a digital format. We employ a hybrid deep learning technique that combines Convolutional Neural Networks (CNNs), Bidirectional Long Short-Term Memory (BLSTM), and Connectionist Temporal Classification (CTC). We collected datasets that cover a wide range of Arabic text variations. We have also created a pre-processing pipeline. Our methodology successfully achieved an accuracy rate of 99.52%. At the level of recognizing the letters of the word, with an accuracy of 98.36% at the level of the full word. In order to evaluate the effectiveness of our suggested method for recognizing handwritten text, we utilize two essential metrics: Word Error Rate (WER) and Character Error Rate (CER) to compare its performance. The experimental research demonstrates a WER of 1.64 % and a CER of 0.48%.

Keywords—Deep learning; convolutional neural networks; bidirectional long short term memory; connectional temporal classification; Arabic handwriting recognition

I. INTRODUCTION

The Arabic language, known for its intrinsic beauty and cultural significance, presents a unique challenge in the digital age. Its intricate handwritten script, defined by graceful curves and intricate loops, encapsulates centuries of wisdom, knowledge, and artistic expression [1]. However, converting handwritten Arabic text into a digital format poses a formidable task, given the language's complexity.

Arabic is celebrated for its distinctive calligraphy, which adds to the complexity of recognizing and converting handwritten text. Unlike Latin-based scripts, Arabic script is cursive, with characters that change shape based on their position within a word [2]. As shown in Fig. 1. Furthermore, Arabic words often feature descending letters, supra-line letters, and dots, making the recognition process exceptionally challenging.

A hybrid deep learning paradigm combining Convolutional Neural Networks (CNN), Bidirectional Long Short-Term Memory (BLSTM), and Connectional Temporal Classification (CTC) is emerging as a critical solution to this complex problem. CNN captures local spatial relationships to extract significant characteristic features from Arabic handwritten text. The BLSTM component incorporates past and future contexts to model temporal dependencies and contextual information. This lets the model reflect Arabic handwriting's sequential nature, where character shapes change based on their location in a

Letter	Initial	Medial	Final
ب	ب	ب	ب
ت	ت	ت	ت
ث	ث	ث	ث
ج	ج	ج	ج

Fig. 1. Examples of some arabic letters and their position.

word or sentence. By aligning predicted feature sequences with ground truth labels, the CTC component allows end-to-end training and sequence alignment.

In a world where the Arabic language plays a vital role beyond linguistic communication, the importance of preserving and accessing handwritten texts is undeniable. Documents, letters, and literary works are gateways to knowledge, culture, and identity. As these texts age and grow more fragile, the urgency to preserve them intensifies [3].

In addition, the hybrid model of Deep Learning to convert handwritten Arabic text to digital form is poised to bridge the gap between the enduring legacy of the Arabic language and the boundless possibilities of the digital era. As we embark on this journey, we recognize the importance of preserving the treasures of the Arabic script, making them accessible to the world, and ensuring that the beauty of the language endures in the digital age.

The significance of this mission lies not only in its technological complexity but in the cultural responsibility it carries. The Arabic language, with its unique script and intricate calligraphy, has been a symbol of beauty and sophistication. However, as we embrace the digital age, we are faced with the challenge of transforming handwritten Arabic text into a digital format.

The problem stems from the intrinsic complexities of Arabic script, which is a cursive and context-dependent writing system. Handwritten Arabic text exhibits significant variations in writing styles, ligatures, and contextual letter forms. Arabic handwriting varies greatly between individuals, encompassing diverse writing styles, character shapes, and ligature formations, which can confound traditional OCR systems.

To tackle this problem, the development of a hybrid deep learning model that combines CNN, BLSTM, and CTC is essential. Hybrid deep learning has demonstrated success in various tasks, making it a promising approach for Arabic handwriting conversion.

Ultimately, this work not only adds to the conservation and acknowledgment of Arabic script, but also carries significant cultural and technological importance. It facilitates progress in the field of deep learning models and difficult language recognition, while also connecting the historical practice of handwritten Arabic text with the modern digital era. As we begin this endeavor, we acknowledge the significance of safeguarding the valuable elements of the Arabic script, enabling their availability to the global community, and guaranteeing the longevity of the language's elegance in the era of digital technology.

In this paper, it is organized as follows: Section II provides the background information. In addition, Section III summarizes related work. Following Section IV, where the methodology is presented, Section V showcases and reviews the experimental settings and outcomes of the methods. Finally, in Section VI, the conclusion and propositions for future work are made in Section VII.

II. BACKGROUND

This section provides the essential background information required to explain the main concepts of this study, including Arabic script and Arabic language, handwriting recognition, the Convolutional Neural Network, the Bidirectional Long Short-Term Memory, and Connectional Temporal Classification.

A. Arabic Script and Arabic Language

Arabic, one of the world's most ancient and rich languages, boasts a script that holds a unique position in the tapestry of global written languages. It is not just a means of communication but a symbol of cultural heritage, religious significance, and historical depth [4].

The Arabic script is characterized by its distinctive right-to-left writing direction and an intricate system of connecting letters. Its letters change shape depending on their position within a word, as shown in Fig. 2, adding a layer of complexity that has fascinated linguists and calligraphers alike. Arabic calligraphy, with its artistic and aesthetic value, has been revered as a form of visual art for centuries [1].

The Arabic language itself is a linguistic marvel, known for its eloquence and precision. It is the language of the Quran, the holy book of Islam, and plays a central role in the spiritual lives of millions worldwide. Arabic is also the native tongue of over 400 million people, making it one of the most widely spoken languages globally. Beyond its spiritual and regional importance, the Arabic language is vital for conducting business, academic research, and fostering cultural understanding in the Arab world [6].

This study delves into the realm of Arabic script and Arabic language, exploring their intricacies and significance, particularly in the context of handwriting recognition. Understanding the challenges and nuances of Arabic script and language is a

Fig. 2. Example of baseline, ascenders, and descenders in arabic script[5].

fundamental step toward developing effective recognition models and enhancing their performance. Whether the goal is to protect cultural heritage, improve human-computer interaction, or broaden the reach of artificial intelligence.

B. Handwriting Recognition

Handwriting recognition is a computer vision problem that pertains to the automation of script identification by a computer. This is achieved by converting the text from various sources, including touchscreens and documents, into a format that is comprehensible to machines. The input image may be obtained offline, from a material object like a photograph or sheet of paper, or online, from a digital source like touchscreens [7], as shown in Fig. 3.

Fig. 3. Example of handwriting arabic dataset[8].

Traditional methods of handwriting recognition relied on features like edge detection, contour analysis, and statistical methods, which often required extensive feature engineering and were not as effective in handling variations in handwriting styles [9].

Deep learning, especially CNN and recurrent neural networks (RNN), revolutionized handwriting recognition by allowing the system to learn intricate patterns and representations from the raw input data, such as images of handwritten text [10].

C. Convolutional Neural Network

A CNN is a class of deep learning artificial neural networks designed specifically for tasks related to pattern recognition in images, videos, and other grid-like data structures. CNN have become the go-to architecture for image-related tasks and have demonstrated remarkable performance in various computer vision applications. Often referred to as ConvNets or Convolutional Networks, have revolutionized the field of computer vision and have extended their impact into various other domains [11].

In the digital age, our world is inundated with images, from security cameras and medical scans to social media photos. Extracting meaningful information from these images is a complex task. This is where CNN come into play. They have an innate ability to understand and recognize visual patterns, making them indispensable for applications like image classification, object detection, facial recognition, and even in emerging technologies like autonomous vehicles [12].

The CNNs involve the application of different hidden layers, each serving a specific purpose. The neural network typically consists of three primary neural layers: convolution layers, pooling layers, and fully connected layers. Each layer has a distinct function and transforms the input volume into an output neural activity volume [11], as shown in Fig. 4.

Fig. 4. CNN Components[13].

D. Bidirectional Long Short-Term Memory

An example of a neural network model used for training sequential data is the BLSTM. The system employs two separate Long Short-Term Memory LSTM models: a forward LSTM processes the input sequence in a left-to-right manner, while a backward LSTM processes the sequence in a right-to-left manner. The LSTM model was initially introduced in [14] as a solution to address the issue of gradient vanishing. The BLSTM model was proposed as a means to extract high-level features from a sequence of input features. Moreover, the BLSTM networks expand upon the LSTM by incorporating an additional layer, wherein the connections between hidden and concealed layers occur in a reverse temporal sequence. The model possesses the capability to alter both previous and future data.

E. Connectional Temporal Classification

The CTC is configured to label sequences without segmenting the input. Basically, the CTC is a softmax layer that generates probabilities at each step based on the length of the probability sequence given into it, which is T. This sequence represents all the potential label alignments in the input sequence. It complicates matters in two ways: 1) The loss value is calculated during training using both the BLSTM output matrix and the ground truth text; 2) the predicted text is provided during inference using only the output matrix. The CTC was initially presented in [15].

III. RELATED WORK

In the literature, Deep learning models have demonstrated superior performance compared to traditional machine learning approaches on a range of handwritten recognition datasets, establishing themselves as the current leading approach.

CCNs demonstrated high efficacy in Arabic Handwritten Recognition, especially when dealing with datasets containing characters and diverse writing styles, this is shown in a study [7] and [16] and [17].

Nayef et al.[18] developed a novel convolutional neural network (CNN) architecture with an improved leaky ReLU activation function for recognizing handwritten Arabic characters. On four separate datasets, this design achieved accuracy rates over 99%, significantly higher than those of previously used methods.

Albattah et al. [8] developed and evaluated HCR deep learning and hybrid models. The hybrid models used deep learning feature extraction and machine learning classification. The best results were obtained. Where hybrid models that integrate machine learning and deep learning methods can also yield favorable outcomes on handwritten recognition problems this is shown in [19]

Transfer learning can enhance the efficacy of deep learning models on handwritten recognition problems as in a study [20] and [21] and [22].

In addition the [5] study showed that data augmentation is a powerful method that may be used to tackle class imbalance and enhance the overall performance of deep learning models by increasing their ability to generalize. . On the other hand,

studies conducted in [23], [24], and [25] indicates that deep learning has great potential as a method for recognizing handwritten writing and transcribing music scores. Deep learning models have the capability to be trained in order to acquire intricate patterns in handwritten data, even when there is noise and unpredictability present. This renders them very suitable for jobs such as identifying antiquated and deteriorated handwritten papers and musical scores. Nevertheless, there remain certain obstacles that require attention and resolution. An obstacle is in the scarcity of extensive and top-notch datasets required to train these models.

IV. METHODOLOGY AND APPROACH

This section starts with an overview of the approach to discovering handwritten text that includes complex words with ascending and descending letters and periods. Then, presents the data collection and data pre-processing steps. Afterward, includes the details of the model architecture.

A. Methodology Overview

In this paper, an approach to converting handwritten Arabic text into digital form using a hybrid deep learning model that combines CNN, BLSTM, and CTC is proposed. The approach involves several essential steps. First, the handwritten text dataset is collected, augmented, and preprocessed to prepare the data for digital conversion. Subsequently, The CNN was utilized to extract sequence features from the input photos. Moreover, the BLSTM is employed to transmit information within this sequence. It generates a matrix of character scores for each element in the sequence. The CTC procedure is established to compute the loss value for training the proposed model and to carry out the inference during this phase. Finally, the CTC algorithm reads the BLSTM output matrix to figure out what text is in the image that it is given. The presence of these two interconnected networks within the CTC enables the recognition of words at the level of individual words without the need for segmenting characters. The project's primary objective is to effectively transform handwritten Arabic text into a digital representation, ensuring accuracy and legibility. Fig. 5 illustrates the methodology framework for this project, showcasing the steps involved. Additionally, our experiments included evaluating the performance of the model and the quality of the digital output to ensure that it accurately reflects the original handwritten text.

B. Dataset

The study included the collection of data pertaining to handwritten Arabic words. The data, obtained from a sample of 30 adult participants, was manually transcribed using 60 words. The word count reached 1800. The Riyadh Dictionary, published by the King Salman Academy for the Arabic Language [26], is where the words are all in Arabic. The word set has a diverse range of intricacy, encompassing attributes such as hamzas, ascending or descending characters, and dots. In addition, Two datasets were merged for this study: the ADAB dataset introduced by Boubaker et al. [27] and the AHAWP dataset provided by Khan [28]. The finalized dataset had files in CSV format with 15009 entries. The complete dataset was divided into two subsets: one for training and one for testing.

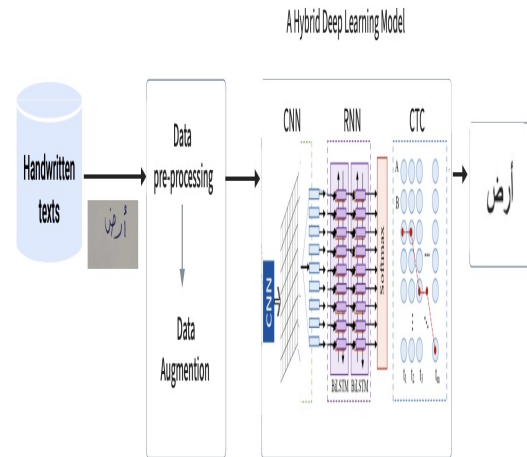

Fig. 5. Methodology framework.

C. Data Preprocessing

Prior to training the models using the dataset, several preprocessing and data augmentation techniques were applied to the data to enhance its compatibility with the models and increase its resilience to real-life scenarios. Data preprocessing is a critical component in the development of deep learning models, particularly in tasks involving complex data types such as Arabic text. This part presents a proposed data preprocessing pipeline specifically designed for Arabic text recognition tasks. The pipeline encompasses multiple stages, including filtering Arabic text, preprocessing text labels, resizing images, and encoding image labels. Python libraries such as TensorFlow and OpenCV are leveraged for efficient data manipulation. Additionally, the part provides comprehensive insight into the size of images, character encoding, and other pertinent details of the preprocessing steps. Fig. 6 shows the proposed preprocessing pipeline.

Fig. 6. Proposed preprocessing pipeline.

Arabic text filtering: The raw text data undergoes a filtering process to eliminate non-Arabic text. This process utilizes regular expressions to detect and preserve exclusively Arabic text that falls inside the Unicode range [0600-06FF]+, which includes Arabic script and whitespace characters.

Text Label Preprocessing: Text labels are subjected to

a variety of preprocessing procedures in order to guarantee the integrity and consistency of the data. Extraneous spaces surrounding text labels are removed to standardize label layout and prevent conflicts during processing.

Dealing with Missing Values: Rows containing missing or NaN labels are eliminated from the dataset to ensure data integrity and prevent errors in the following phases.

Maximum Label Length: Labels that surpass a certain maximum length, usually established at 12 characters, are eliminated in order to control computational complexity and ensure equilibrium in the dataset.

Image Resizing: Image resizing involves adjusting the dimensions of the image data to meet a defined size that is appropriate for input into a model. The process of resizing entails the subsequent steps:

Aspect Ratio Preservation: Images are scaled to a specified width and height while maintaining their original aspect ratio. This guarantees that the resized photos retain their dimensions and avoid any distortion. **Target Dimensions:** The target dimensions for scaled images are defined as a width of 256 pixels and a height of 64 pixels. The interpolation method used for resizing is OpenCV's INTER_AREA. This method is particularly suitable for reducing the size of images and effectively maintaining image sharpness and detail.

Image Label Encoding: Image labels are encoded into integer representations using TensorFlow's StringLookup capability, similar to how text labels are encoded. The encoding procedure guarantees uniformity in data representation across text and visual modalities, enabling effortless incorporation into deep learning pipelines.

D. Data Augmentation

Data augmentation was used to enhance the quantity and variety of photos, allowing the dataset to be expanded without the need to acquire additional data [29]. The CustomDataGenerator class in this project incorporates data augmentation techniques. The code employs the ImageDataGenerator class from the Keras package, which offers a straightforward means to apply various data augmentation techniques to the photos. The employed techniques included:

Rotation: The photos underwent a rotation of a specific angle by utilizing the rotation range parameter in ImageDataGenerator. This facilitates the model's ability to discern things from various viewpoints.

Rescaling: The photos underwent resizing to various dimensions by utilizing the zoom range parameter in ImageDataGenerator. This aids the model in generalizing to objects with different scales.

Shear: The photos underwent a shearing treatment by utilizing the shear range parameter in ImageDataGenerator. This feature introduces distortions and enhances the model's ability to process objects with diverse geometries.

E. Model Architecture

The architecture of our proposed model is specifically built for the recognition of Arabic text in handwriting. Employing

a hybrid deep learning architecture that integrates multiple components in order to attain precise handwriting recognition. The process commences with input layers that receive the input images and target labels utilized for training purposes. A reshape layer prepares the data, a dense layer encodes features, bidirectional LSTM layers model sequences, and a final output layer predicts class probabilities. The design is made up of convolutional layers that extract features. The training of the model is conducted via the Connectionist Temporal Classification (CTC) loss function. Fig. 7 displays the proposed architecture.

Fig. 7. Proposed model architecture.

1) *Input layers:* The model's "input images" layer is responsible for receiving the input images used for handwriting recognition. On the other hand, the "input labels" layer is designed to accept the target labels that correspond to the input images during the training phase.

2) *Convolutional layers:* The model contains three sets of convolutional layers, which are crucial for extracting information from the input images. Every set is accompanied by a maximum pooling layer. The number of filters progressively grows across the sets, beginning with 32 filters in the first set, followed by 64 filters in the second set, and ultimately reaching 128 filters in the third set. The convolutional layers employ a kernel size of 3x3, apply the ReLU activation function to introduce non-linearity, and leverage the He normal initialization method to effectively capture hierarchical features.

3) *Reshape layer:* The reshape layer in the model is tasked with converting the output of the convolutional layers into a format that is appropriate for subsequent processing. The function does a transformation on the output tensor, modifying

its dimensions in terms of height and width. More precisely, it transforms the tensor to have a height equal to one-eighth of the input shape [0] and a width equal to the product of one-eighth of the input shape[1] and 128. The purpose of this reshaping stage is to prepare the data for the succeeding dense layer in the model.

4) *Dense layer (Encoding Stage)*: The dense layer in our model has a vital function in transforming the retrieved characteristics into a condensed representation. The system consists of 64 units that serve as a bottleneck, capturing the most crucial characteristics. The dense layer utilizes the Rectified Linear Unit (ReLU) activation function, which introduces non-linearity and enhances the model's ability to effectively learn intricate patterns. The dense layer's weights are initialized using the He normal initialization method, which promotes a steady and efficient learning process. In order to address overfitting more effectively, a dropout layer is implemented after the dense layer. This dropout layer has a dropout rate of 0.4, which means that during training, a portion of the layer's outputs are randomly set to zero. This helps improve the model's ability to generalize and reduces its dependence on specific characteristics.

5) *Bidirectional LSTM Layers (Decoding Stage)*: The bidirectional LSTM layers of the model are tasked with capturing the sequential relationships inherent in the encoded features. The model incorporates two stacked bidirectional LSTM layers to effectively capture both preceding and subsequent information concurrently. The LSTM layer comprises 128 units, facilitating the model's ability to proficiently capture long-range dependencies within the data. In order to mitigate overfitting and enhance generalization, a dropout rate of 0.25 is implemented on the LSTM layers. During training, the dropout rate is applied to randomly deactivate a portion of the layer's outputs. This technique helps decrease the model's dependence on specific patterns and enhances its capacity to generalize to new, unseen data.

6) *Final output layer*: The final output layer in the model is accountable for producing the anticipated probabilities for every class label, encompassing a distinct empty label. The layer is densely packed with $\text{num classes}+1$ units, where num classes indicates the total number of unique character classes. The softmax activation function is utilized to guarantee that the predicted probabilities aggregate to 1, hence rendering them interpretable as probabilities of different classes.

7) *CTC Loss layer*: Our model employs the CTC loss function during training. The CTC loss layer, which is implemented using the proprietary CTCLayer class, computes the CTC loss by comparing the anticipated output with the input labels. This loss function incorporates the changeable alignment between the input and target sequences, enabling the model to properly handle sequences of varied lengths.

V. RESULTS AND DISCUSSION

The section starts by showing the experimental settings. Afterwards, The practical implementation details of the experiments were discussed. Finally, the results of the model used in the approach were analyzed.

A. Experimental Settings

In this part, the experimental parameters that were used to train the hybrid deep learning model are detailed. It goes over the optimization technique, training settings, and hyperparameters used for training.

1) *Important parameters*: Here are the hyperparameters that were used throughout the experiment:

Rate of Learning: A learning rate of 0.001 is used with the Adam optimizer.

Rate of Dropout: Overfitting may be reduced with the use of dropout regularization. The encoding layer has a dropout rate of 0.4, while the LSTM layers use a rate of 0.25.

Batch Size: In order to handle several samples at once, the training data is separated into batches. The training set uses a batch size of 128 whereas the testing set uses 64. The number of full iterations across the training dataset is 120 epochs, which is how long the model is trained.

Calculus of Loss: Loss function CTC (Connectionist Temporal Classification) is used.

2) *Configuration for training*: The configuration of the training procedure includes the following settings:

Data Generator: Both the training and testing sets use custom data generators. The generators in question are responsible for managing the loading and preparation of data in batches, hence guaranteeing optimal memory use throughout the training process.

Termination at an early stage: In order to mitigate the issue of overfitting and identify the most optimum model, the technique of early halting is used, with a duration of 10 epochs. If the validation loss does not improve for 10 consecutive epochs, the training will be terminated.

Model checkpointing: is a technique used to preserve the optimal weights throughout the training process. The weights of the model that exhibit the lowest validation loss will be preserved for further use or assessment.

Decrease in Learning Rate: The ReduceLRonPlateau callback is used to apply a technique for reducing the learning rate. If the validation loss does not improve for 5 consecutive epochs, the learning rate is decreased by a factor of 0.5. This dynamic modification aids in refining the model's performance.

Optimization:- The Adam optimizer is used for model optimization, with a learning rate of 0.001. The Adam method is well recognized for its ability to adjust the learning rate on a per-parameter basis, resulting in enhanced convergence speed and improved overall performance.

B. Implementation

The experimental implementations of all models are trained using the Google Colaboratory environment on a NVIDIA GEFORCE 64-bit computer with an Intel (R) Core (TM) i7-8565U CPU at 1.80 GHz and 1.99 GHz.

C. Evaluation Methods

In order to evaluate the performance of our model, we will compute the word-level accuracy Rate and Character-level Accuracy for the train and test sets of the dataset.

1) *Word-level accuracy* : Focuses on word-level accuracy: It evaluates the percentage of words that are successfully recognized by the system. The formula for WAR is given below Eq. 1:

$$WAC = \frac{\text{Number of correctly recognized words}}{\text{Total number of words}} \quad (1)$$

2) *Character_level accuracy (CAC)*: Concentrates on accuracy at the character level; specifically, it evaluates the proportion of characters that the system adequately recognizes. The formula for CAR is given below Eq. 2:

$$CAC = \frac{\text{Number of correctly recognized characters}}{\text{Total number of characters}} \quad (2)$$

D. Results

The deep learning approach, which integrated CNN, BLSTM, and CTC, was implemented on a dataset consisting of 15009 handwritten Arabic words. This dataset was divided into two subsets: a training set and a test set. The model was assessed using accuracy measure.

The results indicate the model achieved a good level of precision in word identification, achieving an accuracy rate of 98.36%. This demonstrates the model's capability to precisely identify Arabic words written by hand. In the context of character recognition The model's ability to detect Arabic characters is indicated by an accuracy rate of 99.52%.

To better understand the model's performance and convergence, representations of the training and validation losses throughout the epochs were created. The CTC loss trended downward in the graphs, showing that the models learnt well from the data and became better in making predictions over time. These visuals validated that our models were properly trained as seen in Fig. 8, 9, 10.

As shown in Fig. 8, the graph showing the training loss of a hybrid deep learning model for transforming handwritten Arabic into digital form exhibits a constant and continuous decline over a span of 80 epochs. At the beginning, the CTC loss score is rather high, approximately 25. However, it quickly diminishes within the first 20 epochs, suggesting efficient early learning. As the training progresses, the decrease in loss becomes more slow but consistent, indicating continuous enhancements in model performance. During the last stages, the loss reaches a low value and remains constant, indicating that the model has achieved successful convergence. This evolution showcases the model's aptitude for efficient learning and mistake reduction during the training process.

As shown in Fig. 9. The graph demonstrating the validation loss for the handwriting recognition model demonstrates a noticeable and constant decline during 80 epochs, indicating successful acquisition of knowledge and ability to apply it to

Fig. 8. Training loss.

Fig. 9. Validation loss.

new examples. At the start, the CTC loss score is approximately 22, but it rapidly decreases within the first 20 epochs, indicating significant progress. As the training continues, the decrease becomes less steep but still consistent, indicating a continuous improvement of the model. During the last stages, the validation loss reaches a low value and remains constant, indicating that the model has successfully converged and the learning process has been effective. This pattern highlights the model's capacity to effectively apply its knowledge to unfamiliar data, validating its resilience and precision in transforming handwritten Arabic into digital form. In Fig. 10, the graph depicting the training and validation losses of the hybrid deep learning model demonstrates a distinct and triumphant learning path. At first, the losses reduced significantly, indicating a rapid acquisition of knowledge. As the training continues, the rate of decrease in performance slows. However, the model consistently maintains a close alignment between the losses observed during training and validation, which suggests that it is capable

Fig. 10. Training and validation losses.

of generalizing well. Ultimately, both losses reach a stable point at low values, indicating convergence and successful learning. The consistent learning rate facilitates a seamless and steady training procedure, highlighting the model's capacity to effectively execute handwriting recognition.

Additionally, a comparison test was conducted using two main metrics: word error rate (WER) and character error rate (CER) to assess the effectiveness of our suggested method for recognizing handwritten text and to highlight the mistakes made during recognition. In result we found that the WER was 1.64%, and the CER was 0.48%. The low error rates seen in the sample serve as evidence of the model's capacity to accurately detect words and characters.

In overall, the study's model clearly demonstrates a high level of accuracy in the conversion process, both at the word and character levels, based on the obtained results. Regrettably, the recognition process identified a few errors. Various factors, including different fonts and the complexity of the written language with dots and letters above and below the line, contribute to the errors encountered in the recognition process. There were some errors that occurred, which resulted in character substitutions that impacted the overall accuracy of the recognition process.

The current findings are quite promising, suggesting that the handwriting recognition model utilized in the study is both efficient and effective. Nevertheless, there is potential for enhancement by rectifying the specific errors and further refining the model through additional training and improvements.

VI. CONCLUSION

The Arabic language has additional complexities in the realm of deep learning due to its unique alphabet, which often presents issues when converting it into digital format. This study will aim to present a method for recognizing Arabic handwritten words using Hybrid Deep Learning. The results have shown good performance based on the metrics used. This endeavor will contribute to the conservation of linguistic

diversity while also propelling the progress of Arabic language processing.

VII. RECOMMENDATIONS AND FUTURE WORKS

As part of future tasks, the intention is to validate the model in an actual application as a proof of concept. This will help determine the feasibility of applying these experiments to real-world scenarios. Specifically, when employing the model in an online writing application, the model is provided with a distinct input type, with the expectation that it will excel in this scenario due to the superior clarity of images derived from online handwriting compared to offline images. This enhanced clarity facilitates the model's ability to readily identify distinctive attributes. Ultimately, anticipations were made that the achieved results could find application in various engineering fields. These tasks encompass improving systems for human-computer interaction, creating robots that can interpret handwritten text, integrating our model into assistive technologies for individuals with learning disabilities, and converting sketches and annotations into digital format for computer-aided design. However, as attention is directed towards the intricate patterns of handwriting, the potential applications of this model in educational apps for teaching dictation will become a compelling use case for this research. Furthermore, this work will be a valuable contribution to the wider domain of artificial intelligence and machine learning, serving as a source of inspiration for researchers to address other intricate challenges, such as sentence or language recognition. This will exemplify the extensive influence and practicality of the research across various engineering disciplines.

User-Friendly Privacy-Preserving Blockchain-based Data Trading

Jiahui Cao¹, Junyao Ye^{*2}, Junzuo Lai³

School of Information Engineering Jingdezhen Ceramic University, Jingdezhen, 333403 Jiangxi Province, China^{1,2}
College of Information Science Technology, Jinan University, China³

Abstract—As the digital economy flourishes, the use of blockchain technology for data trading has seen a surge in popularity. Yet, previous approaches have frequently faltered in harmonizing security with user experience, culminating in suboptimal transactional efficiency. This study introduces a personalized local differential privacy framework, adeptly tackling data security concerns while accommodating the individual privacy preferences of data owners. Furthermore, the framework bolsters transaction flexibility and efficiency by catering to needs of data consumers for detailed queries and enabling data owners to effortlessly elevate their privacy budget to achieve greater financial returns. The efficacy of our approach is validated through a comprehensive series of experimental validations.

Keywords—Data trading; blockchain; personalized local differential privacy; data security; user-friendly

I. INTRODUCTION

The ongoing shift towards informatization in society has resulted in a tremendous increase in data volume. Data trading, evolving as a novel business model, is gaining pivotal importance in today's digital economy. A notable number of users are inclined to offer their personal data in return for access to online services. Nevertheless, as individuals become more aware of the ramifications of companies utilizing their data, understanding the potential consequences and recognizing the intrinsic value of personal data, there is a growing trend towards expecting compensation for the usage of such data [1].

To facilitate this model of data trading, private data trading has emerged as a significant research field, prompting the development of various innovative solutions like FairQuery [2], FairInnerProduct [3], SingleMindedQuery [4], and SmartAuction [5]. These methods utilize Differential Privacy (DP) [6, 7] to safeguard data while providing query results to data consumers (DC), instead of directly handing over the data. Commonly, these solutions engage three key stakeholders: Data Owners (DO), Data Consumers, and a data broker (DB).

DO are individuals who possess data and are interested in commercializing it. This group includes people with diverse types of data, such as social, financial, location, or health-related data. Entities like advertisers, software developers, and retailers represent DC—those in search of external data to support their decision-making processes. They aim to query aggregated information tailored to certain demographics, all within a specified budget. DB collaborates with DO, collects data, and provides query results to DC, thereby benefiting financially from this process.

The depicted transaction model is fundamentally segmented into two principal components: Value Exchange and Information Processing, as delineated in Fig. 1. Within the Value Exchange phase, inputs include DO' data valuation, privacy requirements, and DC' budget. The consequent outputs encompass the remuneration for DO partaking in the transaction, along with the privacy compensation accorded to them. The Information Processing segment entails furnishing DC. with query outcomes, augmented with noise, which typically conform to differential privacy standards to guarantee robust protection of DO' privacy. The architecture of these solutions customarily incorporates several essential attributes to ascertain equity in data trading, such as incentive compatibility, individual rationality, and budget feasibility.

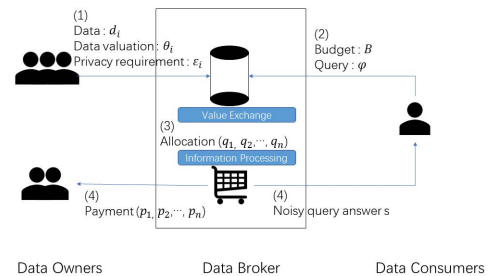

Fig. 1. Data trading.

However, previous models depend on a trusted third party for storing the original data of DO. While centralized storage enhances data integration and processing efficiency, it introduces potential security vulnerabilities. For instance, should the central server be compromised by hackers or if internal staff illicitly access data, the confidentiality of sensitive information cannot be assured. Such uncertainties undermine privacy and integrity of data, impacting the viability and trustworthiness of data transactions. Despite efforts to address these issues through local differential privacy (LDP) [8] and blockchain-based data trading, these approaches have not adequately accounted for the unique privacy preferences of DO and the budgetary limitations of DC, making the process less user-friendly and decreasing transaction efficiency.

To navigate these challenges, personalized local differential privacy (PLDP) [9] emerges as a refined strategy. In this framework, DO are not required to upload their raw data to DB's database. Instead, they apply PLDP measures tailored to their privacy needs and upload the altered data. This method not only safeguards individual privacy but also accommodates the varied privacy demands of different DO, maintaining data

usability and enabling *DC* to perform statistical analyses. Essentially, this technique eliminates the risk of data exposure since only data that has been processed for PLDP is shared, keeping the original datasets confidential and securely with the *DO*.

Moreover, to ensure transactions are both fair and adaptable, *DC* must be empowered to request additional conditions, such as more detailed queries, thus filtering out data not meeting specified privacy standards. This provision fosters a balanced data trading ecosystem and encourages *DO* to supply data of higher quality and relevance.

As *DO* engage in multiple transactions and see tangible rewards, their confidence in the data trading system grows. Eventually, they might be inclined to increase their privacy budgets for better compensation. However, frequent data re-uploads can significantly hamper transactional efficiency. Therefore, we introduce a solution enabling *DO* to effortlessly raise their privacy budgets with the assistance of *DB* under suitable conditions. This arrangement not only streamlines transactions but also guides *DO* in aligning their data more accurately with its real-world value, thus reinforcing the reliability and steadiness of data exchanges.

In summary, we have developed a data security and user-friendly data trading model that innovatively employs PLDP technology. This method ensures that the original data of *DO* does not need to be uploaded, fundamentally preventing privacy risks associated with data breaches. Additionally, we provide *DO* with a convenient method to increase their privacy budgets. However, due to the current limitations of PLDP technology, this method is currently only applicable to numerical data, which represents a limitation of this study.

Overall, the principal contributions are summarized as follows:

- The deployment of PLDP technology markedly bolstered data security and minimized leakage risks while adeptly catering to *DO* individual privacy preferences.
- The refinement of query mechanisms to accommodate *DC* requirements for granular inquiries, thereby elevating data precision and pertinence, which in turn enhances the utility of data and improves the consumer experience.
- The formulation of a scheme enabling data owners to augment their privacy budgets in pursuit of greater compensation, thereby fostering the dissemination of superior data.
- we have made our entire source code and the detailed experimental procedures available on GitHub [10] (<https://github.com/cjh20000613/User-Friendly-Privacy-Preserving-Blockchain-Based-Data-Trading>).

II. RELATED WORK

A. Private Data Trading

Our research includes a comprehensive review of privacy-preserving data queries. The seminal work by Ghosh and Roth [2] established fundamental frameworks in this domain, notably the Value Exchange and Information Processing, and

introduced the FairQuery (FQ) concept. FQ utilizes a greedy algorithm for reverse auctions, aiming to maximize the selection of *DO* in value exchanges. Additionally, it employs the Laplace mechanism [11] for information processing, facilitating count queries on binary data (0/1 values).

Danderkar et al. [3] extended this research to more general query types, specifically linear predictors, and developed FairInnerProduct (FIP). FIP employs a knapsack problem-solving mechanism for value exchange and provides extra compensation to *DO* with the highest data value. This model effectively deters *DO* from underreporting their data value to gain compensation.

Nget et al. [12] proposed two distinct compensation mechanisms: a logarithmic function for conservative approaches (low risk, low return) and a sub-linear function for liberal approaches (high risk, high return). Their goal was to engage *DO* with varied privacy expectations. Additionally, they tackled the issue of *DC* arbitrage by employing sampling before querying and imposing restrictions on *DC* to prevent repetitive queries.

Mengxiao Zhang et al. [4] introduced a pivotal assumption that *DO* are single-minded, agreeing to sell data only if their privacy demands are met. Building on this, they developed the SingleMindedQuery (SMQ), which incorporates the Bayesian static game approach in its value exchange mechanism and an enhanced exponential mechanism [13] for information processing, thus achieving genuine personalized differential privacy protection. Further, [5] they adapted this mechanism to the blockchain, integrating RSA encryption and signature technology to secure data transmission processes.

Wang et al. [14] and Fallah et al. [15] presented the PDQS, enabling data owners to locally distort their private data to guarantee LDP. Nonetheless, they overlooked the budget limitations of *DC*. Li et al. [16] proposed a perturbation mechanism that permits *DO* to submit either accurate values or randomized values with a specific probability. This approach, by weaving together the facets of value exchange and information processing, seeks to refine the precision of query results.

B. Blockchain-based Data Trading

Blockchain-based data trading presents solutions to several issues inherent in traditional centralized data platforms, adeptly addressing concerns such as privacy violations, elevated transaction costs, and limited interoperability. Thanks to blockchain's distributed architecture, data trading activities are decentralized, occurring across various nodes in the network, which diminishes the dependence on *DB*.

Xiong et al. [17] developed a data trading platform that harnesses smart contracts. *DO* store their data with dedicated data storage entities. Upon completion of a transaction, *DO* transfer tokens to *DC*, who in turn utilize these tokens to access the data. To ensure transactional fairness, an arbitration entity is implemented. If *DC* discover that the downloaded data fails to meet their criteria, they can seek arbitration. The arbitration entity leverages similarity learning technology to evaluate the consistency of data. In cases of identified inconsistencies, *DC* are compensated with a refund, while the deposits of *DO* are seized.

Dai et al. [18] developed a Data Exchange Ecosystem (SDTE) grounded in Ethereum and Intel SGX technologies. In their system, buyers are not granted direct access to raw data. Rather, they receive only the analytical results or processed outputs of the specific data elements they require. Enhanced security is achieved through SGX's authentication mechanisms, which facilitate the secure exchange of keys necessary for encryption. The use of enclaves ensures that both data and key codes remain shielded from external access. This architecture not only guarantees data security and privacy protection but also adeptly addresses the challenges faced by *DC* and *DB* in the data transaction process.

III. PRELIMINARIES

A. Personalized Local Differential Privacy

Local Differential Privacy (LDP) [8], recognized as a robust privacy protection mechanism underpinned by a solid mathematical foundation, negates the necessity of trusting any third party and effectively safeguards user data privacy. In LDP algorithms, users apply randomization techniques to introduce noise into their sensitive data at a local level. This altered data is then transmitted to the server, rendering it infeasible for attackers to ascertain the original data of any individual user.

Definition 1. Local Differential Privacy: Considering a specified privacy budget $\varepsilon > 0$, a random algorithm $A : D \rightarrow G$ adheres to ε -LDP for users. For any pair of inputs $d \in D$ and $d' \in D$, and for any resultant output $g \in G$, the algorithm meets the ensuing inequality:

$$Pr(A(d) = g) \leq e^\varepsilon \times Pr(A(d') = g) \quad (1)$$

Here, Pr denotes the probability derived from the coin toss in mechanism A .

While LDP offers robust privacy protection, it may not always align with the diverse privacy preferences of individual users in practical scenarios. For instance, celebrities and students might have different sensitivities towards their address data. To address this, PLDP [9] model is proposed, providing customization to meet varied user privacy needs. In PLDP, users are required to define two parameters: the security parameter τ and the privacy budget ε .

Definition 2. Personalized Local Differential Privacy: For any two privacy parameters ε and τ of a user, a random algorithm $A : D \rightarrow G$ is considered (τ, ε) -PLDP compliant for that user. For any output $g \in G$, user records $d \in \tau$, and any other value d' within τ , $\tau \in D$, the model adheres to the following inequality:

$$Pr(A(d) = g) \leq e^\varepsilon \times Pr(A(d') = g) \quad (2)$$

Here, Pr denotes the probability generated during the coin toss in mechanism A .

In the (τ, ε) -PLDP framework, the parameter τ specifies the range within which user records are indistinguishable from one another. For example, if a user's data is 0.5 and they select τ as $[0, 1]$, then under PLDP, the value 0.5 is indistinguishable from any other values in the $[0, 1]$ range. The parameter ε signifies the level of indistinguishability. If all users set D as their security region and standardize the privacy budget ε , then PLDP effectively becomes equivalent to the standard LDP model.

B. Smart Contract

A smart contract [19], as embedded in blockchain technology, operates in a manner akin to traditional contracts. It is essentially a code that outlines a set of predetermined rules and autonomously enforces them through its execution. On the Ethereum platform [20, 21], a smart contract represents a compilation of code and data situated at a specific blockchain address, often referred to as a contract account. Notably, smart contracts maintain their own balance and can receive transactions, yet they remain beyond the control of any individual entity.

Once deployed on the blockchain, a smart contract is rendered immutable, making it impervious to removal. This feature implies that all interactions with the contract are permanent and irreversible. Such immutability is a fundamental attribute of blockchain technology, ensuring that records inscribed onto the blockchain are resistant to alteration. Consequently, this enforces the reliability and security of the contract's execution.

C. Symmetric Encryption

Symmetric Encryption (SE) [22] is a cryptographic method where the same key is employed for both the encryption and decryption processes. In this approach, both the sender and receiver must possess the same key in advance. This key is utilized to encrypt data for transmission and subsequently decrypt it upon receipt.

Definition 3. Symmetric Encryption:

- $Setup(1^\lambda) \rightarrow k$: The initialization algorithm. It takes a security parameter 1^λ as input and generates the encryption key k .
- $Encrypt(k, M) \rightarrow C$: The encryption algorithm. Given the key k and plaintext message M as input, it produces the corresponding ciphertext C .
- $Decrypt(k, C) \rightarrow M$: The decryption algorithm. Using the key k and ciphertext C as inputs, it reconstructs the original plaintext message M .

In the selection of a symmetric encryption algorithm, factors like the encryption process and key length play pivotal roles. In this context, the Advanced Encryption Standard (AES) [23, 24] emerges as a superior option. Consequently, we have chosen the AES128 symmetric encryption algorithm to assure the security of data during its transmission and storage phases.

D. Elliptic Curve Cryptography

Elliptic Curve Cryptography (ECC) [25, 26] is a form of public-key encryption, with its security hinging on the complexity of solving the Elliptic Curve Discrete Logarithm Problem (ECDLP) [27]. The core challenge in ECC is to identify an integer k for which $Q = kP$ holds true for two given points P and Q on an elliptic curve, a task that is computationally demanding. The robustness of ECC lies in the inherent difficulty of efficiently resolving the ECDLP within a finite timeframe.

Definition 5. Elliptic Curve Cryptography:

- $KenGen(1^\lambda) \rightarrow (pk, sk)$: The key generation algorithm.
 - Input the security parameter 1^λ .
 - A random elliptic curve E and a generator point G on it are selected. A large prime number n is chosen as the order of points on the curve.
 - A private key $k \in [1, n - 1]$ is picked.
 - The public key $Q = [k]G$ is calculated.
 - The outputs are the public key $pk = (E, G, Q)$ and the private key $sk = k$.
- $Enc(M, pk) \rightarrow C$: The encryption algorithm.
 - Takes the plaintext message M and public key $pk = (E, G, Q)$ as inputs.
 - A random number $r \in [1, n - 1]$ is generated.
 - The elliptic curve point $C_1 = [r]G$ is computed.
 - The elliptic curve point $S = [r]Q$ is calculated. If S is the point at infinity, a new k is selected and recalculated.
 - The ciphertext $C_2 = M \oplus H(S)$ is formed, where \oplus represents the XOR operation and H is a hash function.
 - The ciphertext $C = (C_1, C_2)$ is produced.
- $Dec(C, sk) \rightarrow M$: The decryption algorithm.
 - Inputs the ciphertext $C = (C_1, C_2)$ and private key $sk = k$.
 - Computes $S = [k]C_1$.
 - Derives the plaintext $M = C_2 \oplus H(S)$.
 - Outputs the plaintext message M .

The choice of appropriate elliptic curve parameters is critical for the security of ECC. Hence, in this paper, we have selected the SM2 [28] elliptic curve standard.

E. InterPlanetary File System

The InterPlanetary File System (IPFS) [29] represents a paradigm shift in file storage and sharing, designed as a distributed system that contrasts sharply with traditional centralized storage approaches. Unlike conventional systems where files are stored on a single central server, IPFS distributes files across multiple network nodes. It utilizes content addressing, where a file's unique identifier is derived from its content's hash value. Consequently, even minor alterations in the file content lead to a drastically different hash, thereby assuring the file's uniqueness and integrity. This architecture positions IPFS as a decentralized, secure, and reliable alternative for data storage and distribution.

IV. TRADING FRAMEWORK

The process of our private data trading framework, as depicted in Fig. 2, integrates the value exchange within the blockchain, ensuring that DB computation and publication of results are transparent and subject to user oversight. This placement combats the potential underutilization of DC 's budgets by the DB . DB still processes information locally to retain the efficiency of data handling.

In our framework, the transactions are not limited to one-on-one interactions but involve multiple DC and DO , with

Fig. 2. private data trading.

DB facilitating transactions between them. For simplicity, we will first describe a single transaction before expanding on the broader mechanics of value exchange and information processing within the scheme.

A. Value Exchange

In every transaction within our framework, a single Data Consumer (DC_j) engages with multiple Data Owners (DO_i), where $1 \leq i \leq n$, the following principles are applied:

- DO_i commits to active participation in the transaction once they receive sufficient compensation, which is calculated based on their personal data valuation, denoted as θ_i . This valuation θ_i indicates the worth of DO_i 's data and is bounded within $0 < \underline{\theta} \leq \theta \leq \bar{\theta}$, where $\underline{\theta}$ and $\bar{\theta}$ represent the minimum and maximum value limits, respectively.
- For data privacy, DO_i specifies a secure region $\tau_i \subseteq [-1, 1]$ and a positive privacy budget ε_i before entering the value exchange process. They apply Personalized Local Differential Privacy (PLDP) to their data, guided by these two parameters. The actual value of DO_i 's data is thus a function of its privacy protection. A narrower τ_i yields less deviation from the original data and retains a higher true value, whereas a wider τ_i increases data variation post-PLDP, reducing its overall value. For the privacy budget ε_i , a smaller value leads to heavily noised data and lower actual value, while a larger ε_i brings the value closer to the data's original state, signifying a user's consent to limited information disclosure.

Therefore, the actual value of user data, denoted as $v_i = f(\theta_i, \tau_i, \varepsilon_i)$, is expected to conform to certain correlation conditions. Specifically, when a user's data value θ_i is established, the actual value v_i tends to decrease with an increase in the range of the secure region τ_i . Conversely, as the privacy budget ε_i increases, v_i should correspondingly increase. This dual effect ensures that under the umbrella of privacy protection, the real value of user data is optimized, maximizing the extraction of useful information in the value exchange.

In parallel, the valuation θ_i of DO_i 's data may inadvertently reveal sensitive information. For instance, a higher valuation in medical health data might suggest a more severe medical condition. Concerns about such privacy breaches might lead some DO_i to underreport their data valuation θ_i intentionally. To counteract this, DB implements incentive measures to encourage DO_i to disclose their true valuations. Specifically, a portion of DC_j 's budget is reserved for compensating privacy losses. The compensation received by DO_i is proportionate to the privacy loss θ_i they incur. This additional privacy compensation mechanism is designed to

alleviate DO_i 's concerns, encouraging more honest reporting of data valuations, thereby ensuring fairness and transparency in the transaction process.

During the data trading process, DC_j can tailor their resource allocation to align with specific needs and privacy preferences, enabling more nuanced and precise data queries. Specifically, when initiating a transaction, DC_j proposes a privacy requirement εdc , stipulating that the privacy budget of DO_i involved in the transaction must exceed this value. The lower limit of εdc requires no additional expenditure from DC_j . However, as εdc approaches the upper limit of the privacy budget, the cost escalates significantly, potentially reaching infinity. This framework allows DC_j to flexibly balance the privacy level and cost of queries, thereby catering to personalized information needs more effectively.

Integrating these conditions, we conceptualize the value exchange as a 0-1 knapsack problem, where the knapsack's capacity is defined as $B' = B - \frac{(\bar{\varepsilon} - \underline{\varepsilon})e^{\frac{\varepsilon dc - \bar{\varepsilon}}{\bar{\varepsilon} - \underline{\varepsilon}}}}{\bar{\varepsilon} - \underline{\varepsilon} dc} (Fee + fee)$, each item's weight is given by θ_i , and the value is $v_i = \frac{4e^{\frac{4\varepsilon_i}{4}}}{(\varepsilon_i + 1)} \theta_i$. With n items in total, q_i denotes the inclusion of item i in the knapsack. In this scenario, Fee is the intermediary fee by DB , fee is the privacy compensation for DO_i , εdc is the privacy requirement of DC_j , w_i is the size of the secure region τ_i for DO_i , and $\underline{\varepsilon}$ and $\bar{\varepsilon}$ represent the lower and upper bounds of the privacy budget. The goal is to maximize the actual value of the data, ensuring the total value does not surpass DC_j 's budget.

Definition 7. The optimal value exchange, aimed at maximizing the actual value of data, must adhere to the ensuing equation:

$$\begin{aligned} & \underset{q_i, v_i, \theta_i}{\text{maximize}} && \sum_{i=1}^n q_i v_i \\ & \text{subject to} && \sum_{i=1}^n q_i \theta_i \leq B' \\ & && \theta \leq \theta_i \leq \bar{\theta} \\ & && \varepsilon_i > 0 \\ & && \underline{\varepsilon} \leq \varepsilon dc \leq \varepsilon_i \leq \bar{\varepsilon} \end{aligned} \quad (3)$$

By resolving this equation, we can deduce a solution that maximizes the actual value of the data while adhering to budgetary constraints. This solution exhibits the following characteristics:

- (1) Incentive Compatibility (IC): This attribute ensures that DO_i is motivated to truthfully declare their valuation θ_i . This approach guarantees they receive the maximum privacy compensation $q_i \theta_i +$

$$\frac{(\bar{\varepsilon} - \underline{\varepsilon})e^{\frac{\varepsilon dc - \bar{\varepsilon}}{\bar{\varepsilon} - \underline{\varepsilon}}} \theta_i fee}{(\bar{\varepsilon} - \underline{\varepsilon} dc) \sum_{i=1}^n \theta_i}.$$

- (2) Individual Rationality (IR): This principle ensures each Data Owner's willingness to participate, as the benefits of participation outweigh those of non-participation. Assuming non-participation yields a profit of zero, participation results in no privacy

breach and entitles them to privacy compensation of $\frac{(\bar{\varepsilon} - \underline{\varepsilon})e^{\frac{\varepsilon dc - \bar{\varepsilon}}{\bar{\varepsilon} - \underline{\varepsilon}}} \theta_i fee}{(\bar{\varepsilon} - \underline{\varepsilon} dc) \sum_{i=1}^n \theta_i}$.

- (3) Budget Feasibility (BF): This criterion guarantees that the aggregate compensation awarded to DO remains within the fiscal limits of DC_j . Specifically, the total compensation should not surpass the budget B , expressed as $\sum_{i=1}^n q_i \theta_i \leq B' < B$.

Satisfying these three properties—Incentive Compatibility, Individual Rationality, and Budget Feasibility—ensures the fairness, effectiveness, and sustainability of the data value trading process. Moreover, it also safeguards the privacy rights of DO and facilitates the smooth progression of data trading activities.

B. Information Processing

In real-world data trading scenarios, DC often face budgetary constraints that prevent them from incorporating data from DO . Consequently, the value exchange mechanism involves a comparatively smaller group of DO than the total number available. This limitation poses challenges in acquiring a comprehensive understanding of the entire dataset through subsequent counting queries. In practical terms, this restriction might lead to queries that diverge significantly from the actual data, obscuring the overarching trends and characteristics of the dataset.

To address this issue, we propose a strategy where DC_j 's query requests focus primarily on mean queries and linear predictors. This method enables DC_j to discern the general trends and characteristics of the dataset and facilitates reasonable predictions about the unexplored segments of the data.

In this framework, the Piecewise mechanism with Personalized Local Differential Privacy (PWP) [30] is recognized as a highly effective PLDP algorithm. PWP builds upon the original Piecewise Mechanism [31], adapting it to support PLDP and introducing constraints to ensure the parameters in the probability density function achieve an integral of 1 across the entire range.

According to the predefined data boundaries, the data of each Data Owner (DO_i) is normalized to a specific value within the $[-1, 1]$ range, denoted as d_i . The size of the secure region τ , represented by w_i , and the center point of τ_i , denoted as h_i , are determined based on the privacy parameters (τ_i, ε_i) .

The perturbation process within the PWP is outlined in Algorithm I. Initially, DO_i shifts their secure region to a zero-centered symmetric region, effectively moving h_i to the zero point. Consequently, d_i is transformed into $t_i = \tilde{d}_i - h_i$. PWP then processes t_i to produce a sanitized value \tilde{t}_i within the range $[-C_i, C_i]$, where

$$C_i = \frac{w_i}{2} \cdot \frac{e^{\frac{\varepsilon_i}{2}} + 1}{e^{\frac{\varepsilon_i}{2}} - 1} \quad (4)$$

The probability density function (*pdf*) of \tilde{t}_i is a piecewise function as follows:

$$\Pr(\tilde{t}_i = x | t_i) = \begin{cases} p, & \text{if } x \in [l_i, r_i] \\ \frac{e^{\frac{\varepsilon_i}{2}}}{e^{\frac{\varepsilon_i}{2}} + 1}, & \text{if } x \in [-C_i, l_i) \cup [r_i, C_i] \end{cases} \quad (5)$$

where

$$p = \frac{e^{\varepsilon_i} - e^{\frac{\varepsilon_i}{2}}}{w_i(e^{\frac{\varepsilon_i}{2}} + 1)} \quad (6)$$

$$l_i = \frac{2t_i \cdot e^{\frac{\varepsilon_i}{2}} - w_i}{2(e^{\frac{\varepsilon_i}{2}} - 1)} \quad (7)$$

$$r_i = \frac{2t_i \cdot e^{\frac{\varepsilon_i}{2}} + w_i}{2(e^{\frac{\varepsilon_i}{2}} - 1)} \quad (8)$$

Upon determining \tilde{t}_i , DO_i reverts the region to its original position and computes the noisy version of d_i , designated as $\tilde{d}_i = \tilde{t}_i + h_i$, which is then expanded to match the data range (Table I).

TABLE I. PWP: PIECEWISE MECHANISM WITH PLDP

Input: Personal privacy parameters (τ_i, ε_i) , data d_i of do_i .
Output: sanitized values \tilde{d}_i .
1. $w_i = \tau_i $, h_i is the center point of τ_i , $t_i = d_i - h_i$.
2. Sample a random variable a uniformly from $[0, 1]$.
3. If $a < \frac{e^{\frac{\varepsilon_i}{2}}}{e^{\frac{\varepsilon_i}{2}} + 1}$:
3.1 Sample t_i uniformly from $[l_i, r_i]$.
4. Else:
4.1 Sample \tilde{t}_i uniformly from $[-C_i, l_i) \cup [r_i, C_i]$.
5. $\tilde{d}_i = \tilde{t}_i + h_i$.

Definition 8. Algorithm I adheres to the (τ, ε) -PLDP standards for each data owner DO_i with their respective (τ, ε) parameters. Moreover, with an input value of d_i , the algorithm generates a perturbed value such that the expected value $E[\tilde{d}_i] = d_i$, and the variance is given by:

$$\text{Var}[\tilde{d}_i] = \frac{(d_i - h_i)}{e^{\frac{\varepsilon_i}{2}} - 1} + \frac{w_i^2(e^{\frac{\varepsilon_i}{2}} + 3)}{12(e^{\frac{\varepsilon_i}{2}} - 1)^2} \cdot \frac{1}{e^{\varepsilon_i} + 1}$$

Subsequently, DO_i uploads the perturbed data along with certain non-perturbed feature data to DB . Based on the requests of the data buyer, DB performs queries and sends the encrypted results to the data buyer.

Property 1. Sequential Compositionality: Consider two random algorithms, A_1 and A_2 , each conforming to (τ, ε_1) -PLDP. When these algorithms are sequentially composed as $A = (A_1, A_2)$, the composite satisfies $(\tau, \varepsilon_1 + \varepsilon_2)$ -PLDP. A fundamental condition for this property to be valid is that the data d must remain within the secure region τ after being processed by the random algorithm A_1 .

Proof

$$\begin{aligned} \frac{\Pr(A(d) = g)}{\Pr(A(d') = g)} &= \frac{\Pr(A_2(g') = g)}{\Pr(A_2(g') = g)} \times \frac{\Pr(A_1(d) = g')}{\Pr(A_1(d) = g')} \\ &\leq e^{\varepsilon_2} \times e^{\varepsilon_1} \\ &= e^{\varepsilon_1 + \varepsilon_2} \end{aligned} \quad (9)$$

Thus, $A = (A_1, A_2)$ satisfies $(\tau, \varepsilon_1 + \varepsilon_2)$ -PLDP.

After DO_i submits their data, DB reviews it to assess whether further PLDP processing is feasible. Should it be practical to proceed, DO_i , after engaging in multiple transactions, has the option to enhance their privacy level without needing to reapply PLDP with a higher privacy budget and resend the data. Instead, they can authorize DB to apply additional PLDP on the data that has already undergone initial PLDP processing. This approach is designed to minimize costs associated with data retransmission and revalidation, simultaneously reducing the risk of information leakage during the data transfer process.

V. PROTOCOL DETAILS

Prior to examining the specifics of smart contracts and the scheme's overarching process, it is essential to understand the security strategy employed by DO . DO_i may hold various types of data, such as credit card information and health records. Utilizing a single encryption key for all data types presents inherent risks, given that data stored on IPFS is accessible to all, and a key compromise could expose all associated information. To bolster security, DO_i elects to use distinct symmetric keys k for encrypting each data type. This approach ensures that even if one data type's key is compromised, the other data types remain secure. DO_i then amalgamates all the symmetric keys and encrypts them using DB 's public key before sending them to DB for data verification. This encryption strategy effectively mitigates potential risks, thereby elevating the overall security level of the data.

With a comprehensive understanding of the DO 's security strategy in place, we can now explore the detailed functionalities of smart contracts. These include their pivotal roles in data transactions and the verification process.

A. Smart Contract Functionalities

The smart contract \widetilde{SC} offers the following key functionalities:

Data Broker:

1. `\constructor(fee)`: A constructor function that sets the contract owner, intermediary fee (Fee), and privacy compensation (fee).
2. `\DO_data()`: This function enables DB to access information and locations of the first Data Owner in the request queue and integrate them into the DO array.
3. `\update_DO(site, i, change, introduction)`: It allows DB to tag whether the data of DO_i is eligible for subsequent PLDP and includes data introductory details.
4. `\delete_DO(site, i)`: Used by DB to remove the corresponding DO_i at a given position in instances where data fails verification or when DO_i resubmits data, determining if they should be extracted from the DO array.
5. `\tx_generate()`: This function facilitates DB in generating transactions based on the queue and retrieving

query request information from the initial Data Consumer.

6. ``tx_process(_es,_choose,_num,_budget,_fee)``: Enables DB to conclude transactions, dispatching ciphertext and the residual budget to DC_j . Should the count of participating DO be zero, the transaction is considered unsuccessful, and the budget is refunded.

Data Owner:

7. ``dataOwner_Join(_value,_cid,_ek,_privacy,_tao)``: This function permits DO_i to apply for participation but restricts them from joining directly via the contract address.
8. ``dataOwner_Withdraw()``: Enables DO_i to withdraw their earnings, employing a check-influence-swap pattern to mitigate the risk of reentrancy attack vulnerabilities.
9. ``dataOwner_Update(_privacy,_j)``: This function allows DO_i to request an increase in privacy budget for a specific record, signaling that the corresponding data is eligible for another round of PLDP. DB then executes the requisite data adjustments locally.

Data Consumer:

10. ``dataConsumer_Purchase(_privacy,_request)payable``: Facilitates Data Consumers (DC_j) in submitting purchase requests while prohibiting direct joining through the contract address and barring repeat purchases before the completion of an ongoing transaction.
11. ``dataConsumer_Result()``: This function enables DC_j to access the ciphertext of their query results.

B. Overall Process

Now, we will delve into a comprehensive understanding of our solution's operational process by examining the intricacies of data transmission and processing, as well as the pivotal role played by DB . The detailed steps of our solution's overall process are outlined below, with the corresponding sequence diagram depicted in Fig. 3. This thorough exploration will provide insights into how each component interacts and contributes to the efficient functioning of the system.

During the initialization phase, DO_i executes the key initialization algorithm $Setup(1^\lambda)$ to generate their symmetric encryption key k_i . They then apply PWP, informed by their selected privacy parameters (τ_i, ε_i) . The data intended for encryption, post-PWP processing, is encrypted using the algorithm $Encrypt(k_i, \tilde{a}_i | D_i)$, creating the ciphertext C_i . This ciphertext C_i is then uploaded to IPFS, generating a unique hash $hash_i$. Concurrently, DC_j and DB each run the key initialization algorithm $KenGen(1^\lambda)$ to obtain their respective pairs of encryption keys (pk_j, sk_j) and (pk_{DB}, sk_{DB}) . Following this, the smart contract \widetilde{SC} is deployed to the blockchain, establishing the intermediary fee (Fee) and privacy compensation (fee).

Data Collection: In the data collection phase, DO_i , having acquired the public key pk_{db} from DB , executes the encryption

algorithm $Enc(k_i, pk_{db})$ to produce the encrypted key ek_i . DO_i then applies to join the data trading platform via the smart contract \widetilde{SC} , uploading details $(hash_i, ek_i, \theta_i, \varepsilon_i, \tau_i)$ while awaiting verification from DB . Upon receipt of the information $(hash_i, ek_i, \theta_i, \varepsilon_i, \tau_i)$, DB utilizes the decryption algorithm $Dec(ek_i, sk_{db})$ to retrieve DO_i 's symmetric key k_i . Following this, DB , referencing $hash_i$, downloads DO_i 's ciphertext C_i . Subsequently, by executing $Decrypt(k_i, C_i)$, DB acquires the perturbed data \tilde{d}_i and the feature data D_i post-PLDP. This data, upon inspection, leads to the approval of DO_i 's membership application, coupled with an assessment of the feasibility of further PLDP and inclusion of data introduction details.

Data Purchase: DC_j , utilizing the functionality of the smart contract \widetilde{SC} , submits a data query request φ along with their privacy budget ε_j , allocating the budget B for the transaction.

Exchange And Processing: Upon receipt of the query details $(B, \varepsilon_j, \varphi)$ from DC_j , DB implements the value exchange mechanism $E(\theta, \varepsilon, \tau, B, \varepsilon_j, Fee, fee)$, resulting in the selection of a set q and the number n' of participating Data Owners for the transaction. This also includes the calculation of the remaining budget b . Following this, based on the query request φ , the operation $P(\tilde{d}, D, q, \varphi)$ is performed to derive the query result s_j . The result s_j is then encrypted using DC_j 's public key pk_j through $Enc(s_j, pk_j)$, generating the ciphertext es_j . DB subsequently transmits the ciphertext es_j and the remaining budget b to DC_j via \widetilde{SC} . Upon receipt of es_j , DC_j executes $Dec(es_j, sk_j)$ to retrieve the query result s_j .

Withdraw And Update: After a specified period, DO_i can withdraw their earnings from prior transactions $(q_i \theta_i + \frac{\varepsilon_{dc} - \varepsilon}{\varepsilon - \varepsilon_{dc}} \theta_i fee)$ via the \widetilde{SC} contract. Additionally, DO_i can augment their privacy budget through the smart contract \widetilde{SC} .

VI. IMPLEMENTATION AND EVALUATION

In this section, we conduct an experimental evaluation of our scheme by deploying the smart contract on the Sepolia testnet and simulating interactions between the Data Broker, Data Owners, and Data Consumers. A critical aspect of this evaluation involves testing the relative error between the results received by Data Consumers and the actual data outputs.

A. Security Analysis

In the transactions, all cryptographic algorithms used, including SE, ECC, and the hash algorithms of the IPFS, have been extensively validated and are secure. The PLDP algorithm used for data processing also meets the (τ, ε) -PLDP security standard. The smart contracts employed have undergone unit testing. Therefore, the transaction process is secure. DO ' original data is retained locally, and only perturbed data is uploaded. This ensures that DB cannot access the true data of any specific data owner, providing good confidentiality and preventing Man-In-The-Middle (MITM) attacks. Blockchain technology offers tamper-resistance and traceability; events occurring on the blockchain are fully recorded in logs. Thus, the operation information of all entities during the data trading process is completely documented, ensuring good integrity and

preventing any entity from denying their actions during the transaction.

B. Gas Consumption

Within the smart contract framework, *DB* bears the responsibility for deploying the contract and managing its function executions. Other participants in the network, serving as users on the Ethereum platform, have the flexibility to join at any time. The gas fees associated with deploying the smart contract and executing its various functions are contingent on the specific operations being performed. These costs are comprehensively outlined in Table II, offering a detailed breakdown of the gas consumption for different actions.

TABLE II. TRANSACTION FEE

Function	Transaction Fee (ETH)	Gas Price (Gwei)
Deployed	0.0064124	1.58120
dataOwner_Join	0.0031329	1.59848
dataOwner_Withdraw	0.0000554	1.61893
dataOwner_Update	0.0000630	1.73067
dataConsumer_Purchase	0.0003310	1.61856
DO_data	0.0004541	1.60607
update_DO	0.0002137	1.62734
tx_generate	0.0001068	1.60340
tx_process	0.0027604	1.59467

C. Experimental Design

Experimental Environment. The components for value exchange and information processing, computed locally, are implemented using Python. These components are operated on a computer equipped with an AMD Ryzen 5 5600 6-Core Processor and 32GB of RAM. Each experimental iteration is conducted 50 times to ensure accuracy, with the average results being reported for consistency.

Query Types. Our testing encompassed various query types, including average queries and linear predictors. For average queries, we determined the participating Data Owners through the value exchange mechanism, comparing the perturbed mean with the actual mean. In the case of linear predictors, the last row of data was treated as the predictive value, with other rows representing existing Data Owners. We chose a sensitive attribute as the label and other attributes as features. A linear model was constructed using the least squares method, and its predictive outcomes were compared against actual values.

Metrics. One of the key metrics employed is the Relative Error (RE). This metric is crucial in evaluating the scheme's accuracy in mean estimation, measured as follows:

$$RE = \frac{|T_m - E_m|}{|T_m|} \quad (10)$$

Here, T_m denotes the actual value result, while E_m signifies the perturbed value result.

Dataset. For our experiments, we selected four real-world datasets: the Obesity dataset [32], Student Performance dataset

[33], Job Salary dataset [34], and the Obsessive-Compulsive Disorder (OCD) dataset [35]. The details of these datasets are as follows:

- **Obesity Dataset:** The sensitive attribute selected is **age**, ranging from [15, 56]. Other attributes are treated as feature attributes and encoded accordingly. After processing, there are a total of 1552 records.
- **Student Performance Dataset:** Here, the sensitive attribute is the **math score**, within the range of [0, 100]. Other attributes are designated as feature attributes and are similarly encoded. After processing, there are a total of 964 records.
- **Job Salary Dataset:** The sensitive attribute, **Salary**, is compressed to the range of [100, 000, 180, 000]. Attributes other than the job title are considered feature attributes and are encoded accordingly. After processing, there are a total of 1654 records.
- **OCD Dataset:** For this dataset, **Duration of Symptoms** is the sensitive attribute, with a range of [6, 240]. The remaining attributes are classified as feature attributes and encoded as such. After processing, there are a total of 1497 records.

Privacy Parameters (τ_i, ε_i) and Data Value θ_i . The values of the secure region's upper and lower bounds, τ_i , are restricted to the range of $[-1, -0.5, 0, 0.5, 1]$, with specific values being the two closest to d_i , resulting in w_i being set at 0.5. For instance, if $d_i = -0.35$, the secure region would be $[-0.5, 0]$. For the privacy budget ε_i , values are uniformly distributed within $[1, 5]$, randomly selected and rounded to two decimal places. The data value θ_i is randomly determined, selecting integers within the range of $[1, 50]$.

Experiment 1. In our first experiment, we focused on assessing the efficiency of the data processing component. We conducted a thorough comparison between our method and the Laplace mechanism, both of which support continued PLDP. This comparison aimed to highlight the performance disparities between these two data processing approaches under various conditions.

Experiment 2. The second experiment was designed to evaluate the efficiency of the value exchange component. We compared our method against the value exchange mechanisms of FQ and SMQ. The objective of this comparison was to delve into the performance differences among these diverse value exchange methods.

In both experiments, the budget B' allocated by *DC* for purchasing data varied within the range of [1000, 20000], without any additional privacy budget expenditures.

D. Experimental Result

Experiment 1

As depicted in Fig. 4, the mean query results across the Obesity, Student Performance, Job Salary, and OCD datasets highlight the enhanced precision of our BPPDT method over the LAP approach. Notably, the RE diminishes progressively with the increase in budget B' , underscoring our method's ability to leverage additional resources to improve accuracy.

The linear predictor results displayed in Fig. 5 reveal distinct trends across various datasets. In the Obesity and Student Performance datasets, there is a gradual reduction in RE as the budget increases, with the trend eventually plateauing. Our BPPDT method shows superior performance over the LAP-based scheme in these datasets. In the Job Salary dataset, although the LAP scheme starts with an advantage, it experiences significant fluctuations in RE with increased budgets, whereas our method shows a consistent decline in RE. The OCD dataset presents challenges for both methods, with poor performance hinting at weak linear correlations within the data.

Experiment 2

The total value exchange efficiency of our approach is depicted in Fig. 6, where it is evident that our method excels in the value exchange component, attaining the highest level of value exchange efficiency.

The mean query results presented in Fig. 7 demonstrate that across all datasets—Obesity, Student Performance, Job Salary, and OCD—our BPPDT approach consistently yields smaller RE when compared to the FQ and SMQ methods. This advantage is substantial and becomes more pronounced as the budget increases, indicating the superior efficiency of our method in managing value exchange.

The results for the linear predictor as illustrated in Fig. 8 indicate a distinct trend across different datasets. In the Obesity dataset, while the FQ scheme initially exhibits smaller RE at lower budgets, our BPPDT approach surpasses all other schemes with increasing budget. In the Student Performance dataset, the BPPDT method shows competitive REs similar to the SMQ scheme and outperforms other methods, especially at moderate budget levels. Notably, as the budget nears 20000, the SMQ scheme's REs start to decrease significantly. For the Job Salary dataset, the SMQ scheme demonstrates better performance. In contrast, in the OCD dataset, our BPPDT approach maintains commendable performance at lower budgets, showcasing its efficiency.

According to the results of two experiments, the accuracy of mean queries is significantly higher than that of linear queries. This is because linear queries reduce the correlation of the data after submitting perturbed data, whereas mean queries are not affected by this. The more budget DC have, the more data they can purchase, and the higher the accuracy of the data will be. Additionally, the smaller the range of data values, the smaller the added perturbation, and the higher the accuracy of the data. Therefore, this trading model performs better when processing datasets such as grades and salaries.

VII. CONCLUSION

We introduce a data trading model employing PLDP to achieve a harmonious balance between user-friendliness and privacy protection in data transactions. Our innovative approach not only complies with IC, IR, and BF but also satisfies (τ, ϵ) -PLDP requirements. It adeptly caters to DC ' demands for more detailed queries and fulfills DO ' inclination towards augmented privacy budgets. Our experimental findings confirm that our method delivers superior accuracy, even when operating under identical budget constraints. However, the current

PLDP algorithms can only operate on numerical data. As future work, we will discuss the selection of privacy parameters in relation to the value of data owners and aim to expand the trading model by incorporating PLDP algorithms suitable for other types of data, as well as addressing more complex query types.

ACKNOWLEDGMENT

We are grateful to the anonymous referees for their invaluable suggestions. This work is partially supported by the Jiangxi Provincial Department of Education research(GJJ2201037).

Abstract—Breast cancer remains a significant illness around the world, but it has become the most dangerous when faced with women. Early detection is paramount in improving prognosis and treatment. Thus, ultrasonography has appeared as a valuable diagnostic tool for breast cancer. However, the accurate interpretation of ultrasound images requires expertise. To address these challenges, recent advancements in computer vision such as using convolutional neural networks (CNN) and vision transformers (ViT) for the classification of medical images, which become popular and promise to increase the accuracy and efficiency of breast cancer detection. Specifically, transfer learning and fine-tuning techniques have been created to leverage pre-trained CNN models. With a self-attention mechanism in ViT, models can effectively feature extraction and learning from limited annotated medical images. In this study³, the Breast Ultrasound Images Dataset (Dataset BUSI) with three classes including normal, benign, and malignant was utilized to classify breast cancer images. Additionally, Deep Convolutional Generative Adversarial Networks (DCGAN) with several techniques were applied for data augmentation and preprocessing to increase robustness and address data imbalance. The AttentiveEfficientGANB3 (AEGANB3) framework is proposed with a customized EfficientNetB3 model and self-attention mechanism, which showed an impressive result in the test accuracy of 98.01%. Finally, Gradient-weighted Class Activation Mapping (Grad-CAM) for visualizing the model decision.

Keywords—Breast cancer; classification; Convolutional Neural Network (CNN); Vision Transformer (ViT); fine-tuning; transfer learning; self-attention

I. INTRODUCTION

Breast cancer stands as one of the most prevalent and concerning malignancies affecting women globally. In addition, breast cancer poses a significant health burden and remains a leading cause of mortality among women. Breast cancer is a formidable enemy, its impact reverberating through the lives of countless individuals and families worldwide. It causes extreme physical, emotional, and socioeconomic consequences not only in women but also in men. The dangerous nature of breast cancer is its potential to metastasize. Thus, the patient needs to understand the mechanisms, risk factors, and manifestations of breast cancer for effective treatment.

Because breast cancer is one of the most common diseases in modern life, there have been many reports about the

statistical indicators of this disease. Breast cancer is one of the six most common cancers in the world [1] [2] [3] and it is the leading cause of death in women [1]. In addition, there will be 1,503,694 deaths worldwide from breast cancer in 2050 (i.e., 1,481,463 women and 22,231 males) [4]. Moreover, the GLOBOCAN Cancer Tomorrow prediction tool predicts that breast cancer will rise by more than 46% in 2040 [5]. However, the incidence rates are not equal between countries around the world. For instance, developed countries are higher than developing countries at 88%, with 55.9 and 29.7 per 100,000 women, respectively. In the United States, breast cancer was a cause of death among 909,488 women between 1999 and 2020 [6]. As estimated, the US will have 310,720 new cases of female breast in 2024 [7]. In China, there were about 70,400 deaths and 303,600 new cases of breast cancer in 2015. From 2000 to 2015, the age-standardized incidence and mortality rates rose by 3.3% and 1.0% annually, respectively. It was estimated that these rates would rise by more than 11% until 2030 [8].

To resolve this problem, advancements in medical science have assisted multiple approaches aimed at tackling breast cancer from various angles. From surgery to chemotherapy and radiation therapy, treatment strategies continue to develop and help to improve patient treatment and quality of life. Among these methods, ultrasound images have come out as a valuable tool offering non-invasive and radiation-free breast cancer treatment. Addressing breast cancer requires multiple approaches integrating clinical, pathological, molecular, and imaging aspects. Thus, continual improvements in medicine and computer research are imperative to increase early detection, optimize treatment outcomes, and mitigate the impact of this formidable disease on individuals and society.

Besides, computer vision appeared as a new way for classification and segmentation of a lot of aspects of images. In a subset of computer vision, transfer learning and fine-tuning were used for extracting meaningful information from medical images. These methods have gained considerable attention for their effectiveness in adapting pre-trained convolutional neural networks (CNN) to the specific task of breast cancer analysis. Transfer learning employs knowledge from a pre-trained model on a source task and applies it to a related task with a smaller dataset [9] [10] [11]. On the other hand, fine-tuning requires further refining the parameters and layers of the pre-trained

³Corresponding author: Nguyen Thai-Nghe

model on the target task-specific dataset [12] [13] [14] [15]. This approach proves especially beneficial in scenarios where annotated medical image datasets are limited, which facilitates the development of robust classification models for breast cancer detection and characterization.

The advent of Vision Transformer (ViT) architectures represents a significant advancement in the field of medical imaging analysis [16] [17] [18]. Unlike traditional CNN, which relies on hierarchical feature extraction through convolutional layers. ViT introduces a self-attention mechanism that allows for direct interactions between image patches for capturing long-range dependencies within the data. This innovative approach revolutionizes breast cancer classification by enabling the network to dynamically weigh the importance of different image regions, thereby increasing its ability to discern subtle features indicative of malignancy. By using self-attention mechanisms, ViT models demonstrate superior performance in classifying breast cancer images and create more accurate diagnostic outcomes and treatment planning.

Furthermore, a combination of self-attention mechanisms and CNN architectures offers several advantages for breast cancer classification. By selectively attending to relevant image regions, these mechanisms facilitate the extraction of salient features while suppressing noise and irrelevant information. This adaptive focusing capability raises the power of CNN and enables them to effectively differentiate between benign and malignant lesions in breast cancer images. Moreover, self-attention mechanisms enable the network to capture spatial dependencies across multiple scales which allows for a more comprehensive understanding of complex structures within the breast tissue. As a result, CNN models augmented with self-attention mechanisms improve accuracy and reliability in breast cancer classification tasks.

Nowadays, computer technology gives a chance for users a lot of convenience specifically in medical treatment. This study applied several techniques for classifying breast cancer ultrasound images. Begin with applied transfer learning and fine-tuning in CNN and combine a self attention mechanism in ViT. Furthermore, DCGAN was used to augment datasets with new images that are similar to existing ones but slightly different, they can help improve the generalization of machine learning models. Moreover, Grad-CAM was used to explain the classified outcome, which helps describe the model decision.

The contributions of this paper are as follows:

- By using the capabilities of deep learning architectures, this research used DCGAN to facilitate the synthesis of realistic ultrasound images, thereby expanding limited datasets for training classification models. This augmentation process not only raises the diversity and richness of the dataset but also fosters the resilience and efficacy of machine learning algorithms in accurately discerning pathological features indicative of breast cancer.
- This study proposed a combination of CNN with self-attention mechanisms from ViT. It presents a promising approach for classifying ultrasound breast cancer images. By using the ability to extract hierarchical features from CNN and attention mechanism from

ViT for capturing global dependencies. As a result, this hybrid architecture increases accuracy and other performance in breast cancer classification.

- Throughout scenarios, the proposed model demonstrated the effectiveness of augmentation techniques and a self-attention mechanism with an accuracy of 98.01%. It has an increase of 13.39% when compared with do not apply any techniques. Thus, these experiments show the AttentiveEfficientGANB3 (AE-GANB3) framework works usefully, thereby indicating its practical capabilities in medical examination and treatment.
- The utilization of Grad-CAM in classifying ultrasound breast cancer images offers insightful interpretability into the decision-making process of deep learning models in this research. By highlighting regions of interest within ultrasound images that contribute most significantly to the classification outcome, Grad-CAM aids clinicians in understanding the model's reasoning, thereby enhancing trust and facilitating informed decision-making in medical diagnostics.

The research paper includes six main parts. First, the opening section offers an introduction. Next, the subsequent section indicates an extensive review of related literature. The third part elucidates the methodology and provides explanations of the employed techniques. Following this, the fourth section delineates the experiments and details their procedures and assessments. Furthermore, the fifth section presents the results of the most important experiment and compares them with existing methods. Finally, the sixth section encapsulates essential findings and offers an analysis.

II. RELATED WORKS

CNN and ViT are two prominent methodologies employed in the realm of medical image classification. By using convolutional layers, CNNs can automatically learn relevant features from the input data, which is crucial for discerning between malignant and benign tissues in breast ultrasound scans. In [19], Sathiyabhama Balasubramaniam et al. proposed the LeNet model which applied to breast cancer data analysis and reached a high accuracy of 89.91% when classifying malignant and benign tumors. LeNet CNN is a promising technique that could be used in the future to increase the robustness and accuracy of breast cancer prediction. However, the research did not apply data augmentation to increase the training set and explanation techniques for the outcome to understand the model decision. Besides, Hua Chen et al. used ResNet50 and local binary pattern (LBP) to classify 874 breast ultrasound images (i.e. 457 benign and 417 malignant) and reached a great accuracy of 96.91% as reported in [20]. The research demonstrates that the performance of breast tumor diagnosis may be raised by integrating shallow LBP texture characteristics and multi-level depth features. According to [21]. Mohammed Alotaibi et al. employed the VGG19 model to compare three different image preprocessing procedures in dataset BUSI and gained a surprise mean accuracy of 87.8%. Thus, the study focuses on raising the predictions of deep learning models by using image preprocessing. However, the average accuracy is low which can grow by using and demonstrating the effect of data augmentation techniques.

The advancements in CNN are increasing day by day and help to create a perfect system for the classification of medical images. Clara Cruz-Ramos et al. proposed a DBFS-GMI model based on DenseNet201 and various techniques in [22]. It achieved an impressive accuracy on both datasets mini-DDSM and BUSI of 92% and 96%, respectively. Moreover, a combination of two datasets created an increase in accuracy to 97.6%. As a result, the study has developed a hybrid system that uses the CNN architecture for extracting deep learning features and several classifiers including XGBoost, AdaBoost, and MLP are applied to diagnose breast cancer. In addition, Nasim Sirjani et al. improved the InceptionV3 model and achieved an accuracy of 81% in [23]. However, these experiments run on the dataset combined on various sources which can create an imbalance in the dataset. Thus, this should be resolved by data augment techniques. In [24], Hiba Diaa Alrubaie et al. proposed a new CNN architecture which is combined by several layers such as Conv2D and MaxPooling2D to attain an accuracy of 96% in three classes classifying (i.e. benign, malignant, and normal). However, the article does not mention visual explanation techniques, which can help in the visualization of outcomes.

The versatility and adaptability of CNN make them well-suited for handling the complexities and variabilities present in ultrasound images, which facilitates robust and accurate classification of breast cancer cases. Adyasha Sahu et al. proposed a model by combining the benefits of AlexNet, ResNet, and MobileNetV2 and used Laplacian of Gaussian-based modified high boosting filter (LoGMHBF) for pre-processing. As a result, the proposed model achieved the highest accuracy of 96.92% on the BUSI dataset as described in [25]. Additionally, Shao-Hua Chen et al. demonstrated that GoogLeNet and TV models have a huge effect on classifying breast cancer ultrasound images. Through various experiments, authors compare GoogLeNet, VGG16, and LeNet5 to indicate that GoogLeNet has the best accuracy of 96.37% in [26]. Next to that, four different models with VGG-Net, DenseNet, Xception, and Inception were combined to propose a fuzzy-rank-based ensemble network for classifying breast cancer on the BUSI dataset in [27]. Sagar Deep Deb et al. gained a surprising accuracy of 85.25% and they also used Grad CAM for visualization to understand the workings of the proposed model.

Besides studies on the effectiveness of CNN models on ultrasound images, other studies about breast cancer are also provided on Magnetic Resonance Imaging (MRI) or Mammograms. Quy Thanh Lu et al. illustrated the power of a customized MobileNet in classifying multiclass of breast cancer and reached impressive accuracy in four-class classify of 97.24% as reported in [28]. In addition, the study demonstrated the potential of Grad-CAM and other techniques such as data augmentation and preprocessing which increased the model performance and gave a chance to utilize MRI classification in the real world. In [29], Kiran Jabeen et al. indicated enhanced deep learning features and Equilibrium-Jaya controlled Regula Falsi and attained a surprising accuracy on two publicly available datasets CBIS-DDSM and INbreast with an average score of 95.4% and 99.7%, respectively. Thus, the proposed model demonstrated the power of classifying Mammogram images and provided a framework to improve the accuracy. Additionally, Our previous study [30] employed a fine-tuning

strategy, ensemble method, and extracting inherent features to improve model reliability and classification accuracy. As a result, the model obtained an accuracy of 76.79% for binary classification.

On the other hand, Vision Transformers, a relatively novel approach, has shown promise in image classification tasks by attending to the global context of the image through self-attention mechanisms. In an experiment of [31], Ishak Pacal proposed a transformer model and compared it with other CNN architecture to see that their model outperforms other models with 88.6% accuracy. Thus, the author indicates deep learning is effective at classifying ultrasound pictures and will soon be able to be utilized in clinical trials. Besides, Behnaz Gheflati et al. proposed a ViT model to classify breast ultrasound images in the dataset BUSI and BUSI + B and achieved accuracies of 82.00% and 86.7% in [32]. In this article, the author tested the B/32 and Resnet50 models and compared the model's outcomes with the corresponding performance of the state-of-the-art. According to [33], Xiaolei Qu et al. also utilized a CNN module to extract local features and a ViT module to determine the global link between various areas to create a VGGA-ViT network. As a result, the proposed gained the highest accuracy 88.7% in dataset BUS-A and the largest accuracy 81.72% in dataset BUS-B.

Despite their architectural differences, both CNN and ViT offer valuable tools for automated diagnosis in medical imaging, contributing to enhanced efficiency and accuracy in breast cancer detection and classification. In addition, ViT is a newer approach and shows promising results in breast cancer classification tasks, albeit with slightly lower accuracies compared to CNN. Future research should focus on addressing dataset imbalances, integrating data augmentation techniques, and implementing visual explanation methods to increase model interpretability. Additionally, exploring hybrid architectures that combine CNN and ViT could further improve classification accuracy.

III. METHODOLOGY

A. The Research Implementation Procedure

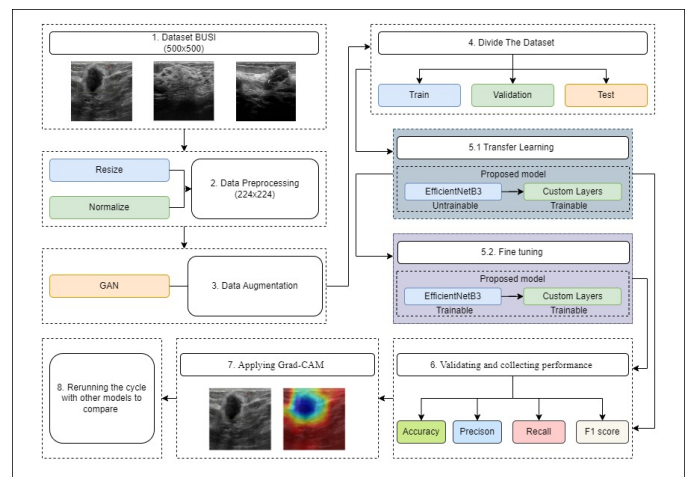

Fig. 1. The AttentiveEfficientGANB3 (AEGANB3) framework was combined with multiple steps which were numbered in detail, including applying GAN and customizing the CNN model.

This research proposed a pipeline consisting of eight steps from input to output shown in Fig. 1. The details of each step are indicated as follows:

1. **Dataset BUSI:** There are three classifications in the Breast Ultrasound Images Dataset (BUSI): normal, benign, and malignant. The total amount of photos is 780, with an average size of 500×500 pixels. Moreover, the LOGIQ E9 ultrasound system and the LOGIQ E9 Agile ultrasound system are tools utilized in the scanning procedure. Additionally, all of the photos were cropped to various proportions to eliminate unnecessary borders. Furthermore, Baheya Hospital radiologists examined and verified every picture.
2. **Data Preprocessing:** In this step, the technique of resizing and normalizing holds paramount importance. Resizing relates to the transformation of input data to a standardized dimension. Concurrently, normalization scales the data to a common range. Together, these preprocessing steps help to increase precision in model training.
3. **Data Augmentation:** This augment methodology involves training a DCGAN on existing data to generate additional samples, thereby expanding the dataset size and enhancing its diversity. The integration of GAN-based data augmentation techniques has demonstrated promising results in various domains which indicates its efficacy in raising model generalization and robustness.
4. **Divide The Dataset:** This scheme allocates 80% of the dataset for training, 10% for validation, and 10% for testing purposes. By following the 8-1-1 scale, this research can effectively measure the performance of breast cancer classification models ensuring reliable results in the domain of medical image analysis.
- 5.1 **Transfer Learning:** In transfer learning, a pre-trained CNN model is utilized as a feature extractor, typically trained on a large-scale dataset like ImageNet. The learned features are then used to initialize a new CNN model, which is subsequently fine-tuned on the target ultrasound breast cancer image dataset. This approach allows the model to leverage the knowledge gained from the source domain to effectively learn discriminative features for breast cancer classification.
- 5.2 **Fine-tuning:** Fine-tuning updates the parameters of the pre-trained model using backpropagation with the target dataset, thereby adapting the model to the specific characteristics of ultrasound breast cancer images. Furthermore, fine-tuning enables the optimization of model performance by adjusting the hyperparameters and architecture of the pre-trained model to better suit the target task of ultrasound breast cancer classification.
6. **Validating and collecting performance:** Validating and collecting the performance of models in classifying ultrasound breast cancer images requires the assessment of various metrics including accuracy (ACC), precision, recall, and F1 score. The study employs annotated datasets of ultrasound images and partitions

them into training, validation, and testing subsets. Subsequently, the model is trained on the training dataset and fine-tuned using the validation set, while performance metrics such as ACC, precision, recall, and F1 score are computed using the testing set.

7. **Applying Grad-CAM:** Applying Grad-CAM for classifying ultrasound breast cancer images enhances interpretability and understanding of deep learning models' decision-making processes. Grad-CAM generates heatmaps highlighting regions within ultrasound images for classification decisions. By visualizing these regions, The study gives insights into which features the model prioritizes when distinguishing between benign and malignant lesions
8. **Rerunning the cycle with other models to compare:** In this phase, the cycle was replayed with other models to compare the performance including EfficientNetB3, DenseNet169, Xception, ViT B16, and ViT B32.

B. Dataset

The BUSI dataset serves as a valuable resource in medical imaging, specifically focusing on breast ultrasound images acquired from female individuals aged between 25 and 75 years old. In addition, this dataset was collected from 600 female patients including 780 images. These images exhibit a consistent average size of 500 by 500 pixels helping to analysis and interpretation in the area of breast cancer detection and diagnosis.

Fig. 2. The distribution between three classes including normal, benign, and malignant in the dataset BUSI.

However, a challenge in the BUSI dataset stays in its class imbalance, which could potentially skew the performance of machine learning algorithms trained on it. The distribution across the classes reveals a notable disproportion in Fig. 2, with 437 instances classified as benign, 133 as normal, and 210 as malignant. Such an imbalance poses a significant obstacle undermining their ability to accurately discern minority classes.

To mitigate this issue and increase the richness of the data set in machine learning applications. Thus, data augmentation techniques prove helpful. By augmenting the minority classes, the balance can be rectified and created equitable across all

classes. Through augmentation in Fig. 3, the instances within the benign, normal, and malignant classes can be increased to 1357, 1333, and 1330, respectively. This augmentation process not only rectifies the class imbalance but also enriches the dataset which improves performance in breast cancer detection and classification endeavors.

Fig. 3. The distribution between three classes in the dataset BUSI after augmentation

C. Data Preprocessing

Data preprocessing is important to ensuring the quality and efficacy of subsequent classification tasks. In the context of ultrasound images for breast cancer classification. Two fundamental preprocessing techniques resizing Eq. (1) and normalization Eq. (2) are integral steps in raising the interpretability and efficiency of classification algorithms.

The resize technique is employed to standardize the dimensions of ultrasound images. In detail, resizing from a larger dimension, such as 500x500 pixels, to a smaller dimension, like 244x224 pixels, is utilized in this study. In this resizing process, each intensity values are recalculated to fit the new dimensions while preserving the structural features essential for accurate classification. Mathematically, Let $I_{original}$ Eq. (1) denote the original ultrasound image with dimensions 500x500 pixels, and $I_{resized}$ Eq. (1) indicates the resized image with dimensions 244x224 pixels. The resizing operation can be expressed as:

$$I_{resized} = \text{resize}(I_{original}, (224, 224)) \quad (1)$$

Where (224, 224) Eq. (1) illustrates the height and width of the resized image. Moreover, the pseudo-code of the resize algorithms is provided in Algorithms 1 which represents an overview of the code flow.

On the other hand, normalization assists in standardizing the pixel intensities in the ultrasound images increasing comparability and mitigating the effects of variations in illumination and contrast. By scaling the intensity values to a common range, typically between 0 and 1, normalization facilitates optimal convergence during the training phase of classification models. Mathematically, the normalization process can be represented as:

$$O(x, y) = \frac{I_{resized}(x, y) - \min(I_{resized})}{\max(I_{resized}) - \min(I_{resized})} \quad (2)$$

The normalization equation presented calculates the normalized pixel value $O(x, y)$ Eq. (2) at a specific position

(x, y) Eq. (2) in the resized image. It involves dividing the pixel value of the resized image $I_{resized}(x, y)$ Eq. (2) by the range of pixel values in the resized image, which is determined by subtracting the minimum pixel value $\min(I_{resized})$ Eq. (2) from the maximum pixel value $\max(I_{resized})$ Eq. (2). This normalization process Eq. (2) ensures that all pixel values in the resized image fall within the range of [0, 1].

Algorithm 1 Resizing Algorithm

Require: Original Image, target_size

Ensure: Resized Image

- 1: Load the Original Image;
 - 2: Define the target_size = (224,224)
 - 3: Resize the Original Image to the target_size using the resize function:
 - 4: $\text{ResizedImage} = \text{resize}(\text{OriginalImage}, (224, 224))$
 - 5: **return** Resized Image
-

As outlined in Algorithm 2, the normalization algorithm computes the minimum and maximum pixel values present within the image. Subsequently, it iterates over each pixel in the image, normalizing its intensity value to fall within the range [0, 1]. This normalization process enhances the comparability and interpretability of images across various datasets and facilitates subsequent analysis, such as feature extraction and classification.

Algorithm 2 Normalization Algorithm

Require: Image to normalize: image

Ensure: Normalized image: normalized_image

- 1: $\min_pixel_value \leftarrow \min(\text{image})$
 - 2: $\max_pixel_value \leftarrow \max(\text{image})$
 - 3: **for** each pixel **in** image **do**
 - 4: $\text{normalized_image}[x, y] \leftarrow \frac{\text{image}[x, y] - \min_pixel_value}{\max_pixel_value - \min_pixel_value}$
 - 5: **end for**
 - 6: **return** normalized_image
-

In conclusion, the integration of resizing and normalization techniques in the preprocessing pipeline for ultrasound images in breast cancer classification not only standardizes the data but also enhances the robustness and performance of subsequent classification algorithms. These preprocessing steps are essential for optimizing the accuracy and reliability of diagnostic systems aimed at early detection and intervention in breast cancer cases.

D. Data Augmentation with DCGAN

DCGAN have gained significant attention in recent years for their ability to generate synthetic data closely resembling real data. In medical imaging, DCGAN holds promise for tasks such as image synthesis, data augmentation, and anomaly detection. These images can then be used to augment the dataset for training a classification model, thereby improving its performance and generalization ability.

In Fig. 4, the Generator model is designed to generate synthetic ultrasound images copying real breast tissue images. The architecture comprises several layers, including dense, convolutional, and upsampling layers. The input to the Generator is a latent vector, typically drawn from a Gaussian

distribution, which is transformed into a high-dimensional representation through dense layers. Subsequently, upsampling layers increase the spatial resolution of the representation, generating images of the desired size. Batch normalization and activation functions such as ReLU ensure stable training and introduce non-linearity, respectively. The final layer produces synthetic images with pixel values normalized between 0 and 1.

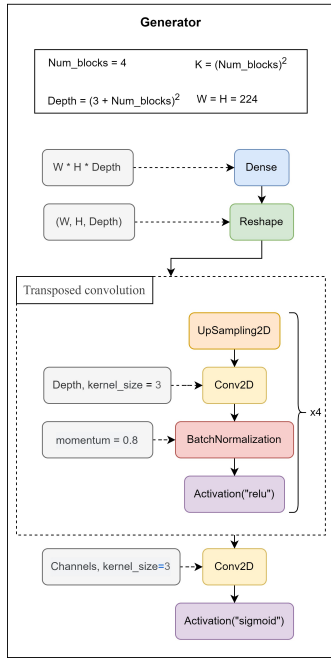

Fig. 4. The generator model of DCGAN.

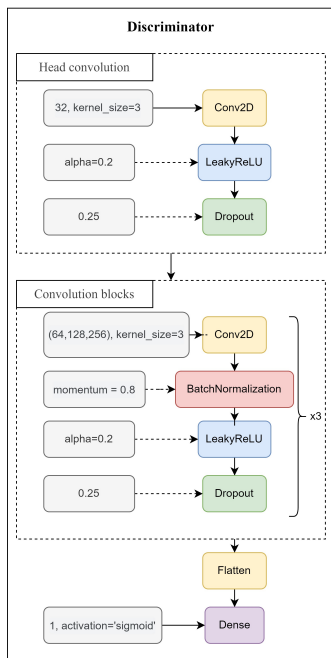

Fig. 5. The discriminator model of DCGAN.

sible for distinguishing between real ultrasound images and synthetic images generated by the Generator. It consists of convolutional layers followed by batch normalization, leaky ReLU activation, and dropout layers. The architecture progressively downsamples the input images, extracting hierarchical features. The final layer performs binary classification, outputting the probability that the input image is real.

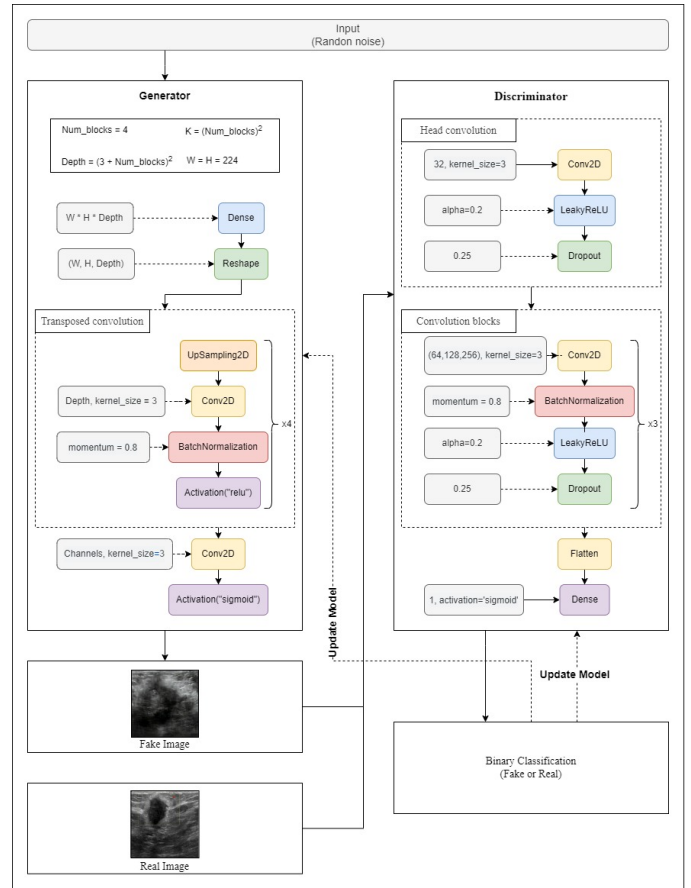

Fig. 6. The architecture of DCGAN.

During training in Fig. 6, the Generator and Discriminator are trained simultaneously in a min-max game. The Generator aims to generate images that are indistinguishable from real images, while the Discriminator aims to correctly classify between real and fake images. The two models are trained iteratively, with the Generator trying to minimize the probability of the Discriminator correctly classifying fake images, and the Discriminator trying to maximize this probability.

By iteratively updating the Generator and Discriminator models, the DCGAN learns to generate realistic ultrasound images, which can subsequently be used for tasks such as breast cancer classification. Integrating GAN-generated images into the training data can potentially improve the robustness and performance of classification models by providing additional diverse examples for learning. Moreover, future research directions include fine-tuning the DCGAN architecture, incorporating additional modalities, and expanding the dataset to improve generalization performance.

According to the Fig. 5, the Discriminator model is respon-

The proposed approach leverages adversarial training to

generate synthetic images that closely resemble real ultrasound images of breast tissue. Experimental results demonstrate the potential of DCGAN in enhancing the availability and diversity of medical image data for improving diagnostic accuracy in breast cancer detection.

E. Transfer Learning and Fine-tuning in AttentiveEfficient-GANB3

Transfer learning and fine-tuning are powerful techniques of deep learning, especially when dealing with tasks like image classification and segmentation. These methods allow using pre-trained models on large datasets and adapting them to new tasks with smaller datasets, thereby saving computational resources and time.

Transfer learning uses a pre-trained model which is usually trained on a large dataset like ImageNet and applying it to a new task. Instead of starting the training process from scratch, the knowledge of a model is transferred to the new task, particularly in extracting useful features from images. This is often achieved by removing the final classification layer of the pre-trained model and replacing it with a new layer suited to the specific task. On the other hand, Fine-tuning takes transfer learning a step further by not only adapting the final layers but also fine-tuning some of the earlier layers of the pre-trained model. This allows the model to adjust its learned representations to better suit the new task while still benefiting from the general features learned from the original dataset.

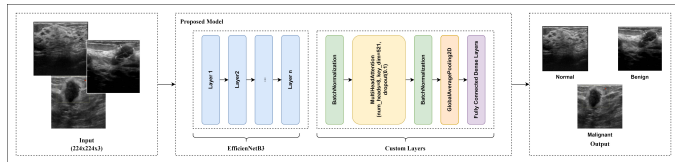

Fig. 7. The architecture of the proposed model.

In the research, transfer learning and fine-tuning can significantly improve model performance, especially when dealing with limited medical image datasets. In Fig. 7, the proposed model architecture utilizes EfficientNetB3 as the base model, which is known for its effectiveness in balancing model size and performance across various image classification tasks. Moreover, the proposed architecture integrates custom layers to further enhance its capabilities. One notable addition is the MultiHeadAttention layer, which introduces a mechanism for the model to focus on different parts of the input data independently. In the context of ultrasound images, this attention mechanism can help the model to effectively identify relevant features associated with breast cancer, thereby improving classification accuracy.

Fig. 7 includes BatchNormalization layers to stabilize and speed up the training process by normalizing the inputs to each layer. GlobalAveragePooling2D layer is used to reduce the spatial dimensions of the feature maps produced by the base model before feeding them into the final classification layers. The Dense layer serves as the final classification layer, where the model outputs predictions regarding the presence or absence of breast cancer based on the extracted features.

By using transfer learning from EfficientNetB3 and fine-tuning with custom layers such as MultiHeadAttention, the proposed model achieved strong performance in classifying breast cancer on ultrasound images, even with limited labeled and imbalanced data.

F. Visual Explanation with Gradcam

Grad-CAM is a technique used for visualizing the regions of an image that are influential in the decision-making process of a deep neural network model. It highlights the regions that the model focuses on when classifying an image. In this study, Grad-CAM can help identify the specific areas of an ultrasound image that contribute most significantly to the model's decision regarding the presence or absence of cancerous tissue. The process begins with a feedforward pass of the ultrasound image through a CNN model. This leads to the generation of feature maps across various convolutional layers. Following this, the gradient of the score of the target class for the feature maps of the final convolutional layer is calculated. Mathematically, this can be represented as (Fig. 8):

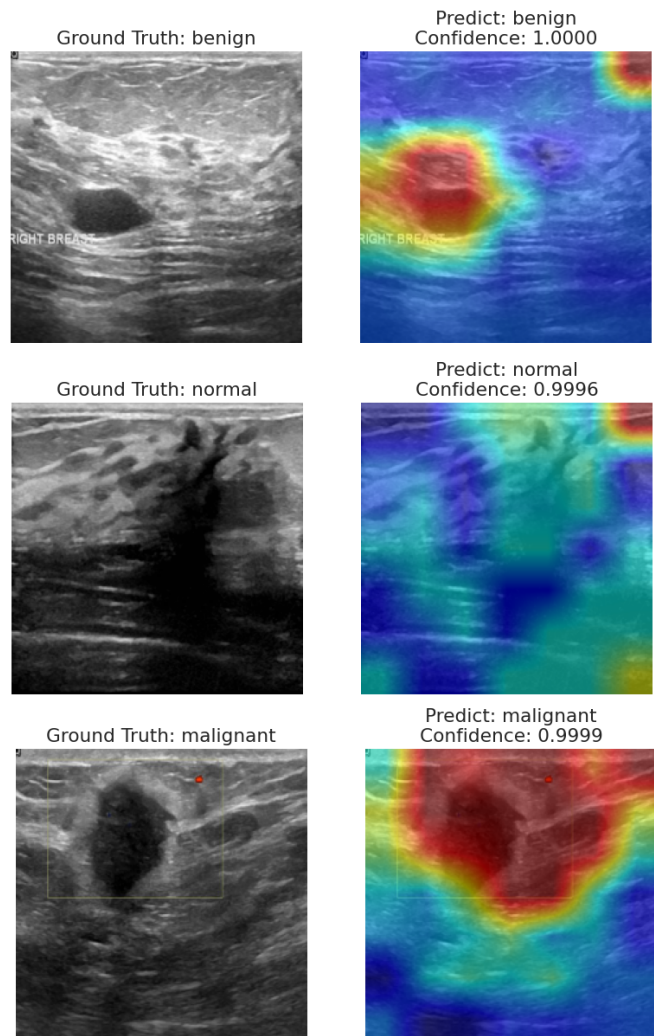

Fig. 8. The result of applying heatmap to the ultrasound image.

$$\alpha_k^c = \frac{1}{Z} \sum_i \sum_j \frac{\partial A_{ij}^k}{\partial y^c} \quad (3)$$

Where α_k^c Eq. (3) represents the importance weight associated with the k -th Eq. (3) feature map for the c -th Eq. (3) class. In addition, Z Eq. (3) is a normalization factor to ensure that the weights sum up to 1, preventing issues with the scale of the gradient values. Moreover, $\partial A_{ij}^k / \partial y^c$ Eq. (3) represents the partial derivative of the output score to the activation map A_{ij}^k Eq. (3). It quantifies how changes in the activation map affect the model's confidence score for class c Eq. (3). Next to that, the weighted combination step assigns the gradients of each feature map. This is achieved by weighting the gradients and applying a Rectified Linear Unit (ReLU) Eq. (4) activation function to ensure only positive influences are considered. Mathematically:

$$L_{\text{Grad-CAM}}^c = \text{ReLU} \left(\sum_k \alpha_k^c A^k \right) \quad (4)$$

Here, $L_{\text{Grad-CAM}}^c$ Eq. (4) represents the Grad-CAM heatmap for the c -th Eq. (4) class. Additionally, $\text{ReLU}()$ Eq. (4) indicates the Rectified Linear Unit activation function, which sets negative values to zero and keeps positive values unchanged. Besides, α_k^c Eq. (4) denotes the importance weight associated with the k -th Eq. (4) feature map for the c -th Eq. (4) class and A^k Eq. (4) signifies the k -th Eq. (4) feature map from the final convolutional layer of the CNN. The equation computes a weighted sum of the feature maps A^k Eq. (4) based on their importance weights α_k^c Eq. (4) for the class c Eq. (4). Finally, This weighted sum is then passed through the ReLU activation function to generate the Grad-CAM heatmap. This heatmap effectively highlights the regions within the ultrasound image that are critical for the decision-making process. By overlaying this heatmap onto the original ultrasound image, researchers and clinicians gain valuable insights into the specific areas that contribute to the model's classification

IV. EXPERIMENTS

A. Performance Metrics

In assessing the performance of breast cancer classification on ultrasound images, several metrics are commonly used: accuracy (ACC), precision, recall, and F1 score. These metrics help quantify the effectiveness of a classification model in correctly identifying cancerous and non-cancerous cases.

Accuracy Eq. (5) measures the overall correctness of the classification model and is calculated as the ratio of correctly classified instances to the total instances:

$$ACC = \frac{TP + TN}{TP + TN + FP + FN} \quad (5)$$

In Eq. (5), TP (True Positives) represents the number of correctly classified cancerous cases, TN (True Negatives) is the number of correctly classified non-cancerous cases, FP (False Positives) is the number of non-cancerous cases wrongly

classified as cancerous, and FN (False Negatives) is the number of cancerous cases wrongly classified as non-cancerous.

Precision Eq. (6) measures the proportion of correctly identified cancerous cases among all cases classified as cancerous. As a result, it highlights the model's ability to avoid misclassifying non-cancerous cases as cancerous:

$$Precision = \frac{TP}{TP + FP} \quad (6)$$

Recall Eq. (7) measures the proportion of correctly identified cancerous cases among all actual cancerous cases. Thus, it indicates the model's ability to correctly detect cancerous cases:

$$Recall = \frac{TP}{TP + FN} \quad (7)$$

The F1 score Eq. (8) is the harmonic mean of precision and recall, providing a single metric that balances between precision and recall. Hence, it gives an overall measure of the model's accuracy in identifying both cancerous and non-cancerous cases while considering the trade-off between precision and recall.

$$F1 = 2 \times \frac{Precision \times Recall}{Precision + Recall} \quad (8)$$

These metrics collectively offer a comprehensive evaluation of the performance of breast cancer classification on ultrasound images, aiding in the assessment and comparison of different classification models.

B. Scenario 1: The Performance of Classifying the Dataset without the Augmentation Method

TABLE I. THE RESULT IN PERFORMANCES OF CLASSIFYING ULTRASOUND IMAGES WITHOUT DATA AUGMENTATION TECHNIQUES

Model	Number of Parameters	Phase	Accuracy		Others metrics		
			Validation	Test	Precision	Recall	F1
DenseNet169	12.647.875	Transfer Learning	70.51%	62.82%	61.60%	62.82%	62.06%
		Fine Tuning	76.92%	73.08%	72.02%	73.08%	72.23%
Xception	20.867.627	Transfer Learning	75.64%	64.10%	63.94%	64.10%	64.00%
		Fine Tuning	80.77%	74.36%	74.34%	74.36%	73.70%
ViT B16	85.800.963	Transfer Learning	73.08%	61.54%	52.52%	61.54%	55.40%
		Fine Tuning	74.36%	66.67%	67.23%	66.67%	65.18%
ViT B32	87.457.539	Transfer Learning	69.23%	67.95%	70.22%	67.95%	64.51%
		Fine Tuning	74.36%	65.38%	66.98%	65.38%	63.72%
Proposed	36.763.954	Transfer Learning	87.18%	84.62%	85.30%	84.62%	84.67%
		Fine Tuning	87.18%	88.46%	88.53%	88.46%	88.47%

Table I presents the performance results of classifying ultrasound images without utilizing data augmentation techniques. It evaluates various models based on their accuracy during both the validation and test phases, precision, recall, and F1 score. Among the models assessed, DenseNet169, Xception, ViT B16, and ViT B32 are included. These models run over two phases: transfer learning and fine-tuning. Notably, the proposed model achieves an accuracy of 87.18% in validation and an impressive 88.46% in test of the fine-tuning phase. Despite having a larger number of parameters, ViT B16 and ViT B32 models show comparatively lower performance metrics than some other models in the table. For instance, ViT B16 has 85,800,963 parameters with a test accuracy of 67.95%, while ViT B32 has 87,457,539 parameters with a test accuracy of 65.35%, both significantly more than the proposed model

Fig. 9. The line graph illustrates about training and validation phases of accuracy in the experiment without data augmentation methods.

with 36,763,954 parameters. In addition, the performance in precision, recall, and F1 of the proposed model also achieved high scores of 85.30%, 84.62%, and 84.67%, respectively.

Fig. 10. The line graph illustrates about training and validation phases of loss in the experiment without data augmentation methods.

With line graphs in Fig. 9 and 10, these graphs show the trend of accuracy and loss scores during the training and validation phases. In Fig. 9, The line graph illustrating the training and validation phases of accuracy in the experiment without data augmentation methods showcases the performance of the model throughout the training process. In this specific experiment, the training accuracy reaches a high of approximately 98.08%, while the validation accuracy peaks at around 87.18%. On the other hand, Fig. 10 illustrating the training and validation phases of loss in the same experiment depicts the convergence of the model's loss function during training. In this case, the training loss reaches a low of approximately 0.0603, while the validation loss peaks at around 0.9298 during the fine-tuning phase. Besides, The confusion matrix in Fig. 11 helps evaluate the performance of breast cancer classification models by providing insight into actual and predicted percentages, enabling assessment of model accuracy and error types.

Fig. 11. The confusion matrix in the experiment without applying data augmentation methods.

C. Scenario 2: The Performance of Classifying the Dataset with Simple Augmentation Methods Such as Rotation, Flip, etc

TABLE II. THE RESULT IN PERFORMANCES OF CLASSIFYING ULTRASOUND IMAGES WITH SIMPLE DATA AUGMENTATION TECHNIQUES

Model	Number of Parameters	Phase	Accuracy		Others metrics		
			Validation	Test	Precision	Recall	F1
DenseNet169	12.647.875	Transfer Learning	70.30%	67.59%	68.15%	67.59%	67.65%
		Fine Tuning	89.10%	89.77%	89.75%	89.77%	89.73%
Xception	20.867.627	Transfer Learning	59.19%	61.62%	62.17%	61.62%	61.60%
		Fine Tuning	73.08%	74.84%	75.02%	74.84%	74.87%
ViT B16	85.800.963	Transfer Learning	59.62%	60.98%	61.71%	60.98%	61.13%
		Fine Tuning	69.02%	67.59%	69.07%	67.59%	67.36%
ViT B32	87.457.539	Transfer Learning	55.34%	55.86%	56.16%	55.86%	55.59%
		Fine Tuning	58.76%	56.29%	58.70%	56.29%	53.84%
Proposed	36.763.954	Transfer Learning	92.31%	92.96%	92.99%	92.96%	92.93%
		Fine Tuning	94.66%	95.31%	95.36%	95.31%	95.29%

Fig. 12. The line graph illustrates about training and validation phases of accuracy in the experiment using simple data augmentation methods.

In Table II, various models are evaluated for their performance in classifying ultrasound images using simple data augmentation techniques. Notably, the proposed model stands out with the highest accuracy rates in both validation and test phases surpassing all other models. Specifically, in the fine-tuning phase, the proposed model achieved an impressive 94.66% accuracy on the validation set and 95.31% on the test set. This significant increase in accuracy suggests that the

Proposed model exhibits superior performance compared to the other models. Considering the other models, DenseNet169 has the largest growth of 22.18% between the two phases in the test set indicating that DenseNet169 is consistent with the augmentation techniques in this experiment. Besides, ViT B16 saw a slight increase when compared with Table I. On the opposite, ViT B16 fell significantly which showed that ViT did not adapt to several simple augmentation techniques.

D. Scenario 3: The Performance of Classifying the Dataset with DCGAN Augmentation Methods

TABLE III. THE RESULT IN PERFORMANCES OF CLASSIFYING ULTRASOUND IMAGES WITH DCGAN DATA AUGMENTATION TECHNIQUE

Model	Number of Parameters	Phase	Accuracy		Others metrics		
			Validation	Test	Precision	Recall	F1
DenseNet169	12.647.875	Transfer Learning	94.78%	94.53%	94.64%	94.53%	94.52%
		Fine Tuning	97.01%	97.51%	97.51%	97.51%	97.51%
Xception	20.867.627	Transfer Learning	84.83%	83.58%	85.18%	83.58%	83.71%
		Fine Tuning	96.02%	94.78%	94.83%	94.78%	94.79%
ViT B16	85.800.963	Transfer Learning	95.27%	94.03%	94.03%	94.03%	94.03%
		Fine Tuning	95.27%	93.78%	94.24%	93.78%	93.85%
ViT B32	87.457.539	Transfer Learning	94.03%	93.03%	93.44%	93.03%	93.09%
		Fine Tuning	95.77%	94.28%	94.63%	94.28%	94.33%
Proposed	36.763.954	Transfer Learning	97.26%	96.52%	96.52%	96.52%	96.52%
		Fine Tuning	97.76%	98.01%	98.01%	98.01%	98.01%

Fig. 13. The line graph illustrates about training and validation phases of loss in the experiment using simple data augmentation methods.

Fig. 14. The confusion matrix in the experiment using simple data augmentation methods.

The accuracy and loss scores for the two training and validation stages are shown in Fig. 12 and 13. This line chart facilitates general evaluation during the training epoch by presenting the accuracy and loss scores in an easy-to-understand and intuitive manner. Moreover, the efficacy of deep learning models for breast cancer categorization is evaluated using the confusion matrix presented in Fig. 14. Normal indicates an impressive percentage between actual and predicted of 99%. Next, benign and malignant have a huge proportion of 92% and 95%, respectively.

The proposed model achieves impressive results in both transfer learning and fine-tuning phases in Table III. In transfer learning, the model achieves a validation accuracy of 97.26% and a test accuracy of 96.52%. Fine-tuning further enhances performance, with validation and test accuracies reaching 97.76% and 98.01%, respectively. Precision, recall, and F1-score metrics also demonstrate high values of 96.52% and 98.01% across both phases, indicating robust performance in classifying ultrasound images. Among other models, DenseNet169 exhibits competitive performance, especially in fine-tuning, with a test accuracy of 97.51%. Xception, although having fewer parameters compared to DenseNet169, demonstrates slightly lower accuracy in both transfer learning and fine-tuning phases. ViT B16 and ViT B32 also exhibit respectable performance, albeit with varying degrees of accuracy across transfer learning and fine-tuning. The comparative analysis highlights the efficacy of the proposed model utilizing GAN data augmentation in ultrasound image classification.

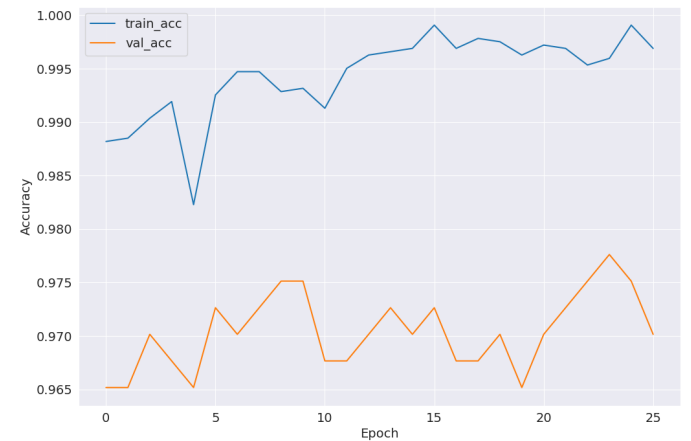

Fig. 15. The line graph illustrates about training and validation phases of accuracy in the experiment employing GAN.

Furthermore, Training and validation on both accuracy and loss scores are presented in Fig. 15 and 16. Following the figures, the evaluation performance of our model presents the balance when the dataset is changed. Moreover, Fig. 17 is provided for evaluating, optimizing, and understanding the performance of deep learning models in classifying breast cancer providing insight into actual and predicted rates that can lead to improved accuracy and reliability.

E. Scenario 4: The Influence of the Self-attention Mechanism on Performance over Experiments

TABLE IV. PERFORMANCE COMPARISON IN RESULTS BETWEEN WITH AND WITHOUT MULTI-HEAD ATTENTION

Data Augmentation	Model	Phase	Accuracy		Others metrics		
			Validation	Test	Precision	Recall	F1
No-Augmentation	Without Attention	Transfer learning	82.05%	82.05%	82.29%	82.05%	81.98%
		Fine tuning	82.05%	84.62%	86.78%	84.62%	85.01%
		Transfer Learning	87.18%	84.62%	85.30%	84.62%	84.67%
	Attention	Fine Tuning	87.18%	88.46%	88.53%	88.46%	88.47%
		Transfer Learning	83.76%	83.58%	83.78%	83.58%	83.63%
		Fine Tuning	92.95%	92.54%	92.57%	92.54%	92.54%
Simple Augmentation	Attention	Transfer Learning	92.31%	92.96%	92.99%	92.96%	92.93%
		Fine Tuning	94.66%	95.31%	95.36%	95.31%	95.29%
		Transfer Learning	97.26%	97.01%	97.05%	97.01%	97.02%
GAN	Attention (Proposed)	Fine Tuning	97.76%	97.26%	97.29%	97.26%	97.27%
		Transfer Learning	97.26%	96.52%	96.52%	96.52%	96.52%
		Fine Tuning	97.76%	98.01%	98.01%	98.01%	98.01%

Table IV provides a comprehensive comparison of model performance with and without multi-head attention across different phases and data augmentation scenarios. It primarily focuses on test accuracy and other relevant metrics like precision, recall, and F1 score.

When analyzing the results, it is clear that models with attention consistently outperform those without attention in terms of accuracy. This improvement is especially notable when data augmentation techniques are applied. For instance,

in the Simple Augmentation scenario, the test accuracy increases from 83.58% to 92.96% when the attention mechanism is added to the model. The proposed attention model in the DCGAN data augmentation scenario shows superior performance compared to other configurations. In the Fine Tuning phase, the proposed attention model achieves a remarkable test accuracy of 98.01%, indicating the effectiveness of the multi-head attention mechanism.

In comparison to the first experience without applied DCGAN and Attention mechanism, the model increased by 13.39% between 98.01% and 84.62% in the fine-tuning phase of test accuracy. The observed increase in test accuracy across various experiments underscores the significance of incorporating multi-head attention mechanisms in deep learning models for enhanced performance across diverse tasks and datasets.

V. RESULTS AND COMPARISON

A. Results

After analyzing the previous scenarios, Fig. 18 was created to visualize the result in the past experiments. Specifically, the DCGAN technique demonstrated the effectiveness on dataset BUSI with an increase of 9.55% in test accuracy when compared without the augmentation technique. Moreover, the proportion is larger than 2.65% when compared with simple augmentation techniques. Other performances such as precision, recall, and f1 score also witnessed a dramatic climb with DCGAN. Besides, the result of a combination of self-attention mechanism was presented in Table IV. Thus, It indicated AE-GANB3 framework truly helped in the classification process with a surprising rise in accuracy by 13.39% from 98.01% to 84.62%. In conclusion, the proposed framework has actively contributed to the process of researching image classification using machine learning

Fig. 18. The result of comparison over scenarios.

B. Comparison with others State-of-the-art Methods

Utilizing comparisons with other state-of-the-art methods is an integral aspect of research. These comparisons serve multiple purposes within the scientific community. Firstly, they establish benchmarks against which new methods can be evaluated, providing a baseline for assessing performance improvements. Secondly, such comparisons validate the effectiveness of proposed approaches, strengthening the case for their adoption. Additionally, they aid in identifying limitations or weaknesses in existing methods, offering insights for further refinement. Understanding how a new method

compares to others also provides context for its significance and relevance within the field, highlighting its innovative contributions. Moreover, comparisons can inspire new ideas for improvement by analyzing the strengths and weaknesses of existing approaches. Thus, Table V was created for comparisons rigorously, considering factors such as dataset and evaluation metrics.

TABLE V. COMPARISON WITH OTHER STATE-OF-THE-ART METHODS IN DATASET BUSI

Reference	Other methods	Year	Accuracy
Mohammed Alotaibi et al. [21]	VGG19	2023	87.8%

	Proposed Model		98.01%

VI. CONCLUSION

In conclusion, this research harnesses the power of deep learning architectures to address crucial challenges in medical imaging, particularly in the early detection of breast cancer. Through the utilization of DCGAN for synthesizing realistic ultrasound images and augmenting datasets, coupled with a novel hybrid CNN and ViT architecture. The study aimed to enhance the accuracy and efficacy of breast cancer classification models. The AttentiveEfficientGANB3 (AEGANB3) framework was proposed with its incorporation of augmentation techniques and self-attention mechanisms. Thus, it showed a remarkable improvement in classification accuracy, reaching an impressive 98.01% in the test set. Moreover, the integration of Grad-CAM provides valuable insights into the decision-making process of deep learning models, which enhances interpretability and fostering trust.

However, it is essential to acknowledge the limitations of this research. One such limitation is the reliance on synthetic data generated by DCGAN, which may not fully capture the variability and complexity present in real-world ultrasound images. Additionally, the interpretability provided by Grad-CAM, while insightful, may not encompass the full spectrum of factors influencing model decisions. Looking ahead, future research endeavors should aim to address these limitations and further increase the robustness and generalization capabilities of breast cancer classification models. This could involve exploring alternative data augmentation techniques, such as generative adversarial networks with more advanced architectures.

In summary, while this research represents a significant step forward in leveraging deep learning for breast cancer detection, there remain opportunities for further innovation and refinement. By addressing the identified limitations and pursuing avenues for future work, the future study can continue to advance the field of medical imaging and contribute to improved patient outcomes in the fight against breast cancer.

Faculty of Control and Automation, Electric Power University, Ha Noi, Viet Nam²

Abstract—A membership inference attack (MIA) on machine learning models aims to determine the sensitive data that has been used to train machine learning models. Machine learning-based applications (MLaaS—machine learning as a service) in finance, banking, healthcare, etc. are facing the risks of private data leaks by MIA. Several solutions have been proposed for mitigating MIA attacks, such as confidence score masking, regularization, knowledge distillation (KD), etc. However, the utility-privacy trade-off problem is still a major challenge for existing approaches. In this work, we explore the KD-based approach to defending against MIA attacks. This approach has received increasing attention in the research community on machine learning safety recently as it aims at effectively addressing the above-mentioned challenge of mitigating MIA attacks. An efficient KD-based defense framework that includes multiple teacher and student models is proposed in this work for alleviating MIA attacks. Three main phases are deployed in this framework: (1) teacher model training; (2) knowledge distillation from the teacher model to the student model based on prediction augmentation and aggregation from the teacher model; and (3) repeated knowledge distillation among student models. The experimental results on standard datasets show the outperforms in both model utility and privacy of the proposed framework compared to other state-of-the-art solutions for mitigating MIA.

Keywords—Knowledge distillation; membership inference attack; teacher model; student model; privacy-utility trade-off

I. INTRODUCTION

A membership inference attack (MIA) is one kind of AI security attack in which the attackers try to determine if the sensitive information used in training a machine learning model. In some AI-based applications, protecting the privacy of training data is an important requirement, such as individuals' bank account numbers, credit/debit card details, transaction data or patients' medical records. In the common MIA attack scenario, two machine learning models are considered: (1) the target model, which is trained on the dataset that needs to be kept private, and (2) a MIA model, which is trained by the attacker. Based on MIA model, the attacker can predict whether a particular data sample is a member or non-member of the private training set. The extent of MIA attacks on machine learning models depends on the information obtained by the attackers. This can be (i) the shadow data, which is the one that has the same distribution as the data used to train a target model; (ii) the knowledge of the target model, including the model architecture, the learned parameters like weights or coefficients, and the learning algorithm. The white-box attacks rely on the knowledge of the target model and the training

data distribution of the target model. In a black-box attack, the attackers can only approach the trained target model (e.g., a target classifier) and get the prediction outputs from this model.

Several solutions have been proposed to mitigate the MIA attacks. They can be classified into four main approaches: confidence score masking, regularization, differential privacy, and knowledge distillation. In the first approach, the confidence scores of class predictions in the output vector of the target model are masked to prevent information leakage from these [1]. This technique is mainly deployed for black-box attacks on the classification models. Therefore, it is easily deployed without any intervention inside the target model. The defensive intervention only happened with model output. However, this defense method can still be breached by attack methods such as label-only attacks [2] or metric-based attacks [3]. The regularization technique aims at preventing model overfitting, which is a key factor in the success of MIA attacks. Several solutions to this approach are proposed, such as L2-norm regularization, data augmentation, and dropout [4], Adversarial Regularization [5]. The regularization technique not only interferes with the output of target models but also their internal parameters. Therefore, it can be applied to both black-box and white-box MIA attacks. Although the regularization technique is widely applied and effective against MIA attacks, the accuracy of the target models is inversely proportional to the privacy level that this technique provides. This means the regularization technique brings high privacy to the target models, but it can also reduce their accuracy [6]. In the defense method of differential privacy, the personal information is added to the noise. This will make it difficult for MIA attackers to identify the original data. However, the challenge when applying this method is to find a reasonable way to balance the effectiveness between the overall accuracy and its privacy against MIA attacks [7]. The last defense approach to MIA attacks is Knowledge Distillation (KD). KD was introduced in [8] as one of the transfer learning methods. The fundamental concept of the KD is derived from the process of human learning, in which information is transferred from a teacher with greater knowledge to a student with less understanding. The teacher models are much larger than the student models. However, based on the knowledge distilled from the teacher model, the student model still achieves almost the same performance as the teacher model. The KD-based defense models for mitigating MIA attacks require two datasets named private and reference datasets. The private dataset is used to train the

teacher model, which is considered the unprotected model. The reference dataset is soft labeled based on the predictions of the trained teacher model. The soft-labeled reference dataset is utilized to train the student model, which is considered a protected model. The reference dataset can be the unlabeled public dataset [9] or the private one [10]. The main challenge for the KD-based defense models is the private-utility trade-off of the protected model. In addition, the student/protected model is desired to have as high accuracy as the teacher model.

Among the above-mentioned approaches, the KD-based method against MIA attacks has been attracting the research community recently because of its higher defense capacity than many other solutions while still ensuring the model's performance. However, the private-utility trade-off is still an open issue with this approach. Focusing on this, in this work, we propose a new framework based on KD for mitigating MIA attacks. It is different from other available KD-based approaches, in this framework, we deploy (1) soft labeling of the reference dataset by prediction augmentation and aggregation from the teacher model and (2) repeated knowledge distillation among multiple student models. The prediction augmentation is executed through teacher model calibration with several temperature parameters. This will output several class probability distributions for each input sample. The prediction aggregation from the teacher model is done based on an optimal selection of the prediction probabilities from the teacher model. This helps to create uniform distribution predictions over all classes and contains no useful information for MIAs while still maintaining the classification performance of the target model. In addition to knowledge distillation from the teacher model to a student model as other works, in this work, we first conduct knowledge transfer from one student model to another student model multiple times. This creates multi-layer masking for the target dataset and helps strengthen the defense ability of the target model against MIAs. The experimental results on standard public datasets show the outperformance of our contributions on not only classification performance but also the defense ability of the target model against MIAs compared to other related state-of-the-art (SOTA) methods.

The remainder of this paper is organized as follows: In Section II, we briefly survey recent related works based on KD for mitigating MIA attacks. The proposed methodology is presented in Section III. The experimental results are analyzed in Section IV. Finally, Section V concludes the paper and states research directions for future work.

II. RELATED WORK

The knowledge distillation technique was originally designed to reduce computational cost and memory requirements while maintaining the performance of deep learning models. This enables deep learning models to be deployed on devices with limited computing and storage capacity. Recently, the KD approach has also been exploited in cyber security with KD-based defense against MIA attacks.

In [9] a KD-based defense solution against MIAs, named DMP (Distillation for Membership Privacy) is proposed. DMP requires two datasets: a private dataset and a reference dataset. The private dataset is the labeled dataset and needs to be

protected from attacks. The reference data is sensitive and unlabeled. It is drawn from the same distribution as the private training dataset and used to train the target model. These datasets are utilized in three phases of DMP, including the pre-distillation phase, the distillation phase, and the post-distillation phase. In the first phase, an unprotected model is trained on a private dataset. This model is then used in the second phase to generate a reference dataset that minimizes membership privacy leakage and transfers its knowledge to the protected model. In the final phase, the protected model is trained on the reference data with both ground truth and predictions from the unprotected model. DMP is the first method based on KD. In comparison with other previous approaches against MIAs, it improved not only the defense capacity but also the model's performance on some benchmark datasets. However, obtaining a large amount of publicly available reference data with the same distribution as private data is challenging in practice. Moreover, the reference data generation by DC-GAN as conducted in [9] seems to be a more reasonable solution for this challenge, but it reduces the performance of the model.

The solution proposed in [11] to address the challenge raised in [9]. The reference dataset in [11] is a part of the private dataset, not the public one as in [9]. In order to overcome the overfitting that can occur with this selection, the authors in [11] proposed KCD (Knowledge Cross-Distillation) for membership privacy. KCD uses multiple teacher models to transfer knowledge to the student model (target model). The private dataset is divided into several parts. The knowledge transfer process is done several times. At each time, consider one part of the private dataset as a reference dataset and other parts as a private dataset. The private dataset is used to train the teacher model, and the reference dataset part is soft labeled by the trained teacher model. Finally, we get soft-labeled reference data parts and utilize them to train the target model. Similarly, the work in [10] proposed a multi-teacher architecture to transfer knowledge to the student model. The private dataset is split into K disjoint partitions of the same size. The teacher models are trained on these partitions in the manner of K -fold cross validation. The soft targets are generated from these trained teacher models, and they are used to train the student model in the distillation phase. In general, in comparison with [9], the multi-teacher knowledge distillation decreases the attack accuracy and improves the classification performance of the target model. However, experimental results on widely used datasets show that the testing accuracy of the proposed target models is only less than 86%. It is still necessary to increase the classification performance of the target model and ensure data privacy against MIA attacks.

In this work, we propose an efficient KD-based framework for mitigating MIA attacks. It is similar to the approach of [11], [10]; in this framework, the sensitive dataset is split into two parts: one for training the teacher model, and the other is softly labeled by the teacher model and used for training the student model. The teacher model are trained in the manner of two-fold cross validation. However, it is different from the above approaches in that soft labeling for the reference dataset is done by prediction augmentation and aggregation from the teacher model. Furthermore, in this research, we add an additional layer of knowledge distillation that is repeatedly implemented by the student models. Other related works only stop at

transferring knowledge from one or more teacher models to a student model and using this student model as a defensive model against MIA attacks. However, in our work, an optimal defense model will be selected from the student models. This aims at creating multi-layer masking for privacy data and then helps strengthen the defense ability of the target model against MIA attacks. The details of the proposed framework will be discussed in the next section.

III. METHODOLOGY

A. The Overall Framework

The overall defense framework against membership inference attacks is shown in Fig. 1. There are three main blocks in this framework: (1) teacher model training; (2) knowledge distillation from the teacher model to the student model (Teacher-Student KD) based on prediction augmentation and aggregation from the teacher model; and (3) repeated knowledge distillation (Repeated Student KD) from the student model θ_S^{n-1} to the θ_S^n , with n is the number of times the student model θ_S is executed.

Inspired by the idea of [11], in this work, we also deploy the sensitive private dataset for our proposed KD-based defense system. The data scenario for the training teacher model and knowledge distillation from the teacher to the student model is shown in Fig. 2.

We have a sensitive private dataset D , and we split it into two parts, D_1 and D_2 . We first use D_1 for training teacher model θ_T . The trained θ_T will be utilized for soft labeling D_2 . Secondly, we train the teacher model θ_T on D_2 and use the trained model θ_T to soft label D_1 . The datasets with soft labels named D_1' and D_2' will be used to train the student model for the first time (θ_S^1). In order to express this generally (in Fig. 1), we refer to the parts of the dataset used for training teacher model θ_T as D_{Pri} and the ones for soft labeling as D_{Ref} :

- $D_{Pri} = \{(x_{1P}, y_{1P}), \dots, (x_{NP}, y_{NP})\}$ ($N_P = |D_{Pri}|$)
- $D_{Ref} = \{(x_{1R}), \dots, (x_{NR})\}$ with the corresponding hard labels $\{(y_{1R}), \dots, (y_{NR})\}$

In block 1, we train the teacher model on the D_{Pri} . The D_{Pri} is split to D_{Pri}^{train} which is used to train the teacher model θ_T , a test split D_{Pri}^{test} and a validation split D_{Pri}^{val} . The teacher model θ_T is trained using D_{Pri}^{train} until the training converges to minimize the loss

$$\sum_{(x_P, y_P) \in D_{Pri}^{train}} L(\theta_T(x_P), y_P)$$

In block 2, we utilize the trained θ_T to soft label the $D_{Ref} = \{x_{1R}, \dots, x_{NR}\}$, and D_{Ref} is labeled by θ_T : $y_{NR}^0 = \theta_T(x_{NR})$. The soft labeled data $D_{Ref}^0 = \{(x_{1R}, y_{1R}^0), \dots, (x_{NR}, y_{NR}^0)\}$ will be utilized as ground truth for training the student model θ_S^1 : $\theta_S^1(x_{NR}, \theta_T(x_{NR}))$ until the training converges to minimize the loss:

$$\begin{aligned} & \alpha \sum_{(x_R, y_R^0) \in D_{Ref}^0} L(\theta_S^1(x_R), y_R^0) + \\ & (1 - \alpha) \sum_{(x_R, y_R) \in D_{Ref}} L(\theta_S^1(x_R), y_R) \end{aligned} \quad (1)$$

where y_R^0 is soft label returned by θ_T for the input x_R , and y_R is the hard label of x_R .

The soft labeling is implemented based on prediction augmentation and aggregation from the teacher model. The details for this will be represented in the next subsection.

In block 3, D_{Ref} will be soft labeled by θ_S^1 : $y_{NR}^1 = \theta_S^1(x_{NR})$. The soft-label data $D_{Ref}^1 = \{(x_{1R}, y_{1R}^1), \dots, (x_{NR}, y_{NR}^1)\}$ will be utilized as ground truth for training the student model θ_S^2 : $\theta_S^2(x_{NR}, \theta_S^1(x_{NR}))$. The soft labeling is implemented based on prediction from θ_S^1 until the training converges to minimize the loss

$$\begin{aligned} & \alpha \sum_{(x_R, y_R^1) \in D_{Ref}^1} L(\theta_S^2(x_R), y_R^1) + \\ & (1 - \alpha) \sum_{(x_R, y_R) \in D_{Ref}} L(\theta_S^2(x_R), y_R) \end{aligned} \quad (2)$$

The soft data labeling and knowledge distillation steps are implemented repeatedly from θ_S^{n-1} to θ_S^n . The final student model θ_S^n will be considered the protected model or a defense model against MIA attacks. The target model θ_S^n is trained until it converges to the loss

$$\begin{aligned} & \alpha \sum_{(x_R, y_R^n) \in D_{Ref}^{n-1}} L(\theta_S^n(x_R), y_R^{n-1}) + \\ & (1 - \alpha) \sum_{(x_R, y_R) \in D_{Ref}} L(\theta_S^n(x_R), y_R) \end{aligned} \quad (3)$$

In the proposed system, we believe that the soft labeling for D_{Ref} by prediction augmentation from the teacher model in block 1 will create uniform distribution predictions over all classes and contain no useful information for MIAs. In addition, the knowledge distillation from the teacher model θ_T to the first student model θ_S^1 is implemented by the combination of learning from ground-truth labels and teacher predictions. Based on this, the student model θ_S^1 can learn more effectively not only from the behavior of θ_T on x_R but also from the D_{Pri} . This helps the student model θ_S^1 have the competitive classification performance with the teacher model. Moreover, in the block 3, the repeated knowledge distillation from θ_S^{n-1} to θ_S^n creates multi-layer masking for the D_{Ref} dataset. This will help strengthen the defense ability of target model θ_S^n against MIAs on the original sensitive private dataset D .

B. Prediction Augmentation and Aggregation from the Teacher Model

The prediction augmentation and aggregation from the teacher model θ_T for soft labeling D_{Ref} are shown in Fig. 3.

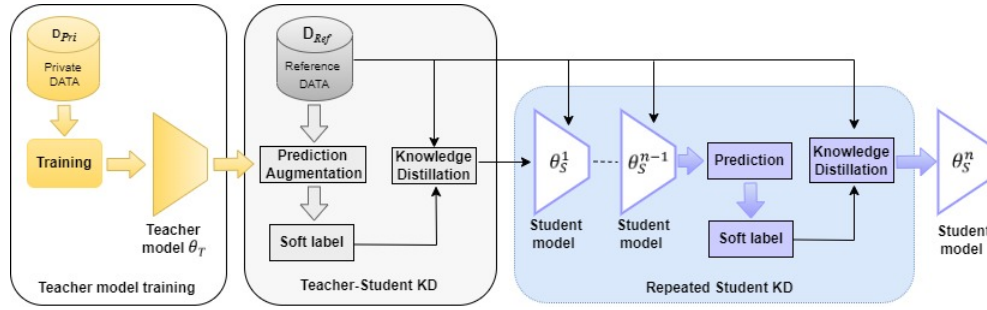

Fig. 1. The overall defense framework for membership inference attacks based on knowledge distillation from prediction augmentation of teacher model and repeated knowledge distillation of student models.

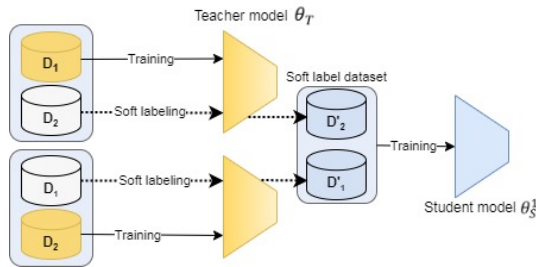

Fig. 2. The data scenario for training teacher and student models.

It should be noted in this figure that the repeated KD from one student model to another is done by prediction augmentation.

We have an unlabeled dataset $D_{Ref} = \{x_{1R}, \dots, x_{NR}\}$ that needs to be labeled by the teacher model θ_T . Given an input x_R , θ_T estimates the probability that $P(y_R = c | x_R)$ for each class value of $c = 1, \dots, C$. Thus, θ_T will output a C -dimensional vector whose elements sum to 1, or give out C estimated probabilities:

$$p_i = \text{softmax}(z_i) = \frac{e^{z_i}}{\sum_{j=1}^n e^{z_j}} \quad \text{for } i = 1, 2, \dots, C \quad (4)$$

where $z, p \in \mathbb{R}^C$ and \mathbf{z} is the output vector of the last layer of the teacher model; $0 < p_i < 1$ and $\sum_i p_i = 1$. Using the temperature parameter in softmax for controlling the softness of the probability distribution, we have the probabilities as follows:

$$p_i = \text{softmax}_T(z_i) = \frac{e^{z_i/T}}{\sum_{j=1}^n e^{z_j/T}} \quad (5)$$

where T is called the temperature parameter. When T gets lower, the biggest value in x_R get more probability, when T gets larger, the probability will be split more evenly on different elements. In this work, we conduct prediction augmentation through teacher model calibration with K temperature parameters. This means, for a single input x_R , the teacher model θ_T will output K probability distributions p_j^k according to K temperature parameters ($k = 1, 2, \dots, K$); j is the number of the classes ($j = 1, 2, \dots, C$), as follows:

$$\begin{aligned} p_j^1 &= [p_1^1, p_2^1, \dots, p_C^1] \\ p_j^2 &= [p_1^2, p_2^2, \dots, p_C^2] \\ &\dots \\ p_j^K &= [p_1^K, p_2^K, \dots, p_C^K] \end{aligned} \quad (6)$$

where p_j^k is calculated as follows:

$$p_j^k = \frac{e^{z_j/T_k}}{\sum_{j=1}^n e^{z_j/T_k}} \quad (7)$$

where T_k is a temperature hyper-parameter ($k = 1, 2, \dots, K$).

In order to avoid the leakage of D_{pri} from MIA attacks, there should be a uniform distribution over all classes for x_R , but we must still ensure the classification accuracy of the model. This means we need to have an uniform probability distribution of the classes but still keep a maximum probability which assigns to a certain class by each output probability distribution respect to each T_k . In order to achieve this goal, we firstly consider the predictions of θ_T in case of the smallest value of T_k , which is equivalent to p_j^k with $k = 1$ or p_j^1 . In the set of $p_j^1 = \{p_1^1, p_2^1, \dots, p_C^1\}$, we examine two subsets of the prediction probabilities. One contains high probability values (HP), and the other includes low probability values (LP). HP contains the $\max_{j=1 \div C} \{p_j^1\}$ and its neighborhoods N_ϵ that are significantly lower than $\max_{j=1 \div C} \{p_j^1\}$, as follows:

$$HP(p) = \left[\max_{j=1 \div C} \{p_j^1\}, N_\epsilon \right] \quad (8)$$

with N_ϵ is represented as follows:

$$N_\epsilon \left(\max_{j=1 \div C} \{p_j^1\} \right) = \left\{ p \in p_j^1 \mid d \left(p, \max_{j=1 \div C} \{p_j^1\} \right) < \epsilon \right\} \quad (9)$$

LP contains the remaining probability values in p_j^1 : $LP(p) = p_j^1 \cap HP(p)$.

At other T_k , ($k = 2, \dots, K$), we have the probability distributions for each class j , ($j = 1, \dots, C$). The final probability

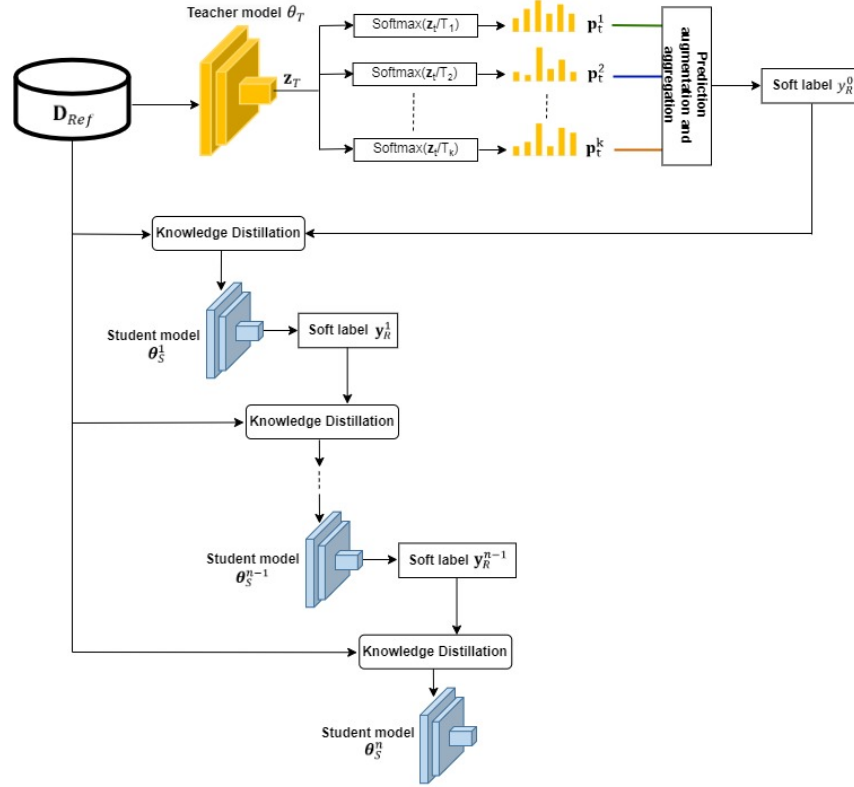

Fig. 3. The prediction augmentation and aggregation from the teacher model for the soft labeling of the reference dataset and the repeated knowledge distillation from one student model to another.

distribution for an input x_R with prediction augmentation from θ_T model by K temperature parameters will be aggregated as follows:

$$p_{j,x_R} = \left\{ \min_{j=1 \div C} \{p_j^k\} \mid p_j^k \in HP(p) \right\} \cup \left\{ \max_{j=1 \div C} \{p_j^k\} \mid p_j^k \in LP(p) \right\} \quad (10)$$

We then label the samples $\{x_{1_R}, \dots, x_{N_R}\}$ of reference dataset D_{Ref} according to the maximum probability element in p_{j,x_R} predicted by the teacher model θ_T .

IV. EXPERIMENT AND RESULT

A. Experimental Datasets and Teacher, Student model Structures

In this work, several datasets are utilized for experiments: Purchase100¹, Texas100², CIFAR10, CIFAR100 [12], MNIST³, MS-COCO [13], and ImageNet [14].

The Purchase100 dataset used in this work is set as in [6]. It contains 197,324 records of the user's product transactions each year. Each record contains 600 binary features that represent whether the user has purchased the product or not.

The records are grouped into several classes, each representing a different purchase style. The Purchase100 dataset is set for 5 different classification tasks with a different number of classes: 2, 10, 20, 50, 100. The classification task is to predict the purchase style of a user given the 600-feature vector.

Texas100 dataset as used in [6] for the classification task. The dataset contains 100 classes of patient records with 67,300 binary feature vectors with a dimension of 6,170. Each dimension corresponds to symptoms and its value states if the corresponding patient has the symptom or not; the label represents the treatment given to the patient.

CIFAR10 and CIFAR100 are popular image classification datasets. CIFAR10 contains 60,000 RGB images with the size of 32×32 pixels for each. Each image is labeled in one of 10 classes. CIFAR100 has 100 classes containing 600 images each. There are 20 super classes out of 100 in the CIFAR100. Each image is labeled with the superclass and the class to which it belongs.

MNIST dataset contains 70,000 grey-scale images of handwritten digits. There are 10 classes, one for each digit '0' to '9'. MS-COCO dataset is a mainstream dataset for object detection, with 118,000 training images and 5,000 validation images from 80 categories. ImageNet is a benchmark dataset for image classification, with nearly 1.3 million training images and 50,000 images for validation. The images come from 1,000 categories.

In this work, we use the same architecture for teacher and student models. The dataset split for experiments and the

teacher/student model structures are shown in Table I. For example, in the Purchase100 dataset, 10,000 samples are set for each D_{Pri} and D_{Ref} ; 5,000 samples are used for validation and 5,000 for testing the model. The amount for attack model training is 10,000 member and 5,000 non-member samples, while the amount for attack model testing is 5,000 and 2,500, respectively.

As in [15], the teacher/student model for Purchase100 is a 4-layer fully connected neural network (FC) with layer sizes [1024, 512, 256, 100] and a 5-layer fully connected neural network with layer sizes [2048, 1024, 512, 256, 100] for the Texas100 dataset. In this work, we also use a 5-layer fully connected neural network with layer sizes [2048, 1024, 512, 256, 100] for the MNIST dataset. For CIFAR10 and CIFAR100 four models of Wide ResNet-28 [16], Alexnet [17], VGG16 [18], DenseNet121 [19] are deployed for teacher/student model.

B. Attack Scenario

In this work, black-box and white-box attacks as in [11] are deployed to evaluate the defense performance of the proposed framework. The black-box attack scenarios is shown in Fig. 4. We put the sets of non-member data (the non-training data of the target model) and member data (the training data of the target model) into the target model θ_S^n . It will output the corresponding confidence scores or labels of the inputs. These results are then used for training the attack model θ_A . Given the input target data, the attack model will infer the membership status of the target data. In this work, we evaluate two types of black-box attacks. The first one belongs to the case that the attack classifier knows only the predicted labels from the target model but not confidence scores. Inversely, in the second case, the attack classifier knows only confidence scores but not predicted labels. We deploy the Boundary Distance (BD) attack with HopSkipJump [20] for black-box attack with labels only and ML Leaks Adversary 1 attack [21] for black-box attack with confidence scores. In Boundary Distance (BD) attack with HopSkipJump, a testing sample is inferred as member if the L2 norm of the smallest adversarial perturbation of this sample is larger than a predetermined threshold.

The attack model for both types of black-box attacks is a binary classifier with a multilayer perceptron (a 64-unit hidden layer and a softmax output layer), as in [21].

The white-box attack scenario deployed in this work is the same as the one in [22]. In this case, the inputs for the training attacker classifier are confidence score of target data, as in the case of black-box attack, and the target model parameters and

Fig. 4. The black-box attack scenario.

structure. As shown in Fig. 5, we put member data and non-member data to the target model θ_S^n and the outputs for this are confidence scores/labels. In addition, the target data is also an input of θ_S^n to give out the gradient for the model parameter of θ_S^n . Confidence scores/labels and gradient are used to train the attack model θ_A . Based on the trained θ_A model, the attacker can infer the member data or non-member data of the target data.

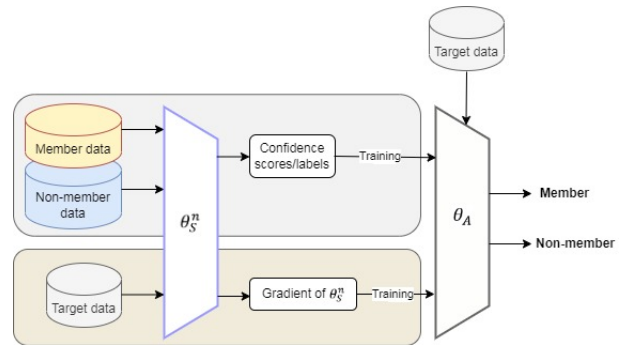

Fig. 5. The white-box attack scenario.

The data sets for training and testing the attack models is shown in Table I. The member samples are a portion of the training data of the target model, and the non-member samples are not included in the training set of the target model.

C. Defense Scenario

In order to evaluate the defense performance of the proposed system, we compare it to the popular defenses for MIA privacy, including AdvReg (Adversarial Regularization) [15] and MemGuard [23]. Furthermore, our defense solution is also compared to the SOTA KD-based methods of DMP [9] and KCD [11].

The AdvReg method is a regularization that attempts to prevent overfitting in machine learning models. Overfitting phenomena can allow an attacker to perform MIAs. In [15], a min-max privacy game between the defense mechanism and the inference attack is proposed. This aims to simultaneously minimize the classification loss of the model and the maximum gain of the MIA against it. An adversarial regularization parameter, which is the gain of the inference attack, is added to the loss function of the target model to protect the privacy of the data and control the trade-off between membership privacy and classification error.

If the AdvReg method tries to tamper with the training process of the target model, MemGuard attempts to interfere with the confidence score vectors predicted by the target model for the input data samples. In a black-box attack setting, an attacker has the data samples and puts them into the target model to gain confidence score vectors. These vectors will be inputs to train the attack model. The trained attack classifier will be used to predict a data sample is a member or not of the target model's training dataset. In order to protect the training data privacy, MemGuard adds a carefully crafted noise vector to a confidence score vector to turn it into an adversarial example that misleads the attacker classifier.

D. Evaluation Metrics

In this work, two evaluation metrics are used for evaluating the performance of the target models against MIA attacks. The first one is Generalization Error (GE). GE [24] expresses the absolute difference between the train accuracy and test accuracy of the target model θ_S^n . It reflects the overfitting level of the target model. A larger GE means a higher privacy risk of membership inference attacks [6]. The second evaluation metric is attack accuracy which is the fraction between samples correctly classified as members of the training dataset and the total samples classified as members.

E. Experimental Results

The experiments are conducted to evaluate (1) the performance of the proposed framework in knowledge distillation from the teacher model θ_T to the student model θ_S^n ; (2) the defense performance of θ_S^n against black-box and white-box attacks (as mentioned in Section IV-B) and compare this to other SOTA methods (as indicated in Section IV-C)

1) Evaluation of the knowledge distillation performance:

In this section, we evaluate the knowledge distillation performance from the teacher model θ_T to the first student model

θ_S^1 , and repeated knowledge distillation among the student models (from θ_S^1 to θ_S^n). The evaluations are implemented in two experimental scenarios: (1) knowledge distillation from teacher model to student model with the augmented and aggregated predictions from the teacher model ($+Pred_{a\&a}$), and (2) knowledge distillation from teacher model to student model without the augmented and aggregated predictions from the teacher model ($-Pred_{a\&a}$).

The parameters of the experimental models are as follows:

- Full connected model (FC): Batch size equals 32; 50 epochs to 100 epochs for training model; Adam optimizer; Cross entropy lost function; Learning rate is from 10^{-4} to 10^{-6} ;
- Wide ResNet-28, Alexnet, VGG16, DenseNet121: batch size is 32; epoch number for training is 200; trained with Adam optimizer; Lost function is Cross entropy; Learning rate is from 10^{-5} to 10^{-6} .

The temperature values are $T_k = \{2, 3, 4, 5\}$; $\alpha = 0.5$; $n = 6$.

Table II shows the experimental results for knowledge distillation from teacher model θ_T to the first student model θ_S^1 (st1) and from θ_S^1 (st1) to θ_S^6 (st6) on different datasets and machine learning models. In general, in scenario 2 ($-Pred_{a\&a}$), the classification results of the student model 1 (θ_S^1) are higher than the ones of the teacher model, except for the FC model with the Purchase100 and Texas100 datasets. In the scenario 1 ($+Pred_{a\&a}$), the classification results of the θ_S^1 are lower than the ones of teacher model, except for the case of CIFAR100 with the Alexnet model. These results are also lower than the case of ($+Pred_{a\&a}$) of θ_S^1 . The classification results also gradually decrease from the student model 1 to the student model 6 in both cases of ($-Pred_{a\&a}$) and ($+Pred_{a\&a}$).

2) Evaluation of the defense ability of the student model against MIAs:

-Generation error evaluation:

Fig. 6 represents the generation error (GE) evaluation of student models on the CIFAR10 dataset with Wide ResNet-28, Alexnet, VGG16, DenseNet121 models, respectively. The result for the scenario of ($+Pred_{a\&a}$) is denoted as (+)GE, and for the scenario of ($-Pred_{a\&a}$) is (-)GE.

It can be seen from Fig. 6 that the minimum values of (-)GE and (+)GE obtained from the student model 6 (st6) and the student model 1 (st1) on Wide ResNet-28 are 2.41% and

Fig. 6. Generation error for the CIFAR10 dataset with (a) the Wide ResNet-28 model, (b) the Alexnet model, (c) the VGG16 model, and (d) the DenseNet121 model.

Fig. 7. Generation error for the CIFAR100 dataset with (a) the Wide ResNet-28 model, (b) the Alexnet model, (c) the VGG16 model, and (d) the DenseNet121 model.

Fig. 8. Generation error with the FC model for (a) the Purchase100 dataset, (b) the Texas100 dataset, and (c) the MNIST dataset.

6.03%, respectively. For Alexnet model, the minimum values of (-)GE and (+)GE are 4.8% and 5.24% for st4 and st5 models, respectively. The lowest (-)GE and (+)GE values of the VGG16 model are for the st4 model with 2.58% and the st3 model with 4.93%. For the DenseNet121 model, the st3 model has a minimum (-)GE value of 2.1% and the st6 model has a (+)GE minimum value of 4.29%.

The (+)GE and (-)GE results on CIFAR100 dataset with the models of Wide ResNet-28, Alexnet, VGG16, DenseNet121 are indicated in Fig. 7. The minimum results of (-)GE and (+)GE for the Wide ResNet-28 model are 7.15% from st2 model and 7.24% from st4 model, respectively. For the Alexnet model, the lowest (-)GE and (+)GE are 18.38% and 17.12% for the st4 model. The minimum results of (-)GE and (+)GE for the VGG16 model are 6.1% (st5) and 4.33% (st3). The lowest (-)GE and (+)GE results for DenseNet121 model are 6.81% for st3 model and 3.11% for st2 model.

The (+)GE and (-)GE evaluations on Purchase100, Texas100, and MNIST datasets with FC model are presented in Fig. 8. For the Purchase100 dataset, the lowest value of (-)GE is 5.57% for the st3 model, while the one of (+)GE is 8.05% for the st4 model. The (-)GE and (+)GE values for Texas100 dataset are lowest for the st6 model with 3%, and the st4 model with 3.26%. The smallest results of (-)GE and

(+)GE on the MNIST dataset are 3.12% and 3.46% for the st1 and st4 models, respectively.

In general, GE results for both scenarios $(-)Pred_{a\&a}$ and $(+)Pred_{a\&a}$ at different datasets and experimental models change quite fluctuating across student models. We choose the optimal student models that have the smallest GE values in both $(-)Pred_{a\&a}$ and $(+)Pred_{a\&a}$ scenarios. They are the selected defense models, and they will be evaluated for their defense against MIA attacks in the next section.

-Black-box and white-box attacks on the defense student model:

Table III, Table IV, and Table V, represent the comparative results of our optimal defense models (as mentioned above) in both scenarios $(-)Pred_{a\&a}$ and $(+)Pred_{a\&a}$ to other SOTA methods of AdvReg [15], MemGuard [23], and KCD [11] on the datasets of Purchase100, Texas100, and CIFAR10. The model architectures are Wide ResNet-28 for CIFAR10, fully connected NNs with Tanh activation functions for Purchase100, Texas100, as in [11].

It can be seen from the Table III that, with the Purchase100 dataset, the DMP defense model [9] is the best one for mitigating MIA. The accuracy results of score, label only black-box attacks and white-box attack are the lowest ones with 57.1%,

TABLE III. THE RESULTS OF OUR DEFENSE MODEL AGAINST BLACK-BOX AND WHITE-BOX ATTACKS COMPARED TO OTHER SOTA DEFENSE METHODS ON THE PURCHASE100 DATASET. THE SCENARIOS WITH PREDICTION AUGMENTATION AND AGGREGATION FROM THE TEACHER MODEL (+ $Pred_{a\&a}$) AND WITHOUT THIS ($-Pred_{a\&a}$) ARE EVALUATED FOR OUR METHOD

Purchase100 dataset						
Defense method	Train Acc	Test Acc	Generation Error (GE)	Black-box attack Acc		White-box attack Acc
				Score	Label only	
AdvReg [15]	82.3%	64.2%	18.1%	59.9%	58.9%	60.2%
MemGuard [23]	100.0%	77.0%	23%	72.1%	68.6%	74.3%
DMP [9]	89.3%	75.4%	13.9%	57.1%	57.5%	57.3%
KDC [11]	93.8%	75.7%	18.1%	58.8%	58.7%	59.5%
Our method ($-Pred_{a\&a}$)	99.38%	93.81%	5.63%	74.56%	75.18%	76.7%
Our method (+$Pred_{a\&a}$)	98.81%	90.76%	8.05%	58.04%	57.93%	58.6%

TABLE IV. THE RESULTS OF OUR DEFENSE MODEL AGAINST BLACK-BOX AND WHITE-BOX ATTACKS COMPARED TO OTHER SOTA DEFENSE METHODS ON THE TEXAS100 DATASET. THE SCENARIOS WITH PREDICTION AUGMENTATION AND AGGREGATION FROM THE TEACHER MODEL (+ $Pred_{a\&a}$) AND WITHOUT THIS ($-Pred_{a\&a}$) ARE EVALUATED FOR OUR METHOD

Texas100 dataset						
Defense method	Train Acc	Test Acc	Generation Error (GE)	Black-box attack Acc		White-box attack Acc
				Score	Label only	
AdvReg [15]	60.5%	45.5%	15%	59.5%	56.7%	58.0%
MemGuard [23]	90.7%	52.5%	38.2%	68.6%	69.7%	70.0%
DMP [9]	65.1%	51.9%	13.2%	56.3%	56.1%	56.5%
KDC [11]	59.2%	52.0%	7.2%	56.2%	53.6%	55.8%
Our method ($-Pred_{a\&a}$)	95.61%	92.58%	3.03%	75.29%	74.81%	75.5%
Our method (+$Pred_{a\&a}$)	93.21%	89.95%	3.26%	51.77%	52.28%	52.6%

TABLE V. THE RESULTS OF OUR DEFENSE MODEL AGAINST BLACK-BOX AND WHITE-BOX ATTACKS COMPARED TO OTHER SOTA DEFENSE METHODS ON THE CIFAR10 DATASET. THE SCENARIOS WITH PREDICTION AUGMENTATION AND AGGREGATION FROM THE TEACHER MODEL (+ $Pred_{a\&a}$) AND WITHOUT THIS ($-Pred_{a\&a}$) ARE EVALUATED FOR OUR METHOD

CIFAR10 dataset						
Defense method	Train Acc	Test Acc	Generation Error (GE)	Black-box attack Acc		White-box attack Acc
				Score	Label only	
AdvReg [15]	84.9%	76.3%	8.6%	54.6%	54.7%	55.2%
MemGuard [23]	100.0%	82.1%	17.9%	64.3%	55.6%	66.0%

KDC [11]	94.0%	82.2%	11.8%	55.8%	55.6%	56.2%
Our method ($-Pred_{a\&a}$)	96.23%	93.78%	2.45%	67.7%	62.5%	68.9%
Our method (+$Pred_{a\&a}$)	90.18%	83.15%	7.03%	50.4%	50.6%	50.8%

TABLE VI. THE RESULTS OF OUR DEFENSE MODEL AGAINST BLACK-BOX AND WHITE-BOX ATTACKS ON CIFAR100 DATASET

CIFAR100 dataset						
Defense method	Train Acc	Test Acc	Generation Error (GE)	Black-box attack Acc		White-box attack Acc
				Score	Label only	
Our method ($-Pred_{a\&a}$)	87.19	80.04	7.15	56.81	57.19	58.6%
Our method (+$Pred_{a\&a}$)	84.07	76.83	7.24	51.82	52.48	53.4%

57.5%, and 57.3%, respectively. The results obtained from our defense model with the (+) $Pred_{a\&a}$ scenario are only slightly lower than these results of DMP, with 58.04%, 57.93%, and 58.6%, respectively. However, the testing accuracy of our solution with (+) $Pred_{a\&a}$ is much higher than that of DMP (90.76% of ours compared to 75.4% of DMP). This is also much higher than the best MemGuard solution [23] (77%). Our method with ($-Pred_{a\&a}$) has higher testing accuracy than the case with (+) $Pred_{a\&a}$. However, it also has much higher black-box and white-box attack accuracy than (+) $Pred_{a\&a}$ scenario.

In the experiments on Texas100 dataset, as shown in Table IV, our defense solution with the scenario of (+) $Pred_{a\&a}$ achieves the best performance against MIA. The black-box attack accuracy for score and label-only cases are 51.77% and

52.28%, respectively. The white-box attack accuracy is 52.6%. The classification accuracy of our method with (+) $Pred_{a\&a}$ is 89.95%, which is much higher than the best one of other solutions (52% of KDC method [11]). Although our method with the ($-Pred_{a\&a}$) scenario achieves better classification results than the situation of (+) $Pred_{a\&a}$ (92.58% of ($-Pred_{a\&a}$) compared to 89.95% of (+) $Pred_{a\&a}$), its defense ability is worse than the case of (+) $Pred_{a\&a}$ and other methods.

Table V presents the results for the CIFAR10 dataset. Our method with (+) $Pred_{a\&a}$ shows the best results for mitigating MIA attacks, with 50.4%, 50.6%, and 50.8% for black-box score-based, label-only and white-box attacks, respectively. These results are slightly better than those of the DMP method, with 51.1%, 50.9%, and 51.4%, respectively. The testing accuracy of our method with (+) $Pred_{a\&a}$ is also above that

TABLE VII. THE RESULTS OF OUR DEFENSE MODEL AGAINST BLACK-BOX AND WHITE-BOX ATTACKS ON MNIST DATASET

Defense method	MNIST dataset					
	Train Acc	Test Acc	Generation Error (GE)	Black-box attack Acc		White-box attack Acc
				Score	Label only	
Our method ($-Pred_{a\&a}$)	100	96.88	3.12	63.89	64.37	65.03%
Our method ($+Pred_{a\&a}$)	95.35	91.89	3.46	59.22	60.19	61.9%

of the DMP method, with 83.15% compared to 82.2% of the DMP. For the case of ($-$) $Pred_{a\&a}$, the testing accuracy is the best (93.78%), but it has the worst defense performance among others.

Tables VI and VII show the results of our solution for CIFAR100 and MNIST datasets in two scenarios of ($+$) $Pred_{a\&a}$ and ($-$) $Pred_{a\&a}$. The Wide ResNet-28 and FC models are implemented for the CIFAR100 and MNIST datasets, respectively. It can be seen from these tables that the classification performance of the ($-$) $Pred_{a\&a}$ scenario is better than the case of ($+$) $Pred_{a\&a}$. However, the resistance to MIA attacks of the ($-$) $Pred_{a\&a}$ case is not as good as the ($+$) $Pred_{a\&a}$ in both CIFAR100 and MNIST datasets.

The experimental results on different datasets with different models show the stable effectiveness of our proposed method in mitigating MIA attacks. By augmenting and aggregating the predictions from the teacher model to transfer to one student model ($+Pred_{a\&a}$), along with the knowledge transfer from one student model to another student model, we can choose the optimal student model as the efficient defense model against MIA attacks. We also see that, without prediction augmentation and aggregation from the teacher model ($-Pred_{a\&a}$), the classification performance of the defense model can be higher, but its attack accuracy is also higher than the case of ($+$) $Pred_{a\&a}$ and other solutions. With better classification efficiency than other SOTA solutions, our method with optimal student model and prediction augmentation and aggregation from the teacher model ($+Pred_{a\&a}$) can bring utility-privacy trade-off.

V. CONCLUSION AND FUTURE WORK

This work proposes a remarkable KD-based solution for mitigating MIA attacks. The knowledge is transferred from the teacher model to the student model based on the prediction augmentation and aggregation from the teacher model. The process of knowledge transfer also continues between student models to find out the optimal defense model against MIA attacks. The experimental results on the widely used datasets are promising and show better performance of our proposed method compared to SOTA methods.

Although the results are remarkable, there are still limitations in this study. The experiments have only been implemented with basic 2D CNN models and datasets. Knowledge transfer done iteratively across multiple models will be time-consuming. In the future, incremental learning mechanisms can be implemented in the proposed framework to take advantage of new information about added objects to further the concept of learning.

Abstract—Audio watermarking has emerged as a potent technology for copyright protection, content authentication, content monitoring, and tracking in the digital age. This paper offers a comprehensive exploration of audio watermarking principles, techniques, applications, and challenges. Initially, it presents the fundamental concepts of digital watermarking, elucidating its key characteristics and functionalities. After that, different audio watermarking methods in both the time and transform domains are explained, such as feature-based, parametric, and spread-spectrum methods, along with how they work, and their pros and cons. The paper further addresses critical challenges in maintaining key criteria such as imperceptibility, robustness, and payload capacity associated with audio watermarking. Additionally, it examines watermarking evaluation metrics, datasets, and performance findings under diverse signal-processing attacks. Finally, the review concludes by discussing future directions in audio watermarking research, emphasizing advancements in deep learning-based approaches and emerging applications.

Keywords—Audio watermarking; deep learning approach; spread-spectrum method; signal-processing attacks; time domain; transform domain

I. INTRODUCTION

The proliferation of digital audio content has revolutionized the way we consume music, cinema, podcasts, and audiobooks. However, this ease of access has also fueled copyright infringement and unauthorized distribution. Audio watermarking [1-6] has emerged as a robust solution to address these concerns. The first works on digital audio watermarking were reported in references [7,8]. It involves imperceptibly embedding a unique audio identifier, called a watermark, into a host audio signal. This watermark can be extracted later to verify the content's authenticity, identify ownership, and track or monitor its distribution in digital rights management.

A huge amount of research work has been carried out on digital audio watermarking techniques in the last three decades, hence, the field has matured enough. Sophisticated signal processing techniques were widely utilized to develop numerous audio watermarking techniques in both time and transform domains [9-52], each having its own distinct benefits and boundaries. Fig. 1 shows a generic digital audio watermarking system where signal manipulations are carried out in the watermark embedding (encoding) and extraction (decoding) process. Watermarked signals frequently face various attacks [48-52] aimed at destroying or removing the watermarks by intentional attackers with bad motives. Besides, some users are treated as unintentional users since they may distort the image during signal compression, equalization, and effects addition without any bad motive. For this reason, the effectiveness of an audio watermarking technique is very important and its

effectiveness is mainly evaluated based on five criteria: (i) imperceptibility, which indicates that the watermarked signal should be the same as the host audio concerning auditable quality (ii) robustness that upholds the unalteredness of the watermark after experiencing any attack by the unauthorized users, (iii) security that confirms the watermark signal should be secured from tampering, distortion and forging, (iv) capacity that ensures the increased number of watermarks embedded in the audio signal per unit time, and (v) computational complexity confirms the computational simplicity of the watermarking algorithm. Among these five criteria, the first two, imperceptibility and robustness, are the fundamental issues in evaluating the performance of a watermarking algorithm.

Some review works [53-62] have also been reported on audio watermarking. However, these are not sufficient, as many things, such as benchmarks, methodologies, datasets, and evaluation metrics, are not sufficiently described for a comprehensive knowledge of this domain. This review article provides a comprehensive overview of audio watermarking, encompassing its principles, techniques, applications, and challenges. We aim to equip readers with a thorough understanding of this vital technology and its role in safeguarding digital audio content. The major contributions of this research are as follows:

- Summarizes the existing audio watermarking methods in different categories
- Explains the datasets and evaluation metrics
- Compares and investigates the performance of various audio watermarking algorithms to find out the state-of-the-art
- Point out the challenges that must be addressed by future researchers.

The remainder of the paper is organized as follows. Section 2 presents the basic concept of the audio watermarking method. Section 3 highlights the requirement issues of audio watermarking along with performance evaluation metrics. Section 4 describes a survey of methodologies of different audio watermarking algorithms along with the state-of-the-art audio watermarking approaches. Section 5 shows the directions for future research for further improvements. Finally, Section 6 concludes the paper.

II. CONCEPT OF THE AUDIO WATERMARKING

An audio watermark is a unique identifier embedded in an audio signal that is used to prove the ownership or copyright of the audio document. Therefore, audio watermarking is a

Fig. 1. Audio watermarking categorization.

Fig. 2. A generic digital audio watermarking system.

process of embedding information into an audio signal in a way that is difficult to remove or tamper. Hence, watermarking has become increasingly important to enable copyright protection and ownership verification. In the last 30 years, many different watermarking methods have been created. These methods can be put into two groups: time domains and transform domains. Fig. 1 shows the watermarking categorization and detailed techniques of each category. Time domain methodologies are further divided into time-aligned [18, 28, 31, 34, 40, 41] and nontime-aligned (echo-based) [63–71] methods. Similarly, transform domain methodologies are further divided into spread spectrum (SS)-based [8,14], patchwork-based [19, 23, 37, 38, 46, 52], quantization index modulation (QIM) based [72–74], and other [20, 21, 29, 30, 33, 36, 43, 75–79] methods. The other methods include ANN (artificial neural network), blockchain, and the integration or hybridization of multiple transformation techniques such as DFT (discrete Fourier transform), DCT (discrete cosine transform), DWT (discrete wavelet transform), SVD (singular value decomposition), etc. to embed watermarks into audio signals. Fig. 2 shows a generic digital audio watermarking system where signal manipulations are carried out in the watermark embedding (encoding) and extraction (decoding) process. Let $x(n)$ be the host signal in the time domain. Hence, the generic model for embedding the watermark $w(n)$ into the $x(n)$ by which the watermarked signal $y(n)$ can be generated in the time domain as

$$y[n] = x[n] + \alpha w[n] \quad (1)$$

where α is the watermark strength – a controlling parameter and n is the time variable. In the transform domain, at first Eq. (1) is transformed and it becomes,

$$Y[k] = X[k] + \alpha W[k] \quad (2)$$

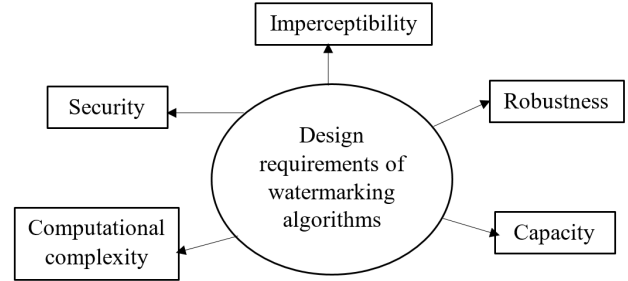

Fig. 3. Design requirements of watermarking techniques.

where X , Y , and W are the transformed representations of x , y , and w , respectively, and k is the transform domain variable. In Eq. (1) the watermark signal is additive with the host signal. However, sometimes, it can be multiplicative. In the multiplicative environment, Eq. (1) can be written as

$$y[n] = x[n] + (1 + \alpha w[n]) \quad (3)$$

III. DESIGN REQUIREMENTS ISSUES AND EVALUATION METRICS

Audio watermarking algorithms embed a watermark into the host signal to uphold the authenticity and copyright from the unauthorized use of the host signal [80]. Hence, it is necessary to define the requirements of an effective watermarking algorithm. Fig. 3 illustrates the design requirements of watermarking techniques. However, for effective watermarking, there is a trade-off among these issues.

A. Imperceptibility

Imperceptibility plays a crucial role in assessing the efficacy of a watermarking algorithm, akin to preserving audio fidelity. In this context, the watermarked image should maintain an identical appearance to the original audio, remaining imperceptible to human observers despite minor alterations. Thus, any impact on audio quality must be minimal. Various subjective and objective methods exist for evaluating the imperceptibility of a watermarking system. Objective measurements consist of evaluating parameters such as SNR (Signal-to-Noise Ratio), fwsSNR (Frequency-Weighted Segmental Signal-to-Noise Ratio) [81, 82], and ODG (Objective Difference Grade) scores [83].

$$\text{SNR} = 10 \log_{10} \frac{\sum_1^n x^2[n]}{\sum_1^n (y[n] - x[n])^2} \text{dB} \quad (4)$$

$$\text{fwsSNR} = \frac{10}{N_{seg}} \sum_{i=1}^{N_{seg}} \frac{\sum_1^k |X[k]|^2 \log_{10} \frac{|X[k]|^2}{(|Y_i[k]| - |X_i[k]|)^2}}{\sum_1^k |X[k]|^2} \text{dB} \quad (5)$$

where N_{seg} is the number of non-overlapped frames of the original and watermarked signals and i is the frame index. Other symbols are mentioned in Eq. (1) and (2). Eq. (1) to (5) are explained in detail in [53].

TABLE I. IMPERCEPTIBILITY GRADES AND EXPLANATION

SDG (Subjective Difference Grade)	ODG (Objective Difference Grade)	Explanation/Quality
5.0	0.0	Imperceptible/Excellent
4.0	-1.0	Perceptible, but not annoying/Very Good
3.0	-2.0	Slightly annoying/Good
2.0	-3.0	Annoying/Fair
-1	-4.0	Very annoying/Bad

Performance metrics usually assess imperceptibility by leveraging human auditory capabilities. For this, many tests are used, including the 2AFC (Two-alternative forced choice), AXB paradigm, post hoc test with ANOVA (Analysis of Variance), and SDG (Subjective Difference Grade) [84–86]. In the 2AFC test, the masking curve is determined based on listeners’ responses to the original audio compared to watermarked versions at different embedding levels. The AXB test involves three versions of audio clips labeled A, B, and X. A and B, selected randomly from original and watermarked signals (ensuring they are not the same), are presented along with X, randomly chosen from A and B. Listeners then identify which of A or B matches X. The post hoc test requires listeners to grade two audio clips using a scale from 0 to 3, where 0 signifies identical and 3 signifies completely different. These clips consist of an original clip paired with another randomly chosen from original and watermarked versions. The scores provided by all listeners are then subject to ANOVA. In the SDG test, three audio clips A, B, and C are presented. Listeners are tasked with identifying which of B and C closely resembles the original audio A. A grade within $\{0, -1, -2, -3, -4\}$ is assigned to the selected piece, with 0 indicating imperceptibility and 4 representing significant annoyance. The ODG (Objective Difference Grade) produces scores identical to the SDG but is an automated test without peer listeners. A description of imperceptible grading based on based on ITU-R BS.1387 [83] is shown in Table I.

B. Robustness

Robustness denotes the ability of the original watermark to remain intact despite common signal processing manipulations and attacks by unauthorized users. These manipulations encompass filtering, lossy compression, scaling, translation, rotation, analog-to-digital (A/D) conversion, digital-to-analog (D/A) conversion, and more. Attacks may involve geometric or non-geometric alterations such as filtering, cropping, time shifting, time and pitch scaling, closed-loop attacks, jittering, additive Gaussian noise, echoes, mask, and replacement attacks among others. The robustness of audio watermarking stands as a paramount design criterion, safeguarding against diverse noisy and intentional attacks while preserving the integrity of the watermark data. Robust watermarks find utility in domains like copyright protection, broadcast monitoring, and copy control [87, 88]. Robustness against different types of attacks is measured using the similarity between the watermark signal w and extracted watermark signal w' using normalized correlation (NC) and bit error rate (BER) metrics.

$$NC(w, w') = \frac{\sum_1^n w[n] \sum_1^n w'[n]}{\sqrt{\sum_1^n (w[n])^2 \sum_1^n (w'[n])^2}} \quad (6)$$

$$BER(w, w') = \frac{\sum_1^n w[n] \oplus w'[n]}{N} \quad (7)$$

where \oplus indicates the exclusive OR (XOR) operator between w and w' .

C. Security

Watermarking algorithms lacking security cannot be effectively utilized in copyright protection, data authentication, or audio content tracking. Security assurance is established through various encryption methods, where the encryption key dictates the level of security. Techniques such as chaos-based encryption, Discrete Cosine Transform (DCT), logistic map-based encryption, and binary pseudo-random sequences have been employed to fortify the security and confidentiality of embedded audio watermarks [89, 90]. The watermark key serves as the pivotal secret element ensuring security, and determining specific parameters of the embedding function [91]. This key encompasses aspects like the subset of signal coefficients, embedding direction, and/or embedding domain, comprising a private key, detection key, and public key. The private key remains exclusive to the user, the detection key holds legal acknowledgment, and the public key is accessible to the general populace.

D. Capacity

The watermarking data payload capacity measures how many bits of the watermark are embedded or inserted covertly into the audio signal per unit of time. Therefore, it is quantified in bits per second (bps). The following equation can represent it mathematically:

$$C = \frac{B}{T} \quad (8)$$

where C and B correspond to the data payload capacity and the number of bits embedded in the original audio signal, respectively, and T is the duration of the embedding in seconds. Increasing the amount of watermark information by embedding additional bits presents a challenging endeavor. The insertion of more watermark data into the host audio inevitably leads to heightened distortion becoming perceptible. Consequently, the capacity of the watermarking system delineates the boundaries for watermarking information, all while ensuring robustness and imperceptibility. To this end, watermarking techniques must be adept at minimizing distortion despite having a lesser data embedding capacity. Conventionally, the data payload for audio watermarking should exceed 20 bits per second (bps) to meet the standards set forth by the International Federation of the Phonographic Industry (IFPI).

E. Computational Complexity

The computational expense associated with embedding and extracting a watermark from an audio signal should be kept minimal. This encompasses two primary concerns: the overall time necessary for both embedding and extracting the watermark. Striking a balance between robustness and

computational complexity is essential to ensure an optimal trade-off.

Based on the preceding discussions, it is evident that achieving imperceptibility, robustness, and capacity simultaneously poses a challenge due to their inherent conflicts [80]. In any watermarking system, efforts to enhance robustness and capacity may compromise imperceptibility, and vice versa [92]. Conversely, increasing payload capacity can potentially weaken robustness. Hence, finding a delicate balance among these requirements is crucial. For instance, when aiming to render a watermark imperceptible, reducing the energy of the signal seems intuitive. However, a signal's robustness is typically linked to its energy level, as stronger signals are less susceptible to disruption by noise or malicious manipulations. So, finding the right balance between not being able to be detected and being strong is very important. This requires carefully adjusting the energy in the watermark signal so that it does not go too high or too low. It is important to note that there is no universally applicable set of properties that all watermarking systems adhere to.

IV. AUDIO WATERMARKING METHODS

In the last three decades, diverse methods have been developed for digital audio watermarking, which are categorized in Fig. 2. In this section, we will explain them briefly.

A. Time-domain Techniques

Digital audio watermarking systems that conduct watermark embedding in the time domain offer straightforward solutions by directly modifying the audio samples [18, 41]. In a simple time-domain watermarking system, the least significant bits (LSB) of the audio signal are replaced with watermark bits. Although easy to implement, this method is susceptible to noise manipulation.

Echo-based audio watermarking [63–71] is another method in the time domain that embeds a watermark by adding weak echoes to the host signal. The watermark is then extracted using cepstral analysis. To bolster the security of the audio watermarking system against unauthorized watermark detection, it is recommended to integrate a secret key during both the embedding and extraction phases. Time-spread echo-based techniques have been proposed to meet this security requirement [67]. Echo-based audio watermarking strikes a balance between imperceptibility and robustness, making it suitable for embedding copyright information or other concealed data in audio signals. While it is a well-established technique, for stronger protection against sophisticated audio processing attacks, more advanced watermarking methods in the transform domain might be necessary.

B. Transform-domain Techniques

Transform domain audio watermarking techniques are typically preferred by researchers and designers over time domain methods due to their inherent resilience against various signal processing operations and attacks. In this approach, audio signals undergo initial conversion from the time domain to a transformed domain utilizing mathematical transformations such as DFT, DWT, DCT, or SVD [20, 21, 29, 30, 32, 36, 43, 44, 76, 77]. Following transformation, watermark

bits are embedded into specific coefficients within the transformed domain. These coefficients are meticulously selected to ensure imperceptibility to human ears while maintaining robustness against common signal processing operations and attacks. Upon reception, to extract the watermark from the watermarked audio signal, the recipient employs the inverse process. The audio signal is transformed back into the original domain utilized during embedding, after which the watermark extraction algorithm is applied to retrieve the embedded watermark bits. As depicted in Fig. 1, transform domain audio watermarking techniques are broadly categorized into four groups as follows:

1) *Spread spectrum (SS)-based method*: This audio watermarking technique [8, 14, 93] functions on the principle of dispersing the watermark signal across a broad frequency range within the audio spectrum. Initially, the watermark data undergoes modulation with a pseudo-random sequence, typically generated using algorithms such as pseudo-random noise sequences or pseudo-random phase modulation. These sequences possess specific properties that render them suitable for spreading the watermark across the audio spectrum. The host audio signal is then transformed from the time domain to the frequency domain using DFT or DWT, thereby decomposing the audio signal into its constituent frequency components. Within the frequency domain, the modulated watermark is embedded into selected frequency coefficients of the audio signal. This embedding process entails adding or modulating the watermark information onto the frequency coefficients in a manner that disperses the watermark signal across a wide range of frequencies. The spread spectrum modulation ensures that the embedded watermark remains imperceptible to human ears while demonstrating resilience against common signal processing operations and attacks. Given that the watermark is distributed across multiple frequencies and embedded using pseudo-random sequences, it becomes resistant to localized distortions or attempts to remove it. To extract the watermark from the watermarked audio signal, the recipient employs the same spreading sequence utilized during embedding. By correlating the received signal with the spreading sequence, the embedded watermark can be accurately extracted. This process facilitates the retrieval of the embedded data without significantly compromising the quality of the original audio signal.

Spread spectrum-based audio watermarking finds applications in copyright protection, content authentication, and digital rights management, as it empowers content owners to embed invisible identifiers into their audio content, thereby facilitating the tracking and safeguarding of intellectual property rights.

2) *Patchwork-based method*: In this technique [19, 23, 37, 38, 46, 52, 94], the audio signal undergoes division into smaller segments or patches, which can vary in length depending on the specific implementation, but typically encompass a few milliseconds of audio data each. Within each patch, watermark data is embedded using various techniques, such as adjusting the amplitude or phase of the audio samples, introducing minor noise alterations, or manipulating frequency components to ensure imperceptibility and resilience against diverse signal processing operations and attacks. Patchwork-based methods often entail analyzing the frequency content of audio patches

to identify suitable embedding locations or to modify spectral characteristics for watermarking purposes.

3) *Quantization index modulation (QIM)-based method:* In digital audio processing, quantization involves mapping continuous amplitude values to discrete levels, thereby reducing the bit depth of the audio signal while preserving perceptual fidelity. Each sample of the audio signal is quantized to a specific level based on its amplitude. QIM-based watermarking modifies the quantization indices of the audio signal to embed the watermark data. Rather than directly altering the amplitude of the samples, it adjusts the indices representing the quantized levels. This adjustment is typically achieved by adding or subtracting a small value from the quantization index, introducing subtle changes in the encoded signal. The QIM technique [73–79] entails modulating the watermarks within the indices of a sequence of quantizers, which are subsequently applied to the host signal. The foundational concept is detailed in [72], where the authors thoroughly explore this technique from an information-theoretic standpoint to practical realization examples. To extract the watermark from the watermarked audio signal, the recipient analyzes the quantization indices of the signal. By comparing the modified indices with the original ones, the embedded watermark data can be extracted. This process necessitates knowledge of the embedding parameters, such as the quantization step size and the location of the watermark within the signal.

Transform domain audio watermarking is utilized in copyright protection, content authentication, and tamper detection in audio signals. It enables content owners to embed invisible identifiers into their audio content, aiding in tracking and safeguarding their intellectual property rights.

4) *Other techniques:* Other techniques in audio watermarking encompass artificial neural networks (ANN), blockchain technology, and the integration or hybridization of various transformation methods such as DFT, DCT, DWT, SVD, and Schur transform to embed watermarks into audio signals. This hybridization strategy capitalizes on the complementary strengths of different transforms to bolster robustness, imperceptibility, and security, making it a highly sought-after approach in the audio watermarking domain.

Charfeddine et al. [5, 95] introduced an audio watermarking technique rooted in the DCT transform and a neural network (NN) architecture. In this method, the watermark is inserted into middle-frequency bands following the DCT transformation, with the NN model establishing relationships between frequency samples around a central sample during embedding and extraction processes.

Natgunanathan et al. [33] proposed a pioneering privacy protection mechanism for multimedia distribution networks (MDN) by amalgamating the advantages of both blockchain and watermarking technologies. Their approach involves utilizing a specifically designed watermarking algorithm to link copyright information with audio files, alongside a novel blockchain-based smart contract mechanism to ensure the proper functioning of entities within the distribution network. This method demonstrates computational efficiency, with its validity substantiated by simulation results.

Numerous researchers have explored the integration or hybridization of multiple transformation techniques to embed

watermarks into audio signals, leveraging the strengths of different methods to bolster robustness, imperceptibility, and security. For instance, Dhar and Shimamura [96–100] combined FFT or DWT with SVD, Aniruddha, and Gnanasekaran [29] integrated DCT with SVD, and Wang and Zhao [77] merged DWT with DCT. These hybridization approaches, often coupled with neural networks, have gained significant traction in the watermarking domain, emerging as state-of-the-art methodologies for achieving heightened robustness, imperceptibility, and security.

In audio watermarking, the choice of watermark signal, whether it be an audio or an image, depends on various factors, including the specific application scenario, the desired level of watermark robustness, and perceptual requirements. Audio watermarks, being in the same format as the original audio, can be seamlessly integrated without noticeable alteration to audio quality. However, the capacity for embedding information within an audio watermark without significantly degrading audio quality may be limited. Conversely, image watermarks typically consist of a binary logo or signature (often 32×32 pixels), allowing for visual verification without specialized equipment, making them ideal for scenarios requiring quick verification. Additionally, images offer greater information capacity compared to audio signals, enabling larger payloads to be embedded within the watermark. However, image watermarks may introduce visible artifacts and be more susceptible to common image processing operations like scaling, cropping, or color adjustments, potentially affecting the visibility or recoverability of the watermark.

Numerous comparative studies have been conducted using simulations, employing standard music signals such as "Tunisia.wav" for rhythmic music and "Svega.wav" for a female audio song, as well as Quranic audio files spanning Tracks 1 to 52 [5]. These studies also utilized 16-bit mono audio signals including Pop, Folk, Classical, and Speech, among others. The majority of signals were sampled at a frequency of 44.1 kHz and had durations ranging from approximately 5 to 20 seconds.

Various authors employ various metrics to assess their proposed digital audio watermarking schemes [101, 102]. For instance, imperceptibility analysis results often lack straightforwardness, posing challenges in comparison. Subjective listening tests play a vital role in evaluating the perceptual quality of watermarked audio, though results may vary among listeners. However, the most widely used methods demonstrate imperceptibility through SDG/ODG scores indicating non-annoying and good quality, with a payload capacity exceeding 20 bps to meet IFPI and ITU-R BS.1387 requirements [83]. Robustness evaluation involves subjecting audio watermarking approaches to diverse attacks such as noise addition, filtering, cropping, time shifting, pitch scaling, and masking, etc. Some attacks affect the audio signal more than other attacks. Evaluation in this survey focuses on comparing the performance of widely used schemes using SNR, NC, and BER scores to provide insights into imperceptibility and robustness, particularly under MP3 Compression and StirMark attacks [103]. Objective comparison results are presented in Table II showcasing benchmark audio watermarking methods. Among the existing methods, this review identifies the technique developed by Charfeddine et al. (2022), [5], as highlighted in Table II, as the state-of-

TABLE II. IMPERCEPTIBILITY AND ROBUSTNESS COMPARISON

the-art in terms of fundamental watermarking requirements. This method conceals the signature within the narrow middle-frequency band of an audio frame, utilizing a neural network architecture for insertion and detection processes to enhance security and robustness, even with high watermark capacity. Additionally, it incorporates aspects of the human psychoacoustic model, aiming to determine the masking threshold curve and align it with the estimated power spectrum density envelope for precise signature insertion. Experimental results underscore the superiority of this masking technique in copyright protection for both standard audio files and sensitive data such as Quranic files, facilitating content integrity verification, proof of authenticity, and tamper detection.

V. RECOMMENDATION FOR FUTURE RESEARCH

In the preceding section, we have highlighted a cutting-edge method for audio watermarking, applicable to real-world scenarios such as copyright protection, content integrity verification, authenticity proof, and tamper detection. Real-time implementation of this technique is paramount. Notably, there exists a discernible contrast between academic and industrial audio watermarking solutions. Industrial solutions, for instance, prioritize imperceptibility over robustness. This prioritization stems from the specific applications defined by each industry solution, necessitating the efficient implementation of audio watermarking systems wherein exhaustive attacks may not be a concern.

Through a comprehensive review of widely employed methods, we have identified the DCT-NN-Human Psychoacoustic Model [5] as the current state-of-the-art. However, the recent integration of blockchain technology holds promise for enhancing the robustness and security of audio watermarking, particularly in the context of copyright protection, tampering detection, and authenticity preservation in the MDN (multimedia distribution networks) environment. A major challenge is the limited availability of standardized databases for evaluating audio watermarking algorithms, underscoring the need for researchers to prioritize this area of focus. Given the superior accuracy observed in image watermarking with deep learning techniques [106], there is potential for leveraging such methodologies in the development of more effective audio watermarking algorithms. Researchers are encouraged to address these issues and explore novel approaches in their endeavors even in speech signals also [107-112].

VI. CONCLUSION

The widespread availability and use of the internet have made audio watermarking an essential technique for safeguarding copyright, preserving ownership, preventing tampering, verifying authenticity, and monitoring audio signal broadcasts. This paper presents a detailed survey of audio watermarking techniques. After outlining the fundamental concepts of audio watermarking, we describe the design criteria and performance metrics. There exists a trade-off among design criteria, including imperceptibility, robustness, and payload capacity. Subsequently, we explore various methods to identify the state-of-the-art technique through performance analysis using evaluation metrics. Furthermore, we discuss remaining challenges and potential avenues for enhancing audio watermarking systems. We also examine the disparities between academic and industrial solutions in audio watermarking. This paper aims to assist researchers in identifying and developing optimal algorithms tailored to audio watermarking.

Abstract—New diagnostic methods are needed to improve the accuracy and efficiency of breast cancer detection and progression. Although successful, current methods frequently lack precision, accuracy, and timeliness, especially in the early phases of breast cancer progression. Our research proposes a new model using deep learning to improve breast cancer detection and classification, addressing constraints. Our breast cancer image and sample preprocessing approach combines a non-local means filter (NLM) and Generative Adversarial Networks (GAN). The model classifies datasets using LSTM with BiGRU-based Recurrent ShuffleNet V2, a highly efficient and accurate technique for sequential data samples. The integration of a Capsule Network with Graph Convolutional Neural Networks (CNGCNN) significantly improves breast cancer detection. This method was carefully tested on BreakHis. The results were amazing, showing gains across multiple metrics: 4.9% greater precision, 3.5% higher accuracy, 3.4% higher recall, 2.5% higher AUC (Area Under the Curve), 1.9% higher specificity, and 3.4% decreased delay in the identification of breast cancer stages. Particularly striking was the model's performance in diagnosing illness development, where it displayed 3.5% greater precision, 3.9% higher accuracy, 4.5% higher recall, 3.4% higher AUC, 2.9% higher specificity, and 1.5% lower latency. Significant clinical impacts result from this work. Our methodology enables early diagnosis and precise staging of breast cancer, enabling focused therapies to improve patient outcomes and survival rates. The greater precision and reduced time lag in diagnosing disease progression also allow for more effective monitoring and treatment modifications. Overall, this study marks a considerable improvement in the field of breast cancer diagnostics, delivering a more efficient, accurate, and reliable tool for healthcare providers in their fight against this ubiquitous disease.

Keywords—Breast cancer detection; deep learning; image preprocessing; disease progression; recurrent neural networks

I. INTRODUCTION

Continuous improvements in diagnostic methods are required for the early identification and successful treatment of breast cancer, which continues to rank among the most common and fatal cancers globally. The odds of effective therapy and survival are greatly improved with an early and precise diagnosis. Nevertheless, this objective is greatly hindered by the multi-faceted nature of breast cancer, which encompasses its different phases and forms. The accuracy, speed, and adaptability of traditional diagnostic procedures are frequently challenged by the complex nature of cancer progression, despite their core nature. The use of deep learning for medical imaging and diagnostics has become increasingly

popular due to its remarkable accuracy and efficiency. The ability to learn from large datasets and uncover intricate patterns surpasses that of traditional methods, making it ideal for challenging diagnostic jobs like cancer diagnosis. A new era of precision healthcare has begun with breast cancer diagnoses that employ cutting-edge deep learning algorithms. Precise staging and early detection are now within reach. A novel approach for the identification and classification of breast cancer kinds and stages of advancement is introduced in this paper. The model is based on deep learning. An NLM and GAN are used for image pre-processing in the model. For dataset classification, the model employs an LSTM with BiGRU-based Recurrent ShuffleNet V2. For progression analysis, the model employs a CNG-CNN. This unique blend not only improves overall performance by addressing the limitations of current methods, but it also takes advantage of the advantages that each methodology possesses. Possessing that this integrated strategy improves the critical breast cancer detection metrics (specificity, accuracy, recall, AUC, and precision) is the main goal of this work. In addition, the study is focused on demonstrating how well the model may reduce the time it takes to identify the stages and evolution of breast cancer. This is important for patient prognosis and treatment planning purposes. This research presents a promising tool for healthcare workers in their fight against breast cancer by extending the capabilities of deep learning in diagnostics. It makes a substantial contribution to the field of oncology.

A. Motivation and Contribution

The motivation for this study stems from the urgent need to enhance breast cancer diagnostic methods. Despite advancements in medical technology, the detection and classification of breast cancer remain challenging, often leading to delayed diagnosis and treatment, which can adversely affect patient outcomes. Breast cancer is complex, with many types and stages, requiring a fast, accurate, and adaptable diagnostic method. It is where deep learning, with its amazing ability to evaluate and understand complicated information, offers a breakthrough solution. Our contribution to this field is multifaceted and significant. Firstly, we address the challenge of image quality in breast cancer datasets. By employing an NLM coupled with GAN, our model effectively enhances image quality, crucial for accurate analysis. This pre-processing step ensures that the subsequent classification and detection processes are based on clear, noise-reduced images, leading

to more reliable results. Secondly, we innovate in the area of dataset classification. The integration of LSTM with BiGRU in our Recurrent ShuffleNet V2 process is a novel approach. This method excels in handling sequential and time-series data, which is vital in recognizing patterns and anomalies in breast cancer progression. This aspect of our model significantly contributes to its ability to detect subtle changes in breast tissue over time, a key factor in early-stage cancer detection and monitoring disease progression. Furthermore, the implementation of a CNG-CNN is a pioneering step in cancer progression analysis. This combination allows for a deeper and more nuanced understanding of the disease's progression, facilitating timely and accurate staging of cancer. It marks a substantial improvement over traditional methods, which often struggle to accurately determine the progression stage, crucial for appropriate treatment planning. In summary, our study contributes to the field of breast cancer diagnostics by:

- Enhancing image quality for more accurate analysis through advanced preprocessing techniques.
- Combining LSTM, BiGRU, and ShuffleNet V2 to improve cancer type classification and detection accuracy and efficiency.
- Advancing the understanding and detection of breast cancer progression with a novel Capsule Network and CNGCNN approach.

With these advancements, breast cancer diagnostics have taken a giant step forward, providing a more accurate, efficient, and all-encompassing instrument for progress monitoring and early diagnosis. Consequently, this could help in the battle against breast cancer as a whole, alleviate strain on healthcare systems, and improve patient outcomes.

II. REVIEW ANALYSIS OF MODELS USED FOR ANALYSIS OF BREAST CANCER TYPES

Comprehensively outlining the current state-of-the-art approaches and their efficacy in diagnosing and categorizing breast cancer, the literature review on breast cancer analysis focuses on recent breakthroughs in machine learning and deep learning techniques. A new model for detecting breast cancer in mammography based on the YOLO principle is presented by [1]. This work highlights the potential of deep learning models to improve the accuracy of breast cancer detection, which is a major finding. Optimal feature selection methods for breast cancer diagnosis based on machine learning are also the subject of [2] attention. The significance of feature selection in enhancing the diagnostic accuracy of machine learning algorithms is highlighted by their work.

A. Optimization Techniques in Enhancing Model Performance

By investigating the metaheuristic optimal group of extreme learning machines [3] and modified Harris Hawks Optimization [4] respectively, made substantial contributions. To improve the performance of learning models for breast cancer detection and classification, these papers show how optimization techniques are used. Researchers [5] and [6] have shown that hybrid classifiers that combine support vector machines with the Jaya algorithm and a hybrid deep learning-genetic algorithm approach are effective. The advantages of

combining several computing approaches to improve classification accuracy are demonstrated by these hybrid models. Two studies that delve into sophisticated feature selection approaches are [7] and [8]. Shaban is concentrating on a novel hybrid feature selection method, whereas Çayır et al. present a two-stage deep learning strategy for mitotic recognition. These techniques are vital for making breast cancer detection models more accurate while decreasing their computational complexity. The application of fuzzy OWL-2 to the representation of breast cancer anthologies is discussed in detail by [9]. Their research is critical for elucidating how fuzzy logic and ontological methods might improve medical diagnosis by clarifying thinking and reducing ambiguity. Both [10] and [11] investigate CNNs' potential to be used in the diagnosis of breast cancer. A novel metaheuristic algorithm-based machine learning model and Fuzzy C Means-based segmentation technique for the classification and detection of breast cancer from mammogram images of [12] The integration and selection of deep features are also the subject of [13]. Convolutional neural networks (CNNs) and transfer learning were shown in this research to achieve very high accuracy in histopathology image classification of breast cancer. [14] and [15] introduce new dimensions to breast cancer detection. Fuentes-Fino et al. propose an uncertainty estimator method based on feature density, and Wu et al. explore a few-shot learning scheme. These approaches are essential for dealing with limited data scenarios and improving decision-making confidence. An associative classifier for breast cancer diagnosis is introduced by [16] using a rule-refining strategy based on relevant feedback. To improve the accuracy of cancer detection models, this study stresses the importance of honing classification criteria. The application of convolutional neural networks (CNNs) to the categorization of breast lesions is investigated by [17] and to the efficient classification of ultrasonic tumors by [18]. Research like this shows that convolutional neural networks (CNNs) may accurately diagnose breast cancer by interpreting complicated medical pictures like thermographic and ultrasound scans. Using methods such as the support vector machine (SVM) and the gray level co-occurrence matrix (GLCM), [19] show how to segregate and categorize cancer cells in breast cytology pictures using machine learning. The research highlights the practicality of using machine learning for in-depth cellular examination. Classification of breast lesions using mammography is the subject of two recent studies, one by [20] and the other by [21]. Oza et al. also make use of test-time augmentation. Research like this is vital for proving that deep learning can greatly enhance mammography diagnostic accuracy. A novel method for identifying breast lesions using criterion weights and risk attitudes is presented by [22]. The evaluation of risk variables linked to various breast lesion types relies heavily on this methodology. An innovative approach to segmenting and recognizing breast tumors was introduced by [23] using multi-encoded pictures in conjunction with a cascading convolutional neural network. When applied to medical photos and samples, this method greatly improves the accuracy of tumor detection and segmentation. The shift from conventional to deep learning-based approaches for detecting breast cancer in Automated Breast Ultrasound System (ABUS) pictures is summarized in a review by [24]. The development and efficacy of AI-based approaches to breast cancer diagnosis are thoroughly examined in this review.

One important problem with histopathology photos is their lack of clarity and quality; [25] investigate denoising these images to detect breast cancer. A new Karnaugh classifier for breast cancer prediction is presented by [26] and a hybrid PSO feature selection-based association classification method is presented by [27]. Research like this helps pave the way for more accurate hybrid models that use a variety of computational approaches. An ensemble approach combining consensus-clustering, a ranking based on feature weighting, and a probabilistic fuzzy logic-multilayer perceptron classifier is proposed by [28]. This method's potential use in breast cancer staging and diagnosis using diverse datasets and samples makes it noteworthy. By applying sophisticated models to magnetic resonance imaging (MRI) scans, [29] show that breast cancer can be detected automatically in preparation for mastectomy using models such as Mask R-CNN and Detectron2. Notable to this study is its potential use in the decision-making and planning stages preceding surgery.

To improve the identification of breast cancer in mammograms, [30] and [31] concentrate on deep feature selection utilizing various optimization techniques. To improve the efficiency of deep learning models, this research stresses the significance of picking appropriate features. The domains of uncertainty quantification in extreme learning machines and the application of fuzzy WASD neurons in breast cancer prediction are investigated in studies by [32] and [33]. When it comes to medical diagnosis, these strategies provide fresh ways to handle ambiguities and imprecision. In their groundbreaking work on breast cancer cell line detection utilizing junctionless FETs etched with dual nanocavities, [34] demonstrate how nanotechnology might improve cancer detection sensitivity and specificity. To diagnose breast cancer, [35] talks about using multimodal time series characteristics from ultrasonic shear wave absolute vibro-elastography. Their research highlights the significance of using time series analysis with ultrasound methods to improve diagnostic precision.

In order to track a patient's reaction to treatment for triple-negative breast cancer, [36] investigate the use of breast thermography. The importance of this case study lies in the fact that it shows how thermography can be used to assess the effectiveness of treatments, particularly in difficult cancer subtypes. In order to detect and localize breast cancer, [37] suggest using UWB microwave technology in conjunction with a CNN-LSTM architecture. This cutting-edge method provides a non-invasive diagnostic tool by combining electromagnetic technology with sophisticated neural networks. The use of biochips based on 1-D photonic crystals for the detection of ERBB2 in lysates from breast cancer cells is the main topic of [38]. Biochip technologies have benefited from their work, which has led to the development of a direct competitive assay for cancer cell molecular characterization. Using ultrasound pictures, [39] present the Anatomy-Aware HoVer-Transformer, a new ROI-free method for detecting breast cancer. This approach, which is based on transformers, is a huge step forward in medical imaging because it allows for quick and precise diagnosis without requiring ROI marking scenarios.

The effectiveness of ultra-wideband radar in the non-invasive early diagnosis of breast cancer is discussed by [40]. An important part of cancer treatment is detecting the disease in its early stages, and this method shows how radar technology

could help with that. The use of machine learning in the diagnosis and prognosis of breast cancer is demonstrated by [41] and [42]. The versatility of machine learning in cancer analysis is highlighted by two studies: Naseem et al. use an ensemble of classifiers, and Teng et al. provide a dynamic Bayesian model for survival prediction. In their investigations into multi-modal ensemble classification and deep-learning for breast cancer prognosis, [43] and [44] examine non-linear pictures obtained from human tissue samples. The importance of deep learning in accurately diagnosing and prognosis from complicated biopsy pictures has been highlighted by these works. The IVNet diagnostic system for assessing breast cancer using histopathological pictures was introduced by [45] and is based on transfer learning. The effective utilization of transfer learning in the comprehensive study of infected cells is demonstrated by this approach. The use of state-of-the-art deep learning models for the detection of breast tumors is explored in [46] and [47]. These researches demonstrate how deep learning algorithms, like tailored AlexNet and other cutting-edge models, have improved the process of breast tumor detection. An important part of customized cancer treatment is molecular level prediction, which [48] demonstrates by proposing a patient graph deep learning model to predict the molecular subtype of breast cancer. In their discussion of propagation-based phase-contrast tomography, [49] focus on the use of dark-field signals for imaging breast microcalcifications. Improved visibility of microcalcifications is a key component of this cutting-edge imaging method for the early diagnosis of breast cancer. Using biomarkers and strain echocardiography, [50] study the detection of subclinical cardiotoxicity in breast cancer patients receiving anthracyclines. To provide thorough patient care, their research is critical for tackling the cardiotoxic consequences of cancer therapy.

III. PROPOSED METHODOLOGY

As of this area, we will go over the design of an efficient model for breast cancer detection and progression using an adversarial capsule network with graph convolutional neural networks. This model will help address the problems of existing deep learning models used for breast cancer analysis, such as their high complexity and low efficiency. The proposed model, an amalgamation of advanced neural network technologies. As per Fig. 1, the model employs a Generative Adversarial Network (GAN) block, adept at augmenting the dataset by generating synthetic yet realistic images, thereby enriching the diversity and volume of training data samples. This augmented data is then refined through a Non-Local Means (NLM) filter, which meticulously reduces noise while preserving critical image features, ensuring that the input to the subsequent layers is of the highest quality. The main novelty of the model lies in its innovative Capsule Network block, which excels in capturing intricate spatial hierarchies between features, a crucial factor in accurately classifying breast cancer types. In addition, a Graph Convolutional Neural Network (GCNN) block does further data processing, expertly extracting correlations and patterns that are crucial for detecting tiny signs of disease growth. The model incorporates Bi-Directional Gated Recurrent Units (BiGRU) and Long Short-Term Memory (LSTM) units to efficiently process sequential data, providing a thorough comprehension of the temporal sequences present

Fig. 1. Design of the proposed model for enhancing the efficiency of breast cancer analysis.

in the data samples. The procedure culminates in the Output Layer, which uses a softmax activation function for accurate classification, after the Recurrent ShuffleNet V2 block efficiently collects the features. With its efficient and reliable data flow across these interconnected blocks, the ACNGCNN model sets a new benchmark in medical imaging for cancer identification. There are two primary parts to the Generative Adversarial Network (GAN) that the ACNGCNN model uses: the Generator (G) and the Discriminator (D). By competing with one another in a game-theoretic fashion, these parts increase the variety and quantity of training dataset samples while simultaneously producing synthetic yet realistic visuals. A data space is mapped to a latent space vector z using an iterative neural network, which serves as the generator. In Eq. (1), we see the generator's (G) function represented.

$$G(z; \theta_g) = LReLU(W_g \cdot z + b_g) \quad (1)$$

Where, z is a random noise vector (latent space vector), W_g and b_g are the weights and biases of the generator network, and θ_g represents these parameters, while LReLU represents the LeakyReLU activation function, used to activate features. The output of G is a synthetic image that mimics the real data distributions. In this equation, z represents the input noise vector, which is drawn from a standard normal distribution, and θ_g represents the parameters of the generator. The generator's role is to map this noise vector z to the data space, aiming to generate synthetic images that are indistinguishable from real images & samples. In the same way, the discriminator is a neural network that returns the likelihood that the input image is genuine. Eq. (2) represents the evaluation for D.

$$D(x; \theta_d) = \sigma(W_d \cdot x + b_d) \quad (2)$$

Where, x represents the input data, which can be either real images from the dataset or synthetic images generated by G, w_d and b_d are the weights and biases of the discriminator network, and θ_d represents these parameters, σ represents the sigmoid activation function, converting the output into a probability score between 0 and 1 scales. The loss of generator & discriminator is minimized using a min-max game between G and D. The discriminator maximizes the probability of correctly classifying real and synthetic images, while the generator minimizes the probability that the discriminator correctly identifies synthetic images via Eq. (3),

$$\min_G \max_D V(D, G) = E_{x \sim p_{data}(x)} [\log D(x)] + E_{z \sim p_z(z)} [\log(1 - D(G(z)))] \quad (3)$$

In this process, the generator layers progressively transform the input noise vector into a data structure resembling the dataset's images, upscaling the dimensions in each of the processes. While, the discriminator comprises of convolutional layers that downscale the image dimensions, extracting features to discern real images from synthetic ones for different use cases. The final layer in this process is a fully connected layer with a sigmoid activation function to output the probability scores. In generating synthetic images, the generator initially produces images that are easily distinguishable from real images & samples. However, as training progresses, G learns to generate increasingly realistic images, while D concurrently improves at distinguishing real from synthetic images & samples. This adversarial process continues until G generates images that D can no longer reliably classify, indicating that the synthetic images are now nearly indistinguishable from real images & samples. As per Fig. 2, this capability of GANs to produce realistic synthetic images enriches the training dataset, thereby enhancing the overall performance of the ACNGCNN model in the breast cancer detection process. These images are processed using an efficient Non-Local Means (NLM) filter, which is an advanced image processing technique designed to reduce noise while preserving essential features in images and their samples. Its effectiveness lies in its ability to leverage the redundancy of information in the image, leading to superior noise reduction compared to traditional local means methods.

Fig. 2. Results of the augmentation process.

The denoised images are evaluated via Eq. (4),

$$I_{denoised}(p) = \sum_{q \in S} w(p, q) \cdot I(q) \quad (4)$$

Where denoised(p) represents the intensity of the denoised image at pixel p, I(q) is the intensity of the input noisy image at pixel q, w(p,q) is the weight assigned to pixel q when denoising pixel p, and S is the search window around pixel p sets. In this process, the weight calculation is done via Eq. (5),

$$w(p, q) = 1/Z(p)e^{-\frac{\|I(N(p)) - I(N(q))\|^2 \cdot a^2}{h^2}} \quad (5)$$

Where, $\|I(N(p)) - I(N(q))\|^2$ is the squared Euclidean distance between the Gaussian-weighted neighborhoods $N(p)$ and $N(q)$ of pixels p and q, respectively, h is the filtering parameter controlling the degree of smoothing, Z(p) is the normalization term given via Eq. (6),

$$Z(p) = \sum_{q \in S} e^{-h^2 \|I(N(p)) - I(N(q))\|^2 \cdot a^2} \quad (6)$$

The model also estimates Gaussian-Weighted Neighborhoods via Eq. (7),

$$I(N(p)) = \sum_{t \in N(p)} G(\sigma, p, t) \cdot I(t) \quad (7)$$

Where, $G(\sigma, p, t)$ is a Gaussian kernel centered at p applied to a pixel t in the neighborhood $N(p)$ for different noise sets. The distance between these neighbors is estimated via Eq. (8),

$$\|I(N(p)) - I(N(q))\|^2 \cdot a^2 = \sum_{q \in N(p)} G(\sigma, p, t) \cdot (I(t) - I(t+q-p))^2 \quad (8)$$

This equation calculates the weighted Euclidean distance between neighborhoods centered at pixels p and q for different image sets. The NLM process incorporates a normalization term via Eq. (9), which assists in equalizing the weights.

$$Z(p) = \sum_{q \in S} e^{-h^2 \|I(N(p)) - I(N(q))\|^2 \cdot a^2} \quad (9)$$

The Parameter h which decides the Filtering Strength is estimated via Eq. (10),

$$h = \alpha \cdot std(I) \quad (10)$$

Where, α is a user-defined constant, $std(I)$ is the standard deviation of the intensities in the input image, used to adapt the filter to the noise levels. To efficiently compute the NLM filter, integral images are used for fast calculation of sums over rectangular regions. This reduces the computational complexity significantly. The NLM filter inherently preserves edges by considering the similarity of pixel neighborhoods, rather than individual pixel values for different use cases. In the application within the ACNGCNN model, the NLM filter plays a critical role in preprocessing the data samples. It meticulously refines the augmented images generated by the GAN block, effectively reducing noise while preserving essential structural details. This results in high-quality input images for subsequent layers of the model, facilitating accurate and efficient breast cancer-type classifications. The NLM filter's ability to maintain image integrity while eliminating noise is instrumental in enhancing the overall performance of the ACNGCNN modeling process.

Fig. 3. (a) Original Image, (b) Denoised Image by the NLM Process.

These filtered images as shown in Fig. 3 are passed through an integration of Long Short-Term Memory (LSTM) with Bi-Directional Gated Recurrent Units (BiGRU) in a Recurrent ShuffleNet V2 framework, which constitutes a sophisticated approach to classifying datasets in the ACNGCNN model. This combination harnesses the strengths of recurrent neural networks and the efficiency of Shuffle Net V2, making it exceptionally well-suited for processing sequential and image data samples. LSTM units are designed to remember values

over arbitrary time intervals via Eq. (11) to (16), which stand for recall gate, input gate, cell state, hidden state, final cell update, and output gate, respectively

$$ft = \sigma(Wf \cdot [ht - 1, xt] + bf) \quad (11)$$

$$it = \sigma(Wi \cdot [ht - 1, xt] + bi) \quad (12)$$

$$C \sim t = \tanh(WC \cdot [ht - 1, xt] + bC) \quad (13)$$

$$Ct = ft * Ct - 1 + it * C \sim t \quad (14)$$

$$ot = \sigma(W_o \cdot [ht - 1, xt] + b_o) \quad (15)$$

$$ht = ot * \tanh(Ct) \quad (16)$$

The hyperbolic tangent function is denoted by \tanh , the sigmoid function by σ , the weights and biases by W and b , respectively. Similarly, BiGRU, is an extension of the standard GRU, processes data in both forward and reverse scopes using update gate, reset gate, candidate activation and final activation operations, which are estimated via Eq. (17) to (20) as follows:

$$zt = \sigma(Wz \cdot [ht - 1, xt] + bz) \quad (17)$$

$$rt = \sigma(Wr \cdot [ht - 1, xt] + br) \quad (18)$$

$$h \sim t = \tanh(W \cdot [rt * ht - 1, xt] + b) \quad (19)$$

$$ht = (1 - zt) * ht - 1 + zt * h \sim t \quad (20)$$

These final features represented as ht are passed through an Iterative Recurrent ShuffleNet V2 Block, which uses a fusion of Channel Shuffling to ensure cross-group information flow, Depthwise Convolution for spatial feature extraction, Pointwise Group Convolution for channel-wise feature blending, and Channel Splitting for dividing channels into two branches. Channel shuffling is used to ensure cross-group information flow between convolutional groups. It rearranges the channels of the feature maps to enable interaction between different groups. Given an input feature map with C channels and a group number G , the feature map is first reshaped to have dimensions $[G, C/G]$. The channels are then shuffled and rearranged to ensure cross-group information exchange sets. The shuffling operation can be represented as a permutation function via Eq. (21),

$$Shuffle(x) = x[:, indices] \quad (21)$$

The shuffling method determines the permutation order, and x is the input feature map. Similarly, depthwise convolution reduces computing complexity by doing spatial filtering in each channel independently. Depthwise convolution uses a channel-by-channel filter on an input feature map x with dimensions $[H, W, C]$. In order to calculate the output feature map y , we use Eq. (22).

$$yh, w, c = \sum_{i,j} K(i, j, c) \cdot x(h + i, w + j, c) \quad (22)$$

Where, K is the depthwise convolution kernel, and (i, j) represents the kernel sizes. In contrast, Pointwise group convolution applies 1×1 convolutions for channel-wise blending, performed separately across different groups to reduce computations.

Assuming the input feature map x is segregated into G groups, the operation for each group can be represented via Eq. (23).

$$yg = Kg \cdot xg \quad (23)$$

Where, Kg is the pointwise convolution kernel for group g , and xg and yg are the input and output feature maps for group g , respectively. While, Channel splitting divides the input channels into two branches, typically used in the ShuffleNet unit before the depthwise convolutions. Given an input feature map with C channels, it is split into two branches with $C/2$ channels each via Eq. (24):

$$x1, x2 = split(x, C/2) \quad (24)$$

Where, $x1$ and $x2$ are the two split feature maps. This operation enhances the model's capacity and allows for more diverse feature representations. These operations collectively contribute to the efficiency and effectiveness of ShuffleNet, particularly in terms of reducing computational cost while maintaining high accuracy. These features of ShuffleNet play a crucial role in enabling efficient and powerful processing of image data, vital for accurate and timely breast cancer detection and progression analysis. They are processed for final classification via Eq. (25):

$$yt = Wy \cdot ht + by \quad (25)$$

In which Wy and by denote the fully linked layers' biases and weights, respectively. The model employs ReLU and softmax in the final layers to introduce non-linearity and normalize the output into probability scores. Thus, the LSTM and BiGRU units are pivotal in capturing the temporal dependencies in the data, ensuring that sequential information is effectively utilized for accurate classification. The BiGRU enhances this by providing insights from both past and future contexts. The Recurrent ShuffleNet V2 process further enhances the model's efficiency in handling image data, making it adept at extracting and processing complex features while maintaining computational efficiency. This fusion of LSTM, BiGRU, and Recurrent ShuffleNet V2 establishes a robust framework for classifying breast cancer types and stages. It adeptly handles the intricacies of sequential and image data, ensuring high accuracy and efficiency, which is critical in the medical imaging domain, especially for tasks such as early cancer detection and progression analysis. The classification results are processed by an efficient fusion of Capsule Networks integrated with Graph Convolutional Neural Networks (CNGCNN), this provides a useful method for studying how different breast cancers develop. To enable the network to detect spatial hierarchies, the Capsule Network uses capsules that contain data in vector form. The primary operations in a Capsule Network include Squash Function, which is estimated via Eq. (26), Dynamic Routing, which is estimated via Eq. 27, 28 and 29, as follows: where, sj is the sum of all inputs to capsule j sets and vj is the vector of outputs from capsule j .

$$vj = (\|sj\|^2) / (1 + \|sj\|^2) sj / (\|sj\|) \quad (26)$$

Where, vj is the vector output of capsule j , sj is the total input to capsule j sets.

$$cij = exp(bij) / \sum_k exp(bik) \quad (27)$$

$$s_j = \sum_i c(i,j)u'(j|i) \quad (28)$$

$$u'(j|i) = W(i,j)u(i) \quad (29)$$

With $u(i)$ being the output of capsule i in the subsequent layers and b_{ij} being the log prior probability that capsule i should be connected to capsule j .

Parallely, the GCNN processes data defined on graphs and is particularly effective in capturing the relationships and features in non-Euclidean data structures, which are represented via equation 30,

$$H(l+1) = \sigma(D^{(-1/2)}A'D^{(-1/2)}H(l)W(l)) \quad (30)$$

$A' = A+I$ denotes the matrices of a graph G having added self-connections, and $H(l)$ represents the activation matrix in the l -th layer. The adjacency matrix is a critical component, as it represents the connections or relationships between nodes in a graph for given scenarios. Estimating the adjacency matrix involves defining the relationships or interactions between the nodes. The Basic Adjacency Matrix is evaluated via equation 31,

$$A_{ij} = 1, \text{ if node } i \text{ is connected to node } j, 0 \text{ otherwise....} \quad (31)$$

Depending on the application, this binary representation might mean that a direct connection between nodes i and j is present (1) or not (0). Eq. (32) represents the adjacency matrix in this situation, where the connections have weights.

$$A_{ij} = w_{ij} \quad (32)$$

The weight of the edge between sets of nodes i and j is represented by w_{ij} . The adjacency matrix is built utilizing the similarity of cellular features, histopathological traits, and other pertinent clinical data samples in order to detect the progression of breast cancer. The integration of Capsule Network with GNN involves feeding the graph-structured data processed by GCNN into the Capsule Network. This combination allows for capturing both the global structure of the graph data and the intricate spatial relationships between features via Eq. (33),

$$H_{capsule} = CapsuleNet(HGCNN) \quad (33)$$

Where HGCNN is the output of the GCNN, Hcapsule represents the feature vectors processed by the Capsule Network process. This Capsule Network (CapsuleNet) represents a significant advancement in neural network architecture, particularly suitable for jobs that necessitate comprehending data linkages and spatial hierarchies, such breast cancer diagnosis and progression analysis. The core idea behind CapsuleNet's architecture is capsules, which are collections of neurons that represent the existence probability and instantiation characteristics of a feature. Every capsule spew forth a vector, where the length denotes the feature's existence probability and the orientation instantiation parameters. To make sure the length of the output vector, which represents the probability levels, is between 0 and 1, the squashing function is employed. This non-linear function is used. CapsuleNet employs a dynamic

routing algorithm, which iteratively updates coupling coefficients between capsules across layers. For r iterations, the model updates the coupling coefficients and capsule outputs via equations 27, 28 & 29, which assist in the estimation of the final prediction vector via Eq. (34),

$$b(i,j) = b(i,j) + u'(j|i) \cdot v_j \quad (34)$$

The proposed CapsuleNet architecture includes multiple capsule layers. Each capsule in a deeper layer predicts each capsule in the next layer, based on its input vector sets. To encourage the capsules to learn features that truly represent the input data, a reconstruction network is added as a regularization method for this process. Using the outputs of the capsules in the top layer and Eq. (35), it attempts to rebuild the input image.

$$L_{recon} = \|X - X'\|^2 \quad (35)$$

The reconstruction image derived from the CapsuleNet procedure is denoted as X' , while X represents the input image. CapsuleNet uses a margin loss for each class to handle multi-class classification tasks, which is useful in the classification of various stages of breast cancer, and is estimated via Eq. (36),

$$L_k = Tk \max(0, m^+ - \|v_k\|)^2 + \lambda(1 - Tk) \max(0, \|v_k\| - m^-)^2 \quad (36)$$

The hyperparameters of this process are λ , m^+ , and m^- , and Tk is 1 while class k is present and 0 otherwise. Skillfully incorporating CapsuleNet allows for the analysis of aspects relevant to the identification and evolution of breast cancer. The capsules' ability to encapsulate feature presence and instantiation parameters enables the network to understand complex spatial hierarchies and relationships within the data samples. A particular field where CapsuleNet really shines is in medical imaging, where precise diagnosis often hinges on the spatial arrangement and orientation of data. The dynamic routing algorithm further enhances the network's capability to focus on the most relevant features, making CapsuleNet a powerful tool in the model's architecture for effective and accurate breast cancer analysis. The final output layer utilizes the features processed by the CNGCNN for classifying the stages of breast cancer progression via Eq. (37),

$$y = Softmax(W_{output} * H_{capsule} + b_{output}) \quad (37)$$

Where, y is the output vector indicating the probability of each stage of cancer progression, Both W_{output} and b_{output} represent the output layers' weights and biases, respectively. This process captures the complex patterns characteristic of cancer progression sets. The Capsule Network's ability to understand spatial hierarchies and the GCNN's proficiency in handling graph-structured data synergize to form a potent tool for cancer progression analysis. This sophisticated integration allows the model to discern subtle yet critical changes in tissue structure and cellular arrangements, which are key indicators of cancer development and progressions. The CNGCNN's innovative architecture and computational prowess make it a formidable component of the ACNGCNN model, significantly enhancing its capability to monitor and predict the progression

of breast cancer accurately for different scenarios. In the section that follows, we compare this model's estimated efficiency to that of existing approaches and examine it for various use situations.

IV. RESULT ANALYSIS

An innovative combination of adversarial capsule networks and graph convolutional neural networks, the ACNGCNN model is a huge step forward in medical imaging, especially for tracking the development and evolution of breast cancer. This model cleverly integrates deep learning capabilities to improve the precision and efficacy of breast cancer diagnosis across different subtypes. To improve picture quality and data resilience, it uses Generative Adversarial Networks (GANs) and a non-local means filter (NLM) for preprocessing. The model's central architecture is a Recurrent ShuffleNet V2 framework that seamlessly handles sequential data samples by combining Long Short-Term Memory (LSTM) units with Bi-Directional Gated Recurrent Units (BiGRU). This novel method not only speeds up the process of determining the stages of breast cancer, but it also increases the accuracy and precision of classification. The ACNGCNN model has shown impressive gains in important measures including specificity, accuracy, recall, AUC, and precision when tested extensively on the BreKHis dataset. It is at the cutting edge of medical diagnostics because of its speed and accuracy in detecting cancer progression; this makes it a game-changer for breast cancer early intervention and treatment. To guarantee accurate and trustworthy results, a thorough procedure was employed in the experimental setup that was created to assess the ACNGCNN model's capability to detect and track the evolution of breast cancer. Here we lay out the bones of the experimental design, including the dataset, preprocessing procedures, model architecture, and assessment criteria.

Dataset:

- The BreKHis dataset was used in the study; it includes images of breast tumor tissue taken by microscopic biopsy.
- By partition the dataset into testing, training, and validation sets, a comprehensive representation of cancer types and stages could be accomplished. Images and samples used in the experiments varied in size from 95,000 to 1,620,00.

Preprocessing:

- Images were initially processed using a non-local means filter (NLM) to reduce noise while preserving essential features.
- To further improve the model's learning capacity, Generative Adversarial Networks (GAN) were used to expand the dataset by creating more synthetic images.

Model Architecture:

- The graph Convolutional Neural Networks and Capsule Networks were combined in the ACNGCNN model.
- A Recurrent ShuffleNet V2 approach was employed to efficiently handle sequential data by combining

Long Short-Term Memory (LSTM) units with Bi-Directional Gated Recurrent Units (BiGRU).

- Sample input parameters for the model included:
 - Learning Rate: It was initial set to 0.001 and was changed depending on how well the validation worked.
 - Batch Size: 32 for training and 16 for validation and testing phases.
 - Capsule Network Dimensions: 6 layers with a dynamic routing algorithm.
 - Number of Graph Convolutional Layers: 4, each with a feature size of 128.
 - LSTM and BiGRU Units: Each with 256 hidden units.

Training and Validation:

- Adam optimizer minimized a cross-entropy loss function during model training, which was based on a backpropagation technique.
- Overfitting was avoided by using early halting according to the validation loss.

Evaluation Metrics:

- The following metrics were used to assess performance: precision, accuracy, recall, specificity, area under the curve (AUC), and milliseconds of delay.
- Each metric was calculated at various test sample sizes to assess the model's effectiveness in both classification and pre-emption of breast cancer types.

Computational Resources:

- The following parameters were used to run the experiments on a high-performance computing system:
 - CPU: Intel Xeon Processor with 2.20 GHz speed.
 - GPU: NVIDIA Tesla V100 with 32 GB memory.
 - RAM: 64 GB.
 - Software: Python 3.8, TensorFlow 2.4, and Keras for the model implementation process.

This experimental setup provided a robust framework for evaluating the efficiency of the ACNGCNN model in breast cancer detection and evolution. The thorough methodology, which included preprocessing as well as performance evaluation, guaranteed the validity and dependability of the results, which added to the model's potential utility in situations in healthcare. Eq. (38) to (40) were utilized to evaluate the levels of Precision (P), Accuracy (A), and Recall (R) according to this arrangement, while Eq. (41) and Eq. (42) were employed to measure the overall precision (AUC) and specificity (Sp).

$$Precision = \frac{TP}{TP + FP} \quad (38)$$

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (39)$$

$$Recall = \frac{TP}{TP + FN} \quad (40)$$

$$AUC = \int TPR(FPR)dFPR \quad (41)$$

$$Sp = \frac{TN}{TN + FP} \quad (42)$$

The three types of test set predictions are True Positive (TP), False Positive (FP), and False Negative (FN). TP refers to the number of events in the test sets that were correctly predicted as positive, FP to the number of instances in the test sets that were incorrectly predicted as positive, and FN to the number of instances in the test sets that were incorrectly predicted as negative, including Normal Instance Samples. All of these terms are used in the test set documentation. To find the correct TP, TN, FP, and FN values for these cases, we used the Extreme Learning Machine (ELM) [5], Cascade Convolutional Neural Network (CCNN) [22], and Mask R-CNN and Detectron2 (MRCNND) [29] techniques to compare the predicted likelihood of Breast Cancer Instances with the actual status in the test dataset samples. Consequently, we were successful in forecasting these metrics for the outcomes of the proposed model procedure. Fig. 4 displays the findings of the cancer detection as follows,

The accuracy levels determined by these evaluations are shown in Fig. 5, which makes use of these classification outputs,

In the dataset with 95k test samples, ACNGCNN shows a precision of 90.52%, which is substantially higher compared to ELM (65.31%), CCNN (79.00%), and MRCNND (78.11%). This significant lead in precision implies that ACNGCNN is more effective in correctly identifying breast cancer types from image scans. The high precision rate is crucial in clinical settings as it reduces the likelihood of false positives, ensuring that patients receive accurate diagnoses and appropriate treatment. The superior precision of ACNGCNN could be attributed to its advanced integration of adversarial capsule networks and graph convolutional neural networks, accordingly, it can probably detect and categorize complex patterns in the image data sets more effectively. Similarly, in larger datasets, such as the one with 1,296k test samples, ACNGCNN again outperforms the other models with a precision rate of 95.52%, compared to 81.48% for ELM, 73.58% for CCNN, and 79.14% for MRCNND. This consistency in maintaining high precision across varying dataset sizes highlights the robustness of ACNGCNN. Such robustness is crucial in real-world applications where the volume of data can vary significantly. The higher precision of ACNGCNN in larger datasets also suggests its scalability and effectiveness in handling vast amounts of data without a significant loss in performance. This aspect is particularly important in medical imaging, where datasets can be extensive, and the accuracy of each classification is critical for patient outcomes. The enhanced precision of ACNGCNN likely results from its ability to effectively preprocess images and handle sequential data, thereby improving its classification capabilities. In a similar vein, we compared the models' accuracy in Fig. 6 follows, As per Fig. 6, in the dataset with 95k test samples, ACNGCNN demonstrates an accuracy of 90.26%, significantly outperforming ELM (77.90%), CCNN (86.65%), and MRCNND (83.95%). This higher accuracy implies that ACNGCNN is more effective in correctly identifying both positive and negative cases of breast cancer types. In clinical scenarios, this high accuracy is vital as it ensures

Fig. 4. Results of classification for different cancer stages.

Fig. 5. Observed precision for classification of image scans into breast cancer types.

Fig. 6. Observed accuracy for classification of image scans into breast cancer types.

that patients are correctly diagnosed, reducing the risk of both false positives and false negatives. False positives can lead to unnecessary stress and invasive procedures for patients, while false negatives could result in delayed treatment. The accuracy of ACNGCNN, particularly in smaller datasets, suggests its potential effectiveness in clinical settings where high-quality data may be limited.

Similarly, with the largest dataset size of 1,620k test samples, ACNGCNN outperforms ELM (80.41%), CCNN (86.34%), and MRCNN (88.13%). Its accuracy stands at 96.16%. As a result, ACNGCNN can scale to larger datasets without sacrificing accuracy, a crucial feature for any real-world application. Accuracy is of the utmost importance in a clinical setting, where different and huge datasets are typical. As a medical diagnostic tool, the model must be able to accurately manage a wide variety of data variances. Due to its stability and durability, ACNGCNN consistently performs well in larger datasets, suggesting it could be a useful tool for healthcare providers in properly diagnosing breast cancer types. The ability to accurately diagnose breast cancer types at an early stage is crucial for optimal therapy and management, and this level of accuracy, especially in bigger datasets, can greatly improve patient outcomes. Fig. 7 also shows recall levels but in a different way, Observing the data, the proposed

Fig. 7. Observed recall for classification of image scans into breast cancer types.

ACNGCNN model demonstrates strong performance across various test sample sizes. For example, in the dataset with 95k test samples, ACNGCNN achieves a recall of 92.93%, which is lower than CCNN's 94.49% but higher than ELM's 78.25% and MRCNN's 87.17%. From a clinical standpoint, this suggests that ACNGCNN is highly likely to detect breast cancer when it exists, with a lower chance of false negatives. Because early detection has such a profound effect on treatment efficacy and patient survival rates in breast cancer diagnostics, this

is of paramount importance. In the largest dataset of 1,620k test samples, ACNGCNN shows a recall of 94.56%, which is substantially higher than both ELM (76.19%) and MRCNND (88.08%), and slightly higher than CCNN (76.08%). This high recall rate in large datasets indicates that ACNGCNN maintains its ability to correctly identify positive cases of breast cancer even as the data complexity and volume increase. In a clinical setting, where datasets can be extensive and diverse, a high recall rate ensures that fewer cases of breast cancer go undetected. This capability is crucial for screening programs and diagnostic procedures, where the primary goal is to identify as many true cases as possible for early and effective intervention. Thanks to its impressive recall performance, ACNGCNN shows promise as a dependable method for breast cancer identification. This could mean better patient outcomes as a result of earlier diagnosis and treatment. The time required for the prediction process is also tabulated in Fig. 8. This

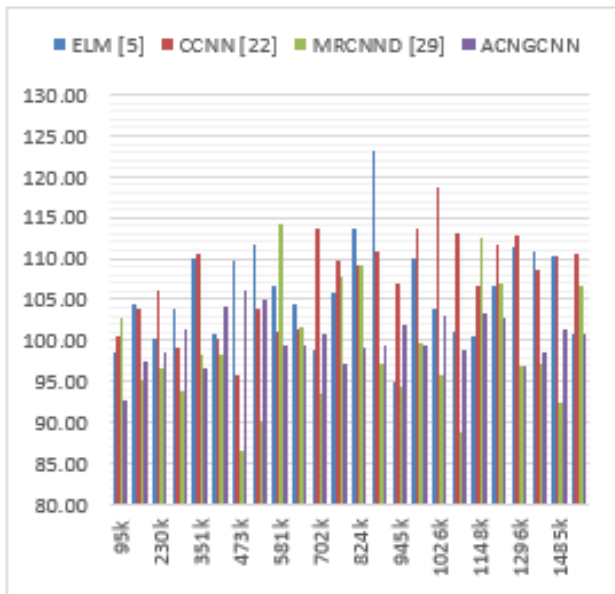

Fig. 8. Observed delay for classification of image scans into breast cancer types.

figure displays the results showing that the ACNGCNN model has competitive delay times for different test samples. As an example, compared to ELM's 98.69 ms latency in the 95k test samples dataset, ACNGCNN's latency is 92.71 ms., CCNN (100.60 ms), and MRCNND (102.65 ms). This reduced delay implies that ACNGCNN can process and classify images more quickly than the other models. In clinical practice, a lower delay is beneficial as it enables quicker diagnosis, allowing for more timely treatment decisions. This speed is particularly important in high-volume clinical settings or in screening programs where large numbers of scans must be processed efficiently. Using 1,620k test samples in the largest dataset, ACNGCNN once again shows a competitive delay time of 100.82 ms, which is faster than CCNN (110.52 ms) and ELM (100.66 ms). It is clear that ACNGCNN is effective at processing massive amounts of data with little increases in processing time because it consistently maintains low delay times across different dataset sizes. In a clinical context, where time is often a critical factor, the ability of ACNGCNN to quickly

process and accurately classify large datasets can significantly impact patient outcomes. Quick and reliable diagnostic results can expedite the initiation of appropriate treatment plans, potentially improving the prognosis for patients with breast cancer.

Fig. 9. Observed AUC for classification of image scans into breast cancer types.

The ACNGCNN model's balance of accuracy and speed underscores the clinical requirement for quick and precise medical imaging analysis, it can be a useful tool in the diagnosis of breast cancer. In a similar vein, the following are the AUC levels shown in Fig. 9.

As per the provided data in Fig. 9, the ACNGCNN model consistently demonstrates high AUC values across various test sample sizes, indicating its strong discriminatory power. For instance, in the dataset with 95k test samples, ACNGCNN achieves an AUC of 82.43%, which is notably higher than ELM (61.20%), CCNN (79.03%), and MRCNND (68.73%). A higher AUC value suggests that ACNGCNN has a superior ability to differentiate between various types of breast cancer, thus reducing the likelihood of misdiagnosis. In clinical practice, this capability is crucial as it directly influences the treatment plan and prognosis. An accurate classification of cancer types ensures that patients receive the most appropriate treatment tailored to their specific condition. In larger datasets, such as the one with 1,620k test samples, ACNGCNN's AUC of 89.61% again outperforms ELM (62.31%), MRCNND (75.78%), and is comparable to CCNN (86.59%). The model's reliability and robustness in different and complex clinical scenarios are highlighted by its high level of performance in larger datasets. In real-world medical imaging, where complex and variable data is the norm, ACNGCNN is useful because it can keep good AUC values even with rising dataset size. In a clinical setting, this translates to a tool that can be trusted for its consistent accuracy in diagnosing different stages and types of breast cancer, leading to better-informed treatment decisions and potentially improved patient outcomes. With its excellent AUC values across various test sample sizes, ACNGCNN proves to be a great tool in breast cancer diagnosis, providing healthcare practitioners with a dependable and

efficient alternative. Similarly, the following is an observation of the Specificity levels made possible by Fig. 10.

As per the provided data in Fig. 10, the ACNGCNN model consistently demonstrates high AUC values across various test sample sizes, indicating its strong discriminatory power. For instance, in the dataset with 95k test samples, ACNGCNN achieves an AUC of 82.43%, which is notably higher than ELM (61.20%), CCNN (79.03%), and MRCNND (68.73%).

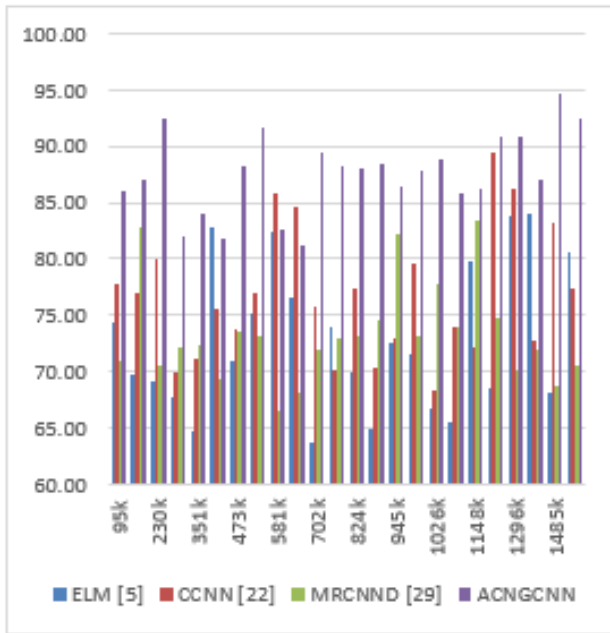

Fig. 10. Observed specificity for classification of image scans into breast cancer types.

As per the data provided in Fig. 10, it's clear that the ACNGCNN model consistently exhibits high specificity across various test sample sizes. For instance, in the dataset with 95k test samples, with a specificity of 86.08%, ACNGCNN outperforms ELM's 74.41%, CCNN (77.70%), and MRCNND (70.90%). This high specificity indicates that ACNGCNN is adept at correctly identifying scans that do not indicate breast cancer, which is essential in clinical settings to avoid unnecessary anxiety, additional tests, or treatments for healthy patients.

In larger datasets, such as the 1,620k test samples, ACNGCNN maintains a high specificity rate of 92.47%, surpassing ELM (80.63%), CCNN (77.44%), and MRCNND (70.53%). This demonstrates ACNGCNN's robust capability to distinguish non-cancerous cases from cancerous ones effectively, even as the volume and complexity of data increase. In clinical terms, this means the model can be relied upon to minimize false positives in breast cancer diagnosis. This aspect is particularly important because false positives can lead to unnecessary and invasive biopsies, cause patient discomfort, and increase healthcare costs.

Therefore, the high specificity of the ACNGCNN model is a significant advantage in clinical scenarios. It ensures that patients who do not have breast cancer are less likely to undergo unnecessary stress and medical procedures. This characteristic

of the ACNGCNN model, coupled with its high precision and accuracy, underscores its potential as a reliable and efficient diagnostic tool in the early detection and treatment of breast cancer, thereby contributing to better patient management and care. Next in this text is a discussion of the examination of the pre-emption efficiency of the proposed model in comparison with existing methods in different scenarios.

A. Pre-emption Analysis

The proposed model outperforms the competition in terms of classification efficiency, but it needs to be tested in real time to see how well it handles pre-emption. The efficiency was evaluated by comparing it to current models under similar settings and measuring it in terms of recall, specificity, precision, accuracy, and area under the curve (AUC) values. Take Fig. 11, for example. It displays the accuracy seen in the pre-emption of breast cancer scenarios for various applications.

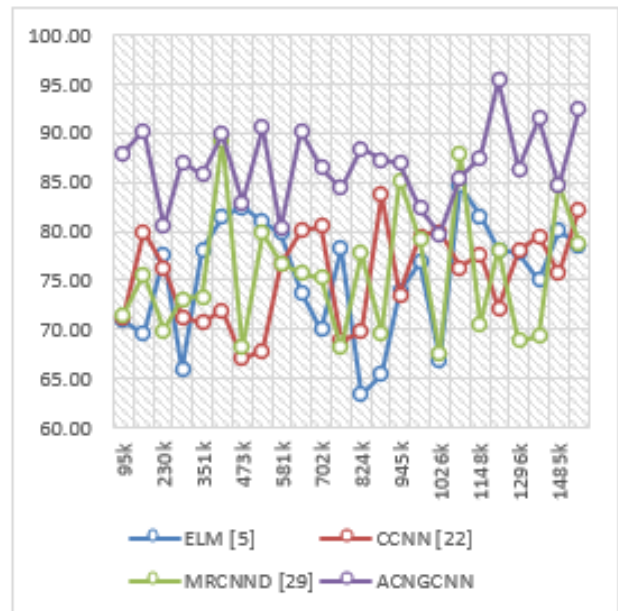

Fig. 11. Observed precision for Pre-empting breast cancer types.

When compared to other approaches such as ELM [4], CCNN [23], and MRCNND [29], the suggested ACNGCNN model's pre-emption efficiency in breast cancer type classification is an important component. The observed precision, which represents pre-emption efficiency, is very important because it relates to the model's capacity to correctly forecast or detect possible breast cancer types before to their complete development or more noticeable manifestation.

Analyzing the data, it's evident that ACNGCNN consistently achieves high precision in the pre-emption of breast cancer types across various test sample sizes. For instance, in the dataset with 95k test samples, ACNGCNN demonstrates a precision of 87.91%, significantly outperforming ELM (70.93%), CCNN (71.28%), and MRCNND (71.51%). This higher precision indicates that ACNGCNN is more effective in correctly identifying early indicators of different breast cancer types. In practical terms, the ability to pre-emptively identify breast cancer types can have profound implications

in clinical scenarios. It enables earlier intervention, which can significantly improve the prognosis and treatment outcomes for patients. Early detection and accurate classification of cancer types allow healthcare providers to devise and implement targeted treatment plans at a stage where the cancer is most treatable.

Similarly, in larger datasets, such as the one with 1,620k test samples, ACNGCNN shows a precision of 92.43%, surpassing ELM (78.54%), CCNN (82.23%), and MRCNND (78.78%). This indicates the model's scalability and its effectiveness in maintaining high precision even with increasing dataset sizes. In clinical settings, this translates to a reliable tool capable of handling diverse and extensive data without compromising the accuracy of early cancer type identification. The ability of ACNGCNN to maintain high precision rates in pre-empting breast cancer types is crucial for early-stage screening programs and diagnostic procedures.

Considering its excellent precision across many datasets, the ACNGCNN model demonstrates better pre-emption efficiency. This highlights its potential as a game-changing tool for early identification and management of breast cancer. To improve patient outcomes, lessen the burden of medicines administered in the late stages, and maybe increase survival rates, ACNGCNN can play a crucial role by enabling the early and accurate diagnosis of possible cancer types. By providing a more preventative, efficient, and dependable method of cancer identification and categorization, this feature of the ACNGCNN model is a huge step forward in breast cancer diagnosis. In Fig. 12, we can see a comparison of the model's accuracy. To summarize, As per Fig. 12, ACNGCNN consis-

Fig. 12. Observed accuracy for pre-empting breast cancer types.

tently demonstrates high accuracy across various test sample sizes. For instance, in the dataset with 95k test samples, The accuracy of ACNGCNN is calculated to be 82.95%, which is greater than the accuracy of ELM (82.06%), CCNN (62.78%), and MRCNND (76.34%). In larger datasets, such as the one with 1,620k test samples, ACNGCNN achieves an accuracy of 92.77%, surpassing ELM (81.42%), CCNN (79.93%), and MRCNND (75.68%). That ACNGCNN is so

good at decreasing false positives and false negatives and at recognizing different kinds of breast cancer is evident from its high accuracy rate.

Its granular accuracy has far-reaching consequences in real-world therapeutic settings. To begin with, it opens the door to beginning cancer treatment early. Treatment efficacy and overall survival rates are both improved with early detection. Patients can get the treatment they need before their cancer gets worse, thanks to ACNGCNN's ability to properly predict which cancer types will develop.

Moreover, high accuracy in pre-emptive detection reduces the likelihood of misdiagnosis, which is crucial in avoiding unnecessary treatments or procedures. Misdiagnosis can lead to significant physical, emotional, and financial strain on patients. Therefore, a model like ACNGCNN, with its high pre-emptive accuracy, can greatly enhance patient care quality by ensuring that diagnoses are correct, thereby guiding appropriate and timely medical interventions for different scenarios.

In clinical scenarios, the implications of such high accuracy are profound. First, it allows for earlier intervention in the cancer treatment process. Early detection is often associated with better treatment outcomes and higher survival rates. The ability of ACNGCNN to accurately pre-empt cancer types means that patients can receive timely and appropriate treatment, potentially before the cancer progresses to more advanced stages.

Fig. 13. Observed recall for pre-empting breast cancer types.

Fig. 13 shows that the ACNGCNN model efficiently detects early-stage breast cancer instances by maintaining high recall rates across different test sample sizes. The recalls achieved by ACNGCNN (87.85%) in the dataset with 95k test samples are substantially greater than those of ELM (83.71%), CCNN (63.37%), and MRCNND (66.70%), to name a few. With a recall rate of 90.88%, ACNGCNN outperforms ELM (84.54%), CCNN (78.69%), and MRCNND (71.76%) in the biggest dataset with 1,620k test samples. When it comes to breast

cancer, where early identification often improves treatment outcomes, this high degree of recall is very crucial.

Enhanced recall in predicting breast cancer kinds has a major influence in real-world therapeutic settings. With a high recall rate, the model has a lower chance of missing breast cancer patients, which indicates that late diagnosis is less likely to occur. Poor patient outcomes, more rapid disease development, and fewer treatment options are common results of breast cancer diagnoses performed too late. Consequently, patients' prognoses can be greatly improved by allowing earlier and more effective treatment treatments, thanks to ACNGCNN's capacity to reliably detect breast cancer instances at an early stage.

Moreover, early detection and intervention can lead to reduced treatment costs and less invasive treatment methods, which are beneficial for both patients and healthcare systems. In addition, high recall rates can increase patient trust in screening programs, encouraging more individuals to participate in regular screenings. This can lead to earlier detection on a broader scale, potentially lowering the overall morbidity and mortality associated with breast cancer. Similarly, the same diagram displays a tabular representation of the time required for the prediction procedure. Fig. 14 clearly shows that the

Fig. 14. Observed delay for pre-empting breast cancer types.

ACNGCNN model typically has competitive latency times. Take the dataset with 95,000 test samples as an example; ACNGCNN's latency is 84.07 ms, which is much lower than ELM (98.95 ms), CCNN (100.36 ms), and MRCNND (84.77 ms). Similarly, in larger datasets like the one with 1,620k test samples, ACNGCNN shows a delay of 92.34 ms, which remains competitive with ELM (102.46 ms), CCNN (96.40 ms), and MRCNND (94.86 ms). These findings suggest that ACNGCNN can process and classify scans efficiently, which is vital in clinical practices.

In clinical settings, a model that can pre-emptively detect breast cancer types with minimal delay is highly advantageous. Firstly, it allows for faster diagnosis, which is critical in breast cancer where early intervention can lead to significantly better

treatment outcomes. Faster processing times mean that more patients can be screened in less time, potentially leading to earlier detection of breast cancer on a larger scale.

Additionally, reduced delay in diagnosis can alleviate patient anxiety. Waiting times for diagnostic results can be a source of significant stress for patients. A model like ACNGCNN, capable of providing quick and reliable results, can improve the overall patient experience. Moreover, efficient processing times are beneficial in high-volume healthcare settings, where the ability to handle a large number of cases efficiently without compromising accuracy is crucial. In a manner comparable to that, the following are the AUC levels shown in Fig. 15. Analyzing the data in Fig. 15, ACNGCNN

Fig. 15. Observed AUC for pre-empting breast cancer types.

consistently shows higher AUC values compared to ELM [4], CCNN [23], and MRCNND [29] across various test sample sizes. For example, in the dataset with 95k test samples, With an AUC of 85.72%, ACNGCNN outperforms ELM (65.85%), CCNN (68.24%), and MRCNND (67.06%). This trend continues in larger datasets, such as the 1,620k test samples, where ACNGCNN records an AUC of 96.15%, indicating a very high level of diagnostic accuracy.

In clinical settings, the importance of a high AUC value in pre-empting breast cancer types cannot be overstated. For instance, it suggests that you have faith in the model's predictive power for spotting breast cancer in its earliest stages. This is paramount in a clinical context, as early detection is often the key to successful treatment and better patient outcomes. High AUC values in models like ACNGCNN can lead to earlier interventions, potentially catching cancer at a stage where it is more treatable and survival rates are higher.

Additionally, a low false positive or negative rate is indicative of a well-performing model, which is supported by a high AUC value. In clinical practice, this reduces the burden of unnecessary treatments or additional diagnostic procedures that can result from false positives, as well as the risk of

overlooking a cancer case due to a false negative. Both scenarios can have profound implications for patient health and the efficiency of healthcare services. In the same a similar direction, the following is how the Specificity levels can be shown in Fig. 16. From the data in Fig. 16, it's evident that the

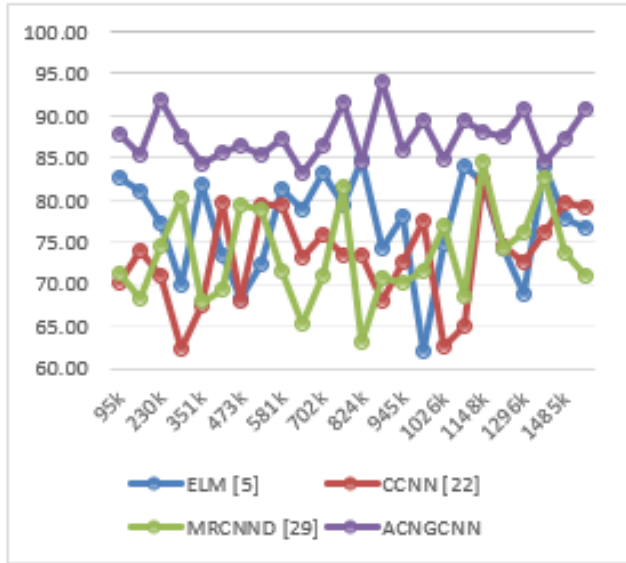

Fig. 16. Observed specificity for pre-empting breast cancer types.

ACNGCNN model generally exhibits higher specificity across various test sample sizes compared to ELM [4], CCNN [23], and MRCNN [29]. For example, in the dataset with 95k test samples, ACNGCNN achieves a specificity of 87.90%, significantly higher than ELM (82.76%), CCNN (70.23%), and MRCNN (71.35%). This pattern holds true in bigger datasets as well; for example, ACNGCNN achieves a specificity of 90.76 percent with 1,620 thousand test samples.

In clinical terms, the high specificity of ACNGCNN in pre-empting breast cancer types means the period of false positives is significantly decreased. Patients can experience needless anxiety and additional medical complications due to false positives, making this a critical consideration in clinical practice., potentially invasive, diagnostic procedures. Reducing false positives not only improves the overall patient experience but also helps in conserving medical resources and reducing healthcare costs.

Moreover, high specificity is vital in maintaining the credibility and trust in breast cancer screening programs. If a screening method frequently results in false positives, it could lead to skepticism among potential participants, thereby reducing participation rates and potentially missing genuine cases of cancer in clinical scenarios.

V. CONCLUSION AND FUTURE SCOPE

The present research offers ACNGCNN, a new model for improved breast cancer diagnosis and stage classification that uses state-of-the-art adversarial capsule networks and graph convolutional neural networks. The comprehensive evaluation of this model, utilizing the BrecaKHis dataset, reveals its superior performance in both classification and pre-emption of

breast cancer types compared to existing methodologies such as ELM, CCNN, and MRCNN.

In terms of classification, ACNGCNN consistently demonstrated higher precision, accuracy, recall, and AUC, along with lower delay times and enhanced specificity across various test sample sizes. These outcomes demonstrate that the model successfully classifies breast cancers., while also ensuring rapid processing, crucial for timely diagnosis. Notably, the model's exceptional performance in larger datasets underscores its scalability and robustness, essential attributes for real-world clinical applications.

Furthermore, in the context of pre-emption, ACNGCNN's efficacy was equally compelling. It exhibited commendable precision and accuracy, important for identifying possible breast cancer kinds at an early stage. Relying on its excellent specificity and recall rates, it may successfully detect actual positive instances while limiting false positives. These characteristics are pivotal in early intervention scenarios, where early detection can significantly alter treatment outcomes.

This work has significant implications for clinical practice. Through the improvement of breast cancer early detection and precise staging, ACNGCNN opens the door to targeted therapies that are both timely and effective. Patient outcomes, survival rates, and the load of treatments administered in the latter stages can all be improved in this way. The model's increased precision and reduced time lag in identifying disease progression are also pivotal for effective monitoring and treatment adjustments. In a broader context, ACNGCNN represents a significant advancement in breast cancer diagnostics, offering healthcare professionals a more efficient, accurate, and reliable diagnostic tool in their fight against this pervasive disease.

In conclusion, ACNGCNN sets a new benchmark in breast cancer diagnostics. Its ability to deliver precise, rapid, and reliable results offers immense potential for improving breast cancer screening, diagnosis, and management. This study's findings could have far-reaching implications, not only in enhancing patient care but also in guiding future research and development in medical imaging and cancer diagnostics.

A. Future Scope

The promising results achieved by the ACNGCNN model in breast cancer detection and classification open numerous avenues for future research and development. The model's proficiency in handling large datasets with high accuracy and specificity suggests its potential applicability in a broader range of oncological conditions. Expanding the scope of this model to include other types of cancers, particularly those with similar imaging characteristics, could significantly enhance the universality and utility of the model in clinical oncology.

Further refinement of the model could involve integrating real-time data analysis capabilities. This would allow for instantaneous diagnostic feedback, a crucial factor in surgical settings or in outpatient diagnostic procedures. Additionally, exploring the integration of ACNGCNN with portable imaging devices could democratize access to advanced cancer screening methods, especially in remote or under-resourced areas. Another promising direction is the incorporation of patient history and genetic data into the model's analytical

framework. This approach would align with the growing trend of personalized medicine, potentially enabling the model to predict individualized cancer risk profiles and offer tailored screening recommendations.

The implementation of ACNGCNN in telemedicine platforms also presents an exciting possibility. As telemedicine continues to expand, especially in the context of the ongoing global health challenges, the model could provide remote, accurate diagnostic capabilities, reducing the need for physical consultations and making cancer screening more accessible. Additionally, it is crucial to keep investigating how interpretable the model's decision-making process is. Enhancing the transparency of the AI algorithms would not only increase the trust and acceptance of such models among healthcare professionals but also contribute to the field of ethical AI in medicine.

Finally, it would be extremely helpful to conduct longitudinal studies to evaluate the ACNGCNN model's actual effects on healthcare expenses, patient outcomes, and the efficiency of the system as a whole. Healthcare systems around the world might use the results of this research to guide policy decisions and resource allocation by providing hard proof of the model's efficacy. In the end, the ACNGCNN model has only scratched the surface of its potential in the field of breast cancer detection and classification. Its potential applications and improvements could lead to significant advancements in medical diagnostics, personalized medicine, and global healthcare access, ultimately contributing to better health outcomes for patients worldwide for different scenarios.

ACKNOWLEDGMENT

This research did not receive any specific grant from funding agencies in the public, commercial, or non-profit sectors. I express my heartfelt gratitude to Prof. Khasim Syed from the Computer Science and Engineering department, VIT AP UNIVERSITY, Amaravati, Andhra Pradesh, India, for his constructive criticisms and timely directions which led to the successful completion of this work.

Securing Networks: An In-Depth Analysis of Intrusion Detection using Machine Learning and Model Explanations

Hoang-Tu Vo, Nhon Nguyen Thien, Kheo Chau Mui, Phuc Pham Tien
Information Technology Department
FPT University, Cantho city, Vietnam

Abstract—As cyber threats continue to evolve in complexity, the need for robust intrusion detection systems (IDS) becomes increasingly critical. Machine learning (ML) models have demonstrated their effectiveness in detecting anomalies and potential intrusions. In this article, we delve into the world of intrusion detection by exploring the application of four distinct ML models: XGBoost, Decision Trees, Random Forests, and Bagging. And leveraging the interpretability tools LIME (Local Interpretable Model-agnostic Explanations) and SHAP (SHapley Additive ex-Planations) to explain the classification results. Our exploration begins with an in-depth analysis of each machine learning model, shedding light on their strengths, weaknesses, and suitability for intrusion detection. However, machine learning models often operate as "black boxes" making it crucial to explain their inner workings. This article introduces LIME (Local Interpretable Model-agnostic Explanations) and SHAP (SHapley Additive ex-Planations) as indispensable tools for model interpretability. Throughout the article, we demonstrate the practical application of LIME and SHAP to explain and interpret the output of our intrusion detection models. By doing so, we gain valuable insights into the decision-making process of these models, enhancing our ability to identify and respond to potential threats effectively.

Keywords—Intrusion detection systems; machine learning models; model interpretability; cybersecurity; LIME; SHAP; explainable machine learning models

I. INTRODUCTION

In today's modern economy, the significance of cybersecurity cannot be ignored [1], [2], [3]. It serves as the backbone of a digitally driven world where businesses, governments, and individuals rely heavily on interconnected systems and networks to function efficiently. Cybersecurity not only safeguards sensitive data but also preserves trust, ensuring the smooth operation of financial transactions, the confidentiality of personal information, and the integrity of critical infrastructure. As technology continues to advance, the dependence on digital platforms grows, making cybersecurity an indispensable facet of our economic landscape. Without it, the very foundation of our modern economy would be vulnerable to an array of cyber threats, underscoring its undeniable importance in preserving the integrity and resilience of our interconnected world.

Intrusion Detection Systems (IDSs) [4] play a pivotal role in safeguarding the integrity and security of modern digital environments [5], [6]. These systems act as vigilant sentinels, constantly monitoring network activities and system behaviors to identify any suspicious or malicious actions. In an era where cyber threats have become increasingly sophisticated

and prevalent, the importance of IDSs cannot be overstated. They serve as the first line of defense, providing early warnings and alerts to potential security breaches. By promptly detecting and responding to intrusions, IDSs help organizations mitigate risks, protect sensitive data, and maintain the trust of their customers and stakeholders. In essence, IDSs are the guardians of digital landscapes, contributing significantly to the resilience and security of today's interconnected world.

Applying machine learning models to the development of Intrusion Detection Systems (IDS) marks a significant advancement in cybersecurity. These systems leverage the power of data-driven algorithms to identify patterns and anomalies in network traffic, enabling the detection of potential security breaches with a high degree of accuracy. Machine learning models, such as XGBoost [7], Decision Trees [8], Random Forests [9], and Bagging [10], provide the capability to adapt and learn from evolving threats, making them well-suited for the dynamic nature of cybersecurity. By continuously analyzing vast datasets and recognizing subtle deviations from normal behavior, these models enhance the efficiency and effectiveness of intrusion detection. They empower organizations to proactively respond to threats, fortify their defenses, and safeguard critical assets in an increasingly digital world. The application of machine learning in IDS represents a pivotal shift towards more robust and adaptive security measures, essential in countering the ever-growing sophistication of cyber threats.

Machine learning models often operate like black boxes, providing accurate predictions but leaving users in the dark about the reasoning behind those predictions. This opacity can lead to a level of distrust among users, particularly in critical domains like cybersecurity. In such cases, understanding why a model flags certain events as threats or anomalies becomes crucial. This is where interpretable machine learning models and techniques come into play (often called XAI—Explainable artificial intelligence [11]). They offer a crucial layer of transparency by explaining the factors contributing to a model's decision, helping users comprehend the rationale behind predictions. In the world of cybersecurity, where trust and accountability are essential, the incorporation of interpretable models and explanations not only enhances the confidence in machine learning systems but also empowers security practitioners to make informed decisions and take effective actions against potential threats.

The primary purpose of this article is to shed light on

the pivotal role of machine learning models, particularly XGBoost, Decision Trees, Random Forests, and Bagging, in bolstering Intrusion Detection Systems (IDS). It delves into the application of these diverse models in identifying network anomalies and potential intrusions, emphasizing their unique strengths and attributes. Additionally, the article underscores the importance of model interpretability in the context of intrusion detection. It introduces and demonstrates the practical use of interpretability tools like LIME (Local Interpretable Model-agnostic Explanations) [12] and SHAP (SHapley Additive exPlanations) [13] to unveil the decision-making process within these models. By combining the power of machine learning with model transparency, this article equips cybersecurity practitioners with the knowledge and tools to enhance their intrusion detection capabilities, fostering a safer and more secure digital landscape.

The organization of the paper is as follows: Part II provides an in-depth review of the relevant literature, presenting essential contextual information. Part III outlines the methodology employed for classifying types of cyber attacks, encompassing aspects such as the Dataset, Preparation of Data and Evaluation Metrics for the Model. Part IV elucidates the experimental setup and presents the ultimate outcomes. Finally, Part V concludes the research by summarizing the discoveries and delivering concluding insights.

II. RELATED WORKS

The development of machine learning and deep learning models has profoundly transformed numerous fields by enabling unprecedented levels of automation, prediction, and data-driven decision-making, such as in healthcare, self-driving car, and agriculture [14–19]. The continuous advancements in these fields highlight the significant impact of machine learning and deep learning on modern technology and industry.

The application of machine learning models to the development of Intrusion Detection Systems (IDS) has emerged as a thriving field of research, characterized by numerous successes. These models, ranging from ensemble methods like Random Forests and Bagging to gradient boosting algorithms such as XGBoost, have demonstrated their prowess in enhancing network security. Researchers have harnessed the adaptability and predictive capabilities of these models to detect even the most intricate forms of cyber threats. By leveraging the wealth of data generated in today's digital environments, machine learning-based IDS have achieved remarkable accuracy rates while minimizing false positives.

Verma, et al. in this paper [20] explores the application of machine learning classification algorithms to enhance IoT security by addressing Denial of Service (DoS) attacks, conducting a comprehensive study of classifiers, evaluating their performance on various datasets, and proposing statistical methods for assessing classifier performance to advance the development of anomaly-based intrusion detection systems for IoT. In the study [21] conducts a thorough survey of machine learning applications in Intrusion Detection Systems (IDSs), introduces two effective approaches for network attack detection using tree-based ensemble learning and optimized training data selection to enhance detection performance while minimizing operational costs. Ziadoon Kamil Maseer, et al.

in the paper [22] conducts a comprehensive review of previous studies on AIDS (Anomaly-based Intrusion Detection Systems) by applying 10 popular supervised and unsupervised ML algorithms to evaluate their performance based on various criteria, including true positive and negative rates, accuracy, precision, recall, and F-Score, with the artificial neural network (ANN), decision tree (DT), naive Bayes (NB) emerging as the most effective in detecting web attacks on a real-world network dataset - CICIDS2017. This research [23] evaluates three machine learning algorithms (Decision Jungle, Random Forest, and Support Vector Machine) for building a Machine Learning-based Network Intrusion Detection System (ML-based NIDS), concluding that Support Vector Machine (SVM) exhibits the highest accuracy, precision, and overall effectiveness in detecting network intrusions on the KDD and CIC-IDS2017 benchmark datasets. Authors in the article [24] introduces a hybrid machine learning approach that combines feature selection and data reduction methods, using feature importance decision tree-based methods and the Local Outlier Factor (LOF) method to achieve high accuracy in detecting network anomalies, particularly in the NSL-KDD dataset, demonstrating superior stability compared to other methods, albeit facing challenges in the UNSW-NB15 dataset. In this paper [25] proposes a taxonomy for Intrusion Detection Systems (IDS) based on deep learning, categorizing IDS literature primarily by data objects and evaluates the performance of three machine learning algorithms (Bayes Net, Random Forest, Neural Network) and two deep learning algorithms (RNN, LSTM) using the KDD cup 99 dataset for accuracy assessment with the WEKA program. In this study [26], Support Vector Machine (SVM) and Naïve Bayes machine learning techniques are employed for intrusion detection using the NSL-KDD dataset, with SVM demonstrating superior performance compared to Naïve Bayes, as measured by accuracy and misclassification rates. In the research [27] explores the detection of anomaly traffic in the NSL-KDD dataset using five machine learning techniques, and it reveals that the Random Forest Classifier achieves the highest accuracy and minimal error rates, surpassing the other classifiers, both with and without dataset normalization.

In addition to the extensive research into traditional machine learning approaches, there has been a significant focus on harnessing the potential of deep learning models in the construction of Intrusion Detection Systems (IDS) [28],[29],[30],[31]. Deep learning, a subset of machine learning, involves the use of artificial neural networks with multiple layers to automatically learn intricate patterns and representations from data. These deep neural networks, such as Recurrent Neural Networks (RNNs) [32] and Long Short-Term Memory (LSTM) [33] networks, have demonstrated remarkable capabilities in capturing complex relationships in network traffic data, making them well-suited for detecting subtle and evolving cyber threats.

The main goal of this article is to highlight the essential role of machine learning models, specifically XGBoost, Decision Trees, Random Forests, and Bagging, in strengthening Intrusion Detection Systems (IDS) used for computer security. It delves into how these diverse models can be used to spot unusual activities on computer networks, which might indicate security threats. Additionally, the article emphasizes the importance of making these models easier to understand for cybersecurity experts. It introduces and demonstrates the

practical use of tools like LIME (Local Interpretable Model-agnostic Explanations) and SHAP (SHapley Additive exPlanations) to clarify how these models make decisions. By improving our understanding of these models, we can enhance computer security and make the digital world a safer place.

III. METHODOLOGY

A. Data Set

In our research, we evaluate the effectiveness of our methods using the CICIDS2018 dataset, which was originally curated by the University of New Brunswick for the analysis of Distributed Denial of Service (DDoS) data. This dataset is structured into multiple files, each corresponding to specific dates, and is provided in CSV format. The CICIDS2018 dataset encompasses a total of eighty columns, each representing an entry in the Intrusion Detection System (IDS) logging system employed by the University of New Brunswick. The complete dataset is accessible online [34] and <https://www.kaggle.com/datasets/solarmainframe/ids-intrusion-csv>. However, for our study, we specifically focus on two CSV files, namely "02-22-2018.csv" and "02-23-2018.csv," which collectively contain 2,097,150 data streams. The dataset's dimensions are (2097150, 80), making it a substantial resource for our research and analysis. Furthermore, it includes four distinct classes: Benign, Brute Force Web, Brute Force XSS, and SQL Injection, making it a valuable resource for exploring various intrusion detection and cybersecurity-related research questions. Table 1 shows further information about the dataset.

TABLE I. CLASS DISTRIBUTION OF DATASET

Class	Total
Benign	2096222
Brute Force Web	611
Brute Force XSS	230
SQL Injection	87
	2097150

B. Data Preprocessing

Data preprocessing is a crucial step in preparing a dataset for machine learning and analysis. It involves several important tasks to ensure the data's quality and suitability for modeling. First, we need to remove instances with missing class labels, as these are the target values we aim to predict, and without them, the data becomes unusable for supervised learning. Second, we should eliminate instances with missing information, which includes removing rows or samples that have incomplete or null data points, ensuring that our dataset is consistent and complete. Additionally, we should identify and drop constant columns, where the variation is zero, as these columns do not provide any meaningful information for modeling and can be considered redundant. By performing these preprocessing tasks, we can create a clean and reliable dataset ready for further analysis and machine learning tasks.

C. The Predictive Models and Explanation Methods

This article delves into the field of intrusion detection, examining the practical application of four distinct machine

learning models: XGBoost, Decision Trees, Random Forests, and Bagging. Additionally, we harness interpretability tools like LIME (Local Interpretable Model-agnostic Explanations) and SHAP (SHapley Additive Explanations) to elucidate the classification results. Comprehensive Machine Learning Workflow for Training an Intrusion Detection Model is presented in Fig. 1 and Flow chart to classify and explain the model's prediction results is presented in Fig. 2.

D. Performance Evaluation Measures

In the context of Intrusion Detection Systems (IDS), the utilization of evaluation metrics like Precision, Recall, F1-score, and Accuracy plays a crucial role in assessing the effectiveness of these systems. Precision measures the proportion of correctly identified intrusion instances among all the instances classified as intrusions. It is essential in IDS to minimize false positives, as they can lead to unnecessary alerts and resource consumption. Recall, on the other hand, evaluates the system's ability to correctly identify all actual intrusion instances. High Recall ensures that the IDS doesn't miss any real threats. F1-score, which is the harmonic mean of Precision and Recall, provides a balanced assessment, especially when there is an imbalance between intrusion and non-intrusion instances. Lastly, Accuracy measures the overall correctness of the IDS predictions, considering both true positives and true negatives. However, in cases of imbalanced datasets where non-intrusion instances are predominant, Accuracy may not be the sole indicator of system performance. In the context of intrusion detection, these evaluation metrics collectively enable researchers and practitioners to comprehensively evaluate the IDS's ability to accurately identify and respond to security threats while minimizing false alarms and missed detections.

$$Accuracy = \frac{TP + TN}{TP + TN + FP + FN} \quad (1)$$

$$Precision = \frac{TP}{TP + FP} \quad (2)$$

$$Recall = \frac{TP}{TP + FN} \quad (3)$$

$$F_1 - Score = \frac{Precision * Recall}{Precision + Recall} \quad (4)$$

In which, TP represents True Positive, TN signifies True Negative, FP represents False Positive, and FN stands for False Negative.

IV. RESULTS AND DISCUSSION

A. Environmental Settings

The experimental results were obtained by conducting the experiments on the Kaggle platform. The system used for the experiments had 13GB of RAM and a GPU Tesla P100-PCIE with 16GB of memory.

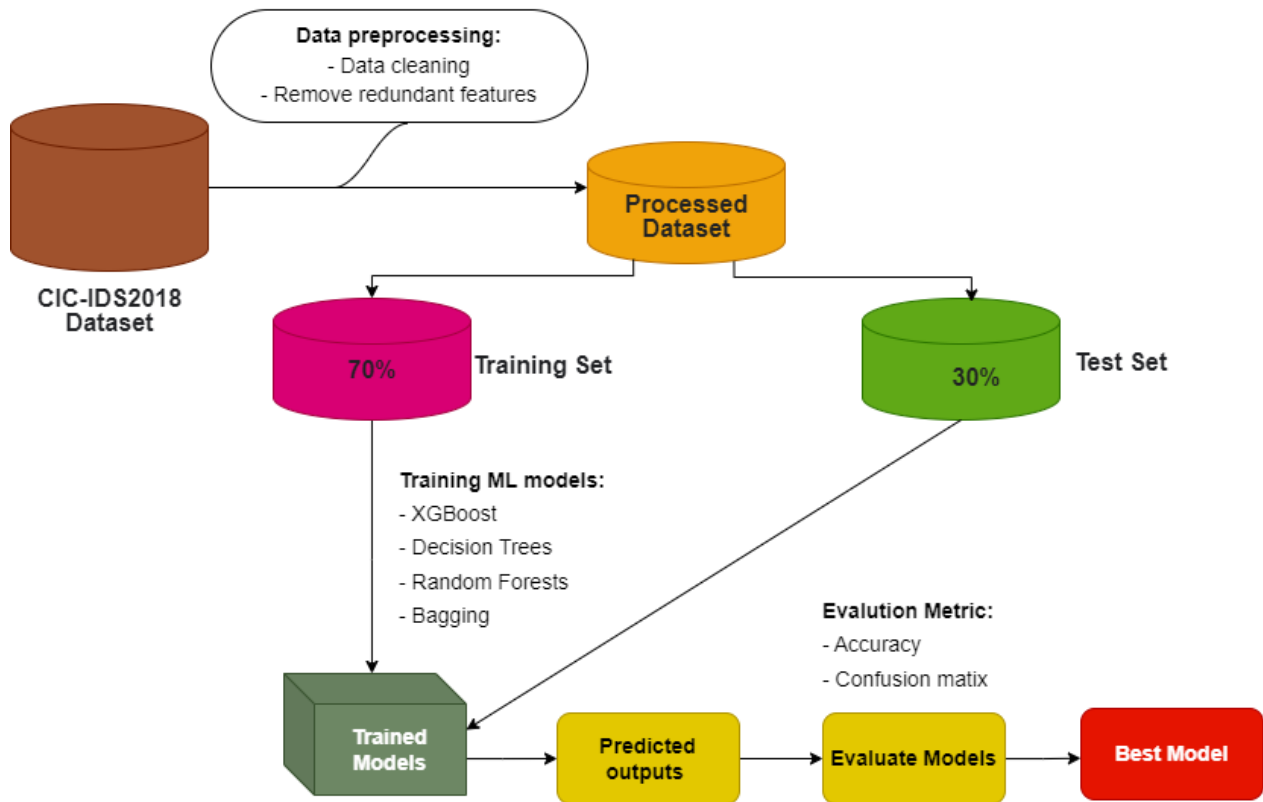

Fig. 1. Comprehensive machine learning workflow for training an intrusion detection model.

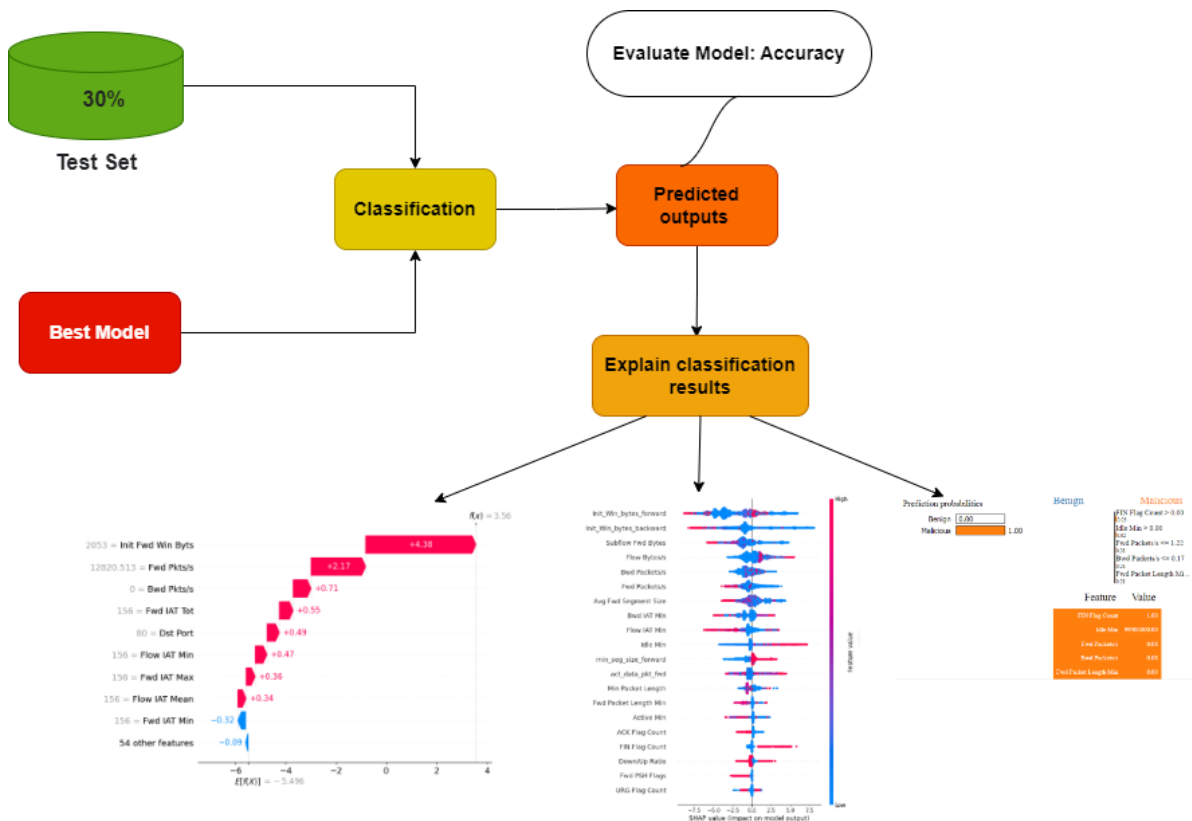

Fig. 2. Flow chart to classify and explain the model's prediction results.

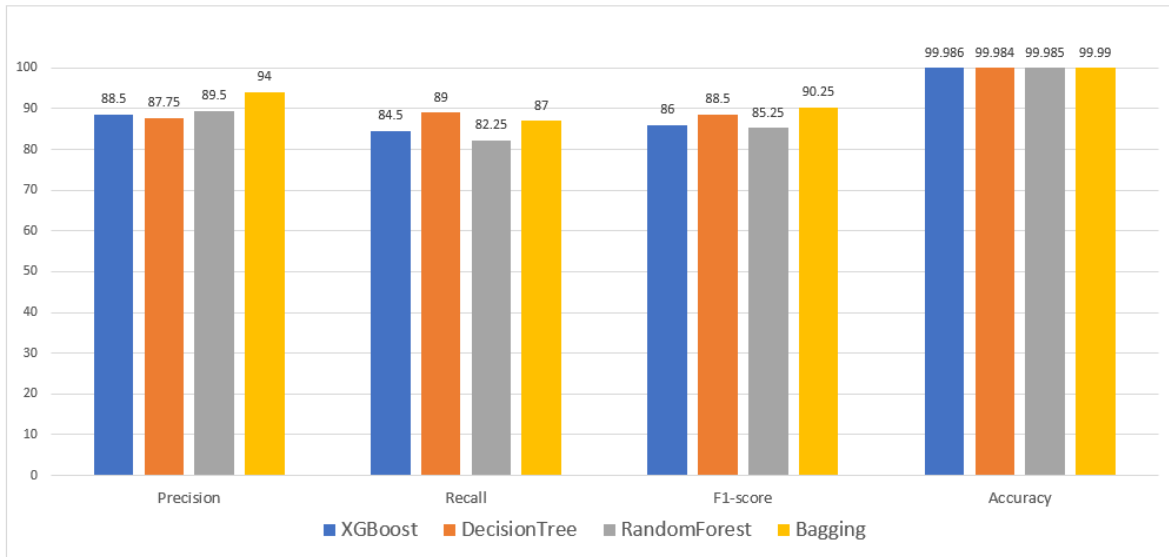

Fig. 3. Comparison chart of precision, recall, F1-score, and accuracy of 4 models.

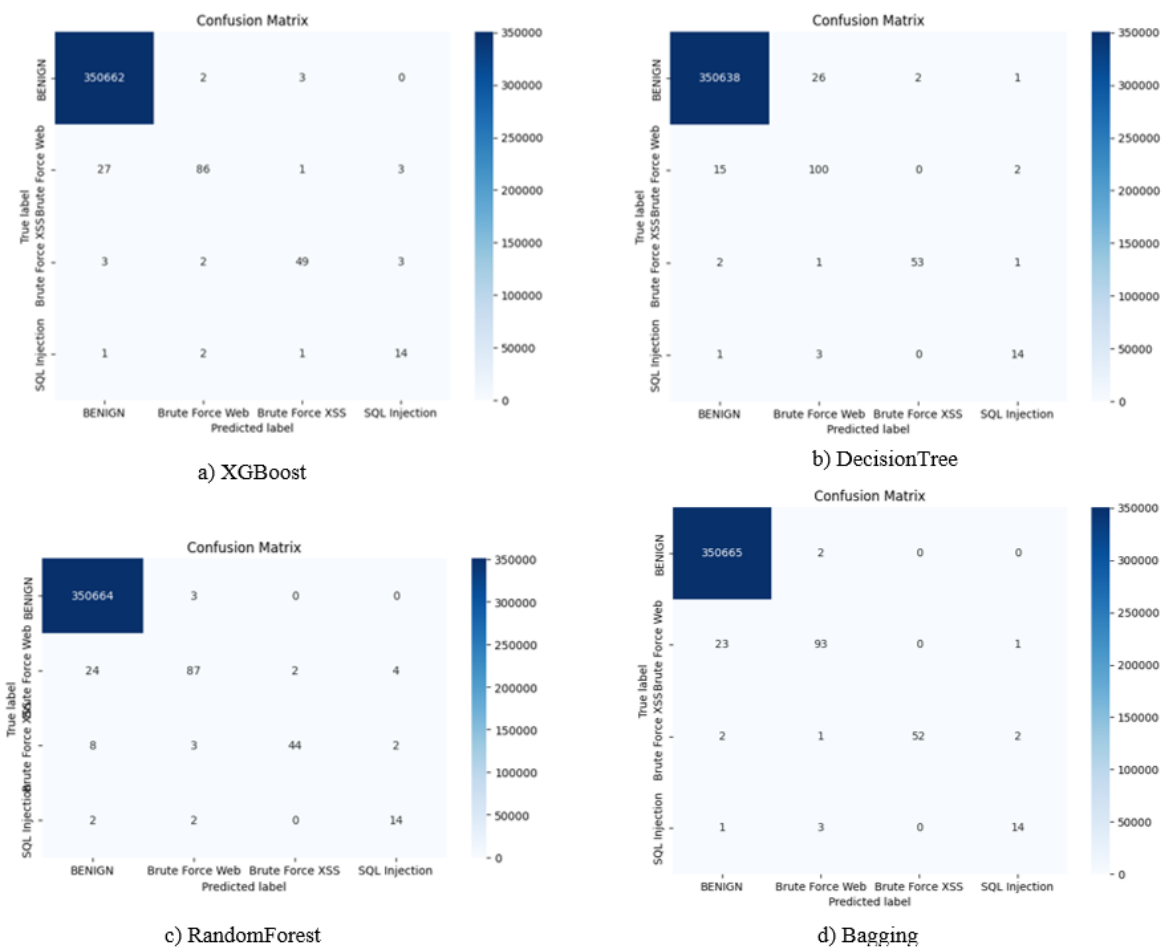

Fig. 4. Confusion matrix of 4 models.

B. Evaluation Overall

In our study, we tried out four different machine learning models – XGBoost, Decision Trees, Random Forests, and Bagging – to tackle the problem of Intrusion Detection. We wanted to see how well each model performs in identifying security threats. After training and evaluating them, we compared their results. This comparison gives us a practical understanding of how effective these models are at spotting intrusions. It helps us see which model might work best for real-world cybersecurity applications, making our research valuable for improving intrusion detection systems. In our performance evaluation of the models, we utilized four key metrics: Precision, Recall, F1-score, and Accuracy, each providing valuable insights into the models’ effectiveness for Intrusion Detection. After a thorough analysis, our findings unequivocally demonstrate that Bagging outperforms the other models across all four metrics. Bagging consistently achieved higher Precision, Recall, F1-score, and Accuracy compared to XGBoost, Decision Trees, and Random Forests. These results are visually presented in Fig. 3 and Confusion matrix of four models are presented in Fig. 4.

C. Visualizing the Interpretation of Model Predictions

In this paper, we employ the Bagging model for classification, leveraging its superior performance based on our evaluation criteria, which encompass Precision, Recall, F1-score, and Accuracy. Our choice of the Bagging model stems from its consistent and notable advantage over the other models we considered. Furthermore, we delve into the intricacies of the Bagging model’s prediction results using two powerful interpretability techniques: Local Interpretable Model-agnostic Explanations (LIME) and Shapley Additive Explanations (SHAP). These interpretability tools provide valuable insights into how the Bagging model makes its predictions, shedding light on the key features and decision factors that drive its classification outcomes. By incorporating LIME and SHAP into our analysis, we aim to enhance our understanding of the model’s decision-making process and uncover actionable insights that can inform and strengthen our intrusion detection strategies.

1) *LIME*: The key idea behind LIME is to approximate the behavior of a complex model using a simpler, more interpretable model locally around a specific instance of interest. By observing how this simplified model behaves in the vicinity of the instance, we gain insights into the factors and features that influence the model’s decision for that particular data point.

We utilize network stream index 10782 within our test set, which is designated as ‘Brute Force Web’. The classification model consistently predicts this network flow as ‘Brute Force Web’ with 100% accuracy, relying on the five most critical features: RST Flag Cnt, Dst Port, Bwd IAT Tot, Fwd Pkts/s and Fwd IAT Mean. Detailed results are presented in Fig. 5.

It is evident that the 10782th network flow is confidently predicted as ‘Brute Force Web’ with a 100% confidence level. This classification decision is based on the following criteria, as validated from the table labeled ‘c’): ‘RST Flag Cnt’ is greater than 0, ‘Dst Port’ is less than or equal to 80, ‘Bwd IAT Tot’ is greater than 25202, ‘Fwd Pkts/s’ is greater than 0.6 and ‘Fwd IAT Mean’ is greater than 104.

Fig. 5. The outcome comprises three primary elements: a) the model’s predictions, b) feature contributions, and c) the actual values for each feature.

Similarly, Network Flow 1735: We use the network stream with index 1735 in the test set labeled ‘Brute Force XSS’. The classification model predicts this network flow as a ‘Brute Force XSS’ network flow with 99% accuracy with the five most important features: RST Flag Cnt, Dst Port, Fwd Pkt Len Mean, Idle Max and Init Fwd Win Byts. Detailed results are presented in Fig. 6.

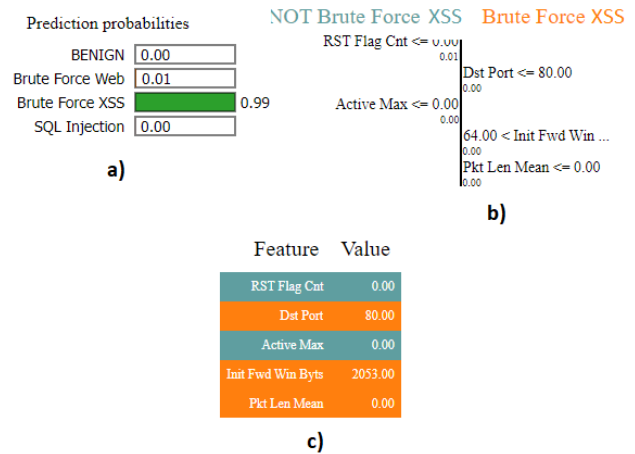

Fig. 6. The outcome comprises three primary elements: a) the model’s predictions, b) feature contributions, and c) the actual values for each feature.

2) *SHAP*: In the context of machine learning, SHAP provides a structured framework to allocate the ‘credit’ or importance of each feature in a model’s prediction. It quantifies the contribution of individual features to the model’s output, allowing us to understand why a model makes a specific prediction for a given instance. SHAP values allow assessing the significance of each feature in the model’s prediction process for each network flow (data point). This helps identify which features strongly influence the prediction outcome, which features have a weak impact, which features counteract the prediction, and which features are not important.

We still use the network stream with index 10782 and use a waterfall chart to explain the prediction results of the

classification model.

Fig. 7. Waterfall diagram for the 10782nd network flow in the test set.

In Fig. 7, there are 63 Shap values. This chart provides a clear overview of each feature's contribution to the classification model's outcomes. Notably, the feature 'Fwd Pkt Len Std' prominently suggests the possibility of this network flow being classified as 'Brute Force Web.' Following closely in importance are the features 'TotLen Fwd Pkts,' 'RST Flag Cnt,' 'Fwd Pkt Len Mean,' 'Fwd Pkt Len Max,' and 'Dst Port.'

Conversely, the features 'Idle Max' and 'Flow IAT Std' do have some influence in reducing the possibility that this network flow is not 'Brute Force Web,' though their impact is relatively minor.

Fig. 8. Waterfall diagram for the 1735nd network flow in the test set.

Likewise, consider Network Flow 1735. Here, we analyze the network stream with the index 1735, sourced from the test set designated as 'Brute Force XSS'. Remarkably, the classification model accurately classifies this network flow as 'Brute Force XSS,' demonstrating an impressive 99% accuracy. Detailed results are presented in Fig. 8.

Evaluate feature importance through Mean SHAP analysis. Within this visualization, features are organized according to their mean SHAP values, with the most critical features positioned at the top and the less influential ones towards the bottom. This representation aids in comprehending the

individual feature impacts on the model's predictions. As depicted in Fig. 9, it is evident that the feature 'Idle Std' exhibits substantial positive/negative SHAP values.

Fig. 9. Average SHAP values showing the most important features.

Fig. 10. Average SHAP values showing the most important features.

In Beeswarm plot is presented in Fig. 10, SHAP values show how each feature affects the model's predictions. This plot is great for understanding these relationships. It helps us see how SHAP values connect to the actual feature values, giving us a closer look at each feature's impact on a specific outcome.

In Fig. 10, for example, with the feature 'Idle Std,' as the values of this feature increase (shown in Red), the SHAP value

becomes more negative. Conversely, when the values of this feature decrease (shown in Blue), the SHAP value becomes more positive. This means that higher values of this feature decrease the model's probability of predicting a specific class. Conversely, lower values of this feature increase the model's probability of predicting a specific class.

V. CONCLUSION

In conclusion, with cyber threats becoming more complex, we urgently need strong Intrusion Detection Systems (IDS). Machine learning (ML) models have proven to be effective in spotting anomalies and potential intrusions.

In this article, we explored four ML models - XGBoost, Decision Trees, Random Forests, and Bagging - and used LIME and SHAP to make sense of their results. We have trained the above models and compared Precision, Recall, F1-score, and Accuracy. Trying to understand how they fit in with intrusion detection.

However, ML models often work like black boxes, so we introduced LIME and SHAP as tools to help us understand how these models make decisions. By applying these tools, we gained valuable insights into the inner workings of our models, giving us an edge in identifying and responding to threats effectively.

The next steps in our journey involve practical implementation and refinement. We will apply the insights gained from our exploration of intrusion detection models and the interpretability tools LIME and SHAP to real-world scenarios. This entails configuring and deploying these models within an operational environment, constantly monitoring their performance, and fine-tuning their parameters to enhance accuracy. Additionally, we will seek to strengthen our models against evolving threats through ongoing research and adaptation, ensuring that they remain effective guardians of digital security.

Log Clustering-based Method for Repairing Missing Traces with Context Probability Information

Huan Fang¹, Wenjie Su²

School of Mathematics and Big Data

Anhui University of Science and Technology, Huainan, China, 232001^{1,2}

Abstract—In real business processes, low quality event logs due to outliers and missing values tend to degrade the performance of process mining related algorithms, which in turn affects the correct execution of decisions. In order to repair the missing values in event logs under the condition that the reference model of the process system is unknown, this paper proposes a method that can repair consecutive missing values. First, the event logs are divided according to the integrity of the trace, and then the cluster algorithm is applied to complete logs to generate homogeneous trace clusters. Then match the missing trace to the most similar sub log, generate candidate sequences according to the context of the missing part, calculate the context probability of each candidate sequence, and select the one with the highest probability as the repair result. When the number of missing items in the trace is 1, our method has the highest repair accuracy of 97.5 percent in the *Small_log* and 93.3 percent in the real event logs *bpic20*. Finally, the feasibility of this method is verified on four event logs with different missing ratios and has certain advantages compared with existing methods.

Keywords—Trace clustering; log repairing; process mining; context semantics; conditional probability

I. INTRODUCTION

In the past few years, process mining has evolved into a discipline focusing on the discovery, monitoring, and enhancement of real processes [1]. Process mining bridges the gap between traditional data analysis techniques like data mining and business process management analysis [2]. One of the key areas of process mining is process discovery, it aims at generating process models that describe the behavior of process event logs as accurate as possible. Once a model is discovered, process analysis and enhancement can be performed to detect potential improvements [3].

Generally, an event log is composed of a set of traces, while each trace is a sequence of events that occur in business systems. We can label each event by an identifier, named case ID, and all events with the same case ID constitute a trace, where event are arranged by time series. Therefore, each event contains several attributes, such as case ID, activity, resources, and etc. All of event attributes reflect the actual execution information of business processes. Process mining construct model discovery frameworks based on various log processing technologies [4], [5].

In the field of process discovery, most process mining algorithms (such as heuristic mining algorithms, inductive mining, etc.) assume that behaviors related to the execution of underlying processes are correctly stored in event logs [6]–[8]. However, in real business processes, event data inevitably contains noise, and there are many reasons for this situation.

For example, manual recording, machine malfunctions, system errors, and network delays, among others. In healthcare systems, errors in medical process event logs are mainly due to manual recording, where the frequency of missing or incorrect case IDs, resource information, and activity tags is higher than that of missing or abnormal timestamps [9], [10]. Thus, low-quality event logs due to outliers and missing values tend to degrade the performance of process mining related algorithms, which in turn affects the correct execution of decisions. It is necessary to address the challenge of improving the quality of event logs, achieving higher-quality business process analysis.

This paper proposes an approach of log repairing method that incorporates context probability information, i.e., the context semantics of event log. The method uses trace clustering technology and is able to repair logs for multiple missing value scenarios. Specifically, all logs are first divided into logs containing only complete traces and logs containing only missing traces. Then, the Levenshtein Edit Distance is used to measure the similarity between traces, and a bottom-up hierarchical clustering approach is used to partition complete logs into k sub-logs. Finally, the cluster with the highest similarity to the missing trace is identified from the k sub-logs, and all possible sequences of behaviors containing the missing part are constructed based on the context of the missing part. The optimal repair sequence is selected by solving the context probabilities of each repair activity.

The contributions of our work is focused on:

- A clustering-based approach is proposed to repair multiple consecutive missing activities.
- Behavioural relationships between contexts and activities of arbitrary length in the log are considered.
- Calculate the contextual probability of each repairing activity to select the optimal repair sequence to improve repairing results.

The remainder of this paper is structured as follows. Section II introduces the related work, Section III presents an illustrative motivation example. Section IV reviews some basic concepts and notations, and Section V introduces the proposed method of this work, Section VI conducts experiments and analyses the experimental results. Finally, Section VII concludes this paper.

II. RELATED WORK

In order to improve the quality of process mining analysis, the work in [11] developed a process mining methodology as

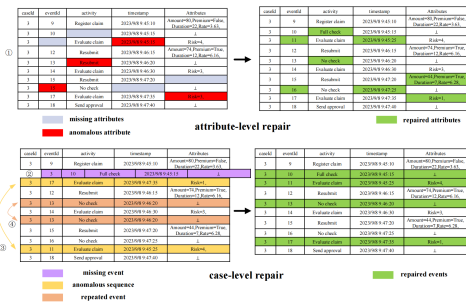

Fig. 1. The framework of proposed Log repairing method.

a guide for projects using event logs for process mining, with a focus on data cleaning steps. Similarly, the work in [12] categorized event log quality problems into four types: missing data, incorrect data, imprecise data, and irrelevant data. In this section, we mainly categorize the existing repairing log work into two types: attribute-level repair and case-level repair.

A. Attribute-level Repair

The repair at the attribute level involves explicitly identifying the missing positions of attributes, including activity attributes or determining the positions of abnormal attributes based on anomaly detection of attributes. Specifically, as shown in problem 1 in Fig. 1, the entire table represents a case in the log, where each row represents an event and each cell represents the attributes contained in the event. The red cells in Fig. 1 indicate detected abnormal attributes, while the gray cells indicate missing attributes.

In [13], detecting abnormal values and reconstructing missing values at the attribute level in event logs are focused on. It consists of two processes: log cleaning and reconstruction. In event log cleaning, abnormal values are those with high reconstruction errors in the autoencoder decoding step. In event log reconstruction, the autoencoder is used to reconstruct missing values in the input dataset. This method does not rely on any prior knowledge of the business process that generates the event log and has shown significant performance in terms of activity labels and timestamps in artificial event logs. In PROELR [14] and SRBA [16], trace clustering methods are used to cluster complete traces, which are traces without any missing activity labels. Each incomplete trace, referring to traces with missing activity labels, is assigned to the nearest cluster. Subsequently, the incomplete traces are repaired based on the characteristics of the corresponding trace clusters. It is worth noting that both [14] and [16] can only repair missing values at the individual activity level. MIEC [17] is a likelihood-based multiple imputation technique for repairing missing data in event logs. In addition to repairing missing activity labels, it can also repair all other missing attributes in the event log. MIEC relies on the dependencies between event attributes. For example, certain activities may always occur on weekends or be performed by specific groups of people. When such dependencies do not exist or the event log contains limited attribute data, effective repair of the event log may not be possible. In [18], a decision tree learning algorithm is proposed to discover rules for missing values in event logs. In [19], a novel classification event imputation

method is proposed, which can recover missing categorical events by learning structural features observed in the event log. In [20], an LSTM-based prediction model that uses the prefix and suffix sequences of events with missing activity labels as input to predict the missing labels is proposed, demonstrating high repair capability. In [21], the BERT4Log model and weak behavior profile theory, combined with a multi-layer multi-head attention mechanism is introduced, for interpretable repair of low-quality event logs. In [22], a convolutional neural network model that incorporates trace behavior features to repair missing activities in traces is proposed, and its core idea is to transform the event log of a business process transition into spatial data based on the dimensions of time attributes and activity attributes, convert it into an image matrix, and train a convolutional neural network model to predict the missing activities.

B. Case-level Repair

The existing techniques for case-level repair mainly focus on solving problem 2 in Fig. 1, where there is a missing entire event in a case. A method combining random Petri nets, alignment, and Bayesian networks was proposed in [23] to recover missing activities and timestamps in event logs. The work in [24] developed advanced indexing and pruning techniques to reduce the search space, and the work in [25] utilizes process decomposition techniques and heuristic methods to effectively prune unfeasible sub-processes that fail to produce minimal repairs. Both works of [24] and [25] aimed at minimizing the search space as much as possible to improve the efficiency of repairing events.

C. Summary of Existing Work

The attribute-level repair techniques are effective in repairing known anomalies or missing attributes but are unable to handle cases where the missing information is unknown or when there are sequence anomalies and activity repetitions, as shown in problems 3 and 4 in Fig. 1. On the other hand, case-level repair techniques rely heavily on process models and may not perform well in the absence of a process model. The specific comparison of existing techniques is shown in Table I, where the symbol \checkmark represents the scope of techniques considered. The specific meanings of the symbols are as follows:

F1: Deterministic repair for known anomalies or missing attributes, where the position of the anomaly or missing attribute is clearly identified.

F2: Recovery of a single attribute's missing values in a trace, mainly activity names.

F3: Recovery of multiple attributes' missing values in a trace.

F4: Incorporation of process models.

F5: Uncertain repair for missing attributes, where the position of the missing attribute is unknown.

F6: Uncertain repair, where the position of the missing attribute and the existence of event repetitions or sequence changes are unknown.

F7: Interpretable missing attribute repair.

TABLE I. THE COMPARISON OF EXISTING TECHNIQUES

Repair type	Existing technologies	F1	F2	F3	F4	F5	F6	F7
Attribute-level repair	[13], [17], [19], [20]	✓		✓				
	[14], [16], [22]	✓	✓					
	[18]						✓	
	[21]	✓	✓					✓
Case-level repair	[23]–[25]			✓	✓	✓		
The methods in this paper				✓		✓	✓	

Based on the aforementioned issues, this paper introduces the concept of an activity feature graph to detect and repair the mentioned problems. It utilizes activity feature graphs to compare abnormal behaviors with repaired behaviors, thereby identifying the causes of anomalies. Additionally, it enables further analysis of the impact of data. Furthermore, this paper also proposes the recovery of average behavior characteristics for missing values in the activity feature graph.

III. MOTIVATION

Table II presents an event log containing 9 activities $a, b, c, d, e, f, g, h, i, j$ and 10 trace variants. The superscript of a trace denotes its occurrence frequency, and the symbol $-$ represents missing value. Take the missing trace $\langle a, i, e, -, g, f \rangle$ for example, if the repair method of [14] is used, the repair result should be $\langle a, i, e, d, g, f \rangle$, as the highest frequency activity occurring between activities e and g is d . The repair method of [14] repairs the missing activity based on the highest frequency of occurrence between the predecessor and successor of the missing activity. However, this result is incorrect. The reason is that the method of [14] can only repair one missing activity based on its predecessor and successor activities, which may not represent the key information of the missing trace. If the method from this paper is used with a context length of 2, the correct repair result can be obtained as $\langle a, i, e, k, g, f \rangle$, which is the correct one.

TABLE II. AN EXAMPLE OF EVENT LOG

ID	Traces
1	$\langle a, c, b, e, d, h, f \rangle$
2	$\langle a, c, b, e, d, g, f \rangle^2$
3	$\langle a, i, b, e, d, g, f \rangle$
4	$\langle a, i, e, k, g, f \rangle$
5	$\langle a, i, c, b, h, k, f \rangle^3$
6	$\langle a, b, c, g, d, j \rangle^2$
7	$\langle a, i, c, e, d, k, g, j \rangle$
8	$\langle a, c, b, e, b, d, k, g, f \rangle$
9	$\langle a, i, c, g, k, j \rangle$
10	$\langle a, b, c, i, k, h, j \rangle$

Furthermore, the repairing work of [8] selects the most frequently occurring segment between the preceding and succeeding contexts of the missing portion to repair the missing trace. The drawback of this method is that, although it considers more contextual information, it can only repair the missing trace variants occurring more than 2 times, and ignores the behavioral relationships between activities. For example, for the missing trace $\langle a, i, e, -, -, h, f \rangle$, the original

log in Table I does not find the corresponding length of the missing segment when the method of [8] is directly used. Comparatively, when the proposed method in this paper is used, a kind of behavioral graphs of activities is constructed, and then the repaired result based on contextual probabilities is calculated as $\langle a, i, e, d, k, h, f \rangle$.

Therefore, in order to extend the research content of existing research, this paper proposes a clustering-based method that can repair multiple consecutive missing activities. The proposed method not only considers arbitrary lengths of context in the logs but also takes into account the behavioral relationships between activities. Experimental results show that compared to existing research, the proposed method has significant advantages in repairing missing activities.

IV. PRELIMINARIES

In this section, we briefly review a couple of terminologies such as events, traces, event log, log clustering and missing trace, in order to ease the readability of this paper.

A business process is a set of activities executed in a given setting to achieve predefined business object [26]. An activity is an expression of the form $Act(a_1, a_2, \dots, a_{n_A})$, where Act is the activity name and each a_i is an attribute name. We call n_A the arity of A . The attribute names of an activity are all distinct, but different activities may contain attributes with matching names.

We assume a finite set A of activities, all with distinct names; thus, activities can be identified by their name, instead of by the whole tuple. Every attribute a_i of an activity A is associated with a type $D_A(a_i)$, i.e., the set of values that can be assigned to a_i when activity is executed.

An event is the execution of an activity and is formally captured by an expression of the form $e = A(v_1, v_2, \dots, v_{n_A})$, where $A \in Act$ is an activity name with $v_i \in D_A(a_i)$. The set of events is denoted as $Event$.

A trace is formally defined as finite sequences of events $\sigma = \langle e_1, e_2, \dots, e_n \rangle$ with $e_i = A_i(v_1, v_2, \dots, v_{n_{A_i}})$. Traces model process executions, i.e., the sequences of activities performed by a process instance CID . A finite collection of executions into a set L of traces is called an event log.

Definition 1 (Levenshtein Distance): Let $\sigma_1, \sigma_2 \in L$ be two traces in the log L , $Lev(\sigma_1, \sigma_2)$ denotes the minimum number of edit operations required to transform σ_1 to σ_2 , which is the edit distance. There are three types of edit operations: delete, insert, and replace.

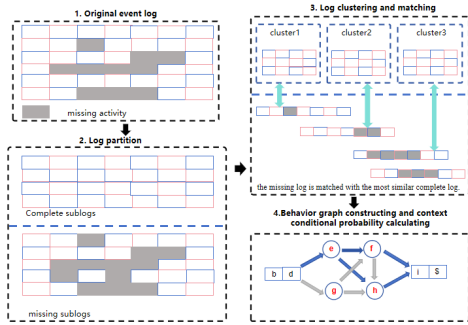

Fig. 2. The framework of proposed log repairing method.

For example, for $\sigma_1 = \langle a, c, d, e, h \rangle$, $\sigma_2 = \langle a, b, d, e, g \rangle$, after two replacement operations on σ_1 , it becomes σ_2 , thus the edit distance $Lev(\sigma_1, \sigma_2) = 2$.

Definition 2 (Log Clustering): Let $CN = \{C_1, C_2, \dots, C_m\}$ be a set of clusters, and m be the number of the clusters. If CN is the clustering result of log L , then CN is a clustering of L if and only if $C_i \cap C_j = \emptyset$ ($1 \leq i, j \leq n \wedge i \neq j$) and $\bigcup_{i=1}^n C_i = L$.

Definition 3 (Missing Trace): A missing trace be $\sigma^* = \langle e_1, e_2, \dots, e_n \rangle$ and n be the length of σ^* , if and only if $\exists i \in [1, n] : e_i = ' - '$, where $' - '$ denotes the missing value *null*. The incomplete log L^* is the set of all missing traces.

For example, $L_1 = \{\langle a, d, b, -, h \rangle^{56}, \langle a, d, c, -, -, c, d, e, h \rangle^8, \langle a, d, c, -, -, -, b, e, g \rangle^2\}$ is an incomplete log.

V. THE PROPOSED LOG REPAIRING METHOD

This section introduces the proposed method for repairing multiple consecutive missing activities based on clustering and context integration. The research framework is shown in Fig. 2, where the original log is first divided into complete logs and missing logs, and then clustering methods are used to segment the complete log into several sub-logs. Subsequently, each missing trace in the missing log is matched with the most similar sub-log. Next, a behavioral graph is constructed based on the context of the missing parts and the behavioral relationships of similar clusters, generating candidate repair sequences. Finally, the conditional probabilities of each candidate sequence are calculated in conjunction with the context, and the candidate sequence with the highest probability is selected to repair the missing trace.

A. Log Clustering

Clustering is used to partition process logs into trace clusters, which helps reduce heterogeneity and improve understandability [16]. Trace clustering splits observed different behaviors into several groups of multiple sub-logs with similar behaviors. This paper aims to identify a group of activity sequences similar to the missing trace from the complete logs, in order to enhance the accuracy of missing trace repairing. Therefore, this paper uses trace clustering as a preprocessing stage for log repairing. Firstly, the traces are encoded using Bag of Activity (BOA) encoding, and the similarity between traces is measured using Euclidean distance to construct a

similarity matrix of traces. Then, spectral clustering is used for clustering.

Definition 4 (Similar Clusters): Let $\sigma^* \in L^*$ be a missing trace, then $C_i \in CN$ is the cluster most similar to σ^* , if and only if C_i satisfies eq (1).

$$C_i = \underset{i=1}{\operatorname{argmin}}^{|CN|} \frac{\sum_{\sigma \in C_i} Lev^*(\sigma, \sigma^*)}{|C_i|} \quad (1)$$

Where, $Lev^*(\sigma, \sigma^*) = \frac{Lev(\sigma, \sigma^*)}{\max(|\sigma|, |\sigma^*|)}$ represents the normalized edit distance, and $Lev^*(\sigma, \sigma^*) \in [0, 1]$.

Algorithm 1 Locating the candidate cluster C^* that most similar to the missing trace MT

Input: Original log L' , Number of clusters n , Missing trace MT

Output: Candidate cluster C^*

```

1  $SM \leftarrow null$  // Initialize the similarity matrix
2 foreach  $\sigma_i \in L'$  do
3   foreach  $\sigma_j \in L'$  do
4      $SM(i, j) \leftarrow Euclidean(\sigma_i, \sigma_j)$ 
5   end
6 end
7  $CN \leftarrow SC(SM)$   $C^* \leftarrow null$   $SV \leftarrow 0$  foreach  $C_i \in CN$ 
8   do
9      $S_i \leftarrow (\sum_{\sigma \in C_i} Lev^*(\sigma, MT)) / |C_i|$  if  $SV > S_i$  then
10     $SV \leftarrow S_i$   $C^* \leftarrow C_i$ 
11 end
12 return  $C^*$ 

```

In Algorithm ??, lines 1-5 use Euclidean distance to calculate the similarity between traces represented by BOA encoding, using SM to store the similarity values between traces, and then use spectral clustering to divide the complete log into n sub-logs. Lines 8-13 select the most similar cluster based on the minimum edit distance SV from the missing trace to the traces in each cluster according to Eq. (1).

B. Repairing Missing Traces by Context Probability

In order to achieve more accuracy and reduce the complexity of repairing missing events, this paper defines the concepts of begin sequence and end sequence in relation to the behavior graph. The begin and end sequences refer to the activity sequence around the missing part, while the behavior graph stores the solution space that satisfies all possible activity behaviors from the start sequence to the end sequence in the similar cluster.

Definition 5 (begin sequence, end sequence): Given a missing trace $\sigma \in A^*$, the contextual behavior of the missing part is defined as $con(\sigma, l, r) = \{(\sigma', \sigma'') | \sigma', \sigma'' \subseteq \sigma \wedge |\sigma'| = l \wedge |\sigma''| = r\}$, where σ' corresponds to the begin sequence of σ with precede length l , and σ'' corresponds to the end sequence of σ with successor length r .

For example, given a missing trace $\sigma = \langle a, d, c, -, -, -, b, e, g \rangle$, the context of its missing parts is denoted as $con(\sigma, 2, 3)$, $con(\sigma, 2, 3) = (\langle d, c \rangle, \langle b, e, g \rangle)$, where $\langle d, c \rangle$ represents the Begin Sequence (BS) with precede

length 2 and $\langle b, e, g \rangle$ represents the End Sequence (ES) with successor length 3.

To identify the activity sequences of the missing parts in the missing trace, first, in the candidate clusters, identify the activity sequences $SeqSet$ that satisfy from the BS to the ES , i.e., $SeqSet = \{\phi(\sigma_i, BS, ES) | \exists \phi(\sigma_i, BS, ES) \in \sigma_i \wedge \sigma_i \in C^* \wedge 1 \leq i \leq |C^*|\}$, where $\phi(\sigma_i, BS, ES) = \{\sigma_i(o, p) | o = PosB(\sigma_i, BS) \wedge p = PosE(\sigma_i, ES)\}$, $PosB(\sigma_i, BS)$ indicates the index where the begin sequence BS first appears in trace σ_i , $PosE(\sigma_i, ES)$ indicates the index where the end sequence ES last appears in trace σ_i , and $\sigma_i(o, p)$ represents the activity sequence in trace σ_i between indices o and p . Then, a behavior graph is constructed based on $SeqSet$.

Definition 6 (Behavior Graph): The behavior graph G is a directed graph, i.e., $G = DiGraph(V, E)$. The nodes set V represent the activities in $SeqSet$, the directed edges $E = \{(x, y) | \exists x \rightarrow y \in SeqSet\}$, $x \rightarrow y$ indicates that activity y immediately follows activity x .

For the missing trace $\langle \#, \#, a, c, d, e, f, b, d, -, -, \$, \$ \rangle$, for ease of computation, we added the symbols $\#$ and $\$$ at the beginning and end of the trace, respectively, representing the precede context at the start and the successor context at the end.

Algorithm ?? describes the process of finding all possible valid behavior sequences from the initial sequence to the final sequence. Lines 1-10 define a method $deep_search$, used to calculate a depth-first search starting from a certain activity with a length of $(n + 2)$. Line 14 indicates searching for the first activity in the initial sequence, for example, for the missing trace $mt = \langle \#, \#, a, c, b, e, -, -, f, \$, \$ \rangle$, when the context lengths are set to 2, searching procedure starts from activity b in the original sequence, returning all found behavior sequences $repair_seq = \{\langle b, e, d, g, f, \$ \rangle, \langle b, e, d, h, f, \$ \rangle\}$. Lines 15-17 filter the found behavior sequences based on the length of the final sequence and the missing trace, finally obtaining candidate repairing sequences $CT = \{\langle b, d, e, h, \$, \$ \rangle, \langle b, d, e, g, \$, \$ \rangle\}$.

Algorithm ?? can generate candidate repair sequences for missing traces. In order to select the most suitable missing sequence, this paper adopts eq. (2) to calculate the next activity under the current window based on the context of the missing parts.

Definition 7 (Context probability): Given a sliding window size of w , a candidate trace $ct \in CT$, and the cluster C that is most similar to ct , the context probability of act under the window w is denoted as $CoverProbably(act)$.

$$CoverProbably(act) = \frac{|Wact(ct, w) \cup Next(Wact(ct, w)) \in C|}{|Wact(ct, w) \in C|} \quad (2)$$

Where $act \in A$, $A = \{ct(i) | w \leq ilen(ct)\}$, $Wact(ct, w)$ represents the activity sequence in the candidate trace ct under the window size of w . $Next(Wact(ct, w))$ represents the next activity in this sequence. The probability of the candidate trace ct sliding backward is denoted as $BP(ct)$, shown as eq. (3).

$$BP(ct) = \prod_{act \in A} CoverProbably(act) \quad (3)$$

Similarly, the probability of the candidate trace ct sliding forward is denoted as $FP(ct)$, $FP(ct) = BP(ct^{-1})$, where

Algorithm 2 Generating candidate repair sequences

Input: Behavior Graph G , begin sequence BS , end sequence ES , number of missing values n

Output: Candidate repair traces CT

```

12 def deep_search(h, k, current, G): // search from
    current, h is the current depth
13 repair_seq ← {} if h ≤ k then
14   foreach sct ∈ G.node() do
15     if ∃current → act // Nodes with paths to
        the current activity
16       then
17         temp_seq ← deep_search(h + 1, k, act, G)
18         foreach seq ∈ temp_seq do
19           misseq ← current ∪ {seq}
20           repair_seq.add(misseq)
21   return repair_seq CT = {} Bact = Firact(BS)
    // The first activity in the initial
    sequence
22 Elen = len(ES); Blen = len(BS) // length of the
    begin sequence, end sequence
23 repair_seq = deep_search(0, n + 2, Bact, G) foreach
    seq ∈ repair_seq do
24   if seq[Elen :] == ES and len(seq) == n + 2 then
25     CT.add(seq)
    // Evaluate candidate sequences
26   end
27 return CT

```

ct^{-1} represents the reverse order of the candidate trace activity sequence ct . Therefore, the final context probability of the candidate trace ct is calculated as $P(ct)$, $P(ct) = \frac{BP(ct) + FP(ct)}{2}$.

Algorithm ?? describes the process of calculating the conditional probability to select the final repair result from the candidate repair sequences. Lines 1-5 initialize parameters. Lines 6-9 calculate the probability of the next activity under the current window from forward and backward directions. The conditional probability calculated by the forward sliding is saved in FP , and the conditional probability calculated by the backward sliding is saved in BP . Then, the average of the probabilities calculated from both directions is taken as the repair probability P for that candidate repair sequence. Lines 10-13 select the candidate sequence with the highest probability as the repair result and return it.

In order to illustrate the main idea of proposed method, an example is taken here. Suppose the missing trace $mt = \langle \#, \#, a, c, b, e, -, -, f, \$, \$ \rangle$ is generated from Table I that to be repaired. Fig. 3 shows the distance matrix obtained by calculating the Euclidean distance after encoding the logs in Table II using BOA, and then generates a weighted undirected graph based on spectral clustering, where nodes represent the IDs of 10 variants, edges represent the distances between traces. The original event log is divided into 2 clustering results, with the most similar cluster $\{1, 2, 3, 4, 6, 8\}$ determined based on eq. (3). Next, setting the context of the missing trace as $con(mt, 2, 2) = (\langle b, e \rangle, \langle f, \$ \rangle)$, and candidate repair sequences are obtained as $CT = \{\langle b, e, d, g, f, \$ \rangle, \langle b, e, d, h, f, \$ \rangle\}$ through Algorithm ?. Finally, Algorithm ?? is used to calcu-

Algorithm 3 Context probability calculating algorithm

```

28  $pre\_ct \leftarrow null$   $max\_P \leftarrow 0$  foreach  $ct \in CT$  do
29    $BP \leftarrow 1$   $FP \leftarrow 1$  while  $Next(Wact(ct, w)) \neq null$ 
      do
30      $BP \leftarrow BP * CoverProbably(Next(Wact(ct, w)))$ 
        $FP \leftarrow FP * CoverProbably(Next(Wact(ct^{-1}, w)))$ 
31   end
32    $P = (BP + FP)/2$  if  $max\_P < P$  then
33      $max\_P \leftarrow P$   $pre\_ct \leftarrow ct$ 
34 end
35 return  $pre\_ct$ 

```

Fig. 3. Weighted undirected graph generated by spectral clustering method.

late the conditional probability.

Tables III and IV record the context probability of candidate repair sequences with a window size of 2, with the probability of the candidate repair sequence $ct_1 = \langle b, e, d, g, f, \$ \rangle$ being $3/5$, and $ct_2 = \langle b, e, d, h, f, \$ \rangle$ being $1/5$. Therefore, the final repair result is $\langle \#, \#, a, c, b, e, d, g, f, \$, \$ \rangle$.

TABLE III. THE CONTEXTUAL CONDITIONAL PROBABILITY BETWEEN CANDIDATE TRACES $ct_1 = \langle b, e, d, g, f, \$ \rangle$

Direction	Sliding window	Conditional probability	Result
Backward sliding	$be \rightarrow d$	$4/5$	$3/5$
	$ed \rightarrow g$	$3/4$	
	$dg \rightarrow f$	1	
	$gf \rightarrow \$$	1	
Forward sliding	$\$f \rightarrow g$	$4/5$	$3/5$
	$fg \rightarrow d$	$3/4$	
	$gd \rightarrow e$	1	
	$de \rightarrow b$	1	

VI. EXPERIMENTAL EVALUATION

In this section, a series of experiments are conducted to validate the feasibility of the proposed method. Firstly, the repair effectiveness of traces with different missing ratios is tested on four kinds of event logs. Secondly, the impact of different context lengths and whether clustering preprocessing is conducted on repairing missing traces is compared.

TABLE IV. THE CONTEXTUAL CONDITIONAL PROBABILITY BETWEEN CANDIDATE TRACES $ct_2 = \langle b, e, d, h, f, \$ \rangle$

Direction	Sliding window	Conditional probability	Result
Backward sliding	$be \rightarrow d$	$4/5$	$1/5$
	$ed \rightarrow h$	$1/4$	
	$dh \rightarrow f$	1	
	$hf \rightarrow \$$	1

	$fh \rightarrow d$	1	
	$hd \rightarrow e$	1	
	$de \rightarrow b$	1	

A. Logs Information

Table V describes the basic information of one synthetic log and three real logs. These logs come from different environments to compare the feasibility of the proposed method in different environments. *Small_log* is an artificial log generated by the plg tool that comes from the literature [15]. BPI Challenge 2020 (*bpic20*) contains event data related to travel expense reimbursement over two years. *sepsis* records sepsis case events from a hospital’s ERP system, with each trace corresponding to a case. BPI Challenge 2013, incidents (*bpic13_inc*), consists of event logs of Volvo IT incidents and problem management.

TABLE V. DESCRIPTION OF EVENT LOGS

Event log	number of traces	Trace variants	Average length of traces	Number of activities
<i>small_log</i>	2000	12	14	14
<i>Bpic20</i>	2099	202	8.693	29
<i>Bpic13_inc</i>	7554	2278	8.675	13
<i>sepsis</i>	1050	846	14.49	16

B. Effectiveness Evaluation

In this paper, each experimental log is divided into complete logs containing complete traces and incomplete logs containing missing traces. The experiment divided them in this way three times, with the proportion of incomplete logs in each division being 5%, 10%, and 15% of the entire log respectively. Secondly, this paper randomly deletes some activities from each trace, in order to simulate the situation of lost activities in a real environment, which generates the incomplete logs. In experimental evaluation, three random deletion ratios have been performed on the traces in the incomplete logs of each log, with each deletion removing 1 to 3 activities from the trace.

Fig. 4 depicts the repair situation of each event log using the method proposed in this paper under different missing ratios and varying numbers of missing activities per trace. From the Fig. 4, it can be seen that the best repair effect is achieved when each trace is missing one activity. As the number of missing activities increases, the accuracy of repair gradually decreases. This result is expected because with more missing activities in the trace, there are potentially multiple behavior combinations that could exist, making it challenging to obtain the true repair sequence solely based on the control

Fig. 4. Repair effects with different numbers of missing items under 10% missing ratio.

Fig. 5. Repairing effects under different context lengths.

flow. Additionally, from this result, it can be observed that the repair effect of synthetic logs using the method proposed in this paper is superior to that of real event logs. This is because real logs are generated by complex systems, characterized by high concurrency, a wide range of event types, and inherent abnormal situations, all of which can influence the accuracy of repair.

TABLE VI. REPAIRING EFFECTS UNDER DIFFERENT MISSING RATIOS

Number of missing items in traces	Missing ratio	<i>Small_log</i>	<i>Bpic13</i>	<i>Bpic20</i>	<i>sepsis</i>
1	5%	0.975	0.828	0.933	0.754
	10%	0.957	0.8	0.929	0.838
	15%	0.92	0.783	0.857	0.81
2	5%	0.945	0.782	0.967	0.698
	10%	0.925	0.751	0.924	0.729
	15%	0.902	0.731	0.917	0.655

Table VI respectively displays the repair effects of traces missing 1 and 2 activities under log missing rates of 5%, 10%, and 15%. From the data in Table VI, it can be observed that as the missing rate of the log increases, the repair rate of the activities gradually decreases. Moreover, as the number of missing activities per trace increases, the repair effect decreases as well. Therefore, both the missing rate of the log and the number of log missing activities per trace will have an impact on the log's repair.

Fig. 5 illustrates the impact of different context lengths on repair. Four different context lengths were set in this experiment, and the results show that the accuracy of repair is lower when the context length is set to 1. This is because it is difficult to determine the main information of the current trace with just one start and end activity. As the context length increases, the repair effect gradually improves, as a certain length of context contains the main information of the trace and can filter out activity sequences more similar to the missing trace. For logs *bpic13* and *sepsis*, a decrease in repair rate occurs when the context length reaches 4. This is because these two logs have a high number of variants, and longer context lengths filter out a large number of candidate traces, making it difficult to find similar behavioral relationships.

Fig. 6. Comparison of repairing methods.

Fig. 6 presents the comparison between the method of repairing multiple missing activities (*MY_MUL*) proposed in this paper and the method of repairing single activity (*MY_ONE*), compared with the methods named *CFC*[13] and *PCR* [12], respectively. It can be seen that our proposed method outperforms existing methods both in the case of repairing multiple activities or a single activity. And the method of spectral clustering has a more significant improvement over other existing clustering methods for preprocessing of missing activity repair. Our proposed method has a good advantage in repairing multiple consecutive missing events, but for the time being, only the direct consecutive relationship between the activities is considered, and the long-term dependency between them is not taken into account. Furthermore, Table VII illustrates the improvement in repair after clustering preprocessing. Dividing the logs and matching the missing traces to more similar clusters can reduce the impact of unnecessary trace pairs on the repair effect.

TABLE VII. THE IMPACT OF CLUSTERING PREPROCESSING ON REPAIRING EFFECTIVENESS

Method	<i>Small_log</i>	<i>Bpic13</i>	<i>Bpic20</i>	<i>sepsis</i>
clustering	0.957	0.751	0.924	0.729
No clustering	0.92	0.557	0.8	0.562
Enhancement	4%	34.8%	15.5%	29.7%

Fig. 7 describes the impact of using different clustering methods, such as *kmeans*, *spectralclustering*, *SOM*, *UPGMA*[17] method, on the repairing effectiveness of logs. It can be seen from the Fig. 7 that the repair method based on

Fig. 7. The impact of different clustering methods on repairing effectiveness.

spectral clustering is better in the four logs.

VII. CONCLUSION

This paper proposes a method for repairing multiple missing activities in event logs without relying on process models. We use spectral clustering to partition the complete event log into sub-logs with similar behaviors, identifying the most similar cluster based on the minimum Levenshtein edit distance between the missing trace and traces in these clusters.

Behavior sequences are then constructed in the context of the missing parts. Using a bottom-up hierarchical clustering method, we refine the sub-logs and identify clusters most similar to the missing trace. The best repair sequence is determined by solving the contextual probability of each repair activity, examining relationships between contexts and activities of arbitrary lengths. A sliding window technique predicts the next activity based on the current context, averaging forward and backward probabilities to select the sequence with the highest likelihood.

Our method effectively repairs multiple consecutive missing events by considering direct dependencies and contextual semantics. However, this paper only considers control flow dependencies between events and ignores data flow dependencies. In future work, in order to consider data flow dependencies of events, some more complicated sequential patterns of traces will be further investigated.

ACKNOWLEDGMENT

This work was supported by the National Key R&D Program of China (Nos. 2023YFC3807500 and 2023YFC3807501).

We also gratefully acknowledge the helpful comments and suggestions of the reviewers, which have improved the presentation.
